## **PREFACE**

This 12-volume encyclopedia contains 160 chapters covering a broad range of topics related to marine biology. Subjects discussed in this encyclopedia include the ecotoxicology, genetics, and conservation of sea turtles; the ecological health of coral reefs and the species of plants and animals that inhabit them; the interaction of aquatic organisms with harmful algal blooms; the utilization of algae and seaweed for commodity chemicals, feeds, high value products, biofuels, cosmetics, fertilizers, and materials production; the biology and global distribution of tropical and subtropical copepods; the health, behavior, and factors affecting the meat quality of common carp; the prevalence of toxic metals, microplastics, and other pollutants among marine life and its environmental and ecological impact, as well as strategies for mitigation of pollution and cleanup; the distribution, ecophysiology, toxicology, and ecological impact of dinoflagellates; and the impact of climate change and fisheries on the overall marine ecosystem.

## **ABSTRACT**

The relationship between morphology, performance and ecology is critical to understand the evolutionary and ecological processes that lead to phenotype evolution. Despite the existence of a generalized life history model for sea turtles based on the biology of green turtles (*Chelonia mydas*), it should be noted that the seven species of sea turtles differ in their ecology and this in turn is reflected in their diet. Differential diets have even been reported between turtles from different populations of the same species present on the same foraging ground. Additionally, as they grow, most sea turtles present ontogenetic changes in habitat and diet, closely related to the shape and function of their skull. Geometric morphometrics have proven highly effectiveness to discriminate closely related species, even in the case of sub-species that are differentiated on the basis of karyotypic differences. The use of this technique leads to the possibility of a deeper understanding of relationships between species, through the identification of landmarks in biologically definable and comparable locations on different specimens which allow the identification of differences due to the shape. Sea turtles are an excellent example of a taxonomic group in which aspects of ecological and environmental adaptations are reflected in morphology. There is a relatively extensive knowledge of food components for these organisms covering a wide range of groups: sponges, jellyfish, corals,

<sup>\*</sup> Corresponding Author's Email: vescalon@ipn.mx, vicreshu@gmail.com.

crustaceans, mollusks, tunicates, fish, certain algae and seagrasses. However, to date few studies have analyzed variations in turtle skull shape while taking into account that the sources of variation could be: inter-specific, intra-specific, geographic, etc. Considering the above, this chapter addresses the application of geometric morphometrics as an approach to assess specific structure variations in cranial anatomy of sea turtles, and the relationship of these variations with these organisms with their ecology.

## **INTRODUCTION**

## **Basic Terminology**

Below are some of the most important concepts included in this chapter with their respective definitions.

- **Bending Energy:** Energy necessary to fit a thin straight plate to its new shape. Measuring the amount of difference in the shape, based on the metaphor of the thinplate splines; so the bending energy corresponds to the amount of energy needed to set an infinitely thin metal plate at given amplitude between selected landmarks (Zelditch et al. 2004).
- **Centroid:** It is the center of gravity of a specimen, according to the configuration of given landmarks (Slice et al. 1998); mean x, y of all coordinates considering all landmarks (Polly 2012). It does not respond to physical properties of the material but the shape, and for this and because of this reason does not change through the analysis (Zelditch et al. 2004).
- **Centroid Size:** It is calculated as the square root of the sum of the squared distances of a group of landmarks to its centroid (Slice et al*.* 1998). It is a measure of size used to scale a set of landmarks.
- **Consensus Configuration:** Group of landmarks representing the central tendency of a sample for the process of superimposition (Slice et al. 1998).
- **Geometric Morphometrics:** Morphometric method based on the Cartesian coordinates of landmarks that retain all the information on geometric shape throughout the analysis (Slice 2007)
- **Homology:** Equivalence or similarity between derived attributes that are shared by two or more species, which may or may not have changed and have a common ancestor. The criteria of homology is the primary consideration when selecting landmarks, since its location only makes sense if a match occurs and has a biological meaning (Zelditch et al. 2004).
- Landmarks: Specific markers located on a biological shape according to scale (Slice et al. 1998), taking into account the criteria of homology in which they develop, they are biologically definable and comparable between specimens.
- **Morphometry:** Consists in measuring the shape of an organism or their constituent parts. The study of shape from a morphometric perspective examines central tendencies, variation, differences between groups and associations in relation to extrinsic groups (according to the comparisons desired).
- **Position:** One of the removed effects via Procrustes analysis. The centroid of the object is displaced to the origin of the coordinate plane  $(0, 0)$  and the relative positions of the points remain the same, but their coordinates vary (Rohlf & Slice 1990).
- **Procrustes Analysis:** The analysis of the shape coordinates from the superimposition of corresponding landmarks, based on the estimation of minimum squares of the position, rotation and scale which allow landmarks groups to be aligned in pairs of specimens (Slice 2007).
- **Procrustes Distances:** Approximately, the square root of the sum of squared differences between the positions of the landmarks in two optimally superimposed configurations at centroid size (Rohlf & Slice 1990).
- **Relative Warps:** Refers to the principal component analysis of shape distribution, in terms of Procrustes distances (Zelditch et al. 2004).
- **Rotation:** Another effect removed by means of Procrustes analysis. Points are aligned under the minimal squares criteria eliminating the movement of the object around an axis. The relative location of points is constant, although the coordinates vary (Rohlf & Slice 1990).
- **Scale:** One of the effects removed by means of Procrustes analysis. The effect of the size of the objects is removed by scaling the points to a centroid size equal to one (Rohlf & Slice 1990).
- **Shape:** Defined as all resulting geometric information once all effects of position, scale and rotation have been removed from an object (Kendall 1989).
- **Shape Variables:** Geometric variables that do not vary according to position, rotation or size of a specimen. The superimposed coordinates of the corresponding landmarks are variable in shape (Slice 2007).
- **Thin-plate Splines:** Visualization tools based on the interpolation of the differences between the locations of a set of landmarks from their equivalents (Slice 2007).

The function of any physical attribute of an organism is its action from a morphological perspective, and refers to how the structure works (Linde-Medina 2006). Refers to the emergent properties of the shape of a characteristic; different to the use given by an organism of the uses that a trait offers which defines its "biological role" or "biological function" (Linde-Medina 2006).

Functional morphology is the study of the relationship between the shape of structures in an organism and its functions (Alexander 1967). In the real world which we all study –living organisms- form and function are never separate. Form does not exist in any way that is not a result of function. Form does not exist without function and function does not exist without a formal cause and a context. Our minds take form and function as independent as an analysis exercise: in our reductionist world, we take things apart to understand how they work (Wainwright 1988). Therefore, mechanical design of animal systems is a fundamental subject within functional morphology (Westneat 2003).

The link between form-function and ecology is analyzed through the concept of ecomorphology, which is an approximation to understand the ecological relationships between species that is based on the supposed functional relationship that exists between morphological adaptations of an organism and environmental characteristics in which it is

found (e.g., the shape of structures associated with feeding is related to the characteristics and size of the prey) (Wainwright 1994). The relationship between an organism morphology and its ecological function is subject to the limitations imposed by different selective pressures and changes occurring in ecosystems (Bulté et al. 2010; Brecko et al. 2008). Conceptually, ecomorphology is the "study of the relationship between the morphology of the organism and its environment" (Wainwright & Reilly 1994). Essentially it deals with ecological questions through the phenotypic analysis of organisms (Schwenk & Rubega 2005).

Therefore, the need to know the relationship between morphology, performance and ecology of species and its effect on morphological plasticity, to help us to understand the ecological processes that lead to the evolution of phenotype; the correspondence between the anatomical features that influence the performance of associated species serves as a benchmark to represent the variation of their ecological role. Phenotypic variability present between individuals and species is directly related to ecological differences; so that variants in shape determine ecological strategies within which is found different ways of resource use (Wainwright 1994).

For example, muscle and bone structure in vertebrates jaw reflects the way they capture food (Westneat 2003). The variation in the structures involved in this process may reflect differences in how prey is captured and indirect ecological factors affecting these characteristics such as competition (Hulsey et al. 2005), predation (Ruehl & Dewitt 2005) and environmental conditions (Robinson et al*.* 1996; Ruehl & Dewitt 2005). Also the conditions that affect feeding morphology may affect non-trophic traits through correlated effects with other morphological components such as body shape; therefore a common goal in the analysis of trophic ecology is to predict the composition of individuals diet, taking into account that predators can consume either the prey that is in greatest abundance around them, or can choose to selectively feed on specific prey (Scharf et al. 2000).

Hence, the consumption patterns of prey depend on several factors and among them, one of the most important is predator's efficiency, since only prey that are located, captured, transported and digested can be included within the diet (Franco-Moreno 2011). This efficiency is controlled by the intrinsic properties that are product of the feeding system design of each predator (Wainwright 1994).

Sea turtles in particular are an excellent biological model which aspects of the ecological and environmental adaptations are reflected in morphology. There is a relatively extensive knowledge of the food components consumed by sea turtles that include a wide range of groups: sponges, jellyfish, corals, crustaceans, mollusks, tunicates, fish, algae and seagrasses. However, to date few studies have analyzed the variations in shape of the craniomandibular system of turtles taking into account sources of variation: inter-specific, intra-specific, geographic, etc.

## **SKULL IN SEA TURTLES**

In general, the skull of vertebrates is characterized by a complex anatomical integration in which features such as kinetic union, dentition and mandibular mobility interact collectively, influencing feeding performance parameters (bite force or jaw force).

In general, vertebrate exhibit positive allometry in feeding performance (bite force and velocity) during ontogeny, so that the adults have a relatively higher performance than

juveniles; these allometric growth patterns have often been associated with dietary changes and niche distribution, because an increased performance facilitates consumption of functionally more complex prey (e.g., larger size, hardness and resistance), that younger members of the same species would be unable to consume (Hernández & Motta 1997; Herrel et al. 2002).

Most relevant skeletal components found in skulls of this group are derived from ancestral splanchnocranium; significant ancestral trait in the origin of vertebrates (and more specifically tetrapods), present in the head of practically all of these organisms under any variety in the form-function complex (Schwenk 2000).

The turtle skull is composed of an interior braincase –neurocranium- which contains the brain and an external bone structure—splanchnocranium—whose anterior part and mandibular bones form the jaws. The splanchnocranium also contains the sensory organs and provides attachment points for the jaw, throat and neck muscles. For chelonians this structure consists of strongly articulated bones; a secondary palate is presented and general shape of the skull and palate present differences between species. The following refers to the main anatomical differences for four species of sea turtles found in the west coast of Baja California Sur and Gulf of California, Mexico (*Chelonia mydas*, *Caretta caretta*, *Lepidochelys olivacea* and *Eretmochelys imbricata*). Dimensioning is because the morphometric exercise shown hereinafter will focus on the differences of the shape of the lower jaw of these species.

Figure 1. Skull of green turtle (*Chelonia mydas*) in dorsal view (top left), ventral view (top right) and dentary (below).

In the case of the green turtle *C. mydas* (Figure 1) the skull is rounded with a short snout and shallow parietal notches; the palate presents a pair of ridges that run parallel to the outer

edge of the mandible, between the margins of the upper jaw and internal nostrils. Dentary may have many small cusps in young individuals and these are usually reduced or absent in adults (Lutz et al. 1996).

The skulls of the loggerhead turtle, *C. Caretta* (Figure 2) and olive ridley turtle, *L. olivacea* (Figure 3) are relatively large, wide at the back and with the snout tapering towards the orbits. Parietal notches are presented along the rear edges of squamosal, parietal and supraoccipital bones; mandibles are robust and buccal canal ends sharpened.

For *C caretta* the two maxillary bones are articulated on the midline of the palate before the vomer (Figure 2), in contrast to *L. olivacea* (Figure 3) which has two maxillary bones separated by this structure, which extends to the front and articulates with the premaxillary bones; in both species the secondary palate is long and no alveolar ridges are presented. Particularly, the pterygoid in *L. olivacea* is proportional and its processes are very pronounced (Wyneken 2004).

The skull of the hawksbill turtle, *E. imbricata* (Figure 4) is elongated, narrow and has a length approximately equal to twice its width. This species I characterized by a deep parietal notches and well-developed secondary palate, resulting in the internal nares being located further back compared to other chelonians*.*

Figure 2. Skull of loggerhead (*Caretta caretta*) in dorsal (top left) view, ventral (top right) view and dentary (below).

Figure 3. Skull of olive ridley (*Lepidochelys olivacea*) in dorsal (right) view (left) and ventral view.

Figure 4. Skull of hawksbill (*Eretmochelys imbricata*) in dorsal (top left) view, ventral (top right) view and dentary (below).

Characteristically, turtles have lost their dentition and this is a derived condition (Schwenk 2000); these organisms have completely lost their teeth which have been replaced by a horny structure or ramphoteca. This covers the maxillary, premaxillary and vomer bones in the upper jaw and the dentary bone in the lower jaw (Wyneken 2004) (Figure 5).

The ramphoteca is derived from the outer layer of dead keratinized cells, typical of the integument of all tetrapods; which covers the mandible edges and extends to the palate and ventral part of the mouth, forming a grinding surface to process food. It is characterized by a very sharp apical edge; when the lower jaw is raised, it fits tightly within the upper jaw so that the lateral surface of the lower beak slides over the inner surface of the upper part, simulating the movement of a pair of scissors (Schwenk 2000).

As for the musculature, special attention is paid to those structures closely involved in the feeding process and which perform the following functions: *abduction*, in which a portion of the ventral surface moves away and *adduction*, which brings it towards the ventral surface. In the case of sea turtles these two functions are special because the depressor muscles open the jaws, while the levators close them (Wyneken 2004). Unlike what happens for other vertebrates in which the adductor mandibular muscles are those that are responsible for allowing the mandibular opening and closing.

## **FEEDING PROCESS AND FEEDING SYSTEM**

One of the main functions of any organism is feeding. This process requires the anatomical and functional integration of a large number of components; one of the highlights of the feeding function in sea turtles, as a group, is its diversity (Schwenk 2000). The relative functionality of the feeding system has a major impact on individual survival and of course, in reproductive success, therefore it is reasonable that this system is under strong selection and that variations in its morphology significantly affect performance (Schwenk 2000). The importance of this system for survival and adaptation stands out due to its great impact on the body plan of tetrapods, mainly through its influence on cranial shape (Schwenk 2000).

For practical reasons, it is considered that the feeding type of sea turtles would consist of two phases: the first involves prey capture and it is defined mainly by mandibular prehension, with two variants: tearing and piercing. Specifically piercing would be the mechanism presented by these organisms, because it is typical in homodont or toothless species which trap and transport their prey with their jaws. The adjustment generated between the upper and lower beak creates a cutting action and additionally can generate a grinding action toward the lateral side, between the upper and lower surfaces.

The second phase, ingestion, would take place by suction; sea turtles are characterized by a large, articulated and ossified hyoid apparatus that is associated with the ability to generate significant amount of force that allows them to move large amounts of water during ingestion (Figure 6).

Figure 5. Skull of green turtle (*Chelonia mydas*), highlighting the horny structure or ramphoteca.

Figure 6. Feeding process for vertebrates. Sea turtles have phase 1 and 2 separated and not chewing presents, so after ingestion step into the esophagus occurs. Taken and modified: Hiiemae (1967).

## **FEEDING HABITS OF EACH SPECIES**

Although sea turtle populations present different diets depending on the availability of characteristic sources within their habitats, in this chapter we will pay special attention to populations of the eastern Pacific. Particularly those living in the waters of Baja California Peninsula and the Gulf of California.

## **Green Turtle (***Chelonia mydas***)**

The East Pacific green turtle –known regionally as the black turtle– has a distribution ranging from southern Canada to Chile (Parker & Wing 2000; Márquez 2000), with important nesting areas in Mexico, Panama and Ecuador (Cliffton et al. 1982). The coastal lagoons of Baja California Peninsula are considered important areas for development and supply of juveniles and sub-adults of this species (Márquez 1990; Gartner & Nichols 2001), which recruit the ±35 cm curved carapace length (CCL) (Seminoff et al. 2002a, López-Castro et al. 2010) and can inhabit lagoon channels for over 20 years, while reaching sexual maturity (Koch et al. 2007).

It is the only one of the seven species of sea turtles, -which in most of its populations- in subadult and adult stages presents an herbivorous diet (Balazs 1982; Bjorndal & Bolten 1988), so it has been considered to occupy a unique ecological niche among this group of reptiles (Mortimer 1982). Its ontogenetic habitat changes, in turn, have a strong influence in modifying its diet (Bjorndal 1997). It is considered the most carnivorous of the *C. mydas* populations, since its diet plus algae and seagrasses include lots of invertebrates throughout its life (Seminoff et al. 2002b; López-Mendilaharsu et al. 2005; Amorocho & Reina 2007; Carrión-Cortez et al. 2010; Rguez-Baron et al. 2011, un-publishing data) (Table 1).

#### **Loggerhead (***Caretta caretta***)**

The west coast of the Baja California Peninsula and to a lesser extent the Gulf of California, represent one of the most important feeding areas for North Pacific loggerheads (Bowen et al. 1995). These turtles which are born exclusively on the coast of Japan, travel across the North Pacific to find the productive waters of the Gulf of Ulloa (Baja California) and the Gulf of California (Nichols et al. 2000). It has been estimated that they can stay there up to 30 years until they reach sexual maturity and return to Japanese waters to reproduce (Nichols et al*.* 2000; Peckham et al*.* 2011).

The diet of juveniles that inhabit Mexican waters is mainly composed of red crab (*Pleuroncodes planipes*), demersal fish (discarded from fishing operations) and jellyfish (Peckham et al. 2011) and differs significantly from that reported by Parker et al. (2005) for the central North Pacific (Gastropoda, Hydrozoa, Maxillopoda, Malacostraca, Thaliacea, Cephalopoda, Actinopterygii, Actinopterygii eggs, Polychaeta and algae) (Table 1). This is interesting as these juvenile turtles are from the same reproductive stock (Bowen et al. 1995).

#### **Olive Ridley (***Lepidochelys olivacea***)**

Unlike most species of the Cheloniidae family, the olive ridley has a mainly oceanic behavior (Bolten 2003). Its great mandibular strength allows it to access prey with hard bodies such as snails and crustaceans; it also feeds regularly on benthic fish, sea urchins and jellyfish (Carr 1961; Mortimer 1982; Márquez 1990) (Table 1).

The nesting beaches of the Baja California Peninsula represent the northern limit of the north Pacific olive ridley reproductive stock. In the Gulf of Ulloa, juveniles and adults of this species are sympatric to juvenile *C. caretta* (Peckham unpublished data). This behavior has already been reported in Hawaii by Polovina et al. (2004); however, their diets differ significantly, which can be attributed to differences in patterns of diving behavior: olive ridleys spend 20% of their time on the surface and present deeper dives than those of the loggerhead turtles, which spend 40% of time on the surface (Polovina et al. 2004).

#### **Hawksbill (***Eretmochelys imbricata***)**

This species is considered to be more faithful to its habitats once it recruits to neritic areas after its oceanic phase. It is characterized by a considerably smaller range of distribution when compared with other sea turtle species (Bolten 2003). Most research on hawksbill ecology have focused on studies about coral reef systems and to a lesser extent on sea-grass beds, where until it was recently believed to be the limit of their distribution (Bjorndal 1997; Bjorndal & Bolten 1988, 2010).

Since in the eastern Pacific there was no evidence of their presence in these ecosystems, hawksbills were considered functionally extinct (Bjorndal 1997). However, Gaos et al. (2012) demonstrated by means of satellite telemetry, that adult hawksbill turtles gather in mangrove systems during certain periods, giving important information about their life history.

Their diet in the Caribbean is mainly spongivourous (Meylan 1988), although depending on the foraging area, cnidarians (Leon & Bjornadal 2002), false corals (Rincón-Díaz et al. 2011), algae (Berube et al. 2012) and sea-grass (Bjornadal & Bolten 2010) have been identified as major components in their diet. Even though studies have not been undertaken on East Pacific hawksbill diet, due to its use of habitat, it is thought to feed mainly on mangrove structures, sponges and tunicates (Gaos et al. 2012) (Table 1).

## **METHODS**

## **Morphological Analysis through Geometric Morphometrics**

Any quantitative measure or numerical analysis of morphological features of an organism is called Morphometry; the quantitative representation and analysis of shape using geometric coordinates instead of measurements is known as Geometric Morphometrics (Polly 2012).

## **Table 1. Feeding components of the diet of four species of sea turtles (***Chelonia mydas, Caretta caretta, Lepidochelys olivacea* **and** *Eretmochelys imbricata***)**

One important purpose of morphometric studies is to understand the variations in size and shape of an organism's body within a broad evolutionary context. This tool allows us to relate morphology with ecological attributes such as predation, competition, environmental performance in obtaining food and mating (Davis et al. 2010); enabling us to answer questions such as "how different are two organisms?" or "with which factors differences in shape are correlate?".

In this regard, Geometric Morphometrics allows the analysis of variation in shape based on the location of landmarks (Adams et al. 2004), which by taking into account the criterion of homology in which they develop are biologically definable and comparable between specimens, and they constitute specific natural points which are located on biological shape according to a scale (Slice et al. 1998). According to Bookstein (1991), there are three main types, which correspond to three ways of addressing epigenetic explanations that are in principle subject of these measurements:

**Type I: Juxtaposition of tissues.** Includes conventional points in which homology is based on a robust biological interpretation (anatomical: sutures and insertion of different structures, etc.). Although its location is limited to the edges of structural components of a shape or to regions defined by where different tissues are juxtaposed, it is not determined by general contour characteristics (MacLeod 2001).

**Type II: Maximum curvature or other local morphogenetic processes.** These include the protuberances apices and invagination valleys. The skeletal processes where muscle adhesion occurs are also included.

**Type III: Extreme points.** Include points that characterize a region of body design that may include information of a finite number of separate regions (extreme points of a diameter, intersections in segments found between type I landmarks). Although they are considered "deficient" because they do not have all the coordinates and it is not common to include them in the analysis, its displacement is significant mainly when are located in segments or areas of the structure, whose boundaries are defined by type I landmarks. Due to the variable nature of this type of landmarks and its dependence on a wide variety of conditions, they have been redefined as semi-landmarks (Bookstein 1997; MacLeod 2001). Polly (2012), defines these as marks that are positioned arbitrarily using an algorithm, often by defining extreme (or limit) landmarks, within which a specific number of semi-landmarks are placed.

To define landmarks that will represent shape(s) structure(s) or specimens to be evaluated, it is important to consider three main factors:

- The landmarks should proportion information that allows us to test the proposed hypotheses.
- They should adequately represent the shape and.
- They must be presented in all specimens.

In such a case, if what is sought is to relate morphology with ecological aspects such as changes in feeding habits on a inter or intraspecific level, landmarks must be located on the individuals craniomandibular system and focus on those structures involved in the feeding process (prey capture).

For each individual, landmarks are quantified on a bidimensional plane, at coordinates (x, y); once all landmarks on all of the specimens coincide as closely as possible, the differences between the coordinates for each landmark can be comparable.

To achieve this, landmark configuration from one specimen is overlapped on another as to coincide as closely as possible (Rohlf & Marcus 1993); the variation that is not due to shape and is generated by changes in position, rotation and scale of specimens is then removed (Slice et al., 1998). The most common method of superimposition is Procrustes analysis, which estimates the position and orientation parameters minimizing the sum of the distances squares between the configurations of two corresponding landmarks (Bookstein 1991).

This is achieved in three steps (Slice & Rohlf 1990; Polly 2012):

- $\bullet$  The centroid of each individual is moved to the origin  $(0, 0)$ ; the centroid of the shape for each pair of landmarks is subtracted (Figure 7a).
- Generally all shapes are scaled to the same size (which usually corresponds to the centroid size; this is calculated from the mean shape and each of the "new" shapes) (Figure 7b).
- The shape is rotated around the origin, until the sum of the distances squares between corresponding landmarks is minimized (Figure 7c).

Figure 7. Processes of (a) position, (b) scale and (c) rotation that are removed by Procrustes analysis.

The result of this process is the elimination of size effects, thus the first principal component is shape. Additionally, this allows the configurations of landmarks to be directly comparable when putting in the same coordinate system and facilitates the formulation of hypotheses regarding organism shape, by minimizing the distances between landmarks, ensuring that any difference between shapes is "true" (Polly 2012).

For each specimen, iterations of the process are performed, obtaining the average shape (consensus configuration), after this, the landmark configurations are placed in a common coordinate system, and these are used as shape variables (Adams et al. 2004).

The most common method to visualize the differences between a specimens shape is by thin-plate splines. In these representations it is assumed that landmarks are placed on an infinitely thin metal plate; if we have two specimens, one of the configurations of landmarks may be found on a straight plate while for the other, the plate must be deformed to adjust to the first configuration (Bookstein 1991). The difference in shape between the two specimens, can be expressed as the energy needed to adjust the straight plate to its new shape (bending energy). The deformation of the plate shows where the differences between specimens exist, considering the variation of each landmark separately (Figure 8).

This form of visualization allows the interpretation of the results directly within the context of cranial anatomy and has been used for a little over a decade (i.e., Klingenberg  $\&$ Zaklan 2000; Klingenberg et al. 2001a; Bookstein et al. 2003).

Finally an ordination plane of the distribution of the shape in terms of the Procrustes distances is obtained. The visualization method by thin-plate splines from relative warps, was developed by Bookstein (1989, 1991) to analyze the morphometric variation within a population using landmarks; each warp is taken as a change in the direction of the shape in respect to the average. These are used to describe the trends in the variation of the shape between specimens and can be interpreted as the deformation in a physical space for each landmark, with respect to the mean. Furthermore, these warps can be shown as displacement vectors for each landmark with respect to reference specimen (Rohlf 1993), facilitating the visualization of the location, direction and magnitude of morphological change.

Figure 8. Deformation grid for landmarks with respect to a mean shape in a physical space (thin-plate spline).

Lastly, morphometric distances are considered as the main measure of differences between individuals, for all variables that were represented; for Geometric Morphometrics the primary measure of differences would be the Procrustes distances, i.e., distances between shapes after performing superimposition (Polly 2012).

Specifically with respect to morphometric analysis of the skull, we must take into account that the parts of this structure are integrated with each other as they develop, operate and evolve together. However integration is not absolute, but is divided into modules which are relatively independent within the entire unit (Klingenberg 2008, 2010). Thus the concepts of integration and modularity are closely linked and must be considered together. This is demonstrated in the example shown in the following sections.

Geometric morphometric methods are suitable for the investigation of morphological integration and modularity for several reasons. Firstly, it provides a wide range of powerful statistical tools to answer specific biological questions concerning modularity and integration. The combination of the geometry with multivariate statistics ensures that the shape of a structure is completely characterized without repetition. Additionally, all spatial relationships between landmarks or other geometric characteristics included are taken into account, without the need to define a set of features to include in the analysis *a priori*.

### **FUNCTIONAL ANALYSIS BY BIOMECHANICAL MODELS**

Biomechanics in functional morphology covers the physics of biological materials and the environment that surrounds them, with the respective consequences for organism shape, function and evolution (Schwenk 2000). It is based on mechanics, engineering, anatomy and physiology among other disciplines; through which a precise description and analysis of the movement of the systems that composed living organisms and its causes are realized.

Measuring the performance associated with the mandibular system of vertebrates allows us to analyze how processes of feeding, prey capture, mating and defense from predators occur. The bite force is closely linked to the design of the craniomandibular system and therefore can be used as an indicator of the overall performance of the whole organism in relation to its morphology (Anderson 2009).

The study of biomechanics allows us to design and explore models that explain how mechanical forces act within organic systems and structures of living beings. The increased force provides an ecological advantage in the resources distribution and niche differentiation, diminishing competition and increasing the spectrum of availability prey allowing for the coexistence of several species within the same habitat (Kiltie 1982; Herrel et al. 2001; Herrel et al. 2005; Dumont et al. 2005; Wroe et al. 2005).

Biomechanical models outline the physical and physiological principles that determine the functions in organisms, allowing ecological and functional inferences based on morphology (Westneat 2006). In general, the jaws of vertebrates is a simple lever which closure is permitted by the adductor mandibulae muscles, which pull the jaw around a rotation point (formed by the jaw joint) creating a third order mechanism (Figure 9) (Westneat 2010). In this the effort lies between the resistance and fulcrum, and it is characterized because the input force being higher than the output force; it is employed when increased velocity transmitted to an object is required or the distance travelled by this.

Figure 9. Third order simple lever.

The generation of force and velocity through this system, depends on the input force  $(I_f)$ and the distance between the point at which the effort is generated, regarding the input  $(I_f; I:$ in-lever arm) and output forces ( $O_f$ ; O: (out-lever arm) and the fulcrum. The above generates a corresponding (d) displacement (Figure 10).

For sea turtles the rotation point (fulcrum) of the lever would consist by the quadratojugal-mandibular joint (towards the articular bone), around which would turn the other bone elements by the action of adductor mandibulae complex that presents several parts: these originate in the parietal, quadratal and supraoccipital bones (Figure 11) and converge in a tendon that is mainly inserted into the lower jaw (dentary, with small insertions in the squamosal bone after the jaw joint) (Wyneken 2004).

Figure 10. Generation of force and velocity in a third lever order. Input force  $(I_f)$ , output force  $(O_f)$ , in-lever arm (I), out-lever arm (O) and displacement (d). Taken and modified: Herrel & Aerts 2003.

Figure 11. Cranial structure of *C. mydas* highlighting the bones in which adductor mandibulae complex is origin and the quadratojugal-mandibular joint (fulcrum of lever: red triangle).

## **EXAMPLE**

To show the scope of Geometric Morphometrics, we developed a preliminary exercise in order to describe the main differences in the morphological features of the mandibular system of the four species of sea turtles listed above (*C. mydas*, *C. caretta*, *L. olivacea* and *E. imbricata*), distributed along the west coast of the Baja California Peninsula and Gulf of California.

We digitized 129 images of the lower jaw of the four species (*C. mydas*: 35, *C. caretta*: 78, *L. olivacea:* 11 and *E. imbricata:* 5), retaining the same conditions when photographing each specimen. Subsequently landmarks (Table 2, Figure 12) were located to describe the mandibular design and to carry out the comparisons. In this process we employed type I, II and III landmarks (mentioned above), because using only the first type is not enough, particularly when the design of the structure to be analyzed is composed by surface, contours or edges (as applicable) where it would be difficult to locate them. Given these considerations located landmarks corresponded to (Figure 12, Table 2):

Subsequently relative warps for each landmark were obtained, creating a matrix in which the shape variables are grouped. We obtained thin-plate splines, which as explained above help us to visualize the changes in the disposition of landmarks with respect to the mean shape, as deformations generated in the grids when they try to adjust to the average shape.

Figure 12. Landmarks (top) and semi-landmarks (below), placed to describe mandible shape.

#### **Table 2. Landmarks and semi-landmarks placed to describe the mandibular shape of the four sea turtles species**

Figure 13. Thin-plate splines obtained from landmarks placed on the lower jaw of the four sea turtles species.

From the thin-plate splines (Figure 13) it is possible to identify that the main differences in the lower jaw of the four species occur at the anterior region of the dentary. It corresponds to the left end of the first axis of variation, where we would find *C. caretta* and *L. olivacea* characterized by a dentary that differs markedly from the ascending process of the articular bone, which is wide and whose apex is blunted (Figure 14). Towards the right end of the ordination plane we would find *C. mydas* and *E. imbricata*, characterized by the absence of a marked difference between the dentary and the articular bone, whose ascending process has a pointed apex (Figures 13 and 14). These differences could be generating variations in feeding performance for these species, as it is in the lower jaw that the movement to carry out this process is generated, and the anterior region of the dentary would constitute the point of grip or press prey.

The second axis of variation was characterized by differences presented towards the posteroventral area of articular bone; in this case, the positive values are associated with the species *C. caretta* and *E. imbricata* characterized by a sharp termination of the articular bone (posterior region of the lower jaw) compared with negative values that relate to *L. olivacea* and *C. mydas* in which a blunt termination was observed (Figures 13 and 14). As for the variations due to the first axis, the differences could be affecting mandibular performance: the posterior region of the mandible is the area of junction with the skull and therefore, the rotation point that allows the movement of this structure. However, in this example we do not quantify the performance variables of the four species by using biomechanical models.

Figure 14. Dentary structure for the four sea turtles species.

We can then determine the relevance of the anatomic features whose morphological variation (measured from the Geometric Morphometrics technique) has functional consequences in the feeding performance of sea turtles. The success in the feeding event and more specifically during the prey capture can be developed using different strategies, which are facilitated by the characteristic shape of each species. This ultimately allows us to define the ecological role of each species in the ecosystem and if processes of interspecific competition are present or not.

### **ABSTRACT**

This chapter is a review of studies in the toxicology of sea turtles and describes some ecotoxicological analytical procedures. A variety of chemical pollutants (heavy metals, persistent organic pollutants and polycyclic aromatic hydrocarbons) are found in the tissues and bones of sea turtles, including: kidney, muscle, gonads, lung, heart, pancreas, liver, adipose tissue, eggs, blood, faeces, carapace, spleen, bone, spinal cord, brain and urinary bladder. These pollutants have been reported in six species of sea turtle: *Caretta caretta, Chelonia mydas, Dermochelys coriacea, Eretmochelys imbricata, Lepidochelys kempii* and *Lepidochelys olivacea*. Moreover, this chapter will describe studies of *Chelonia mydas* ecotoxicology in Brazil and highlight ecotoxicological prospects in these species as tools for the conservation of sea turtles.

## **INTRODUCTION**

Coastal areas are subjected to constant pressure by human activities, due to their socioeconomic importance and provision of various resources upon which local populations depend. Currently, coastal regions cover less than 20% of the planet's surface. However, these areas contain more than 45% of the human population; host 75% of megacities (with populations greater than 10 million people) and produce approximately 90% of global fishery

 $\overline{a}$ 

Corresponding Author's Email: teca@ vetorial.net.

stocks. Coastal regions constitute an important area of food production through farming, fishing and aquaculture. These regions are a focal point of industrial development and transport due to: significant mineral resources (including oil and natural gas) and heavy tourism demands. Beyond this, coastal areas are an abundant reservoir of biodiversity and ecosystems, upon which significant global functions depend (GESAMP 2010).

Pollution of coastal regions is associated with direct or indirect anthropogenically driven introduction of substances or energy into the marine environment, resulting in deleterious effects. Harm to living resources, hazards to human health and the hindrance of marine activities including fishing, reduction in quality of sea water or amenities likely result. Stressors resulting from pollution are associated with features of toxicity, persistence and bioaccumulation of substances in living organisms. Groups of potentially harmful substances that exist in marine environments, and for which critical issues have been identified include: oil derivatives, domestic sewage, heavy metals, radioactive materials and organochlorines (GESAMP 2009). In this scenario, estuaries and coastal regions generally act as the final receiving body of these substances. The sensitivity of estuarine and coastal regions to environmental impacts will depend on the ecological and biogeochemical characteristics of each particular region, including the presence or absence of human activities in that area (Lana et al. 2006). It is necessary, therefore, to design indicators of estuarine and coastal areas, able to provide reliable scenarios to diagnose the quality of the environment and the impacts of compromised systems on living organisms.

Ecotoxicology can be defined as the science of assessing effects of toxic substances on ecosystems. The primary goal of this field is the protection of entire ecosystems, and not merely isolated components (Hoffman et al. 2003). Previously, reptiles have been used as indicators or sentinels of environmental pollution. These species play a significant role in the transport of pollutants between trophic networks, which is underestimated by a lack of studies (Gardner & Oberdörster 2005); however further emphasizes their potential for environmental pollution modelling. The direct and indirect effects of environmental pollution and climate change can hardly be quantified, further inhibiting our understanding of potential factors that influence populations and their habitats. Long term monitoring of populations of reptiles should be standardized in order to identify possible causes of the decline in reptiles worldwide (Gibbons et al. 2000).

### **ECOTOXICOLOGY AS A TOOL FOR CONSERVATION OF SEA TURTLES**

Sea turtles represent an interesting species to be used as biological indicators of environmental pollution, as they are subject to various threats linked to the dramatic ontogenetic changes in their life cycle. Development of sea turtles begins in the terrestrial environment, before moving to a pelagic phase, and finally returning to coastal areas to feed. As such, these individuals occupy a wide variety of ecosystems such as rocky shores, mangroves, coral reefs, seagrasses and offshore environments (Plotkin 2003; Bolten 2003). Developing within a wide range of environments increases the possibility of interacting with anthropogenic impacts including pollution, predation or changing environments (Marcovaldi et al. 2006; Gilman et al. 2007).

Adding to their high mobility throughout different ecosystems, the long life history of sea turtles enables an extended exposure period to polluting substances, both spatially and temporally. These attributes make these species an excellent model of pollution indicators or sentinels for monitoring the degree of costal contamination. A variety of chemical pollutants have previously been reported for sea turtles (heavy metals, persistent organic pollutants and polycyclic aromatic hydrocarbons) (Keller et al. 2004; Hamann et al. 2010; Lazar et al. 2011; Camacho et al. 2013).

Review studies regarding the toxicology of sea turtles have assessed six species (*Caretta caretta, Chelonia mydas, Dermochelys coriacea, Eretmochelys imbricata, Lepidochelys kempii* and *Lepidochelys olivace*a), however, *C. mydas* and *C. caretta* are more highlighted in this field. Studies with heavy metals and persistent organic pollutants (POPs) have identified a range of contaminants in various sea turtle tissues (kidney, muscle, gonads, lung, heart, pancreas, liver, adipose tissue, eggs, blood, faeces, carapace, spleen, bone, spinal cord, brain, urinary bladder). Differences in the accumulation rate depends on species, sizes and tissue type, along with environmental differences between species including: pelagic or sedentary life strategy, trophic levels, food items, and growth rates (Caurant et al. 1999; Pugh & Becker 2001; Gardner et al. 2006; Talavera-Saenz et al. 2007; Keller et al. 2006; Innis et al. 2008; Andreani et al. 2008; D'Ilio et al. 2011).

Some studies have been conducted to identify concentrations of heavy metals in sea turtles, reporting a higher accumulation of copper (Cu) and lead (Pb) in the kidney (Lam et al. 2004; Anan et al. 2001; Caurant et al. 1999) and copper (Pugh & Becker 2001; Fitzgerald 2004; Lam et al. 2004; Anan et al. 2001; Caurant et al. 1999; Innis et al. 2008; Andreani et al. 2008) and iron (Fe) (Aguirre 2004) in the liver. Silva et al. (2014) reported that zinc (Zn) concentrations for *C. mydas* in the muscle was the highest of all metals analysed, and the highest concentrations of lead, cadmium (Cd) and zinc were found in the kidney. The liver, however, was found to contain the highest values of silver (Ag) and copper.

Others studies that investigated metal profiles as environmental markers in green turtles demonstrated excellent correlations between the state of pollution in these foraging environments and the metal accumulation in the turtle (Talavera-Saenz et al. 2007; Franzellitti et al. 2004). Storelli et al. (2008) in the Mediterranean region, showed that the distribution of metals at the subcellular level and in the cytosol of liver and kidney cells plays a crucial role in the accumulation of metals such as Cd, Cu and Zn for *C. mydas*. However, many controversies related to the physiological and metabolic differences possible within the same species and exposure levels associated with the migratory routes remain (Fitzgerald 2004). Previous studies determined the concentrations of heavy metals in green turtles from the Caribbean (*C. mydas*) and loggerheads from the Italian Mediterranean (*C. caretta*), and evaluated hepatic and renal concentrations of methalothioneins (MT) as biomarkers of metal exposure, thus providing a useful tool in the long-term conservation of sea turtles (Andreani et al. 2008).

Assessments of persistent organic pollutants (POPs) have increased in recent years, as these pollutants possess characteristics to pose a significant environmental risk. POPs are persistent in the environment at a decadal scale; capable of becoming highly concentrated in fatty tissues. These can then become subsequently transferred great distances along trophic levels; a process linked with serious health effects in humans and other living organisms (WHO 1993).

Additionally, these substances undergo processes of bioaccumulation greater at each increasing level along the food chain (Peruguini et al. 2007). POPs reported within sea turtles include polychlorinated biphenyls (PCBs), organochlorine compounds (OCs) and perfluorinated compounds (PFCs) as the most studied. Among OCs, organochlorinated pesticides and hexachlorobenzene (HCB) are the two most important classes investigated (Cobb & Wood 1997; Alam & Brim 2000; Corsolini et al. 2000, Storelli & Marcotrigiano 2000; Keller et al. 2004, 2005; Storelli et al. 2007; Monagas et al. 2008; Oros et al. 2009; Richardson et al. 2010; Lazar et al. 2011; D'Ilio et al. 2011; Camacho et al. 2012, 2013).

Despite significant oil spills at sea, the impact of oil on sea turtles remains relatively unknown. However, studies have assessed polycyclic aromatic hydrocarbons (PAHs) due to the potential for metabolizing and subsequent biomagnification of these substances within the marine food chain (Camacho et al. 2013). Oil exposure can affect turtles via increased egg mortality and developmental defects; direct mortality due to oiling in hatchlings, juveniles, and adults; negative impacts to the skin, blood, digestive and immune systems, and salt glands of individuals (Milton et al. 2003). Stressor conditions for exposure to PAHs can inflict long-term impacts on sea turtle populations, due to decreased fitness of sea turtle individuals, and subsequent increases in population susceptibility to environmental pressures. Previously, Hutchinson and Simmonds (1992) proposed a relationship between low-level chronic exposure to contaminants and the occurrence of cutaneous fibropapillomatosis in sea turtles. Camacho et al. (2012) reported baseline concentrations of PAHs in loggerhead sea turtles from two populations of the West Africa coast; however, they suggested that further studies are necessary to evaluate the long term deleterious effects of PAH exposure.

The use of non-invasive biomarkers in apex species that are in danger of extinction such as seals, dolphins, hawks, cormorants, herons and whales has been reported in previous studies (Casini et al. 2003; Fossi et al. 1999). The application of non-invasive biomarkers for species threatened with extinction allows the use of animals found in the wild as indicators of the state of conservation of ecosystems and long-term monitoring. Techniques investigating the detection of vitellogenin in green turtles, as non-invasive biomarkers, found associations between the expression of this precursor molecule for egg yolk proteins, lipovitellins and phosphovitins with xenoestrogens as environmental stressors (Sifuentes-Romero et al. 2006).

The first study that implemented non-invasive biomarkers was developed with green turtles in Uruguay through the use of porphyrins for the detection of heavy metals and PAHs (Berrondo 2007). Porphyrins are byproducts of oxidative metabolites, intermediate metabolites of heme biosynthesis and are synthesized by organisms via cellular respiration. Porphyrins include Coproporphyrins and Uroporphyrins.

These metabolic products are stored in heritopoyetic tissues (liver, kidney) and excreted in urine and faeces (Berrondo 2007; Fossi et al. 1999). The presence of pollutants such as PAHs, PCBs and heavy metals alter hemosynthesis by interfering with biosynthesizing enzymes and subsequently altering the profile of excreted porphyrins. Through accumulation of uroporphyrins it is possible to identify the presence and concentration of PAHs, and through accumulation of coproporphyrins and uroporphyrins it is possible to detect PCBs (Berrondo 2007).

Sea turtles applied as bioindicators of pollution in marine ecosystems are of increasing interest because they are long-lived species that may bioaccumulate organic and inorganic contaminants from food, sediment and water (Andreani et al. 2008). These characteristics enable ecotoxicological studies to assess the response of sea turtle populations to pollutants in

ambient environment. This is enabled by the recovery of valuable information from dead animals of endangered populations, promoting the development of monitoring protocols over long-term periods that link mortalities with the harmful effects of pollutants.

# **ANALYTICAL PROCEDURES USED IN SEA TURTLES ECOTOXICOLOGY STUDIES**

The differences in metabolized forms of chemical substances necessitates the detection and evaluation of the impact of pollutants in exposed organisms. This leads to the study and development of morphological, molecular, biochemical or physiological biomarkers that detect biological effects on organisms (Bianchini et al. 2006).

This chapter will use the biomarker terms defined by Livingstone (1993): body fluids, cells or tissues, physiological, behavioural or energetic responses of organisms that may indicate the presence or exposure to contaminants. We then describe any biomarkers used in the ecotoxicological assessment of sea turtle studies.

# **CHEMICAL DETERMINATION OF METALS: USE OF TISSUE RESIDUES IN SEA TURTLE ECOTOXICOLOGY**

Although metals are considered contaminants, it is important to remember that they are natural substances (Walker et al. 2004). Through geological and biological cycles, they are redistributed naturally in the environment; in rocks, minerals, soil, water and air. These levels are generally low and widely dispersed. Rainwater dissolves rocks and physically transports the material to rivers and streams, and eventually into the ocean (Goyer 1991; Novotny 1995). The atmosphere represents a major entry pathway of certain metals into the ocean.

In terms of human exposure and toxicological significance, anthropogenic activities present greater importance in relation to the concentration of metals in the environment, as metal concentrations likely increase with human activities (Silva et al. 2014). Metals have been used throughout human history to make utensils, machinery, and in mining and smelting, while more recently such elements have been used in industry, agriculture and medicine. These activities generate an increase in environmental levels of metals.

With the increased levels of these contaminants in the environment their toxic effects can be felt in many sectors of the biota. This is due to metals being highly reactive and bioaccumulative, i.e., organisms are not able to completely eliminate the metals absorbed. Living things require small amounts of metals to perform vital functions in the body; however, these elements in excessive levels can be toxic (Silva et al. 2014). Other metals, such as mercury, lead and cadmium, have no function in organisms and their accumulation can cause serious illness, especially in vertebrates. When released as industrial waste in water, soil or air, these elements can be absorbed by plants and animals nearby, causing poisoning along the food chain, since they tend to accumulate in aquatic biota (Mazzuco 2008).

For a metal to exert its toxicity, it must cross the membrane and enter the cell. If the metal is of a lipid soluble form, such as methylmercury, it easily penetrates the membrane. However, when attached to proteins such as cadmium bound to metallothionein, the metal enters the cell by endocytosis, while other metals such as lead, can be absorbed by passive diffusion. The toxic effects of metals typically involve interaction between the free metal and cellular target, such as specific biochemical processes and/or cellular and subcellular membranes (Cope et al. 2004).

Based on the above, it denotes that all forms of life are affected by the presence of metals, depending on the concentration and chemical form of these. As previously mentioned, many metals are essential for the growth of all types of organisms, from bacteria to humans, but they are only required at low concentrations and can damage biological systems when present in high concentrations (Silva et al. 2014). The manifestation of toxic effects of metals is associated with their concentration, which can be distributed throughout the body, affecting various organs and altering biochemical processes and cellular structures (Salgado 1996).

In the marine environment, bioaccumulation of metals occurs in many ways, but mainly through the ingestion of food and suspended particulate matter containing metals, and directly from the acquisition of metals from bottom sediments pore waters and removal of metals in solution (Kennish 1997).

The concentration of metals in the tissue of vertebrates has been used as a parameter to evaluate the quality of diverse environments. In the marine environment, mammals, turtles and birds are often affected by pollution due to the longevity of these groups. Furthermore, the position of these species in the trophic web creates susceptibility associated with the cumulative power of cadmium, chromium, lead, mercury and others. This can result in serious damage to the health of diverse populations (Furness & Rainbow 1990).

Assessing hazards and risks to life through metal concentrations in biological tissues is very important, because these residues generally provide a better understanding of the exposure conditions experienced by an organism compared to the concentrations of contaminants in the surrounding environment. In order to use these data for wildlife preservation, we should exercise caution with a number of factors regarding contaminant accumulation; results represent the bioavailability according to the physical-chemical characteristics of the area and chemical speciation of the contaminant as well as ecological and physiological characteristics of organism, which may influence uptake and accumulation (Hopkins 2005).

Reptiles are important members of ecosystems and generally have life history characteristics that make them vulnerable to the accumulation of metals (long life, high trophic level, aquatic habitat). Sea turtles are of increasing interest as potential bioindicators of metal pollution in marine ecosystems, due to the long life of metals in vertebrates, and because these species can accumulate inorganic contaminants through food, water and sediments (Andreani et al. 2008). Since sea turtles inhabit coastal waters, human activities can endanger these animals.

Due to all of these factors, several studies have measured the levels of metals in the tissues of juvenile and adult sea turtles worldwide (Anan et al. 2002; Barbieri 2009; Bezerra et al. 2012; Day et al. 2005; D'Ilio et al. 2011; Godley et al. 1999; Maffucci et al. 2005; Sakai et al. 2000a, 2000b; Silva et al. 2014; Storelli et al. 2005).

The literature shows that muscle, kidney and liver tissues are the most analyzed for quantification of metals, while organic compounds are usually investigated in the tissues of liver and adipose tissue.

Thus, such tissue samples are collected (in addition to samples from other tissues such as heart, pancreas, gonad, skin, brain and lung) in dead individuals. Already in living individuals are collected blood, skin biopsy fragments carapace. The determination of contaminants in the blood is very important because this is the first means of transport of these elements throughout the body and before targeting organs, which may indicate a recent contamination. The elements most frequently analyzed are cadmium, Cu, Hg, Ni, Pb, Se and Zn are the most investigated metals in sea turtles. Cu, Ni, Se and Zn have an essential role in metabolism and animal growth. Cu in particular plays a role in oxygen transport, energy production and enzyme activity (D'Ilio et al. 2011). Zn is essential for the structure and function of many proteins and enzymes for proper functioning of the immune system. Cadmium is generally accumulated in the kidneys over the long-term; this is mainly due to its connection to metallothioneins, as Cu and Zn tend to accumulate in the liver (Andreani et al. 2008) and Pb in the bones. In the aquatic environment, inorganic mercury is microbially transformed into methylmercury, a more bioavailable and toxic organic form (MeHg), with a strong tendency to biomagnify in aquatic food webs (D'Ilio et al. 2011).

For quantification of elements in tissues of sea turtles, the protocol is generally the same, or very similar in all studies, except for some differences in relation to the volumes of reagents employed. The samples are thawed, weighed and usually 1 g of wet weight is placed in an oven to dry  $(60^{\circ}C)$ . After this process, the samples are then digested in concentrated nitric acid (HNO3  $65\%$ ) and then diluted with MilliQ water<sup>®</sup>. The metal concentrations are determined by atomic absorption spectrophotometry (AAS). The two types of atomizers used in AAS are flame and graphite furnace; and there is a third method, by hydride generation. In the case of Hg, samples are usually analyzed through the technique of atomic absorption spectrophotometry with cold vapor (CV-AAS) using a hydride generator coupled to an atomic absorption spectrophotometer.

As more of the form used to quantify metals in tissues of sea turtles is through atomic absorption spectrophotometry with flame. Briefly, the method involves determining the presence and amount of a particular metal in a solution based on the principle that the steady state free atoms can absorb light at a certain wavelength. The absorption is specific to each element. The source most commonly used for atomic absorption measurements is a hollow cathode lamp consisting of a tungsten anode and a cylindrical or zirconium cathode, constructed with the metallic element of interest itself, and supported by a glass tube containing inert gas, such as argon. At one end the electrodes are positioned while the other end is sealed with a transparent window (usually quartz) calibrated for the wavelength of interest (Krug et al. 2004). To assess the concentration of a sample by atomic absorption spectrophotometry, the method involves creating a calibration curve with standardized element solutions and then inserting the sample points on the curve. This yields a concentration to be subtracted against the calibrated points to white.

Data are generally expressed in μg metal/g dry weight tissue; however, some studies express results in wet weight, so such samples do not pass through the drying process. There are no baseline data on the concentration of metals in tissues of sea turtles. Baseline data are typically used to perform a comparison with levels in other environments. However, caution is needed when comparing individuals of a given environment with another geographical area as there are a variety of factors that influence the accumulation of contaminants in wildlife. For example, sex: there may be differences due to changes in behavior, feeding ecology, or reproduction, and in addition, adult females maternally transfer contaminants to their eggs resulting in a disposal route for such individuals (Guirlet et al. 2008).

Age is another factor that may influence the accumulation of contaminants, e.g., metals are accumulated continuously throughout the life of an animal, which would be expected to result in higher residues in the tissues of older animals. This may be true for most species of sea turtles but not for *C. mydas*. A number of studies have reported negative correlations between concentrations of metals in the tissues (As, Cd, Cu, Mn, and Zn) and the turtle size (curved carapace length, CCL) (Gordon et al. 1998; Saeki et al. 2000; Sakai et al. 2000a, b; Silva et al. 2014). An explanation for this trend is the variation in eating habits between youth and adults of *C. mydas*.

In general, green turtle juveniles feed on zooplankton whereas adults graze on grass and seaweed after returning to their feeding grounds in coastal waters (Sakai et al. 2000b). Vegetable items have comparatively lower concentrations of metals than zooplankton, such that the amount of metal available through diet for adults is lower than that of juveniles. A maximum exposure would then be expected to occur early in the life cycle, when the dietary intake of green turtles is based on higher trophic level prey in the food chain (Silva et al. 2014). McKenzie et al. (1999) suggested that the charge of the metal body in green turtles could decrease as the animal grows, due to a dilution effect associated with the reduced intake of contaminants as individuals grow and alter carnivorous feeding habits to herbivorous.

The global importance of marine turtles in the transport of contaminants throughout food webs and ecological systems represents another very interesting situation. For example, turtles are known to be major contributors of nutrients and energy in ecosystems of coastal dunes during the nesting season. Indeed, in some systems where spawning is intense, as in Tortuguero in Costa Rica, approximately 80,000 green turtles lay an average of over 100 eggs per spawning. Turtles can be one of the most important biological transporters of energy and nutrients.

Since maternal transference in sea turtles typically involves high concentrations of contaminants passed on to eggs, the role of turtles in contaminant transport from the ocean to the food chains of coastal dunes should be evaluated (Hopkins 2005). So, working with concentration of contaminants in tissues is very important to increase awareness about the wildlife being affected by human manipulation of the environment, and how this ultimately affects other environments.

To reach our main goal in the conservation of these endangered species, future studies should focus on how a contaminant is accumulated, which influences its accumulation and division among the tissues, and that the accumulation is important for the body. Thus, the tissue concentrations of metals will be more useful to understand the concentration of the surrounding environment and the possible effects resulting from this exposure.

### **OXIDATIVE STRESS BIOMARKERS**

All cells utilize oxygen in respiration for generating energy, a fundamental process without which much of life could not exist. The oxidation process creates free radicals as a byproduct, which in large proportions can cause damage to cells. However, oxidative stress is caused by an imbalance between the production of such reactive oxygen species (ROS) and the ability of a system to rapidly detoxify these biological intermediate reagents or repair the resulting damage.

Oxidative stress represents a large increase in cellular reduction potential or a large decrease in the reducing capacity of redox molecules. This reducing environment is preserved by enzymes that maintain this state through a constant input of metabolic energy. Imbalances in this normal redox state can cause toxic effects through the production of peroxides and free radicals that damage all cellular components, including proteins, lipids and DNA (Gardner and Oberdorster 2005). Thereby, enzymatic and molecular concentrations related with redox processes can be used as biomarkers for ecotoxicology assessments.

Oxidative stress can cause severe damage and cellular death – moderate oxidation can trigger apoptosis, whereas severe oxidation may cause necrosis. Assessing the oxidative stress of cells can determine the toxic effect of pollutants in exposed individuals, elucidating the degree of injury to which they are subjected and to identify detoxification pathways in organisms.

#### **Reduce Glutathione (GSH)**

Reduced glutathione (GSH) is a tri-peptide molecule found intracellularly in high concentrations, essential to all aerobic organisms (Huber et al. 2008). GSH provides a protective function to the cell by reducing oxidative species (*ex*. ROS) giving rise to their importance in the evaluation of oxidative stress (Manaham 2000). Many reactions of GSH involve a highly polarizable sulfhydryl group. This group is a strong nucleophile for reactions with electrophilic chemical compounds, making it an electron donor to other compounds and highly reductive. Thus, GSH is a protective biochemical cell against ROS and electrophilic compounds generated by oxidative processes, both in body and in the environment (Huber et al. 2008).

Concentration of GSH can be determined by the method of Sedlak and Lindsay (1968) for GSH and nonprotein thiols. For each  $250 \mu l$  of sample (ex. supernatant of liver, homogenized with 0.3 mg for tissue in 0.5 mL of potassium phosphate buffer 0.1 M) 50  $\mu$ l of trichloroacetic acid (TCA) is added to 48% concentration for protein precipitation. Subsequently, samples are centrifuged at  $1,000 \times g$  for 15 min at  $4^{\circ}$ C. 50 µl microplate sample of supernatant (soluble protein fraction) and 230  $\mu$ l Tris- base buffer (400 mM, pH 8.9) are added to readings. Blank sample are used with 230 µl of Tris base and 400 mM and 50  $\mu$ l of TCA 8% in PBS. Finally, 20  $\mu$ l DTNB (5,5 '-dithio- bis -2- nitrobenzoic acid) is added to 2.5 mM (in 25% methanol buffer, 300 mM Tris- base, pH 8.9) and immediately measure for absorbance ( $\lambda = 415$  nm). Determinations of GSH content are made by comparison with a standardized curve for GSH (0, 1, 2, 4, 8, 16, 24 and 32 mM GSH). Unit measurements are expressed in micromoles of GSH and nonprotein thiols per milligram of protein.

#### **Glutathione S-Transferases (GST)**

Glutathione S-transferases (GST) are a group of isoenzymes and can be of cytosolic, mitochondrial or microsomal origin. GSTs perform a number of functions within cells: removal of reactive oxygen species (ROS) and the conjugation of reduced glutathione (GSH) with hydrogen sulfide group, essential in the process of cellular detoxification (Sheehan et al.

2001). GSH also act as transport proteins and are related to the transfer of lipid hydroperoxide (LOOH) between lipid structures such as vacuoles and microsomes (Leaver & George 1998).

The activity of GST is measured using the method of Keen et al. (1976), however with certain modifications, through indirect determination for thioether substrates GSH (endobiotic molecule) formed from 1-chloro-2,4 -dinitrobenzene (CDNB, synthetic substrate to determine activity of most GST isoforms) measuring absorbance ( $\lambda = 340$  nm). Samples are thawed on ice, subjected to ultrasound (6 cycles of 4s each) and centrifuged at 9,000 x g for 30 min at 4°C. A volume of 50 µl of supernatant (soluble protein fraction) of the sample is added to wells of a 96-well microplate, and 100 mL of assay medium containing 1.5 mM GSH, CDNB 2 mM potassium phosphate buffer 0.1 M (pH 6.5) is added immediately before readings are conducted. Gradual increases in absorbance are monitored and record by an absorbance microplate reader at 15 second intervals for a total period of 3 minutes. Total GST activity is expressed in micromoles of thioether formed per minute per milligram of protein.

#### **Glutathione Peroxidase (GPx)**

Glutathione peroxidase is an antioxidant enzyme that converts  $H_2O_2$  into  $H_2O$ . This reaction with glutathione is then oxidized to glutathione disulfide, which can be converted back to glutathione by glutathione reductase in an NADPH-consuming process (Dröge 2002).

GPx activity may be measured by the method of Flohé and Günzler (1984) by monitoring the decrease of NADPH concentration during reaction with H<sub>2</sub>O<sub>2</sub> as a substrate (at  $\lambda = 340$ ) nm). One unit of GPx activity is defined as the amount of enzyme that oxidizes 1 μmol of NADPH min−1 .

#### **Superoxide Dismutases (SODs)**

The superoxide dismutases (SODs) are antioxidant enzymes that constitute the first line of defence against ROS. Cu, Zn-SOD is principally a cytosolic enzyme and Mn-SOD is mainly found in the mitochondria. Their function is to dismutate cellular concentration of O2•  $-$  to hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) and oxygen (Lesser 2006). SODs are the most important of theose defences, when coupled with the necessary mechanism for full detoxification of ROS.

Determination of total SODs isoforms enzymes can be assayed following the method of Suzuki (2000). This occurs via through inhibition of the reduction of nitrotetrazolium blue chloride (NBT) by the superoxide radical  $(O2-)$ , which is generated as a by-product of xanthine/xanthine oxidase system. Absorbance is measured per minute at  $\lambda$  =560 nm order to calculate the rate of change over time. One unit of SOD activity is defined as the amount of enzyme needed to inhibit the reaction by 50% of the superoxide radical NBT reaction. Activity is expressed in units of SOD per mg of protein.

#### **Catalase (CAT)**

Catalase is an important enzyme involved in the detoxification of  $H_2O_2$  from cells, which may be converted into water in a similar manner to glutathione peroxidase (GPx). Furthermore, decreased catalase and increased SODs activities can accelerate  $H_2O_2$ generation by increasing the conversion of  $O_2^-$  into  $H_2O_2$ . This may cause cellular oxidative damage such as lipid peroxidation and/or cell death (Dröge 2002). Furthermore, prolonged hypoxia in green turtles has been associated with elevated CAT and SOD activity (Valdivia et al. 2007).

The assay for CAT may be performed following the method of Pippenger et al. (1998), for the disappearance of H<sub>2</sub>O<sub>2</sub> (10 mM) in KPi (50 mM, pH 7.0) at  $\lambda$  = 240 nm. One unit of enzyme activity is defined as the amount of catalase needed to reduce 1  $\mu$ mol of H<sub>2</sub>O<sub>2</sub> per min. Results are expressed in units per mg of protein (Valdivia et al. 2007).

### **Protein Carboxylation (PCO)**

Oxidative stress results in the formation of carbonyl groups (e.g., aldehydes and ketones group) with a biochemical response termed as protein carbonylation (PCO) (Cattaruzza & Hecker 2008). Protein carboxylation tends to be hydrophobic and resistant to proteolysis, which can cause cellular damage via chemical changes in these macromolecules (Wong et al. 2008; Suzuki et al. 2010).

Determination of protein carbonyls can be performed indirectly by reactions with 2,4 dinitrophenylhydrazine (DNPH) to form dinitrophenyl hydrazones, which are detectable at 358-370 nm (Levine et al. 1994; Quinlan & Gutteridge 2000). 200 µl of supernatant samples (soluble protein fraction) are added to 800  $\mu$ l of DNPH to 10 mM (prepared in 2 M of HCl) following centrifugation. Blank samples contain an equal volume of DNPH. Samples are vortexed for 5 minutes, and kept in water bath at 30°C for 1.5 h. After incubation, the proteins are precipitated by addition of 1 ml TCA (trichloroacetic acid) to 28%. It is subsequently centrifuged at 9,000 x g for 10 min. The protein pellet is washed by suspension (3x in ethanol/ethyl acetate 1:1) and then homogenized by vortexing and centrifuged. Proteins are resuspended in 6 M guanidine chloride, centrifuged at 9,000 x g for 5 min to remove insoluble material.

Carbonyl content is determined through spectrophotometry ( $\lambda = 360$  nm) in microliter plates using the molar absorption coefficient for the hydrazone of  $2.1 \times 10^4$  M<sup>-1</sup> cm<sup>-1</sup>. Before and after the reaction occurred proteins were quantified (in a reserved rate of soluble protein fraction, and proteins in guanidine chloride respectively) to avoid errors due to losses during the procedure. Results are expressed as nanomoles of carbonyl per milligram of protein (quantified after the test and corrected by the initial concentration of proteins).

#### **Lipid Peroxidation (LPO)**

Lipid peroxidation represents a cellular process which can be measured as a proxy for oxidative stress (Dröge 2002). Toxic effects resulting from oxidation of cellular components such as thiols, enzyme cofactors, proteins, nucleotides and lipids, mediated by reactive oxygen species (ROS) and reactive nitrogen species (ERN), generally known as free radicals (FR), trigger this process by removing hydrogen atoms to methylene group of polyunsaturated fatty acids chains in cell membranes, altering the fluidity and functionality of these (Lima et al. 2001).

Production of lipid hydroperoxides is verified by the FOX method (ferrous iron oxidation ammonium sulphate) and quantified by complex formation of  $Fe^{+3}$  - xylenol orange (source of light absorption) in the presence of butylated hydroxytoluene as a stabilizer (Jiang et al. 1991, 1992).

Samples are sonicated for 2 min on ice, after addition of methanol (500 μl) and centrifuged at 1,000 x g for 10 min at  $4^{\circ}$ C. For reading, 30  $\mu$ l of sample (soluble protein fraction) is added to 270  $\mu$ l of reaction medium and pipetted into the microplate [(xylenol) orange at 100 mM, 25 mM  $H_2SO_4$ , BHT (butylated hydroxytoluene) at 4 mM, FeSO<sub>4</sub>.NH<sub>4</sub> (ferrous ammonium sulfate) at 250 mM (in 90% methanol)]. The reaction is completed after 30 minutes at room temperature and capped microplates, to reduce evaporation of methanol. Absorbance of samples are measured ( $\lambda = 70$  nm; reading range = 550-570 nm), with blank sample and positive control (30  $\mu$ l of 50% methanol and 1  $\mu$ l of hydrogen peroxide 30%, respectively).

### **Antioxidant Capacity (ACAP)**

Animals use molecular  $\alpha$ ygen  $(O_2)$  for the oxidation of food and power generation. During this process, reactive oxygen species (ROS) are continuously produced in aerobic organisms as byproducts of cellular respiration, causing numerous deleterious effects to the cells (Halliwell & Gutteridge 2007). ROS are continuously produced as unwanted toxic byproducts of normal metabolism of various endogenous processes.

It is estimated that approximately 1 to 3% of  $O_2$  consumed in animal systems is converted to ROS, which mainly include the superoxide anion  $(O2-)$ , hydrogen peroxide  $(H_2O_2)$  and hydroxyl radicals (OH•) (Storey 1996). In a normal healthy cell, antioxidant defenses act to reduce ROS. These defenses include the antioxidant enzymes superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPx), glutathione S-transferases (GST) and glutathione reductase (GR). Beyond these there are non-enzymatic antioxidant defenses including: ascorbic acid, flavonoids,  $\alpha$  tocopherol, lipoic acid and glutathione. As such, there is an important balance between the production of pro-oxidant and antioxidant defenses. However, increases in ROS production may overcome the antioxidant defenses, resulting in a state known as oxidative stress. Such stress can lead to damage of macromolecules and changes in critical cellular processes such as lipid peroxidation, inactivation of enzymes, oxidation of DNA bases and protein degradation.

Oxidative stress can occur when cells are subjected to stressful environmental factors, such as exposure to intense light, ultraviolet (UV), contaminants (metals and organic compounds), heat shock, hypoxia, and hyperoxia (Borges 2013). Organic metal compounds can stimulate ROS production by a variety of biochemical pathways, including redox cycle bipiridílicos herbicides; redox transition metal (e.g., Co, Cr, Ni, Va) with O2 and other ROS, self -oxidation of specific oxygenases (e.g., cytochrome P450 (CYP); induction of enzymes (e.g., CYP reductase flavoprotein); and disruption of electron transport through the membrane by depletion of lipophilic contaminants and antioxidant defenses (Livingstone 2003).

When the production of free radicals and/or reactive species exceeds the capacity of action of antioxidants, it promotes the oxidation of biomolecules, generating specific metabolites and oxidative stress markers, which can be identified and quantified. Such markers are derived mainly from the oxidation of lipids (malondialdehyde - MDA), proteins

(protein carbonyls) and DNA (quantification of oxidized bases). Another approach to the evaluation of oxidative stress is by employing indirect methods, based on the total antioxidant capacity against peroxyl radicals (ACAP).

There is limited published data regarding sea turtles, however previous studies have examined possible correlations between chemical contaminants (Labrada-Martagón et al. 2011) and ingestion of garbage (Yoshida 2012) with respect to indicators of oxidative stress in the blood of green turtle (*C. mydas*), without assessing total antioxidant capacity.

ACAP is determined by detection of ROS via fluorimetry (excitation/ emission: 485/520 nm) using  $2^7$ ,7'- dichlorofluorescein-diacetate (H<sub>2</sub>DCF-DA) as a substrate. Each sample is homogenized (1:5, w: v) in a buffer solution and exposed to peroxyl radicals generated by thermal decomposition (37°C) of 2,2'- azobis (2 methylpropionamidine) dihydrocloride (ABAP, 1 mM). Fluorescence is then measured for 30 min. in a fluorometer. ACAP is determined based on the difference between the area of fluorescence generated in the presence and absence of ABAP, and the normalized fluorescence value obtained in the absence of ABAP.

### **MICRONUCLEUS ASSAY**

The Comet assay (test of individual cells in agarose gel) is a technique for the evaluation of damage and DNA repair in proliferating and non-proliferating cells individually. This technique employs extremely small cell samples. Cells with increased DNA damage show an increase in the migration of chromosomal DNA in the nucleus towards the anode, which resembles the shape of a comet (Speit & Hartmann 1999). The Comet assay has broad applications in genetic toxicology, genotoxicity in vitro, in vivo tests, and biomonitoring. Comet assay slides are analyzed by first adding  $20 \mu l$  of ethidium bromide for staining, after which are immediately analyzed under an epifluorescence microscope with 400x magnification in a blind test, with 1000 cores on each blade. Cores are classified according to the damage, as the length of the tail formed after electrophoresis. Classified core is as follows: 0 (no apparent damage), 1 (little damage), 2 (medium damage), 3 (maximum damage) and 4 (core destroyed or apoptosis) (Ferraro et al. 2004).

Monitoring was performed *C. mydas* by evaluating the genotoxic potential of mixtures of pesticides. This was achieved by micronucleus tests in peripheral blood erythrocytes (biomarker of exposure and effect on DNA). A clear reduction in micronucleated cell number was observed as sampling sites moved away from the Canal. This aids in developing a protocol for analysis and repair of DNA damage by comet assay on individuals in the rehabilitation center Sea Turtle Karumbé (Montevideo) (Borrat et al. 2011).

# **ORGANIC POLLUTANTS INTO SEA TURTLES**

Regarding the presence of organochlorine pollutants in tissues of sea turtles, previous studies (Aguirre et al. 1994; Rybitski 1995; Corsolini et al. 2000; Gardner et al. 2003; Mckenzie et al. 1999; Juarez 2004, Innis et al. 2008; Camacho et al. 2012, 2013) have reported the presence of PCBs in tissues and eggs of different species (*C. caretta, C. mydas,*  *D. coriacea, L. olivace*a). However, it remains difficult to relate cause of death with presence or concentration of pollutants due to lack of basic data for comparison (Pugh & Becker 2001; Guillete 2000). It is necessary to generate baseline information of pollution levels in wildlife populations in environments with low anthropogenic impact, as this enables comparisons with populations in polluted regions.

The first studies on this topic have reported the presence of Aroclors 1254, 1242, 1248, 1260 (McKim & Jonson 1983; Thompson et al. 1974) but recent studies report enroll as coplanar congeners 77, 126 and 169 as well as mono- ortho 28, 56, 60, 66, 108, 118, 105, 156, 189 and 153 by highlighting the occurrence in most studies conducted both in the Atlantic, Mediterranean and Pacific (Pugh & Becker 2001; Corsolini et al. 2000; Alam & Brim 2000). There are records of the presence of DDT in tissues of loggerhead turtles (*C. carreta*) (Pugh and Becker 2001) and lindane (Mckenzie et al. 1999). In *D. coriacea* the presence of the pollutant aldrin and its derivatives has been reported (Mckenzie et al. 1999). Among the most common pollutants found in sea turtles are chlordanes cis-chlordane, transchlordane, cis-nona chlordane, trans-nona chlordane, ocichlordane, heptoclor epoxodico) recorded for *C. mydas*, *C. caretta* and *D. coriacea* (Pugh & Becker 2001). The presence of endosulfan and hexachlorobenzene in samples of *C. mydas* and *L. olivacea* have also been reported (Gardner et al. 2003).

### **CASE STUDY:** *CHELONIA MYDAS* **ECOTOXICOLOGY IN BRAZIL**

There are few studies on the ecotoxicology of marine turtles in Brazil, and most have been conducted with green turtles (*C. mydas*). These report concentrations of metals in the tissues of animals found stranded dead. Herein, we talk about 5 papers, 3 of which are already published and the other 2 from undergraduate degree completion projects.

Barbieri (2009) analyzed the concentrations of some metals (Cd, Cu, Ni, Mn and Pb) in tissues (liver and kidney) of 30 green turtles (*C. mydas*), 15 adults and 15 juveniles, which were found stranded dead along the Estuary of Cananéia, along the south coast of the state of São Paulo, between January 2005 and September 2006. In this study organotropism was found, which had already been reported for sea turtles, with Cd levels being higher in the kidney. This study found no significant differences between adults and juveniles. For concentrations of Cu, there were no significant differences in the liver between adults and juveniles. On the other hand, concentrations of nickel in adult livers were significantly higher than those of juveniles and liver tissues were significantly different than that of kidneys. Levels of lead were higher in adults, and the means were not significantly different in both organs.

Comparing these results with other studies, Barbieri (2009) found levels of Cd and Pb lower than those reported for the North Atlantic and both China and Japan. However, this has not enabled conclusions regarding whether this is due to the lower concentrations of these metals in the South Atlantic, or dietary differences between populations of different feeding areas.

Bezerra et al. (2012) determined the concentration of mercury in fragments of shell in 25 green turtles (*C. mydas*), of which 20 were living individuals that were trapped in fishing gear and 5 found dead at a beach on the coast of Ceará (Northeast Brazil). Of these 25 animals, 22 were considered juveniles and 3 subadult/adults.

The highest levels of mercury were observed in juvenile green turtles, with a significant negative correlation between the size of the animal (CCL) and Hg concentration. And, as mentioned earlier in this chapter, the authors related this correlation factor to the change in eating habits between juvenile and subadult/adults of this species. When green turtles are recruiting to coastal habitats their diet changes from an omnivorous diet of a pelagic turtle to a herbivorous diet of an immature coastal turtle. This change results in feeding exclusively on benthic algae and sea grass when they reach sexual maturity (Arthur & Balazs 2008; Bolten 2003; Cardona et al. 2010). When the animal feeds on a more omnivorous diet, it is exposed to higher levels of organic mercury than when feeding on benthic plants such as the case with mature animals. The author points out that, in this way, juvenile turtles preference towards coastal habitats makes them more susceptible to contamination by mercury that is most abundant in these environments, as has been observed on the Ceará coast.

Regarding comparisons of levels found on the Ceará coast and elsewhere, few studies have used fragments of shells of *C. mydas* as a tool for assessing contamination. With these results, Bezerra et al. (2012) concluded that concentrations of Hg found in the carapace of green turtles of the Ceará coast are lower than those observed in the shells of other marine species, and much lower than those reported for internal organs of sea turtles.

Moreover, levels are generally lower than Hg content found in top of carnivorous animals in the marine chain, such as birds and marine mammals.

Silva et al. (2014) determined the levels and distribution of metals in tissues of green turtles (*C. mydas*) stranded at Cassino Beach, Rio Grande, Rio Grande do Sul State (Southern Brazil). Tissue samples (liver, kidney, muscle, and gonads) were collected of 29 juvenile green turtles, where gonads were histologically analyzed for sex determination. Based on results, the sex ratio was calculated as 1.25:1 (female: male).

Relationships between sea turtle size (measured as curve carapace length, CCL) and metal concentrations were not significantly different between males and females; therefore, data were pooled for analysis. In relation to non-significant differences between males and females, with regard to contamination by metals, it is in accordance with data reported for *C. caretta* from the Italian coast in the Mediterranean Sea (Franzellitti et al. 2004; Maffucci et al. 2005; Andreani et al. 2008). In addition, gender differences were not observed for *E. imbricata* and *C. mydas* of Japan (Anan et al. 2001).

Silva et al. (2014) found organotropism between metals analyzed, as mentioned in literature, with highest levels of Cu (Lam et al. 2004; Gardner et al. 2006; Talavera-Saenz et al. 2007; Andreani et al. 2008; Barbieri 2009) and Ag found in the liver; Pb, Cd and Zn in the kidney. In general, Cu levels in the liver were higher than those reported for green turtles in other regions, with the exception of Costa Rica (Andreani et al. 2008) and China (Lam et al. 2004), which were similar, indicating that Cu is present at relatively elevated concentrations in juvenile green turtles from southern Brazil. This trend could be associated with high levels of Cu available in coastal waters and associated biota from this region. Continuous and accelerated urban growth, as well as intense industrial and agricultural development occurring along the southern coast of Brazil over the last decades have been considered as major sources of metals released in estuarine and coastal waters in these regions (Seeliger & Knak 1982; Baumgarten & Niencheski 1998; Niencheski et al. 2005, 2006; Barbosa 2007). Pb concentrations found in the tissues of green turtles in the present study were higher than those

reported for *C. mydas* in other regions such as Costa Rica (Andreani et al. 2008), Mexico (Gardner et al. 2006; Talavera-Saenz et al. 2007), China (Lam et al. 2004), and Cyprus (Godley et al. 1999). Thus, juvenile green turtles that use regions of the southern Atlantic coast in Brazil for feeding and development have had greater concentrations of Cu and Pb compared to other regions. It is difficult, from data reported by Silva et al. (2014), to provide an explanation for variations in levels of metal contamination in tissues of green turtles from different regions.

Differences in quality of marine environments between locations may be a possibility. This would lead to an irregular intake of metals through the food chain. Discrepancies found in green turtles from other regions could be explained by several factors, including differences in eating habits, as well as geographic and temporal differences in environmental exposure to metals.

It is worth emphasizing the importance of analyzing possible correlations among metal concentrations in tissues of sea turtles, and few studies have analyzed these. Silva et al. (2014) found positive correlations between non-essential metals (Ag, Cd and Pb) and essential metals (Cu and Zn) in the liver and kidney of green turtles. These results suggest that correlations observed between non-essential metals and essential metals in tissues of the green turtle *C. mydas* is likely associated with metal-induced metallothionein synthesis induced by Zn and/or Cu. In this case, the essential metals could induce the synthesis of these proteins to protect against the potential toxic effects of non-essential metals (for review: Miles et al. 2000; Coyle et al. 2002).

Medeiros (2011) evaluated the concentrations of Cd, Pb and Hg present in the liver, kidney and muscle of 11 green turtles stranded in northern and middle coast of Rio Grande do Sul State, southern Brazil, from October 2009 to April 2010. Organotropism was previously reported in literature, and Medeiros (2011) concluded that the most striking feature of his study was the presence of high levels of Cd in the kidney and liver of green turtles-analyzed. The presence of high levels of Hg were also highlighted, which makes clear that populations of *C. mydas* are under heavy anthropogenic pressures in coastal regions of Rio Grande do Sul State (Brazil) and that these concentrations of Cd and Hg may be directly or indirectly influencing the population decline of this species. Lorente (2010), unlike the aforementioned studies, examined the occurrence of chlorinated compounds in green turtles collected along the Rio Grande do Sul coast. Therefore, 11 livers were collected, 11 muscles, 2 kidneys and 2 hearts; a total of 17 juveniles. The identification and quantification of PCBs and pesticides were performed on a gas chromatograph with electron capture detector. Low levels of organochlorine compounds detected in *C. mydas* collected on the southern coast of Rio Grande do Sul are possibly related to food habits of this species (organisms of low trophic level), once a major route of organic contaminants accumulation is the diet. Of the two major groups analyzed (PCBs and pesticides), the predominance of PCBs in almost all groups and environments suggests these compounds are highly stable and have been widely used, resulting in a higher bioavailability for turtles unlike chlorinated pesticides. For all analyses reported certified standards were used.

### **PROSPECTS FOR ECOTOXICOLOGY OF SEA TURTLES**

A problem that is of concern to many researchers is the recent increase in fibropapillomatosis (FP) around the world. Focusing research on identifying the cause and understanding pathogenesis of the disease is of primary importance, so that management strategies can be developed to minimize its impact on populations of endangered green turtles (Herbst et al. 1999). FP is a disease that has been characterized as growth of skin tumors, which develop mainly in soft tissues, although can also grow on the carapace and plastron.

Most tumors are benign, however can disrupt basic functions of the individual (Foley et al. 2005).

Some studies have reported physiological changes in animals affected by the disease, including anemia, immunosuppression, hypoproteinemia, electrolyte imbalance, elevated liver enzymes, and propensity to acquire systemic bacterial infections (Work & Balazs 1999; Aguirre & Balazs 2000; Foley et al. 2005).

Regarding of sea turtle ecotoxicology, environmental contaminants have been identified as one of the possible factors contributing to the development of FP on sea turtles by reducing immune function (Balazs 1991). The increased prevalence of FP and other clinical diseases in sea turtles gives merit for further investigation of potential role of contaminants in their etiology.

Some efforts have been made in several geographic areas to elucidate possible correlations between environmental pollution and FP. In some places this correlation is indeed found, which justifies the belief that there may be a relationship, but in other places a lack of correlation confounds understanding of this disease.

In Brazil, several research groups are working with this theme. Recently in the VI and VII Meeting of Research and Conservation of Sea Turtles in the Western South Atlantic (ASO), two studies regarding this topic were presented in poster form.

Silva and Bianchini (2013) above reported some data on this, demonstrating that turtles deemed clinically healthy had considered size (CCC) lower (36.76  $\pm$  1.18 cm) than those with FP (43.2  $\pm$  2.52 cm). Furthermore, turtles with the disease had a lower mean value of cholesterol, bilirubin direct, sodium and Cd.

Rossi et al. (2013), collected blood samples of green turtles from different areas of the Brazilian coast and determined the concentration of PCBs a priority by European legislation: congeners 28 (triclorado), 101 and 118 (pentaclorados), 138 and 153 (hexaclorados) and 180 (heptaclorado).

These authors observed no differences between turtles with and without FP or between the sites studied, although catches have occurred in different Brazilian States.

It is important to note that observations of sample populations with reduced biological variability (sex and size) provide the most reliable results in terms of disease response. Biochemical parameters may vary between genders and stage of life; it is therefore important to minimize these effects to ensure representative observations. Due to the magnitude of the Brazilian coast, researchers continue to focus on studies of this nature so that we may understand a little more about fibropapilomatosis.

### **ACKNOWLEDGMENT**

The authors would like to thank Mr. Andrew Taylor for providing a native English review of this chapter, and for helpful comments that improved the manuscript.

# **SEA TURTLE PHOTO-IDENTIFICATION**

# *Jaime A. de Urioste , Maria Jose Bethencourt and Hector Sicilia*

Fundación Neotropico, Santa Cruz de Tenerife, Spain

# **ABSTRACT**

Individual recognition of marine turtles is necessary to advance a variety of research initiatives. Unique identification of individuals can help researchers analyze population size, stability and density, site fidelity, movement patterns, and seasonal habitat use for example. Identification of individuals can detect frequency of rescued and rehabilitated turtles as well as frequency of nesting females to certain nesting beaches. Datasets collected from these individuals overtime can aid international conservation measures in terms of decision making. Turtle identification is currently based on four semi-successful methods: Passive Integrated Transponders, (PIT tags), flipper tags, living-tags, and satellite tracking. Since each method has significant drawbacks and only limited benefits, photo-identification marking provides a viable solution. This technique presented here involves photo imagery of the scales around the face of each individual turtle. Researchers identify the quantity of scales around the face, their shape and spatial arrangement. Scale arrangement and characteristics are presumed to be unique to each turtle, like a fingerprint. PITMAR is a photo-identification computer algorithm and a facial picture database created by Fundacion Neotropico whose main goals are the control and monitoring of individual sea turtles.

# **INTRODUCTION**

Individual recognition of specimens is needed in research and can be used for a wide range of important analyzes. For example, as researchers identify and collect data on individual turtles, they can better understand population size, density, and stability.

Researchers can identify the degree to which individual associate with one another, site fidelity, movement patterns, and seasonality. At rescue and rehabilitation centers, identification of individual sea turtles can help veterinarians understand frequency in admissions. At nesting beaches, biologists can identify spawning aggregation sites and frequency of nesting by individual females.

The accuracy of these studies is necessary in decision making and implementation of international conservation measures. Different marking systems are currently used to provide researchers the ability to differentiate each individual within a natural population. To be reliable, any wildlife identification method must have a marking technique unique of each individual and constant throughout time to allow subsequent re-identification for long-term studies. The system should also not be invasive, nor influence individual behavior or how other animals behave with the marked specimens. Sub-lethal effects affecting the survivorship of the individual or modifying its recapturing feasibility should also be avoided.

Little work has been undertaken on non-invasive or non-traumatic identification of reptiles. Toe-clipping technique in lizards consists in the removal of no more than two toes per limb in a coded numbering sequence. Applied to lizards it could have potentially negative consequences on their behavior and survivorship, more in arboreal species, reducing their clinging performance (Bloch & Irschick 2004), than in fossorial species, but both are affected. Even though natural foot or toe loss is observed in wild lizards and they can survive with that damage, the welfare of the individual and the natural population of origin must be deeply analyzed before using this method. Looking for non-invasive, non-stressful, and economically sustainable marking procedures, the use of different kinds of physical patterns to identify individuals by pictures is widespread and applied to a growing list of wildlife species.

Photo imagery is a non-invasive and potentially effective means of individual recognition for wildlife. Depending on the image capturing method, the results and quality can be highly variable. For example, aerial photos are collected by aerial means as sea turtles float on the surface of the ocean, from land, or underwater. If pictures are to be taken underwater, light refraction and artifacts from particulate matter in the water column, swimming speed of the individual, and picture angle must be taken into account. Obviously the picture quality affects the level of certainty of the identification and match success.

Since the 1960's researchers have used photo-recognition of individual whales through identification of patterns on the underside of each fluke (Aarabi *et al*. 2000, Beekmans *et al*. 2005, and Kniest *et al*. 2010). Photo-identification has also been used in several species with characteristic marks like body color patterns in octopi, *Wunderpus photogenicus,* (Huffard *et al*. 2008), and dorsal head pattern in salamanders, *Eurycea tonkawae*, (Bendic *et al*. 2013). Photo identification on the flanks of grey nurse sharks, *Carcharias taurus,* both in captive and wild individuals has shown success (Bansemer & Bennett 2008) allowing researchers to reidentify an individual 14 years after the first time it was photographed.

Other studies include: photo-identification of Baltic grey seals *Halychoerus grypus,*  (Hiby *et al*. 2007) through identification of head and neck fur markings, blue whales, *Balaenoptera musculus,* (Olson 2009), through identification of mottling on the back and flanks of individuals, African penguins, *Spheniscus demersus,* (Sherley *et al*. 2010) through identification of chest plumage patterns, and whale sharks *Rhincodon typus,* (Meekan *et al*. 2008, Rowat *et al*. 2009) through identification using spot patterns in the area behind the 5th gill.

The use of photographic identification is a promising alternative marking technique to the above-mentioned invasive method of toe-clipping in lizards. For example, photos have been successful in detecting unique black spot patterns on the ventral scales of wall lizards, *Podarcis muralis* (Sacchi *et al*. 2007). Changes in color, but not pattern, were observed in this species allowing re-identification up to 4 years after the first pictures were taken. For species with less clear ornamentation patterns, the study of individual pholidosis has shown that shape, distribution and size of scales from specific areas of the body can be effectively used to tell apart specimens.

In terms of conservation applicability for endangered species, the survival rates of Florida Manatees, *Trichechus manatus latirostris*, (Langtimm 2004) have been successfully estimated using photo- identification of individual body marks and scars.

Even some species of crustaceans are likely to benefit from photo-identification techniques like the painted crayfish, *Panulirus versicolor*, as photos aid in identification of variable pigmentation patterns on the first abdominal sclerite, (Frisch & Hobbs 2007). This case is particularly interesting because it is very difficult to recognize individuals with classical methods in long-term studies due to the tag loss after molting.

In the case of European lizards, *Podarcis muralis* and *Lacerta bilineata* (Sacchi *et al*. 2010), the use of Interactive Individual Identification System  $(\mathbb{I}^3S)$  software is used to identify unique spot patterns. Unique patterns form at the intersections among pectoral scales, in these two species. , This technique proved accuracy and validity as a recognition system of this software. When a large number of individuals are registered in the database, computer algorithms are used in analysis and reduce time used in specimen query time.

This kind of software has been successfully used for individual recognition in the following cases: Rosalia longhorn beetle, *Rosalia alpine,* based on the contour digitization of the spots present on the beetle's elytra, (Caci *et al*. 2013) whale sharks, *Rhincodon typus,*  using an astronomical pattern-matching algorithm to identify unique individual spot patterns (Arzoumanian *et al*. 2005Collaboration among researchers even has led to the development of initiatives such as The Pacific Islands Photo-Identification Network, (PIPIN), a growing network of researchers studying cetaceans in the Pacific Islands Region through the use of photo-identification techniques.

## **METHODS**

### **Sea Turtle Non-Photographic Identification Methods**

In the case of sea turtles, which are air-breathing reptiles, four methods are currently used by researchers on a global scale. Each of these methods has limited benefits and significant drawbacks.

1. *PIT Tags:* (Passive Integrated Transponders) or microchips are harmless small implantable devices injected subcutaneously or intramuscularly into the sea turtle, usually near the shoulder region, posterior to the neck. This method involves stressful handling of each turtle and momentary pain. Similar in size to a grain of rice, PIT tags consist of a chip, a capacitor and inert wire encased in glass. This technique requires expensive hand scanners to read the unique identifying number implanted in the individual sea turtle. The drawback is that these scanners are not globally calibrated or readily available in every site. Scanners and tags operate in frequencies from 125 kHz to 134.2 kHz (older used 400 kHz frequency with poor range and for that reason it is recommended to avoid those), so not all scanners can read all PIT tags. The radio frequency of the scanner excites the PIT tag which reflects the radio waves in form of a unique alphanumeric code detected by the scanner. PITs can migrate, or could be ejected before the entrance wound heals (producing the tag loss), or be broken by aggressive behavior (Van Dam & Diez 1999; Runyan & Meylan 2005; Smyth *et al*. 2013). While this may be a good marking system at a local level, it does not provide a universal solution.

- 2. *Metal Flipper Rings, Flipper tags:* Flipper tags are small metal clips, like earrings, attached to the front or hind flipper. This individual tagging method has been used for decades. This methods has demonstrated efficacy, however, tags deteriorate over time or become detached. Some researchers are concerned that tags can become entangled in marine debris, thus posing a serious threat to the turtle (Nichols *et al*. 1997, Reisser *et al*.2008). Additional drawbacks of flipper tags are the increased hazard of infections or the impaired swimming performance (Balasz 1999, Reisser *et al*. 2008). Sometimes to compensate the risk of tag loss, researchers mark the individuals in each of the four flippers thus multiplying the jeopardy associated to this marking method. Other materials have been tested. Brightly colored plastic tags could increase the risk of predation because they may affect the animal´s concealment capability. Metal tag insertion procedures are also painful and stressing. During egg deposition, they are attached to females and should only be achieved by trained and experienced researchers as the inaccurate implantation site of metal tags could be the origin of tissue tears or lead to necrosis (Wright 2001). Position and distance from the flipper edge, animal size, tag material, biofouling and time since the tag was applied also affects the probability of its loss (Balazs 1982; Limpus 1992; Bjorndal *et al*. 1996; van Dam & Diez 1999; Reisser *et al*. 2008). Many countries only allow the use of this marking method for registered and authorized researchers. Our recommendation is that it should be removed worldwide from the suggested tagging protocols list for marine turtles.
- 3. *Living tags*: This method was developed in the 1980s. This method involves an invasive surgical technique by removing two bone fragments of separate carapace scutes, one dorsal (dark colored) and one ventral (lighter), and implanting them in a new location on the sea turtle. Coding of selected scutes used in this procedure is consistent for the release year, so researchers can identify the time lapse of the tag (Hendrickson & Hendrickson 1981). This is a traumatic process, generally performed at the hatchling stage and with a limited number of possible combinations. As it is an autograft, no immune response is observed, however, this tagging method requires the turtle to remain in captivity and not to be released until each fragment is healed and fused with plastron and carapace respectively (Mrosovsky *et al*. 2003).
- 4. *Satellite Tracking*: This method started in the 1980s, which involves attaching or harnessing an electronic global positing transmitting device to the carapace of a sea turtle. The device sends signals to a satellite and records the coordinates. The accuracy of the location depends directly on the number of signals received in each overpass by different satellites, from an individual emitter. Depending on the

accuracy and model, additional information such as diving depth, water temperature, swim speed or submergence time, can be received from the transmitter. While this system provides very important information, each device has a very high cost, can be damaged, and is shed with the carapace scales. The use is temporary and due to the high cost, provides only a very small sample within a population thus offering limited efficiency. In addition, all methods to attach satellite transmitters, may affect negatively hydrodynamic efficiency or long distance swimming abilities on marine turtles, or even they could increase their likelihood of entanglement in marine debris. All satellite tags that are commercially available, currently work via the ARGOS system. This system requires an initial set-up with the ARGOS program to purchase satellite use over a specified amount of time. There are different transmitters with a wide range of options and prices. Cost depends on the battery life and amount of data collected. To conserve battery power, these devices are prepared to transmit only when the turtle is at the water surface and can be programmed to work in on/off time cycles. The attachment of the satellite tag to the carapace requires stressful turtle restraint, especially when adult individuals are handled. It is done by one of the following methods: gluing (two components epoxy resins, fiberglass resin or both simultaneously) for hard shelled species. For leatherbacks a harness or tether are used. (Yasuda & Nobuaki 2005; Blumenthal *et al*. 2006; Godley *et al*. 2007).

### **Sea Turtle Photo-Identification**

Sea turtle photo-identification is a non-invasive and harmless marking method, not requiring direct manipulation of individuals and thus reducing stressful handling. Photo imagery does not require tags, thereby avoiding problems of tag loss, hydrodynamic drag and entanglement with floating debris. This method is cost-effective and can be applied to global populations. No special camera equipment is required, even a Smartphone or simple camera can be used to capture the photos. Frames can be extracted from video sequences to obtain useful images for the system. With high definition cameras, pictures can even be taken from a long distance without disturbing the individual turtle. As swimming turtle surface to breathe, their neck exposes the head to facilitate good quality images for individual identification.

While there are drawbacks, they are minimal and easily prevented. As with other species, the main problem with photo-identification based systems is the large amount of time needed to process manually each picture and that it has to be achieved by highly trained personnel to reduce error. Inexperienced or poorly trained workers can cause misidentification or data loss. With a growing amount of available pictures, the total time involved in processing them becomes unmanageable so the use of computer aided individual recognition and the development of more accurate software is helping in this titanic task.

# **Soft Shelled Sea Turtles**

Leatherbacks, *Dermochelys coriacea,* lack scales on their carapace or skin. This increases challenges of attaching satellite tags. The high cost of scanners needed to read PITs has also reduced the efficacy of this identification technique for this critically endangered species In 1996, McDonald *et al.* published a study illustrating that the 'pineal spot' of leatherbacks, a de-pigmented cloudy looking pink macula in the dorsal surface of the head (directly over the

pineal gland, thus its name), is distinct enough to be used as a unique identifier (McDonald *et al*. 1996).

*Software Usage*: Later, the use of identification software has validated this method, for a determined moment in time, showing exclusive individual differences in the spot for a sample of more than 400 leatherback turtles (with 100% accuracy), while eliminating the false negatives (Buonnantoni 2008). Other authors have used this system too with high levels of success (Pauwels *et al*. 2008, Zeeuw 2010). Although the results are promising, stability or the possible deviation within the pineal spot pattern over time (Figure 1), still have to be confirmed in long-term studies.

Figure 1. A stranded Leatherback, *Dermochelys coriacea,* found in Tenerife, being transported to the Turtle Hospital. Notice the pineal pink spot.

The software used to compare and match or reject the identification of an individual in different pictures relies in the Scale Invariant Feature Transform or SIFT (Lowe 2004) that is capable to identify changes in illumination, occlusion, noise and viewpoint. SIFT selects, in a given image, local points of interest or key points giving information in descriptor vectors not affected by image scaling, rotation, illumination or 3D camera viewpoint, with reduced probability of distortions caused by noise, clutter or occlusion by pollution or scars.

Before starting the algorithm matching procedure, the picture has to be manually cropped to a smaller image with the background removed. The red, green and blue components have to be merged into a grayscale image. Finally the contrast needs to be controlled and balanced with a correction factor to highlight the pink spot on the leatherback, thus enhancing contrast and removing flashlight. SIFT finds those regions detached from the background, determining their centers and the best scale and orientation relative to the dominant gradients, giving key points and key point descriptors with data epitomizing local gradient information.

*Comparing images:* To compare two different images, SIFT quantifies their similarity by matching a group of key points based on their corresponding descriptors within a given tolerance level. This step is improved by adding more sets of compared key points in the

images. A large number of consistent key points will show a match between the two individuals compared. A low number of key point results in a false paired match, indicating two different individuals. An intermediate number of matches need new additional verification achieved by a later test. In this case the results are presented to the human operator for a final confirmation or rejection of the matching (Pauwels *et al*. 2008; Zeeuw 2010).

# **Other Sea Turtles**

Except for leatherback turtles, the remaining species of marine turtles have scales with individual shape patterns that facilitate their identification. Throughout the life cycle of a turtle, changes in color of *tomium* (scales forming the upper and lower parts of the beak), face, carapace and plastron, make color markings inappropriate as tools for photoidentification (Feliz *et al*. 2010). In the case of hawksbill turtles, *Eretmochelys imbricata,*  tympanic scales present more utility for photo-identification than other cephalic scales due to a high individual variation in number, shape, and arrangement as well as stability over time and visibility in pictures (Feliz *et al*. 2010).

In some areas and programs, manual processing of pictures is still used with the help of volunteers. To reduce the amount of data to be processed, simple keys, similar to those used to identify species, have been developed with the inclusion of discriminatory features to increase accuracy and working speed. With the help of statistical techniques and a classification criteria matrix the number of steps needed to identify an individual are reduced (Lloyd *et al*. 2012).

Using a ranking system for the characteristics of the scales and assigning them a priority value according to the utility to separate individuals, different factors are used in the developed keys. These factors are (Lloyd *et al*. 2012):

- Number of parietal scales
- Number of parietal scales with tick
- Fronto-Parietal scale with tick
- Frontal scale with tick
- Presence of extra Fronto-Parietal scale
- 2 temporal scales
- 4 temporal scales
- 5 temporal scales
- Prefrontal scale with tick
- Supraocular scale with tick
- Interparietal scale meets Frontoparietal scale
- 3 temporal scales
- Number of spots at parietal scale base

Scale characteristics used in the key by Lloyd *et al.*:

- Tick: lighter color border of the scale extends lineally into a scale.
- Spot: small dark patch of skin, located at the base of Parietal scale or on neck.
- Dot: lighter small dot inside a scale.
- Frontoparietal extra scale: subscale inside Frontoparietal scale.
- Interparietal meets Frontoparietal scale.

Photo-identification of scales for hard-shelled sea turtles requires knowledge of the scale anatomy on the head; dorsal side. Here we present a numerical classification scheme to classify each scale using the following identifying numbers: 1 Prefrontal, 2 Interprefrontal, 3 Frontal, 4 Frontoparietal, 5 Supraocular, 6 Temporal, 7 Parietals, 8 Interparietal, 9 Occipitals. (Figure 2 and Figure 3)

Figure 2. Identification scheme of dorsal scales; shown here a loggerhead turtle, *Caretta caretta*.

Figure 3. Identification scheme of dorsal scales; shown here green Turtle, *Chelonia mydas*.

Photo identification when used to positively identify illness in sea turtles, such as fibropapilloma, a disease shown in turtles with tumors, can be a useful tool. For example, Studying the regression of fibropapilloma afflicting green turtles in the Hawaiian Islands, Peter Bennett and Ursula Keuper-Bennett (with pictures taken since 1988) started to identify each individual using facial scales patterns as shown in their work published together with George Balazs (Bennett *et al*. 2000).

Figure 4. *Chelonia mydas* scale face pattern.

Flipper scale pattern can also be used in a similar way for photo-identification (Bennett *et al*. 2000). However, the high frequency of flipper loss or scale alteration in terms of shape and arrangement makes this method not as widely efficient as head scales (Figure 5).

Figure 5. Singular shaped scales (highlighted with red dots) useful for the photo-identification of this individual of Green Turtle, *Chelonia mydas.*

The use of facial scales for the identification of sea turtles has clear advantages over dorsal head scales because of the large number of facial scales available for analysis. Facial scales have higher variability in number and polygonal shape, thus providing a wider range of possibilities (Figure 5). The following identification scheme of each lateral facial scale is presented here: 1 Tomium, 2 Supraocular, 3 Temporal, 4 Post ocular, 5 Sub temporal, 6 Tympanic, 7 Central (Figure 6). In each individual, both sides of the head present differences. When possible, the storage and use of the two profile photos increase the accuracy and reliability of this method. This makes the patterns exclusive to each individual on a global scale, making it serve as a virtual "fingerprint". Again, some research teams use manual identification of facial scales analyzing their number, shape and position when large groups of photos are available. Grouping images helps to reduce the amount of files and increase accuracy and working speed (Reisser *et al*. 2008, Schofield *et al*. 2008).

Figure 6. Naming Facial Scales in Turtles. 1 Tomium, 2 Supraocular, 3 Temporals, 4 Postoculars, 5 Subtemporals, 6 Timpanics, 7 Central.

One research trend uses the encoding of each scale according to its position and its shape (Jean *et al.* 2010). By dividing the arrangement of facial scales into rows starting from the eye extending to the neck, the first digit of the code indicates in which row the scale is located. The second digit of the code indicates the position of the scale in that row, counting from the upper jaw to the top of the head. The third digit is the number of sides of the scale. Finally, all the codes from one side of the head are arranged to compose a single profile formed by one digit followed by a series of 3-digit codes (every scale codes). The profiles of both sides define the identity of one individual (Jean *et al*. 2010, Chassagneux *et al*. 2013). Through manual analysis of the pictures, one by one, researchers use an identification tree to split the sample into sequential fields based on the shapes of post-ocular scales. The characteristics analyzed are: the identification scheme and pattern of tympanic and central scales, the shape of sub temporal scales and the shapes of temporal scales (Schofield *et al*. 2008).

Several software algorithms have been used or developed to help in the processing of pictures of facial scales of sea turtles. The design of identification software for turtles with scales has the advantage that a single algorithm can effectively work for all the species. For

these computer aided systems, pictures have to be preprocessed and standardized to allow its use. Below we present PITMAR, a software designed specifically for the photo-identification of sea turtles.

**P.I.T.MAR.** (Programa de Identificación de Tortugas Marinas = Marine Turtles Identification Program).

Neotropico Foundation is a private non for profit organization, declared for public interest by Spanish Government. We have been working in the Canary Islands since 2000. In collaboration with the Island Council (Cabildo de Tenerife), Neotropico Foundation rescues and rehabilitates all the stranded marine turtles in the island of Tenerife. With a number of entries ranging between 50 and 100 turtles per year, more than 1000 ill turtles have recovered healthy conditions to be released back to the sea in the past 15 years.

In terms of photo-identification of previously treated individuals, we have accumulated photographic images of individual turtles since 2005. Neotropico Foundation started storing images of both sides of the head of every released sea turtle in Tenerife (Figure 7) and we began developing the first steps to our successful photo-identification program; PITMAR (Program to Identify Marine Turtles). In year 2013, Neotropico Foundation was awarded a grant by Fundacion Biodiversidad (a public Foundation associated with the Environmental Ministry of Spain) to develop the PITMAR individual recognition algorithm and its associated database.

Using both facial scale patterns of the turtle in combination with other data, PITMAR allows the identification of every individual of a potential population up to tens of thousands of individuals. As stated before, the data set formed by the number of scales of this region, their shape and disposition is unique to each turtle as if it were a "fingerprint". This disposition does not vary in shape or number throughout the life of the animal, being naturally modified exclusively by size.

Figure 7. Recapture of Green Turtle, *Chelonia mydas.* First picture was taken by Neotropico Foundation on 16 December 2008. The recapture picture took place 19 August 2011. When the number of stored pictures increases, an automated recognition system has to be applied.

In the wild, traumatic alterations can occur and then they could alter this disposition of scales. To account for alterations, the opposite side of the face region of the same individual can be used for comparison along with other characteristics used in identification and

comparison (size, weight, scars, flipper loss, etc.). For instance, an individual registered the first time with a missing front left flipper will not be included in the file search of those registered later with front left flipper present. The program allows queries of such characteristics to help narrow the search field once the database expands.

Each picture has to be first edited by a human operator to optimize contrast, sharpness and size. In the first phase of development of PITMAR, the operator will also need to mark the intersection points of each face scale, producing a cloud of spots. This procedure is calculated to take 3 to 5 minutes of work. In the near future and with the development of the algorithm, the software should be able to search the intersection point itself, presenting them to the operator for correction or acceptance, thus facilitating the human workload.

PITMAR uses the cloud of spots produced from each picture to analyze similarities with other spot patterns stored in the database looking for positive matches (Figure 8). A total or high level of coincidence would indicate a recapture of the animal, very low level of pattern matching will be considered as a new turtle. If PITMAR finds a stored registry with an intermediate level of matching to the pattern analyzed it will present the results to the operator for final decision on marking it as a recapture or a new registry.

For a greater accuracy of the system, if the opposite side of the turtle's face is available, it will also be used in the matching process thus limiting occurrence of a false positive or false negative.

PITMAR is freely accessible through internet in a web based platform (www.pitmar.net). In any country, with a simple digital camera and a connection to Internet it will be possible to know if the photographed turtle is registered and all the available data stored.

Search of individuals filtered by species, or geographic location, or by user, are also available on PITMAR.

Figure 8. Two Loggerhead, *Caretta caretta,* individuals showing the cloud of spots used by PITMAR.

For injured animals that need to be handled or are going to stay in Rescue Centers for a while, the use of transponder tags are recommended as a collateral marking method and for research purposes.

The potential application of PITMAR to thousands of sea turtle researchers promotes this software as a highly viable conservation tool. It not only provides a beneficial scientific utility program but also encourages a bond for international scientific collaboration. In the associated webpage for PITMAR, environmental education materials will be readily available for use or download making PITMAR also a highly useful device system for educators, naturalists and the general public.

PITMAR is developed in three levels that work jointly.

# **Level 1. Database**

### *Types of Users*

External user: Once registered anyone can use the search tools, view information of the individuals searched, and submit potential new registries to an Operator or Administrator to be introduced in the database. Operator user: Needs to login to use the application. Operator can modify his/her own user and password details, use the search tools, add new capture data to an existing registry and add new turtle specimens to the database. Administrator user: Needs to login to use the application. Administrators can access the general configuration panel, access user profiles or specimens and capture data to modify, delete, insert or search in the database.

### *User Details*

- Id: Internal, autonumeric identifier. Invisible to users.
- User: Nickname (alphanumeric).
- Password: Log in password (alphanumeric). Stored coded and can't be recovered, just modified.
- E-mail: e-mail address.
- Name: Name of the user (alphanumeric).
- Organization: Name of the organization (if applicable).
- User Level: External, Operator, Administrator.

### *Specimen Details*

- Id: Internal, autonumeric identifier. Invisible to users.
- IdPITMAR: Identifier code for each individual formed by year (4 digits)-species code (9 digits)-Autonumeric. Autogenerated. Non modifiable.
- IdTransponder: PIT code.
- IdRingtag: Ring tag code.
- User Id: Identification of the user responsible for the first entry.
- Gender: Male / Female / Unsexed.
- Species: Latin name / common name
- Notes: Observations and singularities of the individual.
- General picture.
- Right side head picture.
- Right side data: geometrical data for picture recognition algorithm.
- Left side head picture.
- Left side data: geometrical data for picture recognition algorithm.

### *Capture Details*

- Id: Internal, autonumeric identifier. Invisible to users.
- $-$  IdPITMAR.
- User Id: Identification of the user responsible for the recapture.
- Date.
- Site: nominally explicit capture site.
- Coordinates: in several formats. Optional place selection over maps.
- LRC: straight carapace length
- LCC: curved carapace length
- ARC: straight carapace width
- ACC: curved carapace length
- RFL: right forelimb present
- LFL: left forelimb present
- RRL: right rear limb present
- LRL: left rear limb present
- Notes: Observations and singularities of the capture circumstances (nesting, feeding, basking, wounded) as well as possible pathologies or traumatic wounds observed in first inspection.

### **Level 2. Monitoring System of Cephalic Scale Pattern**

This module will execute the analysis of the given images from the facial area of the turtles head to recognize the different patterns that serve to detect if that individual has been previously registered in the system (and therefore it is a recapture) or if it appears for the first time (and then a new identifier has to be generated).

# **Level 3. Interface of Use**

The inter-operatively with the system will be done via Web, so that any user of the system will be able to access simply using a navigator. Although the use of a Web platform implies small restrictions for the interface, these are totally compensated by the ease of use, the low resources consumption for the administrators, the possibility to use the application from any place of the planet that has an Internet connection and, mainly, the multiplicity of systems on which this tool can be used.

This last point is of enormous importance since, independent of the operating system (Microsoft Windows, Linux, Macintosh, etc.) or the device (computer, notebook, smartphones, tablets, etc.) visitors or operators, will have access to the tool whenever an internet connection is available. The development of the interface was achieved with standards of prevailing Web building software in mind to make the application operate properly via any browser (Internet Explorer, Mozilla Firefox, Operate, Konqueror, etc.). Also the recommendations of WAI for the accomplishment of accessible Webs will be considered.

## **ACKNOWLEDGMENTS**

We want to thank Juan M. Rguez-Baron, Monica Lara Uc and Rafael Riosmena - Rodriguez for inviting us to participate in this book. We also want to express our gratitude to Stephanie Rousso for the review and translation of this chapter. Finally to all those who with their daily work, even at the risk of their own safety, help in the conservation of the oceans.

# **ABSTRACT**

The use of topological analysis tools in marine trophic networks offers a wide range of possibilities to investigate how the different species are involved in the structuring of a network, as well as to evaluate how important they can be in their organization. This approach allows us to identify the importance of the species from its connectivity and its contribution to the spread of direct and indirect effects in the network and to determine their participation in the mechanisms of ecosystem control. This, to determine if they can be considered as keystone species. Topological analysis will be conducted using a data base from the trophic network of Bahia Magdalena (Mexican Pacific) to determine if green turtles (*Chelonia mydas*) can be considered a highly important structural species based on their connectivity, betwenness centrality and closeness centrality, key species or even species with low topological redundancy, which would give them an important role in the network. Furthermore, the results will deliver evidence on how sea turtles are involved in the different mechanisms of ecosystem control, and whether the absence of these organisms could create major structural gaps in the organization of the network, such as to affect the identified large-scale patterns.

## **INTRODUCTION**

A central theme in the study of trophic networks is how interspecific relationships affect ecosystem dynamics and stability (Pimm 2002; De Ruiter et al. 2005). The importance of these interactions has given rise to the development of concepts such as multispecific management (May et al. 1979; Yodzis 2000) or ecosystem approach (Grant et al. 1997), which recognize the need to know the role of not only one species, but of most or all species to model more accurate responses to the dynamics of each system under study (Jordán et al. 2006). Some authors have suggested that, although changes in species composition are an important indicator to identify perturbed ecosystems, a holistic knowledge allowing identification of structural and functional effects could emerge from the study of communities as networks interconnected by trophic interactions (Dunne et al. 2002; Bascompte et al. 2005). Owing to the relatively stable characteristics of trophic networks, these interactions can provide information on species relationships within a community and how human activities could be degrading ecosystems (Dell et al. 2005).

Network analysis provides a number of tools that can support quantitative community ecology. In particular, there exist techniques for quantifying the positional importance of species (ecosystem components) in food webs. Species that are of high importance in a trophic network can be in either central (like hubs) or unique positions. The latter can be interpreted as species having non-redundant neighborhoods. As a result, their extinction (or overfishing) has profound effects on the ecosystem. This is quite sound in ecology, as a suite of field and theoretical results support the importance of indirect interactions.

Several mesoscale indices have already been suggested in network science, most of them, considering distance between nodes (e.g., closeness and betweenness centrality; Wasserman & Faust 1994). Some of these indices have been applied to ecological problems (Estrada 2007; Jordán et al. 2007). Others have been slightly modified and adapted to ecology (see net status (Harary 1961) and keystone index (Jordán et al. 1999)) or simply developed by ecologists (measuring apparent competition (Godfray et al. 1999; Müller et al. 1999)).

The knowledge about the ability of sea turtles to affect their ecosystem structure and function has been considered one of the most important objectives to be met in the study of the ecology of these species (Bjorndal 2000), in that way we may establish critical habitats for their conservation. Seagrasses are considered the main dietary component in several life stages of green turtles (Bjorndal 1980). In fact, the green turtle is the most abundant large vertebrate consumer of seagrasses in the world (Ogden 1980). In northwest of Mexico, eelgrass (*Zostera marina*) was found in diet samples at canal del infiernillo (Felger & Moser 1973), Bahía Magdalena (Lopez-Mendilaharsu et al. 2005), Laguna de San Ignacio, Punta Abreojos and Laguna Ojo de Liebre (Rguez-Baron unpublished data).

Like other sea turtle species *Chelonia mydas* shows a slow grow and delayed sexual maturity which, along with the intrinsic characteristics of its life history, allows it to spend several decades in different habitats where it uses and modifies the environment (Chaloupka & Musick 1997). Among the main challenges for the sea turtles conservation, is the determination of their ecological role (Bjorndal 1997), because the diet composition strongly influences in their life history, growth and reproduction rates (Wallace et al. 2009). Particularly in immature animals, the selection of diet items has implications on the duration of future life stages and consequently in the required time to reach reproductive maturity,

which is an important attribute in their population dynamic (Seminoff et al. 2003; Jones et al. 2009).

Green turtles from the Eastern Pacific are considered the most carnivorous population of the *Chelonia mydas* complex (Bjorndal 1997). Although generally they feed on algae and seagrasses (Mortimer 1982; Seminoff et al. 2002; Lopez-Mendilaharsu et al. 2005), it has been reported that green turtles are able to ingest pelagic red crabs (*Pleuroncodes planipes*) (Lopez-Mendilaharsu et al. 2005), sea pens (*Ptilosarcus undulates*) (Seminoff et al. 2002; Lemons et al. 2011), tunicates (Amorocho & Reina 2007), hydrozoans, scyphozoans, nematodes, annelids (Carrion-Cortez et al. 2010), sponges (Seminoff et al. 2002) and anemones (Rguez-Baron et al. 2011). A mixed diet has apparently the evolutionary advantage for some species to experience and learn about the optimization of ingested nutrients. The consumption of animal tissues has been associated to protein requirements of immature turtles to enhance their body growth and earlier sexual maturity (Bjorndal 1985).

Associated to these ecological features, Bahia Magdalena probably is one of the more studied green turtle feeding grounds at the Eastern Pacific. Some of the studies include turtle movements inside the channels (Brooks et al. 2009), population dynamics (Koch et al. 2007; López-Castro et al. 2010), diet selectivity and differences in dietary intake associated with turtle size (López-Mendilaharsu et al. 2005, 2008) and health indices across blood biochemistry values and body condition index (Labrada-Martagon et al. 2010a, 2010b). One relevant result is that reported by Koch et al. (2007) suggesting that juvenile of *C. mydas* could live over 20 years inside the lagoon complex until reaching sexual maturity.

Owing to the variety of approaches used to study trophic networks and the large number of topics studied in these systems, we present in this chapter a brief review of a topological analysis of trophic network and its application to assess the importance of green turtles in the coastal lagoon ecosystems.

# **METHODS**

### **Topological Approach**

### *Building the Trophic Network*

Base on the diet matrix of the biomass-balance model (Ecopath) for Bahía Magdalena (Cruz-Escalona et al. 2013) a binary matrix of trophic interactions was building, where 1 represents the presence of prey *i* in the diet of predator *j* and 0 the absence of it. Thus, the number of interactions was determined for all species (predators and prey) in the network. Hence, this analysis focused on trophic interactions between species, not on strength or direction of such interactions, therefore it shows specific information about the topological properties of the studied network area.

To assess the positional importance of the different nodes in the trophic network, and thus infer the positional importance of the species or trophic components under study, we used local and mesoscale indices, whose application in topological analysis has been extensively discussed in multiple publications (Jordán 2001; Jordán & Scheuring 2002; Jordán et al. 1999, 2006; Abarca-Arenas et al. 2007; Gaichas & Francis 2008). These indices are:

### *Node Degree (D)*

This is the most easily applied but least informative index because it only takes into account the number of other nodes connected directly to node *i*. Thus, the degree of node *i*  $(D_i)$  is the sum of its prey (in-degree,  $D_{in,i}$ ) and predators (out-degree,  $D_{out,i}$ ), and was computed using NetDraw as  $D_i = D_{in,i} + D_{out,i}$ .

### *Centrality Indices*

The first index is betweenness centrality (*BC*), which is based on quantifying how often node *i* is on the shortest path between each pair of nodes *j* and *k*. This index was computed using the UCINET IV software package (Borgatti et al., 1996). The standardized index for node *i* (*BCi*) is:

$$
BC_i = \frac{2 \times \sum_{j \leq k} g_{jk}(i) / g_{jk}}{(N-1)(N-2)}
$$

Where  $i \neq j$  and  $k$ ,  $g_{jk}$  is the number of equally shortest paths between nodes *j* and *k*, and  $g_{jk}(i)$ is the number of these shortest paths to which node *i* is incident  $(g_{jk}$  could be equal to 1). The denominator is twice the number of pairs of nodes without node *i*. This index thus measures how central a given node is in terms of being incident to many shortest paths in the network. If  $BC_i$  is large for trophic group *i*, it indicates that the loss of this node will have many rapidly spreading effects in the web.

The second centrality index used was *CC* (closeness centrality), which is based on the proximity principle and quantifies how short the minimal paths from a given node to all other nodes are (Wassermann & Faust 1994). This index was also computed using UCINET IV (Borgatti et al. 1996), and its standardized form (*CCi*) is expressed as:

$$
CC_i = \frac{N-1}{\sum_{j=1}^{N} d_{ij}}
$$

Where  $i \neq j$ , and  $d_{ij}$  is the length of the shortest path between nodes *i* and *j* in the network. This index thus measures how close a node is to the rest of nodes. The smallest value of *CC<sup>i</sup>* will be for that trophic group that upon being removed will affect the majority of other groups.

### *Keystone Index (KI) (Jordán et al. 2006)*

It is used to characterize the importance of species in ecosystems according to their position in the trophic network; it is also known as index of topological importance. This index considers information additional to the nodes directly connected to one another and was defined in detail by Jordán (2001) and Jordán et al. (2006). It is expressed as:

$$
K_{j} = \sum_{c=1}^{n} \frac{1}{d_{c}} (1 + K_{bc}) + \sum_{e=1}^{m} \frac{1}{f_{e}} (1 + K_{te})
$$

Where *n* is the number of predators eating species *i*,  $d_c$  is the number of prey of the  $c_{th}$ predator and  $K_{bc}$  is the bottom-up keystone index of the  $c_{th}$  predator. Symmetrically, *m* is the number of prey eaten by species *i*,  $f_e$  is the number of predators of the  $e_{th}$  prey and  $K_{te}$  is the top-down keystone index of the  $e<sub>th</sub>$  prey. For node  $i$ , the first summation of the equation quantifies bottom-up effects  $(K_{bu})$ , whereas the second summation quantifies top-down effects ( $K_{td}$ ). After rearranging the above equation, the terms that contain the values of *K* ( $\sum K_b \mathcal{A}_c$  + *∑K*<sub>*te*</sub> $f$ <sup>*e*</sup>) refer to indirect effects (K<sub>*indir*</sub>), whereas those that do not contain *K* ( $\sum I/d_c + \sum I/f_e$ ) refer to direct effects  $(K_{dir})$ . The sums of these values of effects  $(K_{buf} + K_{td}$  and  $K_{indir} + K_{dir})$ equal  $K_i = K_{bui} + K_{td,i} = K_{dir,i} + K_{indir,i}$ . In addition to informing about the number of direct connections among nodes, the keystone index informs on how these neighbors are connected to one another (Jordán et al. 2006), emphasizing vertical interactions over horizontal ones (e.g., trophic cascades vs. apparent competition). It also characterizes positional importance, separating direct from indirect effects, as well as bottom-up from top-down effects in the trophic network (Jordán 2001). The keystone index was computed using the FLKS 1.1 software package (provided by F. Jordán), which is designed for characterization of vertical positional importance of species in food webs.

These mesoscale indices have been favored over other more local statistics, such as the distribution of trophic connections (Dunne et al. 2002; Montoya & Solé, 2002), or more global ones, such as food web connectance (Martinez 1992) because the latter for example reflect the global topology of the network but do not provide information on the specific position of individual nodes or their more distant interactions, thus preventing the analysis of important indirect effects, such as apparent competition and trophic cascades (Holt & Lawton, 1994; Menge 1995). Furthermore, mesoscale indices are recommended when the purpose of the study is to understand relationships within a community (Jordán & Scheuring 2002) and especially when one wants to quantify the relative importance of a given species with respect to the rest of species in a system (Jordán et al. 2006).

#### *The Topological Importance Index (TI) (Jordán et al. 2009)*

It is used to analyze indirect interactions of various lengths separately (up to a 3-steplength). It assumes a network with undirected links where interspecific effects may spread in any direction without bias (we are interested in interaction webs, in the broadest sense, but considering only indirect chain effects [Wootton 1994]). The effect of species *j* on species *i*, when *i* may be reached from *j* in *n* steps, is defined as  $a_{n,ij}$ , when n=1 (i.e., the effect of *j* on *i* is direct):  $a_{1,ij} = 1/Di$ , where  $Di$  is the degree of node *i* (i.e., the number of its direct neighbors including both prey or predatory species). We assume that indirect chain effects are multiplicative and additive. When the effect of step  $n$  is considered, we define the effect received by species *i* from all **N** species in the same network.

$$
\psi_{n,i} = \sum_{j=1}^N a_{n,ij}
$$

Which is equal to 1 (i.e., each species is affected by the same unit effect.). Furthermore, we define the *n*-step effect originated from a species *i* as:

$$
\sigma_{n,i} = \sum_{j=1}^N a_{n,ij}
$$

Which may vary among different species (i.e., effects originated from different species may be different). Here, we define the topological importance of species *i*, when effects up to *n* steps are considered

$$
TI_i^n = \frac{\sum_{m=1}^n \sigma_{m,1}}{n} = \frac{\sum_{m=1}^n \sum_{j=1}^N a_{m,ij}}{n}
$$

Which is simply the sum of effects originated from species *i* up to *n* steps (one plus two plus three…up to *n*) averaged over by the maximum number of steps considered (*n*). With this index, it is possible to quantify the origins of effects influencing a particular species, i.e., the internal interaction structure of the network.

The *an*,*ij*-values for species *j* had been defined as its "trophic field" (Jordán 2001). For long indirect effects, every species is connected to every other. It is reasonable to define a *t* threshold of *an*,*ij*-values separating strong interactive partners from weak interactors. Given a maximum length of indirect effects (*n*) and a threshold for interaction strength (*t*), every node may be characterized by its effective trophic range (Jordán et al. 2009). Since the sets of strong interactors of two, or more, nodes may overlap, it is important to quantify the positional uniqueness of graph nodes. The "trophic field overlap" (*TO<sup>n</sup> ij*) between nodes *i* and *j* is the number of strong interactors appearing in both *i*'s and *j*'s effective range. The sum of all *TO*-values between species *i* and others ( $\Sigma TO^{n,t}$ *i* summed over all j with *i* $\neq$ *j*) provides the summed trophic field overlap of species  $i$  ( $TO<sup>n,t</sup>$ <sub>i</sub>), and this may be normalized by dividing it with the maximum value  $(TO^{n,t}_{max})$  for a given network  $(relTO^{n,t}_{i} = TO^{n,t}{}_{i}/TO^{n,t}{}_{max})$ . Note that all this is determined by *t*, *n* and the topology of the network. We define the "topological uniqueness" of species *i* as  $TU^{n,t}$ <sub>*i*</sub> = 1 – *relTO<sup>n,t</sup><sub>i</sub>*. Here, we used *n*= 3 and *t*= 0.001. This index may contribute to the problem of how to quantify species and role and redundancy in ecosystems (Bond 1994; Luczkovich et al. 2003; Shannon & Cury 2003). This index was computed using CosbiLabGraph (Valentini & Jordán 2010).

### **Key Player Problem (KPP)**

To determine whether sea turtles species belong to the key element set of the ecosystem under study (defined as "topological keystone species complexes" by Jordán et al. (1999, 2006) and Libralato et al. (2006)) we used the "key player" problem approach of ecological network analysis (Borgatti 2003a). This approach is used to determine the importance of different species combinations in maintaining network integrity. More specifically, we used Key Player Problem 2 (*KPP-2*), which works under the assumption that "if information is spread from node n, which nodes must be selected to reach the other nodes in the fastest way

in an intact network?" (Benedek et al. 2007). The analysis was run with the Key Player 1.44 software package (Borgatti 2003b).

### **Application of Topological Analysis to Evaluate Ecological Role of Sea Turtles**

We built a trophic network using stomach content data of representative functional groups found in Magdalena-Almejas Bay, located in the south-west coast of the Baja California Sur peninsula ( $24^{\circ}$  16 'N and  $25^{\circ}$  45' N and  $111^{\circ}$  20 'W and  $112^{\circ}$  18' W). This system has three different geomorphological zones: Canals Zone (137 km<sup>2</sup>) located northwest; Magdalena Bay (883 km<sup>2</sup>) located in the center of the complex, and Almejas Bay (370 km<sup>2</sup> ) located in the southeast (Figure 1) (Álvarez-Borrego et al. 1975). Information about diet matrix was taken from Cruz-Escalona et al. (2013) and includes a 24 trophic components.

Figure 1. Geographic location of Bahia Magdalena in Baja California Sur, Mexico.

## **Results of Topological Analysis**

Based on the degree of node (*D*), suprabenthic invertebrates were the highest value node (18), followed by sea lions (14), other crustaceans and penaeid shrimps (12). *Chelonia mydas* obtained a degree of node of 9 and was ranked tenth within the 24 nodes (Figure 2).

Centrality indexes showed that suprabenthic invertebrates have the highest betweenness value ( $BC = 43.2$ ) followed by the green turtle ( $BC = 37.1$ ) and sea lions ( $BC = 14.2$ ). Meanwhile green algae (Chlorophyta), brown algae (Phaeophyta), red algae (Rhodophyta), and gray whale showed the lowest intermediate values (Figure 3a). As for species closeness (*CC*), suprabenthic invertebrates (*CC* = 52), sea lions (*CC* = 56) and penaeid shrimps (*CC* = 58) had the most representative values (Figure 3b). As with the degree of node, turtles showed a middle point value (10 position) in terms of closeness index within the network.

Figure 2. Degree of node index of the studied area's trophic network. The size of the node is proportional to the importance value. Explanation of the initials in the Table 1.

Figure 3. Centrality indexes of the studied area's trophic network. A) Betweenness Index (BC), the size of node is proportional to the importance of the node. B) Closeness Index (CC), the size of node is inverse to the importance of the node.

The keystone index (*K*) showed the highest values for dolphins and sea lions, suggesting that their removal could result in significant structural changes in the trophic network. On the other hand, green turtle is in the eighth position, play the main role in this network as a predator ( $K_{td}$ ), directly affecting its prey, algae, sea grass and some invertebrates ( $K_{tdir}$ ) and with few predators in the network (Table 1).

Rank	Species or trophic component	$K_{bu}$	$K_{td}$	$K_{dir}$	Kindir	$\bf K$
1	Dolphins (DO)	0,00	10,68	4,02	6,66	10,68

**Table 1. Results of keystone index of Magdalena Bay**

 $K_{bu}$ = Importance index from bottom to top,  $K_{td}$ = Importance index from top to bottom,  $K_{di}$ = Importance index of direct effect, K<sub>ind</sub>= Importance index of indirect effects.

Regarding the topological importance index (*TI*), which shows those species that have the smallest topological redundancy into the network, revealed that the Dolphins and Sea Lions were the more difficult replacement nodes (Figure 4). The green turtle was at an intermediate level of topological redundancy suggesting that in this ecosystem this species has a trophic function with other repetitive mesopredators. This can be observed in the trophic overlap established between the turtle and stingrays by invertebrates (e.g., crustaceans, suprabenthic invertebrates, shrimp) and with the lobsters and Black Branch by primary producers. On the other hand, the absence of natural predators for this species in the study area influences the outcome of topological significance found.

The graphical representation of the values of *TI* showed that invertebrates and bony fishes have high redundancy in the network and therefore the values (node size) of this index are low in most of the same (Figure 4).

Figure 4. Topological importance index of the trophic network of the study area. The size of the node is equal to the index value.

Finally, analysis of key groups "*KPP-2*" showed that it is composed of a single species, the pelagic red crab (*Pleuroncondes planipes*), being this the most influential in the trophic network interactions, as the dispersion of any effect from this species reaches 100% of the nodes in this network. In this case, being such a short trophic network it is feasible for this to happen, but as more complex trophic networks are analyzed it will be more likely to observed in greater detail the participation of species of interest in the group of keystone species.

### **CONCLUSION**

The topological indices represent a novel and useful tool to evaluate in an easy way, the structure of a trophic network and how the different elements that compose it take part in that structure. In the present study we have implemented these analyses in order to assess the structural importance of the green turtle in a marine trophic network, and make comparisons among our results with other previous approaches which have focused on studying the function of these species in ecosystem through the mass and energy flows and their effects over the population structure of their prey.

The outcomes of this study show how green turtle (*Chelonia mydas*) is a sort of structural value intermediate in the structure of the trophic network in the Bahia Magdalena which is due to an intermediate connectivity and proximity to other network nodes. This means that the species of interest does not provide a high number of trophic interactions with other network components; thus, the proximity of the same for all these nodes is moderate. From this, it follows that green turtle has a mild participation in the velocity dispersion of indirect trophic effects that may occur in this network (trophic cascade, apparent competition, competition for exploitation among others, see Menge 1995). Thereby, the absence of this species would have little current velocity dispersions of these effects, which are considered fundamental for the stability of trophic networks.

Nevertheless, another scenario is presented when the intermediation index (*BC*) outcomes are analyzed. *Chelonia mydas* turned out to be identified as the second most valuable species. This result suggests that if the green turtle does not have a high number of connections within the network, it does play an important role in the dispersion of indirect effects within the same network. This occurs due to the fact that the species of interest becomes an important connection in the flow of trophic interaction among primary producers and top predators. Thus, the loss of this species would force many of the pathways through which the indirect effects are spreading within the network to change and therefore could significantly impact the current network structure.

These results are in line with what some studies have suggested with functional perspective. For example, grazer species may have significant positive effects on grazed areas via their role in enhancing nutrient recycling or availability (McNaughton et al. 1997; Augustine et al. 2003). Repeated cropping by turtles has been found to result in increased nitrogen concentrations in *Thallasia testudinum* in the Caribbean, which was interpreted as improving the nutritional quality of those areas (Bjorndal 1980; Zieman et al. 1984). Moreover, it has been suggested that, historically, grazing by sea turtles played an important role in the maintenance of healthy seagrass beds by removing the seagrass canopy and preventing the build-up of organic matter in seagrass beds (Jackson et al. 2001, Bjorndal & Jackson 2003).

Aragones et al. (2006) through experiments simulated cropping by green turtles by manual removal of plants or plant parts to resemble that made by the animals. The changes to plant chemical composition following grazing were long-lasting, with both *Halophila ovalis* and *H. uninervis* showing significantly elevated whole-plant N concentrations in response to all treatments after 11 and 13 months, respectively. On the other hand, Fourqurean et al. (2010), made protecting experimental plots from grazing by sea turtles caused an increase in the biomass of seagrasses and an increase in the structural complexity of the seagrass canopy, as the length and width of the seagrass blades increased. This shows that green turtles may modify significantly the seagrass beds. Also, through observational evidence, Goatley et al. (2012), showed that green turtles and hawksbill (*Eretmochelys imbricata*) may function as both grazing and browsing herbivores on coral reefs. The green turtles appear to be an important component in tropical seagrass ecosystems in structuring communities through cropping.

From the point of view of ecosystem control, Keystone Index analysis (*K*) identified the top depredators as those who have the top down network control almost exclusively. (See  $K_{td}$ in Table 1). In this index, the green turtle showed that its structural importance in the network regarding the mechanisms of ecosystemic control is mainly given by the direct trophic effects  $(K_{dir})$  or predation being greater the contribution as predator than prey  $(K_{tid} \text{yd } K_{bu})$  and therefore dispersing more strongly its direct effects than indirect for the rest components of the network. This latter result corresponds with the findings in our analyses of topological importance (*TI*) which indicated that *Chelonia mydas* is a species with average levels of topological redundancy and that it shares its predatory function with primary producers with lobsters and Black Brant.

This exercise represents the first study, which uses topological analyses to assess the structural importance of green turtle within a trophic network. The outcomes of this study show this is an important tool for the target mentioned and provides useful information to implement management measures for this species. It is recommended that such studies in

focal areas and hotspots of marine turtles at different life stages, and with this, give a new perspective to the assessment of ecosystem importance of these species.

# **ABSTRACT**

Although subject to several caveats, stranding data may provide information on geographic ranges, seasonal distribution and life history of marine turtle aggregations in nesting, foraging/development, and migratory areas. Strandings are the main source of biological samples for ecological studies on marine turtles. Samples are collected either from live and recovered turtles or from dead ones through necropsy. Moreover, strandings provide data on sex ratios of local aggregations, diseases, and feeding ecology, among other topics. Two methods can be used to record stranded marine turtles on beaches: (1) creating a marine stranding network or (2) organizing beach surveys over the area of interest. In order to provide valuable information, stranding networks must use replicable protocols and be able to record the majority of stranding events. However, the discovery and reporting of washed carcasses depends on observation effort and public awareness, and economic resources are critical for the effectiveness of the network. Beach surveys for stranding records need constant effort over areas of interest. Stranding data can be recorded across wide spatial and temporal ranges at high resolution due to the low cost per unit effort compared to in-water or aerial-based studies. Stranding data is often considered as non-representative of populations at sea, since the probability of stranding varies widely in space and time, as predators, scavengers, winds and sea currents may prevent carcasses from reaching the shore. However, strandings yield reasonable data on the occurrence and distribution of marine turtle species in the adjacent marine area. Thus, stranding data, while an imperfect measure of marine turtle abundance, distribution and activity, provides additional information that can complement research studies at sea. Analyses of stranding data can also contribute to a better implementation of conservation measures and management on endangered marine

turtles in coastal waters through the identification of (1) the areas probably used by marine turtles, and (2) anthropogenic mortality sources in the region of interest. Strandings can also be used for public awareness on the conservation of these threatened species.

### **INTRODUCTION**

This chapter tries to summarize the most relevant techniques used in the study of marine turtle strandings and all the potential data that can be obtained from them. An approach to studying marine turtle aggregations in feeding and development areas can be represented by stranding data, because stranding records do not require high costs as surveys at sea do. Many turtles are found dead, injured or ill on the beach or floating at sea, in coastal waters, especially near important foraging areas.

In recent years, there has been a rising awareness on the global threats affecting marine turtles, such as incidental captures by different fishing gears (Lewison et al., 2004a, b; Lewison & Crowder, 2007; Peckham et al., 2008; Tomás et al., 2008a; Wallace et al., 2008, 2010; Casale, 2011), climate change (Hawkes et al., 2009; Poloczanska et al., 2009; Fuentes et al., 2011), marine pollution (Bugoni et al., 2001; Tomás et al., 2002; Storelli & Marcotrigiano, 2003; Tourinho et al., 2010; Ivar do Sul et al., 2011) and habitat loss in nesting and in marine feeding areas (Musick & Limpus, 1997; Bolten, 2003; Fish et al., 2008). However, it is difficult to determine the relative importance of different threats, particularly those occurring at sea, because knowledge on population demography is still scarce in many areas, and it is essential to understand the impact of each threat on every population for its conservation (Casale et al., 2010). One approach to the study of marine turtle aggregations in foraging areas at sea is the use of stranding data. Carcasses of marine turtles, marine mammals and other marine vertebrates encountered on shorelines can provide valuable information for estimations of mortality rates at sea, and also on causes of death if the animals arrive fresh and can be necropsied (Geraci & Loundsbury, 1993). However, probability of stranding varies widely in space and time, and usually does not exceed 10–20% of total mortality at sea, even in near-shore waters, since predators, scavengers, wind, and currents prevent carcasses from reaching the shore (Epperly et al., 1996; Hart et al., 2006; Mancini et al., 2012). At greater distances from the shore, stranding probability diminishes even more and animals that die offshore may never strand (Koch et al., 2013). Hence, stranding data are often considered as non-representative of population sizes and mortality at sea (Epperly et al., 1996; Siebert et al., 2006; Peltier et al., 2012). However, strandings yield reasonable data on the occurrence and distribution of marine vertebrate species in the adjacent marine area (Maldini et al., 2005; Pyenson, 2010; Peltier et al., 2012). Inferences on stranding data are subject to a number of caveats, i.e.: seasonal and spatial variation in recording, inter annual variation in surveying, influence of coastal currents in stranding distribution, etc. (Lewison et al., 2003). Yet, when integrated over wide spatio-temporal extents, they can provide information about geographic ranges, seasonal distribution and life history of marine turtles, particularly for life stages underrepresented in the literature such as juvenile individuals (Witt et al., 2007; Tomás et al., 2008a).

Most of the literature on strandings focuses on reports of isolated cases. Although valuable because of their detail (they can sometimes provide new biogeographic records and

extensions of the reported range of a species), isolated reports are not integrated into any overall scheme that provides an accurate reflection of stranding patterns and spatio-temporal distribution. To be valuable, data has to be collected in a consistent way, using standard protocols, on the greatest possible number of specimens and over a long period of time. Only then can the information collected contribute to an understanding of the size, shifts or variations, and causes of mortality in a marine vertebrate population.

### **Defining a Stranding**

There have been different proposals for defining a marine turtle stranding: e.g., dead or alive turtles washed or found floating coastal waters (Tomás et al., 2008a); turtles founded dead, injured or ill on the beach or floating at sea (Casale et al., 2010); any dead or alive marine turtle, or remains, washed ashore (Vélez-Rubio et al., 2013); or carcasses of marine turtles encountered on shorelines (Koch et al., 2013). Researchers should decide and describe the different categories in detail within each study (strict stranding, floating in coastal waters, etc.), to allow for comparisons among studies on the same species in different areas. Furthermore, it would be recommended to reach a consensus for this same reason. Nonetheless, in many cases turtles are found near the shore or in coastal waters, and they can be analysed as a stranding; although notes on findings must be taken for filtering data according to the aims of the study and for further comparisons with data taken elsewhere.

### **On the Interest of a Marine Turtle Stranding**

Data on stranded turtles provide essential information about at-site life stages, seasonal distribution, and geographic ranges of marine turtles (Hart et al., 2006; Chaloupka et al., 2008; Casale et al., 2010). Stranded animals present an evident scientific potential but strandings also offer a source of biological material for population studies such as age determination from skeletochronology (e.g., Zug et al., 2002), parasite quantification and general health condition (Deem et al., 2009), and tissue samples for stable isotope analyses (e.g., Cardona et al., 2010), toxicity (e.g., Storelli et al., 2005) and genetic studies (e.g., Naro-Maciel et al., 2012).

However, stranding based studies present a series of caveats linked to random sampling. Most stranded turtles have suffered health problems or were ill before dying, thus having a non-normal behaviour. Therefore, information on healthy individuals of the populations is scarce in this type of studies. On the other hand, stranding causes are not always identifiable, which limits the accuracy with which different impact threats can be assessed.

Nonetheless, stranding studies based on long-term data series can constitute the baseline for conservation planning and management, because they are an easy way to obtain information on local marine turtle populations. Such studies are also very important in raising local conservation awareness, particularly among fishermen, authorities and other stakeholders, and in engaging communities and the general public interested in marine turtle conservation.

*What to Do When Finding a Marine Turtle Stranded on the Beach? Organizing the Response*

In each country or region, marine turtle strandings can be recorded by different actors (Environmental authorities, universities/research centres, civil organizations, NGOs, etc.). These groups normally receive the information through a 24 h hotline specifically set for this purpose. In many cases the police, park rangers or coast guards directly contact the organization in charge. In many regions, several of these entities are part of a coordinated stranding network (see below).

Figure 1. Response flowchart for when a marine turtle is found stranded on the beach. Two paths can be followed when encountering a stranded turtle. If alive, we need to evaluate the health condition of the turtle; if the evaluation is successful we can gather information and take samples, tag the turtle according objectives and means, and release it (in green). If the animal is not in good health, we take the turtle to a rehabilitation centre and activate veterinary protocols (in orange). If the turtle is dead (in red) we should first evaluate the carcass state, if decomposed we just gather as much information as possible and proceed to the disposal of the carcass; if the carcass is fresh we can conduct a necropsy to obtain more information and samples. Blue boxes indicate the most important points for collecting data during the procedure.

The quality and the quantity of information obtained from stranded turtles depends on a number of factors, including: the specimen´s location and state of decomposition, the workteam's motivation and organization, equipment availability, supplies, and shipping and storing of samples. For that reason, it is crucial to organize the response to strandings. An ideal diagram is presented in order to organize the response when finding a stranded marine turtle (Figure 1). There are two main flow lines in the diagram that may activate different protocols: in green and orange we represent when stranded turtles are founded alive (activating veterinary or tagging/sampling protocols); and red represents when they are found dead (activating necropsy or carcasses disposal protocols). In different parts of the chart (blue boxes) we indicate when data recording can be carried out. It is crucial to log as much information as possible along the process. The diagram can be adapted in any particular case

or location, depending on the organization responsible, the interest and motivations of the studies in the area, the extension of the study area, etc.

### **METHODS**

### **Stranded Marine Turtle Sampling Techniques**

How should strandings be monitored? Normally the stranding of a marine turtle is a sporadic event that can occur at any point of the coast distant from our place of work or residence. It is necessary to use simple and clear protocols, easy to implement, and covering large coastal areas. We present three non-exclusive sampling procedures to optimize the recording of marine turtle strandings. Depending on the stretch of coast to be covered and the region, stakeholders and institutions in charge may choose which of these procedures are most adequate for optimizing data recording and aims.

#### *Stranding Network*

The main objectives of a stranding network are (1) to provide rapid and effective actions that serve to recover live stranded animals, (2) to protect the public from possible diseases transmitted by the stranded animals, and (3) to gain the maximum scientific information. A stranding network's general aims should mainly focus on:

- The efficiency and speed of action after the stranding report.
- Recording as many of the strandings as possible (in addition to reporting strandings, systematic surveys should be planned, see section 3.2)
- Increasing knowledge on stranded species conservation biology (in case they are in some way threatened).
- Providing as much information and as many samples as possible.
- Setting up a tissue bank and sample collection.
- Finding partners for the managing of strandings
- Regularly publishing reports on strandings and associated information.
- Providing expertise and training to local and national authorities, local communities, park rangers, beach rescue staff, etc.
- Developing public awareness on conservation of threatened marine species (marine turtles in our case) and the threats affecting them.

To reach these objectives, collecting the appropriate information from a stranded live or dead turtle requires team organization for a quick and effective response. For this reason, a stranding network should host: (1) an emergency response team with well trained staff of both veterinaries and biologists to perform different tasks adequately (such as species identification, recording biometric data, performing a necropsy, taking samples, rehabilitation tasks, etc.), and/or to collaborate with specialist institutions; (2) the necessary equipment to examine the animals *in situ* and to transport them when necessary; (3) a facility for medical treatment and rehabilitation; (4) equipped facilities for carrying out necropsies on carcasses; and (5) an appropriate protocol for collecting, analyzing, and storing samples and data. As we have said, networks must be coordinated via 24-h telephone hotline or via email, and/or social networks. Depending on the reach of the network, stranding events are reported by the general public, fishermen, lifeguards or civil organizations. Other organizations that could benefit the stranding network (police, coast guard, municipal authorities, park rangers, education and research centers, wildlife and conservation groups) should be informed of the network's existence. It is therefore necessary to develop awareness campaigns to involve all these actors. Useful actions are, for example, increasing information availability before holidays and in touristic areas; or providing training courses and workshops to park rangers, lifeguards and other workers aiming to increase reporting effort. The main aim of the network is being able to record 100% of strandings in a determined coastal area during a certain time period.

The network must function within the legal framework established by regional and country authorities, and cooperate with them to ensure effective action and reach long-term goals.

In an optimal scenario, a stranding network would span a country's entire coast. However, according to the length and features of the coast, the general context of the country, and the conservation status of the marine turtle aggregations, several work teams could be expected. A leader should coordinate each team and a national coordinator ought to manage the activities of all teams in order to acquire an overall picture of the situation and to obtain data and conclusions on strandings at a national scale (Bradai, 2009). Wider geographical scale networks (e.g. covering strandings over coasts around basins or enclosed seas) are also desirable, although coordination among working teams and countries is not always easy (but see section 3.3).

#### *Beach Monitoring*

Beach survey efforts can be performed over areas of special interest and as a complement to stranding networks. These surveys have to be constant and should be boosted in specific areas where high numbers of strandings occur, and in areas with on-going in-water studies. For systematic and regular monitoring, the area covered by the surveys must be of a length that can be surveyed at least monthly, and accessible to monitoring staff. Depending on the geomorphology and the length of the beaches and coasts, and also on the resources available, monitoring can be conducted by motor vehicle, bike or by foot. The use of motor vehicles must be carefully considered during surveys over beaches where marine turtle nesting may also occur. Since limited resources may not allow surveying the entire coastline of a country/region, beaches designed as important in previous studies can be chosen for monitoring. Long term monitoring of these beaches will also provide much needed information on population status and threats. When other on-going studies are absent, and resources are limited, pilot beach surveys and interviews to fishermen and coastal inhabitants must be carried out to choose the most important beaches to monitor. One advantage of beach monitoring for strandings, and also of stranding networks, is that in addition to carcasses or injured animals, they can report sporadic or exceptional marine turtle nesting events, providing new locations for the nesting range of different species (e.g., Tomás et al., 2008b).

#### *Integrated Databases*

An interesting way to coordinate and organize data on strandings over large areas, or around basins, and for long periods of time is the use of databases. These databases may be

hosted in committed research institutions or by environmental authorities. The creation of such databases can emerge from international conventions and agreements. Costs of hosting the database can proceed from local, national or international projects, or through funding provided by institutions and countries involved in the agreement. These databases should offer basic data reports, with online access, and may serve as contact means among professionals or working teams. The following are some examples of existing databases:

- TURTLE database operated by Marine Environmental Monitoring (UK): TURTLE is multi-agency project that in 2001 started acting as a repository for records of marine turtle sightings, strandings and incidental captures. Reports of such events are received from members of the public, government agencies or marine environmental organizations. These groups usually collect morphometric and pertinent additional data (e.g. geographic location) from stranded individuals and provide for either rehabilitation or necropsy. Appropriate data is then passed to the TURTLE coordinator who validates and subsequently adds it to the project database, which also contains historical records of marine turtle sightings, strandings and captures since ca. 1758. http://www.strandings.com.
- Sea Turtle Stranding and Salvage Network, STSSN (USA): this network was formally established in 1980 to document and collect information on strandings of marine turtles along the U.S. Gulf of Mexico and Atlantic coasts. The network, which includes federal, state and private partners, encompasses the coastal areas of the eighteen-state region from Maine to Texas, and includes portions of the U.S. Caribbean. Data is compiled through the efforts of network participants who document marine turtle strandings in their respective areas and contribute that data to the centralized STSSN database. By accessing the website, a citizen can report a stranded marine turtle to the state coordinator. http://www.sefsc.noaa.gov/species/ turtles/strandings.htm.
- The United Kingdom Turtle Code: (UK): a code for reporting marine turtle sightings in the UK. All users can help in the effort to protect endangered marine turtles by providing information about their encounters with these spectacular creatures in UK waters. The website also provides information on marine turtles and what to do when finding a sick or entangled turtle on the beach. http://www.euroturtle.org.
- Turtle Research and Monitoring Database System, TREDS (Pacific island countries): this system provides highly valuable information for Pacific island countries and territories to manage their turtle resources. TREDS can be used to collate data from strandings, tagging, nesting, emergence, and beach surveys as well as other biological data on turtles. http://www.sprep.org/marine-turtles/turtle-research-andmonitoring-database-system-treds.
- Stranding Network Locator (STRAND) (worldwide): The Sea Turtle Rehabilitation and Necropsy Database (STRAND) is an effort to streamline and improve the accuracy of the reporting process. Here you can find all the organizations around the world with stranding network or that coordinate the strandings at beaches. Information on sea turtle strandings is collected by hundreds of individuals in USA and around the world. This data is used by local, regional and national resource managers to make decisions regarding fisheries, dredging operations and other

activities that have the potential to impact sea turtle aggregations. Accurate and timely data delivery is crucial for making effective management decisions. http://www.seaturtle.org/strand/contact.shtml.

 The State of the World´s sea turtles, SWOT (worldwide): SWOT works directly with field-based sea turtle researchers across the globe, regularly compiling the most current data available in order to provide an up-to-date global picture of sea turtle status. http://seaturtlestatus.org.

### **Studies Based on Stranded Marine Turtles**

In this section we explain how to prepare and organize a study based on turtle strandings, what the potential goals and restrictions should be, and what data and samples it is best to collect. Finally, we expose some examples of current studies on marine turtle strandings.

#### *Scopes and Limitations*

Stranding records, once analysed with due caution for intrinsic biases, represent a valuable information source on both mortality factors and the spatio-temporal distribution of marine turtles (Casale et al., 2010). Yet stranding records cannot constitute an accurate scientific source of data because they are random phenomena, dependent on parameters such as cause-related mortality, interaction with human activities, environmental features (currents, tides, or prevailing winds); where in many cases several of these factors are convergent (Epperly et al., 1996; Hart et al., 2006).

Most marine turtle strandings involve individuals that perished at sea due to natural or anthropogenic causes such as encounters with fishing gear (NRC, 1990). However, most carcasses show no clear evidence of the cause of death (Sis & Landry, 1992; Turtle Expert Working Group, 1998; Hart et al., 2006). As the carcasses of animals which died in open waters may decompose while trapped in currents and eddies, the number of recorded marine turtle strandings likely represents a minimum estimate of mortality (Murphy & Hopkins-Murphy, 1989; Epperly et al., 1996). Moreover, the relationship between the number of turtles that died offshore and the numbers of stranded turtles remains unknown (Peckham et al., 2008).

Hence, stranding data are often considered as non-representative of populations at sea (Epperly et al., 1996; Siebert et al., 2006; Peltier et al., 2012). However, strandings yield reasonable data on the frequency of occurrence and distribution of marine vertebrate species in the adjacent marine area (Maldini et al., 2005; Pyenson, 2010; Peltier et al., 2012), and the threats that affect them in coastal waters close to study areas (Coles & Musick 2000; Mooreside, 2000). Live turtles incidentally captured in coastal waters and dead carcasses found on shore certainly provide important information on age, size, abundance, growth rates, main sources of threat, geographical patterns, and feeding of local marine turtle aggregations (MacLeod et al., 2004; Chaloupka et al., 2008).

#### *Data Collection*

Marine turtle stranding data collection relies on the people that report the stranding event, and is highly dependent on their training and on the resources available for the task. Type and amount of recorded data should be adjusted to the aims of the program, and to research and conservation purposes in a particular area during a particular period; although there are many constraints (mainly economical, but also social, political, etc.) that may limit data recording.

There are different data form models for data recording on stranded turtles, some of which are presented in Appendix I of the present chapter. In the process of design of data forms we have to consider the person filling out the forms. The information recorded in the data sheet must be easy to understand and adequate for the recorder in each case, i.e.: researchers, fishermen, volunteers, tourists, etc.

Regardless of the type of recorder and constraints, basic data that needs to be recorded from a marine turtle stranding should include:

- Name, address and phone number of the observer/recorder.
- Date and hour of the stranding or detection of the carcass.
- Exact location (latitude/longitude). If coordinates are no available, include local name of the place/beach and/or physical description of the stranding site.
- Identification (confirmed by a trained person) and description of the animal (size, weight, sex if possible, etc.). Asking for photographs is highly desirable.
- Condition of the turtle (alive, dead, fresh, decomposed, bones).
- Final disposition of the turtle (left on beach, buried, salvaged, taking to facility, etc.).

#### *Stranding Location*

Stranding date and time refers to the moment the stranded turtle was first reported or encountered. For the stranding location recorders can provide a detailed description of the stranding site by using reference points (inlets, fishing piers, lighthouses, water tanks, etc.). If a GPS device is available, whoever reports the stranding must provide latitude and longitude of where it took place. This information is important for mapping the strandings and displaying their spatial distribution along the coast, from where areas of high stranding concentration can be identified.

#### *Species Identification*

In order to identify turtle species, it is recommended to keep manuals, books or identification guides handy (e.g., Eckert et al., 1999). If identification is not clear (advanced state of decomposition, possible hybrid, etc.) it is best to write down the species as unknown or unidentified. Depending on the studied area several different species can be detected, since some of the marine turtle species have a restricted distribution (e.g., the Flatback turtle *Natator depressus* restricted to North Australia and adjacent waters) while other are globally distributed, and some of them can share feeding or nesting habitats. Here we provide a brief description of the seven extant marine turtle species for their identification (modified from Pritchard & Mortimer 1999):

#### **Family Dermochelyidae**

*Dermochelys coriacea*: Leatherback (E); Tortue luth (F); Tortuga laúd, baula o siete quillas (S).

#### **Family Cheloniidae**

*Chelonia mydas*: Green turtle (E); Tortue verte (F); Tortuga verde o blanca (S) *Chelonia mydas agassizii* 1: Black turtle (E); Tortue noire (F) Tortuga negra (S) *Natator depressus*: Flatback turtle (E); Chelonée à dos plat (F); Tortuga aplanada (S) *Eretmochelys imbricata*: Hawksbill (E); Tortue imbriquée (F); Tortuga carey (S) *Caretta caretta*: Loggerhead (E); Caouanne (F); Tortuga cabezona, boba o caguama (S) *Lepidochelys kempii*: Kemps ridley (E); Chelonée de Kemp (F); Tortuga lora (S) *Lepidochelys olivacea*: Olive ridley (E); Chelonée olivâtre (F); Tortuga olivácea (S) (E) English, (F) French, (S) Spanish

#### **Leatherback Turtle (***Dermochelys coriacea***)**

This species differs from other the marine turtles in its anatomic and physiologic characteristics. Adults lack scales, scutes and claws. It´s carapace is reduced and formed by a mosaic of small bones. The carapace surface resembles leather, with the skin being several centimetres thick in this part of the body. Dorsal coloration is predominantly black, with variable degrees of white or paler spotting; spots can be bluish or pink on the neck and the base of the flippers. Light pigment predominates ventrally. Forelimbs are long in relation to the body, if compared to the other marine turtle species. Males and females have a characteristic pink spot on the dorsal side of the head (Pritchard & Mortimer, 1999). This species is the largest marine turtle and the heaviest reptile. Adults attain a curved carapace length (CCL) of 130-210 cm, and a weight of 250-900 kg (Goodman & Belskis, 2012).

### **Green Turtle (***Chelonia mydas***)**

This species has a broad oval carapace, with 4 pairs of lateral scutes. It has a relatively small head, with one pair of prefrontal scales, and a slightly serrated, non-prominent beak. Individuals have a single claw on each flipper. Carapace coloration in adults is very variable, normally brown. Head and limbs are dark grey, while the underside is yellowish. This species is the largest of the hard-shelled turtles. Adults attain a straight carapace length (SCL) of 90- 120 cm, and a weight of 120-230 kg (Goodman & Belskis, 2012). In the East Pacific we can find the black turtle (*Chelonia mydas agassizii*), currently considered as subspecies of the green turtle. The black turtle has a slightly smaller size, darker carapace and skin colour, and the posterior part of the carapace narrower than the green turtle (*Chelonia mydas*).

#### **Flatback Turtle (***Natator depressus***)**

This specie has a very broad and rounded carapace, with upturned lateral margins. The carapace presents 4 pairs of costal scutes; the scutes are very thin and have a softer texture than in other cheloniid turtles, with seams often disappearing in old adults. Dorsal coloration is uniformly olive-green in hatchlings and adults, and yellowish ventrally (Pritchard  $\&$ Mortimer, 1999). The species may reach approximately 100 cm of CCL and about 90 kg in weight. It is confined to waters of tropical Australia and southern New Guinea and Indonesia.

#### **Hawksbill Turtle (***Eretmochelys imbricata***)**

This is the only species to have imbricated scutes on the carapace. It has a narrow, ovalshaped carapace with a strongly serrated posterior margin and overlapping scutes. Dorsal coloration of the carapace is dark to light brown, and the ventral side is light yellow to white (Pritchard & Mortimer, 1999). Adults attain a SCL of 65-90 cm and a weight of 60-80 kg (Goodman & Belskis, 2012). This turtle is highly sought after in some countries where their colourful scutes are exploited to use in jewellery, even though this practice is illegal worldwide.

#### **Loggerhead Turtle (***Caretta caretta***)**

It´s carapace is moderately broad, being approximately 80% of the turtle's length. Flippers are relatively short, with 2 claws on each forelimb. Dorsal coloration is primarily brown with occasional individuals retaining some tan or even black, ventral color ranges from yellow to orange (Pritchard & Mortimer, 1999). The head is large in relation to the rest of the body and triangular in shape. Adults attain a SCL of 90-115 cm, and a weight of 100-180 kg (Goodman & Belskis, 2012).

#### **Kemp's Ridley (***Lepidochelys kempii***)**

This species has a relatively short and wide, almost circular carapace which presents a modest marginal serration or scalloping. Juveniles of Kemp's ridley turtle present high vertebral projections, but the carapace is smooth and low in adults. Juveniles are dorsally grey, while a light olive-green colour can be seen in adults. They are ventrally are white or light yellow. The individuals of this species have small pores (four per side) near the posterior margin of the inframarginal scutes in the plastron. Adults attain a SCL of 60-70 cm, and a weight of 35-50 kg (Goodman & Belskis, 2012). The species is distributed almost exclusively in the Gulf of Mexico and Eastern USA, being also reported occasionally in European coasts and even in the Western Mediterranean (Tomás et al., 2003 and references therein).

### **Olive Ridley Turtle (***Lepidochelys olivacea***)**

It is a small turtle with a triangular head. This species presents a short and wide carapace very similar in shape to its congeneric species *L. kempii*, but less wide in adults. The dorsal coloration is dark olive-green in adults, and it is ventrally creamy yellow (Pritchard & Mortimer, 1999). As with *L. kempii*, olive ridleys habe small pores (four per side) near the

posterior margin of the inframarginal scutes of the plastron. They can be distinguished from *L. kempii* because *L. olivacea* individuals have a variable number of coastal scutes in the carapaces (six or more per side). Adults attain a SCL of 70-80 cm, and a weight of 35-60 kg (Goodman & Belskis, 2012).

#### *Sex Determination*

Marine turtles are difficult to be sexed externally until they reach maturity. Depending on their nesting aggregation and population, marine turtles reach sexual maturity at different sizes. This size is generally around 90 cm curve length for green turtles, 130 cm curve length for leatherbacks, 83 cm curve length for loggerhead turtles, 85 cm curve length for hawksbill turtles, 65 cm curve length for kemp's ridleys, 70 cm curve length for olive ridleys and 90 cm curve length for flatback turtles. If the turtle found stranded is of a smaller size than the minimum adult-size described either globally or, if known, locally, then the turtle must be recorded as 'immature' or 'sex undetermined'. However, sex can be determined if a necropsy (if the turtle is dead), laparoscopy, hormonal blood analysis or other test (if the turtle strands alive) can be undertaken. In the case of adults, the length of tail can be used for sex determination, with males having a long tail (exceeding the posterior edge of the carapace) while females possess shorter ones (rarely reaching the posterior edge of the supracaudal scutes). Premature diagnostics based only on external characteristics must be carefully considered, as there have been a few recent cases where turtles showing premature masculine secondary sexual characters were later identified as females after a veterinary diagnostic test (see Crespo et al., 2013). If means are available, laparoscopy examination of the gonads is the most effective way to determine sex and the sexual maturity of the specimen, although this technique must be supervised and carried out with veterinary care and training by experts.

#### *Photography Documentation*

It is important to photograph the carcasses at the stranding site, using a reference scale (e.g., a graduated scale with an identification number to code the animal and other relevant information, Figure 2). Photographs of the animal on the stranding site may provide important information (e.g., on stranding cause, epibionts, etc.) that can be lost or cannot be collected later after moving the carcass or during the necropsy.

Figure 2. An example of an identification white board with a centimetre scale to be placed near or on the carcass when taking photographs. Capital letters indicate D: date, T: time and P: place of the stranding.

Figure 3. Detailed images of interesting features to be recorded in stranded turtles. The figure includes pictures taken for individual identification such as scars from tag removals (A), deformities caused by predators or during development (B), external abnormalities (ectoparasites and epibionts (C) or tumours (D)), or wounds resulting from stranding causes (e.g., missing limbs because of entanglement (E) or dredge strikes (F)). Photos: Karumbe.

Standard photographs to be taken include the following planes: ventral (plastron) and dorsal (carapace), head (dorsoventral and rostrocaudal), forelimbs and hindlimbs, and pictures of any mark (including tag scars or carapace traumas, Figure 3). All photographs should allow for species identification via carapace shape, scale pattern and, if present, notches. In addition to these photographs, it is necessary to take detailed images of any external abnormalities (e.g., epibiont concentrations, tumours, wounds, missing limbs or eyes, deformities, skin lesions, etc.).

Some of these marks and scale patterns (for instance in the dorsoventral portion of the head) can be used for individual turtle identification in live stranded and released turtles (Reisser et al., 2008) in case resources limit the use of artificial tagging.

#### *Tagging*

The primary purpose of tagging is to identify a marine turtle as an individual (Bjorndal, 1999). Physical means of identifying marine turtles include uniquely painted or coloured marks, tattoos, carapace tags or drilled holes, flipper (metal or plastic) tags, coded wire tags, "living tags", and PIT (Passive Integrated Transponder) tags. Hence, a stranded turtle coming from other nesting or foraging areas distant from the studied coast, where other researchers could be tagging, may have one or several of these tag types. Thus, staff recording strandings must check stranded live turtles or carcasses for tag presence.

 Flipper Tags: All four flippers have to be checked, and when finding a tag the information on it has to be recorded. These tags normally have an alphanumeric code for identification and a contact address. Presence of scars produced by previous tag removal should be noted. Most flipper tags used are made of metal (monel or inconel style) or plastic materials (Figure 4).

 PIT Tags: The detection of this type of tags requires electronic equipment (scanner) to read the tag code. They may be either numeric or alphanumeric. All areas on the turtle´s body should be scanned, even if one PIT tag has already been found, because some turtles may carry more than one PIT tag (e.g., a turtle captured and tagged by two different teams), or because the tag can migrate inside the turtle´s body. There is no consensus on the placement of PIT tags, therefore project personnel should examine all possible body parts (i.e., left and right shoulder muscles, left and right fore flippers, left and right rear flippers, and both sides of the neck) for existing tags.

Figure 4. Example of flipper tags (left: plastic Jumbo model; right: different sized metal tags) used to tag marine turtles. Photo: G. Martinez Souza.

 "Living" tags have occasionally been used to identify cohorts of hatchlings or yearlings released in a given year. Contrasting pigmented marks are created by the surgical exchange (referred to as "autografting") of small pieces of tissue between the carapace and the plastron. These marks are retained and increase in size as the animal grows (Balazs, 1999; Eckert & Beggs, 2006). Hence, careful observation of carapace and plastron is needed.

#### *State of Decomposition of the Carcasses*

It is necessary to classify the state of decomposition of the carcasses found. Such state will determine how the stranding will be managed. It is very important to try to estimate the time elapsed since the turtle stranded on the beach until it was encountered.

Depending on a turtle´s condition or a carcass´s degree of decomposition, the turtle can be used for different kinds of studies, and sampling collection must be planned accordingly. The degree of decomposition can be classified in many ways following different objectives or situations in different areas. Here we propose a classification with 5 categories, from 0 to 4, being: 0 Live turtle, 1 Freshly dead, 2 Starting to lose scales/losing eyes, 3 Lost scales/Very rotten, 4 Dried carcasses, Bones only (Figure 5).

Figure 5. Strandings classified regarding condition of the animal. decomposition sate 0: alive; decomposition sate 0 1: fresh; decomposition sate 0 2: without eyes, losing scales; decomposition sate 0 3: rotten; decomposition sate 0 4: dried carcasses, only bones. Photos: Karumbe.

#### *Morphometrics*

There are several ways to measure a turtle, but using a method appropriate for a particular study consistently is most important. Linear measurements can be taken with either callipers (straight-line measurements) or a flexible measuring tape (curved measurements). The decision on what to use depends on the accuracy, precision, cost, and convenience required by the study (Bolten, 1999). For instance, straight measurements of the carapace are more accurate than curved ones, since the latter may vary depending on the state of decomposition of a carcass, which can be inflated due to gas accumulation. However, it´s very important to define measurements clearly on data forms. When describing turtle size, five standard linear measurements are commonly presented: carapace length, carapace width, tail length, head width, and plastron length; although other measurements can be taken if convenient.

For hard-shelled turtles, a few different carapace length measurements have been used according to some manuals (see Pritchard et al., 1983; Bolten, 1999):

- 1) Minimum straight carapace length (SCLmin) or Minimum curved carapace length (CCLmin) is measured from the nuchal notch of the carapace (nuchal scale) to the posterior notch at the midline between the two supracaudal scales, using a calliper or a flexible measuring tape respectively.
- 2) Straight carapace length notch to tip (SCLn-t) or Curved carapace length notch to tip (CCLn-t) is measured from the nuchal notch to the posterior tip of the supracaudals, using a calliper or a flexible measuring tape measure. For consistency, in the curved measurement, the longest supracaudal should be used because the tips of the supracaudals are often not symmetrical.
- 3) Straight carapace width (SCW) or curved carapace width (CCW) is measured at the widest point, using a calliper or a flexible measuring tape, respectively. There are no anatomical reference points for these last measurements, and they are just taken at the point of maximum carapace width.
- 4) Tail lengths: Total tail length (TTL) is the distance from the midline of the posterior margin of the plastron to the end of the tail following the curvature of the tail. Postcloacal tail length (PTL) is the distance from the mid-cloacal opening to the end of the tail following the curvature of the tail.
- 5) Head width (HW), plastron length (PL) and plastron width (PW) are less frequently measured in marine turtles than are carapace length and width; although these measurements can also be of interest in certain studies. Plastron length (PL) is measured along the midline of the plastron. Some variation in measurement is introduced because frequently the anterior and/or posterior edges of the plastron scutes do not completely overlay the anterior and/or posterior edges of the underlying bone. PL should be measured along the midline from the anterior edge to the posterior edge of the underlying bone when it extends beyond the scutes (Bolten, 1999). Plastron width (PW) is measured at the widest point of the plastron, and there are no anatomical reference points for this measurement. HW is measured at the widest point with a calliper. PL can be measured with a calliper, or with a measuring tape (curved), along the midline line. Straight measurements of the plastron are recommended for dead turtles, because decomposition can result in the inflammation of the body, thus altering the curved measure. HW is measured at the widest point with a calliper.

For leatherback turtles there are some variations in biometric measurements that need to be considered (see Biasatti, 2004):

- 1) Both straight carapace length (SCL) and curved carapace length (CCL) are measured from the nuchal notch (anterior edge of the carapace at the midline) to the posterior tip of the caudal peduncle. Curved measurements are made along the side of the midline (vertebral) ridge using a flexible measuring tape. The end of the tape should be securely positioned at the junction between skin and carapace, and the tape pulled taut to the caudal peduncle, allowing the tape to continue the natural position alongside the ridge.
- 2) Carapace width is measured at the widest point; again there are no anatomical reference points. Straight carapace width (SCW) is measured with a calliper. Curved carapace width (CCW) is measured with a flexible measuring tape; the tape measurement does not follow the curvature of the ridges, but rather spans from ridge crest to ridge crest.

Head width can be measured at the widest point with a calliper. Tail length should be measured as described for hard-shelled turtles, and plastron length should be measured with a calliper along the midline from the anterior edge to the posterior edge.

#### *Sample Collection*

In this section we include a descriptive list of samples that can be collected from stranded turtles for different studies on biology, conservation, diseases, and health status of individuals of the different species.

#### **Live Turtles**

In addition to activating the veterinary protocols to evaluate the condition of the turtle and allow its recovery, obtaining important information from the live turtles can help increase knowledge on the biology and conservation of these species.

At the moment of stranding, oesophagus contents can be collected for dietary studies through the oesophageal lavage technique (see Forbes & Limpus, 1993; López-Mendilaharsu et al., 2008, and Carrión-Cortez et al., 2010 for details on the technique). Such contents provide information on immediate feeding behaviour and associated threats, such as debris ingestion.

It is also very important to gather information by routinely classifying and counting epibionts (barnacles, leeches, algae, etc.) on the carapace and skin of turtles. Total number, location and percentage of the turtle´s skin and carapace covered must be recorded. In some species and locations, like the green turtles in Uruguay (Vélez-Rubio, 2011), high epibiont loads may be indicative of health problems. Massive colonization leads to the inability to dive and flotation problems (Bellido et al., 2010; Flint et al., 2009; Badillo, 2007). Epibionts can help us know the turtles movements and migrations (e.g., Báez et al., 2002), and help to identify some behaviours such as brumation (Castro et al., 2007).

Several techniques can be used for sex determination, invasive approaches include (1) laparoscopy (a miniature telescope to view directly inside the peritoneal cavity through minor surgery), (2) gonadal biopsy sampling (small pieces of gonadal tissue can be evaluated histologically to determine the sex of the animal), (3) ultrasonography (ultrasound images, although perhaps less effective on smaller turtles where gonads are less developed), and (4) hormonal levels (testosterone radioimmunoassay, RIA (Owens et al., 1978) If the means and equipment are available, non invasive techniques such as ultrasonography are preferable for sex determination in live turtles (Limpus et al., 1994; Braun-McNeill et al., 2007; Wyneken et al., 2007; Blanvillain et al., 2008; Crespo et al., 2013).

Biopsy samples may be collected from various tissues to provide information on the life history and population biology of local aggregations. There are many manuals and protocols for taking different biopsy samples (e.g., Jacobson, 1999; NMFS, 2008; Flint et al., 2009). Skin biopsies have been collected for toxicological assessment (including toxin levels and presence of heavy metals, polychlorinated biphenyls and organochlorine compounds), microbiological assessment (including isolation and identification of bacteria, viruses, fungal elements and pathogenic protozoa), genetic studies, or foraging behaviour and potentially distributional patterns (stable isotope studies). Blood samples may be also taken for toxicological assessment or genetic studies, and for sex maturity (hormonal levels) or dietary studies (stable isotopes studies). Carapace biopsies are also taken for foraging behaviour and potential distribution patterns (stable isotopes studies). Muscle biopsies can be collected to determine aerobic and anaerobic metabolic capacity, thermal tolerance, and also for stable isotope analyses or genetic studies. Biopsies can also be obtained from visceral structures from live turtles, but in most situations this will be performed in a veterinary hospital under general anaesthesia (see Jacobson, 1999).

#### **Dead Turtles**

Initially, when a dead turtle is found onshore, our first interest is the cause of stranding. Normally, due to problems such as difficult access to many carcasses, degree of decomposition, or lack of resources, the real cause of stranding is difficult to determine, and therefore the impact of many threats is probably underestimated. For example: interaction with fisheries are not easy to assess; only some fishing gears leave evidence on the carcasses (e.g. longline hooks and lines, net fragments and the corresponding injuries). Moreover, some injuries are not always easy to assign with certainty to an interaction with fishing gear (Casale et al., 2010). Ingestion of solid debris is also difficult to assign as the main cause of stranding unless there is a clear physical evidence of obstruction or perforation of the digestive tract. These and other threats (e.g. hypothermia, diseases, etc.) affecting marine turtles are difficult to identify.

Necropsies are one of the basic tools for determining the underlying cause/s of death when a turtle succumbs to illness or injury or is euthanized, if an *antemortem* diagnosis was not obtained. Necropsies also yield general information useful for management, including diet and reproductive condition of a turtle (Annex IV). A good necropsy involves a thorough external and internal examination of a carcass, including careful observations of lesions or abnormalities, and the procurement, labelling, and storage of organ and tissue samples. Laboratory tests on properly preserved tissue allow wildlife disease specialists to systematically evaluate potential causes of mortality (Work, 2000; Bluvias & Eckert, 2010). Even if an animal is in a state of fairly advanced putrefaction (lacerated skin, viscera distended by putrefying gases, rotten smell, etc.), it may be interesting to examining a carcass in order to collect as many samples as possible, including digestive contents, fishing gear remains (hooks, lines, etc.), evidence of other possible threats, bone samples, carapace scales, etc.

Once morphometric measurements and external examinations have been completed, an internal examination may be conducted. A list of tools and equipment required for performing a *post mortem* necropsy is provided in Annex II and III.

The recommended necropsy procedure for an internal *post mortem* examination of a marine turtle starts with the removal of the plastron. It includes the examination of forelimbs, coelomic mesentery, heart, thyroid, liver, trachea, tongue, oesophagus, coelomic cavity, lungs, urogenital system, kidneys, adrenal glands, distal aortas, central nervous system, brain, salt glands, and gastrointestinal tract. To avoid faecal contamination, it is best to remove the whole gut; closing the extremes with strings and to proceed with the internal examination of gut contents after all other tissues and organs have been examined (Flint et al., 2009).

In addition to a standard *post mortem* examination, samples of the eyes, muscle, skeleton, blood and faeces may be collected for studies on histology, toxicology, microbiology, ageing, serology, and parasitology. Parasites found in gut contents must also be collected. It is critical that all organs be systematically examined in the same order on every turtle during the study. For more details on necropsy and sample collection the following three necropsy manuals can be consulted (the first two are also available in Spanish):

- http://www.sefsc.noaa.gov/turtles/TM\_470\_Wyneken.pdf.
- http://www.nwhc.usgs.gov/hfs/Globals/Products/Turtle%20manual%20english.pdf.
- http://www.uq.edu.au/vetschool/content/vet-marti/PM.Guide.MSF.pdf.

The quality and the quantity of the samples taken depend on the sort of necropsy intended. It is frequent to carry out the necropsy *in situ* (at the same place of stranding at the beach). necropsies and sample collection are limited by many factors and working conditions. A necropsy can be improved considerably if we can move the carcass to a veterinary or University facility, with a fully equipped necropsy room. Nonetheless, necropsy procedures can be modified and adapted to the possibilities and needs of each research group, research and conservation interests, available resources, or the biological questions and aims per suited.

### **Actions on Live Animals, First Aid In Situ**

When a marine turtle is found alive on the beach, in addition to engaging in transport the protocol to take it from the beach to a rehab centre (see Walsh 1999), there are first aid technics to give the damaged turtle assistance in order to increase survival probabilities:

- Taking the turtle carefully away from the shore prevents it from getting hit by breaking waves.
- A turtle should be put under the shade.
- Inclining a turtle  $45^{\circ}$  with the head down helps it eject any water it may have swallowed; although the turtle may not seem to have drowned, water may have entered during or before the stranding.
- A turtle should be taken and held carefully by its shoulders and rested on the person´s knees, the front flippers should be moved backward-forward for the water to come out.
- As a last step, the turtle should be left resting in the shade until it recovers or it is time to transport it to a rehab centre. Pouring some water over the carapace and flippers keeps the animal wet. Care should be taken not to pour water into the marines.

# **External Physical Examination**

When the turtle is stabilized, it can be examined to detect signs of illness, scars, wounds or internal injuries. Animals should be examined externally from head to tail for any abnormalities or damage. Photos of any abnormality or for species identification should always be taken. When examining the carcass, the team should do the following:

External damage:

- Plastron, carapace, and skin: check for presence of fresh or old wounds (Ulcerations of the skin of the plastron are more common in chronic debilitated animals), presence and number of epibionts, abnormal growths on the skin, etc. Check if epibionts are fixed to critical parts such as narines, mouth or eyes.
- Cloaca: check if there is something protruding out of the cloaca
- Narines: look for presence of mucus or leaking blood (possible internal wound) or liquid (possible presence of water in the lungs cause by drowning).
- Mouth: Note any ulcers, cuts, plaques, growths, presence of hooks, fishing lines, blood, spots or lumps in the oral cavity.
- Eyes: check if eyes are collapsed, cloudy, or weepy, or if there are abnormal warty growths around them.
- Flippers: check for abnormal growths, presence of fishing line wounds, strangulations causing ischemia and/or necrosis, or hooks embedded in the flipper.
- Finally, check for any other abnormality: lumps, bumps or exudates in unusual places.

General body condition: Turtles in good condition will usually have a nice rounded plastron. In severely emaciated turtles, the plastron is dished in and concave, and in the neck area the back of the skull shows a prominent occipital process that becomes very conspicuous in starved turtles.

Response to stimuli: Evaluate behavioural responses to stimuli. There are three response levels: (1) alert (aware, responsive to environmental stimuli), (2) weakly responsive (responsive only after a lot of stimulation), and (3) non-responsive (not responding to touch). If the turtle is not responding to skin stimuli, try touching one of its eyes to observe a reaction.

Hydration condition: Dehydration normally causes weepy eyes and dry skin.

Breathing rate and type: a continuous wheeze and suffocated breath may indicate a pulmonary disease.

If the turtle seems to be in very good condition after all this examination process, evaluate the buoyancy and locomotion of the turtle before releasing it back to the sea.

#### **Diagnostic Techniques**

If facilities and resources are available, the condition of sea turtles can be further evaluated through complementary diagnostic techniques, which include:

- Biological sampling: blood sample (for a complete blood count and serum chemistry tests), microbiology (2 cloaca swabs, 1 conjunctive swab and 1 nasal swab), and faeces examination (bacterial cultures, presence of parasites, etc.).
- X-ray images for internal damage in bones and viscera.
- Echography study for a general examination of celomic cavity.
- Computerized Axial Tomography (CAT scan), Magnetic-Resonance Imaging (MRI), etc.

#### **Examples of Studies Based on Stranded Marine Turtles**

In the last decades, several studies on marine turtle strandings have been published at different geographical scales in many parts of the world (Southern Spain, Bellido et al., 2010; Northeast Spain, Tomás et al., 2008a; Turkey, Yalcin-Ozdilek & Auregii 2006; Argentina, Gónzalez Carman et al., 2011; Uruguay, Vélez-Rubio et al., 2013; Peru, Rosales et al., 2010).

Here we present some recent studies based on strandings and a brief description of the applications of the stranding data collected in them:

- "The Impact of Turtle Excluder Devices (TEDs) and Fisheries Closures on Loggerhead and Kemp's Ridley Strandings in the Western Gulf of Mexico" Lewison RL, Crowder LB and Shaver DJ (2002): these authors evaluated the efficacy of TEDs and other management actions (e.g., fisheries closures) on loggerhead (*C. caretta*) and Kemp's ridley (*L. kempii*) turtle populations by analysing a long-term stranding data set from the western Gulf of Mexico. Analyses suggest that both marine turtle population growth and shrimping activity have contributed to the observed increase in strandings. Their data set included 1795 and 1279 strandings of loggerhead and Kemp's ridley turtles, respectively. Their analyses suggest that TEDs can be effective in reducing strandings, depending on the level of TED compliance. Because stranding data cannot reflect the proportion of turtles that escape unharmed from TEDs, they were unable to directly measure the reduction in mortality resulting from TED regulations and to verify mortality-reduction estimates from previous research.
- "Back-calculating length from skeletal growth marks in loggerhead sea turtles *Caretta caretta*" Snover ML, Avens L and Hohn AA (2007): these authors used a Skeletochronology technique for the assessment of individual growth rates in marine turtles. They obtained both humeri and carapace length measurements from 243 freeranging loggerhead marine turtles found stranded and dead on beaches along the Atlantic and Gulf of Mexico coasts of the US from Maryland to Texas. As the loggerheads collected along the coast of the US are primarily neritic, their sample was comprised of juvenile and adult turtles between 44.7 and 106.1 cm SCL. They also suggest that, with proper application, back-calculation in combination with skeletochronology can be a powerful tool for studying the growth dynamics of individual marine turtles.
- "Spatio-temporal patterns of juvenile marine turtle occurrence in waters of the European continental shelf" Witt MJ, Penrose R and Godley BJ (2007): authors present data spanning approximately 100 years regarding the spatial and temporal occurrence of marine turtle sightings and strandings in the northeast Atlantic. Records of loggerhead ( $n = 317$ ) and Kemp's ridley ( $n = 44$ ) turtles occurring on the European continental shelf were most prevalent during the autumn and winter, when waters were coolest. In contrast, endothermic leatherback turtles  $(n = 1.668)$  were most common during the summer.
- "Cause-specific temporal and spatial trends in green sea turtle strandings in the Hawaiian Archipelago (1982–2003)" Chaloupka M, Work TM, Balazs GH, Murakawa SKK and Morris R (2008): These researchers recorded five species of marine turtle in 3,861 strandings over a 22-year period (1982–2003) in the Hawaiian Archipelago. Green turtles comprised 97% of these strandings with size and gender composition reflecting the demographic structure of the resident green turtle population in Hawaiian waters. The most common known cause of the green turtle strandings was the tumour-forming disease, fibropapillomatosis (28%) followed by hook-and-line fishing gear-induced trauma (7%), gillnet induced trauma (5%), boat strike (2.5%), and shark attack (2.7%). The specific mortality rate (conditional probability) for fibropapillomatosis was 88%, 69% for gillnet gear and 52% for hook-and-line gear.
- "High mortality of loggerhead turtles due to bycatch, human consumption and strandings at Baja California Sur, Mexico, 2003 to 2007" Peckham SH, Maldonado-Diaz D, Koch V, Mancini A, Gaos A, Tinker MT and Nichols WJ (2008): here investigators assessed anthropogenic mortality of endangered North Pacific loggerhead turtles in the coastal waters of Baja California Sur, Mexico, through the synthesis of 3 information sources: (1) intensive surveys of an index shoreline from 2003 to 2007; (2) bimonthly surveys of additional shorelines and towns for stranded and consumed carcasses from 2006 to 2007; and (3) observations of bycatch by 2 small-scale fishing fleets.
- "Sea turtle strandings reveal high anthropogenic mortality in Italian waters" Casale P, Affronte M, Insacco G, Freggi D, Vallini C, D' Astore PP, Basso R, Paolillo G, Abbate G and Argano R (2010): authors recorded a total of 5938 stranded loggerhead turtles measuring from 3.8 to 97cm curved carapace length (mean: 48.3 cm) for the period of 1980–2008. Their results suggest that anthropogenic factors are the cause of at least 52% of turtle strandings, plus an uncertain but considerable proportion of turtles drowned as a consequence of incidental capture by bottom trawlers.
- "Marine Sponges, Other Animal Food, and Nonfood Items Found in Digestive Tracts of the Herbivorous Marine Turtle *Chelonia mydas* in Hawaii" Russell DJ, Hargrove S and Balazs GH (2011): A total of 2,471 digestive tract samples taken from *Chelonia mydas* along the six main Hawaiian Islands (Kaua'i, O'ahu, Moloka'i, Maui, Läna'i, Hawai'i) were examined between 1975 and 2010. Authors analysed 127 mouth, 43 oesophagus lavage, 2,201 forestomach, 61 stomach, and 39 intestines samples. Although the usual diet of *C. mydas* comes from algae and sea grasses (plant material), animal material has been found in samples taken over the past 35 yr. They reported thirty different kinds of other animals were found in the samples. And among animal food items known to have nutritional value, the protein sponge *C. chucalla* could be contributing as an important nutritive factor.
- "Estimating At-Sea Mortality of Marine Turtles from Stranding Frequencies and Drifter Experiments", Koch V, Peckham H, Mancini A and Eguchi T (2013): researchers evaluated the magnitude and distribution of at-sea mortality of marine turtles along the Pacific coast of Baja California Sur, México during 2010–11. They used a combination of counting stranded animals and drifter experiments. They found a total of 594 carcasses during the study period, with loggerhead (62%) and green turtles (31%) being the most common species. Their study showed that drifter trials combined with beach monitoring can provide estimates for deaths at sea in order to measure the impact of small-scale fisheries, which are notoriously difficult to monitor for by-catch.

# **Parallel Studies That Can be Conducted Associated to Marine Turtle Strandings (in-Water Studies, Aerial Surveys)**

Although stranded turtles give us valuable data about local aggregations, the probability of stranding varies widely in space and time. Strandings do not usually exceed 10–20% of total mortality even in coastal waters, since predators, scavengers, winds and currents may

prevent carcasses from reaching the shore (Epperly et al., 1996, Hart et al., 2006, Mancini et al., 2012, Koch et al., 2013). Stranding probability diminishes for deaths at greater distances from shore even more as animals that die offshore may never strand. It is therefore extremely difficult to estimate total mortality when using stranding frequencies only, even in near-shore waters (Epperly et al., 1996, Hart et al., 2006, Mancini et al., 2012, Koch et al., 2013). For that reason, it is very important to complement with other techniques, normally orientated to in-water studies.

Drifter experiments allow us to understand the main currents that influence the study area and may help explain and predict the spatio-temporal patterns of the strandings (see Hart et al., 2006).

Bycatch surveys (either on-board or interview-based) for estimating catches and at-sea mortality are very useful to assess the impact of different fishing gear on marine turtle bycatch.

For population studies:

- Mark-recapture technique through intentional capture to study growth, movements and populations dynamics (Chaloupka & Musick, 1997). This technique consists in "marking" (any method of identifying individual turtles) and "recapturing" (any method of re-identifying a marked individual at a later time) (see Gerrodete & Taylor, 1999).
- Satellite tracking is used to characterize broad scale behavioural patterns, interseasonal variability, and general high-usage areas among different marine turtle populations. However, it does present some limitations due to a large instrument size, high cost, and low positional accuracy and dive resolution. Ultrasound and radio tracking studies movements and home range (e.g.: Van Dam & Diez, 1998; Seminoff et al., 2002); and time depth recorders (TDRs) enable the research of scaling in dive capacity and habitat use (Blumenthal et al., 2009). In addition, TDRs and ultrasonic tracking combined (Makowski et al., 2006) have successfully elucidated movements and diving behavior.

Aerial surveys are a proven method for examining parameters such as abundance and distribution, and are especially beneficial because they allow large areas to be surveyed in a relatively short amount of time. However, the identification of marine turtle species during aerial surveys can be challenging and inexperienced or untrained observers are likely to be limited in their ability to identify species. In addition, because of their tendency to dive and remain submerged when startled, marine turtles often present observers with the challenge of having to identify species from a single viewing (see Goodman & Belskis, 2012). These surveys can be a cost effective alternative for surveying large lengths of coastline. Such aerial surveys could also be used to obtain other management information such as human usage patterns.

### **CONCLUSION**

The main interest in long term stranding studies is obtaining biological and ecological conclusions on marine turtle species, with implications on their conservation. Bearing in mind the caveats associated to these studies, the analyses of stranding data can contribute to a better implementation of conservation measures and management on endangered marine turtles of different populations in different areas of the world. This can be accomplished through the identification of the areas used by these species, and the anthropogenic sources of mortality in the region covered. The establishment, continuity and improvement of stranding networks over time is one of the most important achievements. Networks have a twofold benefit: (1) the development of long-term temporal series of data which, integrated with complementary studies on distribution, sexual maturity, habitat use and environmental preferences, will help to assess threats affecting endangered marine turtles over time; and (2) the raising of awareness at different social levels, increasing public interest in marine turtle conservation.

# **Annex I. Example of Stranding Data Forms (Modified from STSN)**

٦

Modified from NMFS - Sea<br>Turtle Stranding and salvage network

 $\Box$ 

# **Annex II. Basic Field Equipment for Stranding Studies**

- Photo Camera
- Data taking forms with a specific design according objectives.
- Pencil and rubber (avoid ball pens since ink can be deleted by sea water, sea spray or rain)
- Measuring equipment (flexible measuring tape, calliper rule) and weighing equipment (net or harness and scales preferably)
- Geographical Position System (GPS)
- Discard gloves
- Knives, scissors, scalpel, plastic knives, string or other cutting material. Surgical material is preferably
- Appropriate bottles and containers for the various samples taken
- Unused plastic bags
- Portable coolers (Styrofoam or polyurethane boxes for sample preservation and transport).
- 'Waterproof' markers
- Chemical products to preserve samples (ethanol 70%, formalin 4% or 10%, etc.)

# **Annex III. Equipment for Necropsy in Facilities**

- Coveralls or other appropriate clothing
- Rubber boots or shoe covers
- Rubber gloves
- Masks
- Photo camera
- Calipers and flexible tapes
- Necropsy forms and notebook
- String, labels, assorted bottles, water proof pen
- Forceps of several sizes
- Tissue cutting board
- Necropsy knives and sharpener
- Scalpel blades (#20 and #10) and handles
- Postmortem shears
- Alcohol lamp or butane burner
- Matches or lighter
- $-$  Ethanol 70% and formalin
- Containers of different sizes
- Fixative for electron microscopy such as Trumps solution (should be kept chilled)
- Sterile whirl-pack bags
- Cryotubes
- Microbial culturette swabs
- Microbial transport media
- Dry ice and ice chest or cooler
- Scale
- Stryker saw

# **Annex IV. Example of Necropsy Data Form (Modified from Work 2000)**

# **ABSTRACT**

Knowledge on sea turtle life cycle has been considerably improved over the last decades due to the increased application of genetic techniques. The aim of this chapter is to describe some molecular markers and techniques (Microsatellite Analysis, Restriction Fragment Length Polymorphisms, Single Nucleotide Polymorphism, mitochondrial DNA haplotypes, DNA Barcodes, Next-generation sequencing) used in genetics studies to encourage researchers to contribute to the conservation process of sea turtles. Molecular techniques provide information to different levels of ecological and biological issues. All of them have limitations and their application will be largely determined by the information that is being sought with the use of a molecular marker system, and the availability of resources for the development of these techniques.

The chapter includes illustrated case studies of conservation genetics to *Dermochelys coriacea, Eretmochelys imbricata* and *Caretta caretta*.

# **INTRODUCTION**

The aims of conservation genetics are assess genetic status of populations and propose management measures for genetic diversity preservation and prevent genetic risks that could affect persistence of populations. To this end molecular markers have been relevant for studies in different species. Nevertheless, application of molecular markers is not limited solely to this, in conservation it can also contribute to understanding of evolution history, demography and ecology of species in danger of extinction.

A successful conservation strategies for sea turtles will require information related to distribution, biology and dynamic population. Based on development of genetic analytical procedures, researches have been generating data that are important for managing implications (Bowen & Witzell 1996; Jensen et al. 2013).

Research efforts in this respect, will make it possible to determine population structure of sea turtles and promote sharing of samples and data for global knowledge of life history of these endangered species.

There is a noticeable increase of studies that tend to contribute to understand sea turtles ecology. Among them we can cite natal homing (Meylan et al. 1990; Bowen et al. 2004; Bowen & Karl 2007a), male philopatry (FitzSimmons et al. 1997; Shamblin et al. 2012b), infer genetic structure (Bowen et al. 1994; Dutton et al. 1996, 1999; Encalada et al. 1996; Bass & Witzell 2000; Naro-Maciel et al. 2007; Reis et al. 2010a, Duchene et al. 2012), demonstrate multiple paternity (Kichler et al. 1999, Hoekert et al. 2002; Joseph & Shaw 2011), detect hybridization (Karl et al. 1995; Lara-Ruiz et al. 2006; Reis et al. 2010b; Garofalo et al. 2012), reveal mating behaviour (Jensen et al. 2006), deduce migration trends by inferring connections between rookeries and foraging areas (Bowen et al. 1995; Encalada et al. 1998; Lahanas et al. 1998; Bolten et al. 1998; Roberts et al. 2004; Dutton et al. 2008; Boyle et al. 2009; Blumenthal et al. 2009), resolve taxonomic questions to define priorities for conservation management (Karl & Bowen 1999; Bowen et al. 2005; Campbell & Godfrey 2010; Naro-Maciel et al. 2008, 2010; Wallace et al. 2010).

A complete review of scientific literature about molecular genetics was compiled by Lee (2008) concerning sea turtle research and explains in detail the use of nuclear (nDNA) and mitochondrial DNA (mtDNA) markers.

In another more recent publication, Jensen et al. (2013) described the advances and contribution of molecular genetic studies in aspects such as sea turtle phylogeography, gene flow, dispersal, feeding groups, migratory behavior, mating systems, sex ratios of breeding populations, reproduction biology, conservation and management.

The aim of this chapter is to describe molecular marker techniques used in conservation genetics and explain advantages and limitations of application of these to help researchers to contribute to the sea turtle conservation process, encouraging the development of research with molecular techniques.

Furthermore, in the chapter there are illustrated case studies of genetic conservation of three species of sea turtles (*Dermochelys coriacea, Eretmochelys imbricata* and *Caretta caretta*).

# **METHODS**

### **Analytical Procedures Used in Sea Turtles Genetic Studies**

With the advance of molecular biology techniques, different methods for detecting genetic polymorphism were developed at the DNA level. DNA molecular markers serve as a reference to detect transmission of a chromosome segment from one generation to another. Molecular markers of mitochondrial and nuclear DNA are available for analyses but none of them can be regarded as optimal for all research applications.

Molecular markers are DNA fragments with a defined position within a species genome. Within a marker, if differences in the DNA sequence are observed in a locus (different alleles), they will be called polymorphisms. Markers can also be highly polymorphic (with multiple alleles) or low polymorphic (with few alleles).

These markers reflect differences in the DNA sequences, and separate loci can provide independent tests, thus using many loci can yield extreme sensitivity because of a trade-off between precision and convenience (Sunnucks 2000). Processes such as recombination, selection, genetic drift in different genes and regions of the genome can generate different genealogical histories. Thus each marker (locus) can be considered a sample of the genome and combining results from many loci provides a more precise and statistically powerful way of comparing populations and individuals (Selkoe & Toonen, 2006).

The polymorphism detection can be based on the unique features of each marker type. They can be classified as i) variation on the number of repetitions in a sequence (e.g., microsatellites, minisatellites) and ii) markers that detect specific changes in the genome (e.g., Restriction Fragment Length Polymorphisms (RFLP), Single Nucleotide Polymorphism (SNP), DNA barcodes, etc.)

Mitochondrial DNA has often been used as a marker in investigations of molecular diversity, reconstruction of historical patterns of population demography and speciation. It is characterized as being highly variable due to its elevated mutation rate compared to nuclear DNA, which generates signals for population history over short periods of time. Mitochondrial DNA has highly variable regions (e.g., control region or D-loop) which are typically flanked by more conserved regions (e.g., ribosomal DNA) (Galtier et al. 2009). It has two genes of ribosomal RNA (rRNA), the 12S and 16S rDNA. For analysis of genetic diversity of levels in superior categories such as in the phyla is usually used 12s rDNA, while in analysis of average categorical levels such as in families or genera is used 16s rDNA (Gerber et al. 2001). Characteristic features of various mtDNA and nuclear DNA markers are summarized in Table 1. DNA barcoding is a method that uses COI in animals for rapid and accurate identification of species (Ratnasingham & Hebert 2007). A mitochondrial fragment of 648-bp (*Folmer region*) of the cytochrome c oxidase I gene (COI) has been standardized for molecular taxonomy and identification. However, one of biggest criticisms of DNA barcode is that it is based on information from a single marker. The use of genes (one or more) from a haploid genome can affect correct the identification of species.

In situations where incomplete lineage sorting (due to recent radiation), introgression or pseudogenes are present, the correct taxonomic identification can be wrongly inferred and will interfere in the correct identification of a species, since it is not possible to distinguish these situations from a correct taxonomic classification (Teletchea 2010).

Genetic research in sea turtles is focused in the analysis of maternal lineages, population genetic structure, migratory trends and phylogeography. In the studies with sea turtles four types of nuclear markers have been used (Microsatellites, scnDNA, RFLP, nuclear sequences) and mitochondrial markers. Microsatellites are often used in sea turtle studies, 119 microsatellite loci have been recognized of which 25 are of *Caretta caretta*, 12 of *Chelonia mydas*, 18 of *Dermoclehys coriacea*, 10 of *Lepidochelys olivacea*, 4 of *Lepidochelys kempii*, 11 of *Natator depressus* and 39 of *Eretmochelys imbricata*. Sea turtle hybridization has been studied with molecular markers such as mtDNA, scnDNA and RFLPs (Karl et al. 1995; Seminoff et al. 2003; Witzell & Schmid 2003), research is also being done on the combined use of morphological analysis and mtDNA (Lara-Ruiz et al. 2006; Reis et al. 2010b; Garofalo et al. 2012), and nuclear markers (Vilaça et al. 2012).

In mitochondrial phylogenetic research of sea turtles markers such as cytochrome b (Cytb) (Bowen et al. 1993), D-Loop, ND4 (Dutton et al. 1996), 12S and 16S (Naro-Maciel et al. 2008) and recently the complete mitochondrial DNA genome has been used (Duchene et al. 2012). DNA Barcoding of sea turtles was reported first for 5 species from Brazil by Vargas et al. (2009).

Subsequently, Naro-Maciel et al. (2010) established barcode sequences of all sea turtles species in the Atlantic and Pacific and agreeing the utility of mitochondrial COI for the purposes of barcoding even though they are ancient taxa with slow molecular evolution.

## **Microsatellite Analysis (Simple Sequence Repeats - SSRs)**

Microsatellites are polymorphic DNA loci that contain repetitions of 1-6 nucleotides, found at high frequency in nuclear genomes of most taxa. They represent the more polymorphic class of molecular markers currently known and used (Balloux & Lugon-Moulin 2002). Allelic variation, number of repeats and allelic frequencies are available for thousands of markers across numerous organisms. The ability of researchers to choose from such a large selection of highly informative markers has made microsatellite analysis a widely accepted tool for linkage studies, association studies, and identification of individual organisms (Selkoe & Toonen 2006).

Microsatellites are highly informative and based on the amplification by PCR of individual regions. Each amplified segment can have a different size and corresponds to a different allele from the same locus. The polymorphism is given by the number of repetitions in a loci. For example, in a loci with  $(CA)_n$  repeats, where n is the repeat number, the different alleles will have a distance of two base pairs between them  $(e.g., (CA)<sub>11</sub>$  and  $(CA)<sub>12</sub>$ ). Then either the repeat number (e.g., 11, 12, 13, etc.) or the allele size (e.g., 100 bp, 102 bp, 104 bp) will be extracted and used in statistical analysis (Balloux & Lugon-Moulin 2002).

Development of microsatellite primers for a new species is difficult, laborious and expensive, although genomic era could facilitate this process. Although microsatellites are extremely useful for genetic analysis, there are difficulties concerning their use: (i) they are expensive to develop, as a large number of sequences must be cloned and only a small number of these will be useful for development of SSR markers; (ii) the primers may not amplify any PCR product; (iii) the primer may produce very complex, weak or nonspecific amplification patterns; (iv) the loci may not be polymorphic (Madesis et al. 2013).

Even though microsatellites mainly occur in noncoding sequences, development of expressed sequence tags (EST) in databases revealed that microsatellite repetitive sequences also occur inside coding sequences. Information obtained by EST libraries has been recently used for development of SSR markers (Scott et al. 2000).

Although technology progresses, new genomes and EST libraries become available with help of bioinformatics approaches, development of SSR markers based on EST's through data mining has become a fast, efficient and relatively inexpensive, compared to development of genomic SSRs.

#### **PCR-RFLP Analysis (Restriction Fragment Length Polymorphisms)**

Restriction Fragment Length Polymorphism (RFLP) is characterized as a single combination of restriction enzymes. The technique for detection of RFLPs involves fragmentation of a DNA sample to obtain the difference in specific sequences of nucleotides that are recognized and are cut with specific restriction endonucleases.

In the PCR-RFLP, the digestion is done in a fragment of interest which was amplified by PCR. The detection of polymorphisms in the DNA cutting (or amplified fragment) is performed in an electrophoresis and determining the number of fragments and relative sizes. RFLP analysis can be used in many different settings to accomplish different objectives determination of paternity, characterization of genetic diversity and characterization of breeding patterns in animal populations (Zhang & Hewitt 2003).

The use of PCR-RFLPs as markers to trace the transmission of genes associated with them is useful in that it has the genetic advantages as not depending on ontogenetic status of animal (Brito & Edwards 2009). Moreover, the RFLP technique allows an analysis of all the genome; include inexpensiveness and not requirement for advanced instruments. Furthermore, the design of PCR-RFLP analyses generally is easy and can be accomplished using public available programs.

Disadvantages of technique include the requirement for specific endonucleases and difficulties in identifying the exact variation in the event that several SNPs affect the same restriction enzyme recognition site. Moreover, PCR-RFLP consists of several steps, and it requires relatively time for analysis. This technique is not suitable for the simultaneous analysis of a large number of different SNPs due to the requirement for a specific primer pair and restriction enzyme for each SNP (Berg Rasmussen 2012).

#### **SNP (Single Nucleotide Polymorphism)**

SNP is believed to be the most recent generation of molecular markers, based on the identification of the substitution of one nucleotide for another, representing two alleles. Its frequency oscillates between 1 in 600 and 1 in 1000 base pairs, depending on the organism. They include the classic technique of RFLP but not exactly by detecting the appearance or abolition of a restriction site (Vignal et al. 2002). The fact that they can be detected on "arrays" (chips) from the solid phase without the use of electrophoresis gels is an advantage. The most direct method for detection is sequencing DNA segments, previously amplified by PCR, of several individuals representing the diversity of population.

Primers are designed to amplify DNA fragments and could be derived mainly from interest genes or sequences reported in databases corresponding to express sequences (expressed sequence tags, EST) (Brumfield et al. 2003). This marker has been shown to be mostly bi-allelic, determined by the low mutation rate of single substitutions that cause the SNP. The advantages of this marker are codominant inheritance and its abundance in the genome. Its disadvantages are associated with genotyping methods, which include high cost equipment such as microchips, spectrometry mass, quantitative PCR or sequencing (Morin et al. 2004).

#### **Mitochondrial DNA (mtDNA) Haplotypes**

The extensive use of mtDNA haplotypes also means that the limit of resolution of this marker for distinguishing population genetic structure has probably been reached (Lee 2008). Mitochondrial DNA haplotypes are based in gene sequencing process and four techniques are widely utilized in this process, but the Sanger method is more commonly used because it has been proven technically easier to apply and it has been automated by PCR, also easily applied to long strands of DNA including some entire genes.

The mitochondrial genome contains approximately 16,500 base pairs (bp) and encodes a small fraction of mitochondrial proteins. The mtDNA contains 38 genes: 2 rRNA (12S and 16S), 22 tRNA and 13 structural genes, which encode different subunits of the enzyme complexes of the oxidative phosphorylation system (Arif & Khan 2009). The largest noncoding region, known as the control region or D-loop, occupies 1122 base pairs (aprox.). This region is often used for its high mutation rate and high variability among different populations (Gerber et al. 2001).

The study of mitochondrial DNA is particularly recommended when working with highly degraded samples, as expected in ancient DNA. It is estimated that a cell can contain up to hundreds of mitochondria, and each mitochondrion coexist within 1000 to 10000 copies of mitochondrial DNA. This high number of mitochondrial DNA molecules within the cell makes its recovery in cases where the starting DNA is very low or very degraded much more efficient than, for example, the nuclear DNA or autosomal (Meiklejohn et al. 2007).

Evolutionary properties of mtDNA (metabolically active, highly oxidative environment, complex mutation process, highly variable in space and time) make that it is marker for resolving problems of conservation but not is the ideal marker of molecular diversity and taxonomic identification (Galtier et al. 2009). Nevertheless, one should be cautious with gene-specific, species-specific, and lineage specific evolution in mtDNA. Besides, mtDNA to be a maternal inheritance is a useful auxiliary marker to nuclear DNA (Duchene et al. 2011).

## **DNA Barcodes**

DNA barcodes have been formed from the cytochrome c oxidase subunit 1 mitochondrial region (COI) and have been used to differentiate species (Hebert et al. 2003a, 2003b).

Closely related species can be differentiated because individuals within the same species have similar barcodes (Hebert et al. 2004). Despite the potential of DNA barcodes there are still many drawbacks associated with the use of these techniques.

One concern is that DNA barcodes are not an adequate source to be used alone in taxonomy to discover a species (Rubinoff et al. 2006; DeSalle 2006). It is still generally accepted that DNA barcodes are useful for identifying species after taxonomy has been established. DNA barcoding technique involves gene sequencing for the COI region to generate the DNA barcode for each species. Tissue from the specimen is used for DNA extraction; with the COI is amplified in a PCR and then sequenced. Once the COI sequence has been obtained, it is placed in the Barcode of Life Data Systems (BOLD) database. This is a searchable repository for barcode records, it provides an identification engine based on the current barcode library and monitors the number of barcode sequence records and species coverage (Rubbinof 2006).

DNA Barcode can be developed and used to determine identity of eggs sea turtles and meat in areas where these are consumed or trafficked. This method has used in conjunction with Library Barcode of Life (Barcode of Life Database - BOLD) discovering the illegal presence of products of these endangered species (Vargas et al. 2009).

Moreover DNA barcodes are of utility in conservation biology, being more accepted for identification of samples as of control region haplotypes because is widely utilized in genetic studies.

## **Next-Generation Sequencing (NGS)**

In conservation genetics, new techniques as Next-generation sequencing (NGS) have allowed the development of genomic conservation field. The NGS is characterized by highthroughput DNA sequencing techniques that are opening novel fields and applications as: genomics with detailed analysis of individual genome stretches; precise analysis of RNA transcripts for gene expression, reliable and precise quantification of transcripts for identification and analysis of DNA regions interacting with regulatory proteins in functional regulation of gene expression (Ansorge 2009).

These technologies permit rapid genome-wide characterization and profiling of mRNAs, small RNAs, transcription factor regions, structure of chromatin and DNA methylation patterns, microbiology and metagenomics (Mardis 2008).

NGS techniques are based in randomly fragmenting DNA or RNA into smaller pieces and constructing DNA libraries. These are sequenced at a high coverage and the sequenced reads are then mapped into the reference genome of the species (De Magalhães et al. 2010). The choices of NGS technique depend on the objective of the study and experimental design.

NGS technologies more commons utilized are: i) Roche (454) GS FLX sequencer that works on the principle of pyrosequencing which uses the pyrophosphate molecule released on nucleotide incorporation by DNA polymerase that produces light from the cleavage of oxyluciferin by luciferase; ii) Illumina genome analyzer which is based on concept of sequencing by synthesis to produce sequence reads of  $\sim$ 32-40 bp from tens of millions of surface amplified DNA fragments simultaneously and iii) Applied Biosystems SOLiD sequencer uses a unique sequencing process catalyzed by DNA ligase that is based in couples oligo adaptor-linked DNA fragments with 1-mm magnetic beads that are decorated with complementary oligos and amplifies each bead–DNA complex by emulsion PCR (Mardis 2008).

Ouborg et al. (2010) identify different questions and possible conservation genomic approaches that can be resolved by NGS techniques:

- 1. To assess the impact of habitat fragmentation on selectively important variation
	- a. Use of genome-wide SNPs to obtain a representative estimate of genetic variation
	- b. Perform a genome scan to distinguish neutral from non-neutral markers
	- c. Comparison of patterns of neutral and non-neutral variation
	- d. Undertake an association-mapping approach to find correlations between markers and phenotypic traits important for adaptation
	- e. Candidate-gene studies can be used to search for frequency changes of alleles in relation to environmental change
- 2. To identify genetic mechanisms underlying inbreeding depression
	- a. Population transcriptomics for identify genes associated with inbreeding depression, in different life-history stages and many genotypes
	- b. Quantitative trait locus mapping for identify genomic regions associated with inbreeding-depression phenotypes
	- c. Selection experiments on gene-expression phenotypes
- 3. To characterize the role of gene-environment  $(G \times E)$  interactions
	- a. Population transcriptomics for performed in combination with full factorial experiments to identify genetic, environmental and GxE effects in transcript profiles
	- b. Perform epigenetic screening, using methylation-sensitive AFLP or highthroughput bisulfite sequencing, of small and large populations in high and low quality habitats.
- 4. To identify the role of phenotypic plasticity in the response to environmental challenges
	- a. Epigenetic manipulation experiments to manipulate methylation levels, and study phenotypic effects in relation to population size, inbreeding level and environmental variation
	- b. Screening of methylation levels as a function of the level of phenotypic plasticity in relation to level of inbreeding
- 5. To characterize the effects of habitat fragmentation on gene expression and genomic pathways
	- a. Use microarrays or RNA-seq to screen for changes in genome wide gene expression profiles in response to inbreeding and population size
	- b. Screen gene-expression variation in high- and low-diversity populations and genotypes to disentangle direct gene effects from regulatory changes

# **Studies Case of Conservation Genetic for Sea Turtles**

*Dermochelys coriacea: Molecular Data and Its Use on Leatherback Turtle's Conservation*

The leatherback sea turtle, also known as giant turtle in some countries of its range (e.g., Brazil), is the largest of the seven sea turtle species found in the world. They are found in all ocean basins but the largest nesting populations are located in the Atlantic Ocean: Gabon (Fossette et al. 2008; Witt et al. 2011) and French Guiana/Suriname (Fossette et al. 2008).

Besides, population nesting in Brazil (Espírito Santo State), although very small (about six nests in 1993/1994) (http://tamar.org.br/interna.php?cod=76), shows an increasing trend in the annual number of nests (Antônio P. Almeida, personal communication).

Despite some differences in its biology compared with the other sea turtles species, such as size, long migration capabilities (Pritchard 1976; James et al. 2005), and longtime spending on foraging areas (James et al. 2005), the leatherback turtle is a target of the most important threats affecting all sea turtles species: fisheries bycatch (i.e., incidental capture by marine fisheries operations targeting other species), plunder eggs and meat for human consumption and coastal development (Mast et al. 2005). It is current classified as critically endangered by the International Union for Conservation of Nature and Natural Resources Red List of Threatened Species (IUCN 2015).

A new more accurate context named Regional Management Units (RMU) has been used since 2010 aiming to prioritize conservation and research of marine turtle's species (Wallace et al. 2010). In the light of this novel framework the leatherback populations worldwide are compounded by seven RMU´s distributed in the three oceans. Three of them from the Atlantic Ocean (North West, South East and South West Atlantic), two from the Indian Ocean (North East and South West Indian) and two from the Pacific Ocean (East and West Pacific). For these seven separated RMU´s different levels of threats and risks were evaluated (see Wallace et al. 2011 for details).

Three out of seven RMU´s are considered at High risk-Low threats (HR-LT), two at Low risk-Low threats (LR-LT), two at Low risk-High threats (LR-HT) (Wallace et al. 2011) meaning that the more than 70% (five out seven) of the leatherback´s populations in the world are facing, at least, one from the two major concern in marine turtle conservation.

Molecular data are used in a range of studies regarding conservation of endangered turtle species. The majority of the works regarding molecular techniques deals with the mitochondrial DNA (mtDNA) in a wide range of topics: phylogeography (Dutton et al. 1999, 2007, 2013; Vargas et al. 2008) and mixed stock analysis using mtDNA control sequences (Vargas et al. 2008, 2013; Prosdocimi et al. 2014); barcodes using mtDNA cytochrome oxidase c subunit I (COI) sequences (Vargas et al. 2009); investigation of illegal trade using PCR-RFLP of cytochrome b (Moore et al. 2003). Some recent studies are including microsatellites markers to improve the resolution of the phylogeographic analysis (Dutton et al. 2013), to better understand the demographic history, population dynamics and behavior (Rivalan et al. 2006; Molfetti et al. 2013) to estimate effective population size (Rivalan et al. 2006) and also to reveal multiple paternity in leatherbacks (Crim et al. 2002).

The delineation of the aforementioned RMU's (Wallace et al. 2010) and further conservation priorities actions (Wallace et al. 2011) are also improved by molecular data, showing that a large amount of contexts can be abetted by using molecular tools to improve the knowledge on endangered species and, as a final goal, to avoid the extinction levels as much as possible. In the present chapter, we intend to revisit information on, how and in which context, some studies using molecular data can be useful in the conservation of the critically endangered leatherback sea turtle.

The contexts explored are: (1) the mating systems and multiple paternity, (2) the phylogeography of this species and the mixed stocks at foraging grounds, (3) the population dynamics, demographic histories and estimations of effective population size, (4) the delineations of RMU´s, and (5) barcodes and PCR-RFLP to identify species.

### **Phylogeography and Mixed Stocks at Foraging Grounds**

Although the ability for extensive dispersal in the marine environment many marine species exhibit population genetic structure (Dutton et al. 2013). Phylogeography studies deals with structure levels and their distributions among geographic regions. Only five publications, concerning structure among an overall of about 20 different populations were found for leatherbacks (Dutton et al. 1999, 2007, 2013; Vargas et al. 2008; Molfetti et al. 2013). Despite only seven RMU´s were recognized for this species (Wallace et al., 2010), most of the results from genetic structure values based on mtDNA sequences studies showed high levels of structure among the overall studied nesting populations. Great variation is found if the populations represents different ocean basins, as revealed by Vargas et al. (2008) and whose found which 52.8% of the genetic variation occurring between the Atlantic and Indo-Pacific groups, 36.5% found within populations, and only 10.7% among populations within the Atlantic and Indo-Pacific groups.

The use of nuclear markers (microsatellites) is also revealing new opportunities to understand different gene flow patterns between different gender and among diverse populations (see Dutton et al. 2013 and Molfetti et al., 2013 for two examples of divergent results using mtDNA and nuDNA to infer genetic structure).

Molecular markers can also be used to learn the origin of individuals from feeding aggregations (mixed populations) based on the comparisons with a set of source populations by using Mixed Stock Analysis (MSA) (Bolker et al. 2007). Comparing haplotypes distributions among nesting and foraging grounds, beside the use of MSA, Vargas et al. (2008) revealed a major contribution to a Brazilian pelagic aggregate from Atlantic nesting populations (mean 96.1%) and the existence of six individuals bearing an orphaned haplotype (Dc\_A2) for leatherbacks.

This haplotype, considered an orphaned haplotype because no match with nesting population were found at that moment, had its origin ascertain (Gabon and/or Western Africa) by genetic studies that reanalyzed samples from other study with longer sequences and number of rookeries surveyed (Dutton et al. 2013; Vargas et al. 2013).

Together, analysis of mtDNA control region sequences and tag return data have been used effectively to support the natal homing hypothesis (Dutton et al. 1999), to ascertain the origin of individuals from feeding aggregation in Mixed Stock analysis (MSA) approaches (Vargas et al. 2008, 2013; Prosdocimi et al. 2014) and also to recognize bias effort in samples sites collection by finding animals in feeding aggregation with haplotypes not yet recognized for any rookery sampled.

## **Population Dynamics, Demographic Histories and Estimations of Effective Population Size**

The knowledge obtained by using genetic markers in order to understand demographic histories, population dynamics (recent and historical trends) and effective population sizes (Ne) are essential to outline the real situation about populations regarding loss of genetic diversity and their prospects of long-term survival. For leatherback turtles, two studies used mtDNA and microsatellites data to infer demographic scenarios for population from Atlantic Northwest (NW).

The first one found that a leatherback turtles´s nesting population from French Guiana and Suriname, called Maroni, it can be considered as part of a large metapopulation, whose boundaries remain currently unknown (Rivalan et al. 2006). Despite the high population size known for leatherbacks from this region (2750-20,000 individuals) effective population sizes measured (from 60 to 220 depending on the mutation rate and the mutation model) (Rivalan et al. 2006) are below the lower level of target effective populations sizes for conservation programs for endangered species (500 to 1000) (Lynch & Lande 1998). Contrariwise, Molfetti et al. (2013) in their study revealed that leatherbacks population's dynamics from three different regions from Atlantic NW may be driven by an island model rather than a severe metapopulation model that would suggest successive cycles of extinction and recolonization. Despite the great importance of the aforementioned knowledge to better understand the species historical, recent and consequently future abundance, trends for populations from other regions of occurrence of this species remains unknown.

### **RMU´s and Conservation Priorities**

A recent publication evaluated five criteria (population size, recent trend, long-term trend, rookery vulnerability and genetic diversity) to develop a risk matrix that is used together with a threats matrix as an attempt to plan the global conservation priorities for marine turtles (Wallace et al. 2011). As we can see, the last criterion, genetic diversity, is exclusively calculated by using analyses of the mtDNA and the number of known or inferred genetic stocks (Wallace et al. 2011). Despite this approach is based on biological and environmental data and does not use solely the information about genetic data, is clear the importance of its use in this new and more powerful strategy to guide conservation priorities (Wallace et al. 2010, 2011).

#### **Matings Systems and Multiple Paternity**

When a genetic study is aiming to identify aspects from the paternal lineage from marine turtles, the nuclear DNA has to be used rather than the mtDNA, because the last one is maternally inherited, failing to reveal aspects from the paternal ancestry. Once recognized for some species of sea turtles, the multiple paternity (FitzSimmons 1998, Jensen et al. 2006) was evaluated for leatherbacks (Crim et al. 2002; Stewart & Dutton, 2011). Using microsatellite data, Crim et al. (2002) concluded that leatherbacks from Playa Grande (Costa Rica) exhibit low levels of multiple paternity (10%), with a maximum of three males contributing per each family. They also found evidences of polygyny (two females mating with the same male) by analyzing and matching the genotypes of hatchlings and females from different families. Another study genotyped leatherback females and hatchlings from Sandy Point National Wildlife Refuge (St. Croix, US Virgin Islands) and found multiple paternity levels of 41.7%

(Stewart & Dutton 2011). Both studies showed that multiple fathers contribute unequally to the clutches.

## **Barcodes and PCR-RFLP to Identify Species**

In this chapter we found that assays using COI sequences (DNA barcodes) and PCR-RFLP of cytochrome b can be used to differentiate, at least, five marine turtle species from each other (Moore et al. 2003, Vargas et al. 2009). The use of turtle meat and eggs as food in human populations is reported and "take" is considered one of the five threats studied to guide global conservation priorities (Wallace et al. 2011). Thus, barcode and/or PCR-RFLP methodologies can be applied wherever turtle meat and eggs are eaten or trafficked, as a way of identifying species-source, playing an important role to combat illegal trade. They can also be used during field work, when identifying lost nests, animals stranded on beaches or those killed as part of the bycatch in fishery nets (Vargas et al. 2009).

As we can see, besides the indirect use in management strategies (improving the knowledge on a large range of biological concepts: phylogeography, mating systems, population dynamic, etc.), the molecular data can likewise be useful in direct actions and policies for the conservation of marine turtle species.

#### *Eretmochelys imbricata*

The hawksbill turtle (*Eretmochelys imbricata*) is a species that inhabits the tropical waters of the Indo-Pacific and Atlantic oceans (IUCN 2015). It is considered as critically endangered by the IUCN and is listed in the Appendix I of the Convention on International Trade in Endangered Species (CITES).

The first studies using molecular markers in *E. imbricata* started in the late 1970's. The earliest studies aimed to uncover the taxonomic relations between diverse turtle species (Frair 1979; Chen et al. 1980, see also Mao and Chen 1982 for a review in immunoeletrophretic studies with turtles), and used the serum proteins to uncover the relationships between different species.

Among these techniques, electrophoresis, agglutination, and immunoprecipitation were used to uncover the affinities between different turtle species. Chen et al. (1980) for example, using immunological distances tried to estimate the divergence time between the different genera, which showed to be concordant with data from fossil record.

Since the 1990's, DNA data have been used to investigate the phylogenetic position of *E. imbricata*. The first study using DNA data, published by Bowen et al. (1993), using the mitochondrial gene cytochrome b, observed an evolutionary deceleration in the mtDNA rate among all turtle species, and that spongivory in *E. imbricata* evolved from a carnivorous ancestral. Soon after, another studies using other markers followed, dealing with population genetics and other aspects of the evolutionary history of *E. imbricata* (Broderick et al. 1994; Bass et al. 1996; Bowen et al. 1996a; FitzSimmons et al. 1995; Karl et al. 1995).

Among the new markers, we can list the use of the control region (also called D-loop) of the mitochondrial DNA (Bass et al. 1996; Bowen et al. 1996b), nuclear markers such as microsatellites (FitzSimmons et al. 1995), and anonymous single-copy loci (Karl et al. 1995). Even though the first studies using the mitochondrial DNA used restriction enzymes to estimate the nucleotide divergence (Bowen et al. 1993; Broderick et al. 1994), the first studies

using small sequences of the mtDNA were published in 1996 (Bass et al. 1996; Bowen et al. 1996b).

Currently, diverse markers have been used to study the genetic diversity in *E. imbricata*. These include: microsatellites, restriction fragment length polymorphisms, and mitochondrial DNA. Each marker has its pros and cons and has been used for a variety of genetic conservation studies. The control region (CR or D-loop) of the mtDNA is the most widely used marker when studying *E. imbricata*. It has shown to perform well in phylogenetic (Naro-Maciel et al. 2008) and in phylogeographic studies (Leroux et al. 2012; Vilaça et al. 2013; Bass et al. 1996; Velez-Zuazo et al. 2008), and for species identification (Vargas et al. 2009; Naro-Maciel et al. 2010). This region has been used until today to study diverse aspects of life history. Until recently, only a short stretch of the D-loop was used in *E. imbricata*, corresponding to a sequence of 384 bp (Bass et al. 1996). This fragment formed the baseline data (or reference data) for genetic diversity studies. This short fragment proved to be powerful to perform multiple-stock analysis (given a mixed stock population and a set of probable source population, this method aims to estimate the fraction in a mixed stock population that comes from each source population), and to distinguish between rookeries demonstrating that they are independent entities. Different rookeries within Caribbean and Atlantic Ocean could be characterized according to their haplotype frequencies.

In more recent years, this fragment of the D-loop has been extended to 832 bp (Abreu-Grobrois et al. 2006). This longer fragment has proven to be more efficient in distinguishing between rookeries, since it presents more polymorphic sites than the short fragment, and allowed the unfolding of several short fragments of 384 bp in different haplotypes. Using this fragment, even though most major rookeries could be distinguished by their haplotype frequency or by exclusive haplotypes, some nesting aggregates separated by a few hundred kilometers could not be differentiated in terms of haplotype frequencies. Studies published with this longer fragment could unfold haplotypes previously considered as a single one, and even differentiate geographically close nesting aggregates (Leroux et al. 2012). For example, the haplotype Q, present in Mexican rookeries and several Caribbean feeding grounds, was identified as three different haplotypes (EiA23, EiA41, and EiA43).

Also the rookery of Guadaloupe could be described as a distinct demographic unit, and the total haplotypes that compose the baseline were extended, allowing a better resolution between close nesting areas.

When comparing these longer fragments with the 384 bp in Caribbean samples, Leroux et al. (2012) showed that 75% of total variability was present within the 384 fragment. Also the last 170 bp of the 832 bp fragment showed no variation, and therefore, a 740 bp fragment is sufficient for describing the different *E. imbricata* populations. Using the 740 bp fragment, Vilaça et al. (2013) found new *E. imbricata* haplotypes (hybrids excluded) that distinguished Brazilian rookeries from Caribbean, and also unfolded new haplotypes from the previously 384 bp short sequences. The mtDNA gene Cytochrome oxidase c subunit I (COI) have also been successfully used to uniquely identifying *E. imbricata* samples (Vargas et al., 2009; Naro-Maciel et al. 2010).

These two studies showed that *E. imbricata* can be distinguished from other sea turtle species, with some diagnostic (autapomorphic) characters. Vargas et al. (2009) found six diagnostic characters for Brazilians *E. imbricata*, while Naro-Maciel et al. (2010) found only one for samples from Puerto Rico and Australia.

Mitochondrial haplotypes have been proved to be useful to distinguish *E. imbricata* from other sea turtle species, between rookeries and feeding areas, and to estimate populational parameters of diversity and female gene flow (Bass et al. 1996). But because mitochondria is only one locus, information on diversity across the genome is lost. Also because mitochondria is female inherited, any information from male dispersal (or any other information maledriven) is not recovered.

Microsatellites on the other hand, because are nuclear markers, are informative for the male-mediated gene flow. The first study that used microsatellites for *E. imbricata* showed that these markers are useful for gene flow analysis and paternity, because the loci showed different allele frequencies between rookeries (FitzSimmons et al., 1995). Since then, several loci were specifically isolated for *E. imbricata* (Lin et al. 2008; Miro-Herrans et al. 2008; Shamblin et al. 2013).

Currently, a total of 39 loci microsatellite are available, with the number of alleles varying from 2 to 24 (based on a maximum of 40 samples typed), therefore showing a wide range of polymorphism. Other loci developed for other sea turtle species have also been tested for *E. imbricata*, with several showing successful amplification, and even high levels of genetic diversity (see Phillips et al. 2013 for examples).

Despite the low resolution for detecting population structure, microsatellites have been successfully used to investigate multiple-paternity in *E. imbricata* (Joseph & Shaw 2011; Phillips et al. 2013). Phillips et al. (2013) not only managed to determine the rate of multiple paternity, but also estimated the frequency of polyandry and polygyny, and estimated the frequency, duration and viability of sperm storage. Using a set of 33 microsatellite loci (isolated for *E. imbricata* and other species), they were able to show that almost 91% the offspring was sired by a single male, and those male did not fertilize more than one female in the same season.

Anonymous single loci nuclear (scnDNA) loci were also used in *E. imbricata* samples. These scnDNA loci are initially amplified in a PCR reaction, and after digested with restriction enzymes (Karl et al. 1992, 1995; Karl & Avise 1993). Initially developed for *Chelonia mydas* (Karl et al. 1992; Karl & Avise 1993), scnDNA showed to be able to distinguish different sea turtle species, even though they did not any polymorphisms in *E. imbricata* samples from Brazil (Vilaça et al. 2012). Despite the lack of polymorphisms within *E. imbricata*, these loci are useful to differentiate *E. imbricata* from other sea turtle species, and especially useful when studying hybridization (Karl et al. 1995; Vilaça et al. 2012). Using a restriction fragment length polymorphism (RFLP) generated by the digestion of the PCR product of these scnDNA loci, diverse cases of hybridization involving *E. imbricata* and other three sea turtle species were investigated, and F1 hybrids could be distinguished from later generation (>F1) hybrids (Karl et al. 1995; Vilaça et al. 2012). One advantage of these markers in hybridization detection is their low cost (only a PCR and few low cost restriction enzymes are required) and quick results. When comparing microsatellites with PCR-RFLP, even though the microsatellites markers developed so far are not able to show high population structure, microsatellites have a higher mutation rate, which increases the ability to track coalescence events and detect population-specific alleles.

Nuclear sequences have been standardized for sea turtles only recently (Naro-Maciel et al. 2008). The first study used five different nuclear loci (four exons and one intron) to investigate the phylogeny of sea turtles. Subsequently, populational studies using the same loci, but shorter fragments, were published (Vilaça et al. 2012, 2013; Vilaça & Santos 2013).

Vilaça et al. (2012) investigated the population structure in the Brazilian coast and the patterns of hybridization with other three sea turtles species. Using these five nuclear loci, no population structure was observed in Brazilian rookeries and feeding aggregations, but one loci (Cmos) showed a small differentiation between two rookeries. Two loci (R35 and Cmos) showed private haplotypes for rookeries and feeding areas. In contrast, one loci (RAG2) was monomorphic across Brazilian populations. When comparing the data for these five nuclear loci with other species, most haplotypes found in *E. imbricata* were private, even though two were shared with other turtle species (two RAG1 haplotypes were shared with *L. olivacea*, and the monomorphic BDNF loci possessed the same haplotype as *C. caretta*). Despite the low polymorphism of the nuclear sequences, they were proven to be useful in hybridization, and investigating possible introgression (i.e., the backcrossing of hybrids with one or both parental species) between hybrids of four turtle species in Brazil.

Nuclear markers have the advantage to provide information from male gene flow, but when comparing different populations, they usually fail to show population structure. This inability of nuclear markers to recover population structure was hypothesized to be due to the high levels of male gene flow, but it might also be because of the low evolutionary rates observed in the karyotype, mitochondrial and nuclear genomes of sea turtles (Bowen et al. 1993; FitzSimmons et al. 1995; Matsuda et al. 2005). If this is the case, only a large amount of nuclear markers will permit the distinction between different populations.

When comparing the different markers available for *E. imbricata*, the most commonly used is the control region of the mtDNA. Considering the resolution given by these two types of markers, mtDNA is more efficient in distinguishing between rookeries and feeding areas, but nuclear markers showed to be extremely relevant for studies involving hybridization or paternity investigation.

The use of Next Generation Sequencing (NGS) for developing nuclear markers for *E. imbricata* is promising, since it allows the isolation of hundreds or thousands or markers with relatively low cost. Even though on sea turtle species have its genome sequenced (Wang et al. 2013) and have populational studies using mitogenomic data (Shamblin et al. 2012c), for *E. imbricata* the use of large-scale data was used only in phylogenic studies (Duchene et al. 2012). Duchene et al. (2012) used data from the entire mitochondrial (around 16,000 bp) from samples from Indo-Pacific ( $n = 3$ ) and Atlantic ( $n = 1$ ) Oceans to estimate the divergence time and phylogenetic position of all sea turtle species. The topology and confidence of the trees was similar to the ones obtained by Naro-Maciel et al. (2008) using few mtDNA genes and five nuclear loci, but the divergence dates obtained had a smaller confidence interval. Even though the mitochondrial DNA can be considered as one loci, the use of larger sequences (or the entire mtDNA) can increase the resolution of the analysis and provide more confidence in the results.

Studies with other non-model animal species, with conservation interest, have shown that is possible the development of hundreds of microsatellite markers and Single Nucleotide Polymorphisms (SNPs) by sequencing a small fraction of genome. Techniques like RAD-Seq (Baird et al. 2008; Miller et al. 2007) and Genotyping-By-Sequence (GBS, Elshire et al. 2011) seems promising in dealing with species without a reference genome.

These two methodologies randomly sequence a fraction of the genome, and can be useful for marker discovery, hybridization, phylogenomics, or selection studies.

#### *Caretta caretta*

The loggerhead sea turtle, *Caretta caretta*, is widely distributed in tropical and temperate waters around the world (Pritchard & Trebbau 1984). In Brazil, loggerheads are the most abundant sea turtle species nesting along the country's coastline (Marcovaldi & Marcovaldi 1999). The nesting beaches range from the north of Rio de Janeiro (southeast coast) to Sergipe states (northeast coast); and nesting density is greatest on beaches of Bahia state (Marcovaldi et al., 2005). In fact, the Brazilian nesting population of loggerheads is one of the largest in the world, after the super-aggregations at Masirah, Oman, and Eastern Florida, US (Marcovaldi & Chaloupka 2007; NOAA 2010).

Currently, *C. caretta* is internationally listed as "endangered" by the International Union for Conservation of Nature and Natural Resources Red List of Threatened Species (IUCN 2015). In Brazil, the loggerhead sea turtle was considered "vulnerable" by the Ministry of Environment - MMA (Martins & Molina 2008). However, this status was recently reevaluated to "endangered" by Santos et al. (2011).

Loggerheads have a long history of exploitation in Brazil. Prior to 1980 nearly all eggs laid along the coast were removed, and most nesting females were taken for meat (Marcovaldi et al. 2005). The establishment of Projeto TAMAR (The Brazilian Sea Turtle Conservation Program) by the Brazilian government in 1980, and the enactment of full legislative protection of all sea turtle species in 1986 have contributed significantly to the improving status of the Brazilian loggerhead stock (Marcovaldi & Marcovaldi 1999; Marcovaldi & Chaloupka 2007). However, in more recent years, loggerheads have become exposed to other hazards such as coastal development (Marcovaldi et al. 2006), marine debris (National Research Council 1990; Bugoni et al. 2001; Milton & Lutz 2010), and incidental capture in coastal gillnet and pelagic longline fisheries operating in southern Brazilian waters (Soto et al. 2003; Kotas et al. 2004; Sales et al. 2008). Protection of the Brazilian loggerhead stock is of great importance for the global conservation of this species.

Genetic analyses have been used worldwide to investigate genetic diversity and rookery structure, phylogeography, foraging ground composition, rookery contributions to foraging aggregations, migratory patterns, natal homing behavior, taxonomic relationships, paternity, and hybridization in sea turtles (Bowen & Karl 2007; Bowen et al. 2007; Bjorndal & Bolten 2008; Jensen et al. 2013).

Bowen et al. (1994), in a phylogeographic survey based on restriction-site analyses of mtDNA with 176 samples from rookeries in Greece, Brazil, South Africa, Oman, Japan, Australia, and US, demonstrated the existence of two primary lineages in loggerheads. Both lineages are found in both Atlantic-Mediterranean and Indian-Pacific basins, probably due to the ability of this temperate-adapted species to migrate around southern Africa (Bowen et al. 1994). On the basis of a molecular clock for marine turtles calibrated at 2%-4% per million years (m.y.) (Avise et al. 1992), the deepest bifurcation in the loggerhead mtDNA phylogeny would be around 2-4 m.y. old (Bowen et al. 1994). The absence of a clear matrilineal separation between these oceanic basins could be explained by gene flow around southern Africa that perhaps occurred through the last 20,000 years. These ocean basins were relatively isolated by geography and climate in the Pleistocene. During interglacial periods, the expansion to higher latitudes was possible because of warmer temperatures.

An alternative explanation is that major mtDNA lineages have been retained in both ocean basins for several million years and recent inter-oceanic exchange of mtDNA haplotypes has resulted in the similarity of haplotypes in separate oceans (Bowen et al. 1994).

Bayesian phylogenetic analysis of  $\sim 800$  base pair (bp) mtDNA fragments has recently confirmed the presence of two major loggerhead lineages globally (Shamblin et al. 2014). The deepest bifurcation among loggerhead lineages was estimated at 4.3 m.y.: haplogroup II (containing CC-A2 haplotypes and derived variants) was characterized by shallow structure relative to haplogroup I (represented primarily by CC-A1, CC-A4, and CC-A11 variants). The deepest divergence among clade I lineages occurred between Western Pacific/

Southeastern Indian Ocean haplotypes (haplogroup IA) and the remaining Atlantic and Indian Ocean haplotypes (haplogroup IB). This coalescent was dated at 2.7 m.y. A clade containing Brazilian haplotypes, Caribbean CC-A14, and CC-A11.6 from Oman diverged from the remaining haplogroup IB lineages approximately 1.0 m.y. (see Shamblin et al. 2014 for details). Encalada et al. (1998), based on 380 bp mtDNA control region sequences of 249 Atlantic and Mediterranean loggerhead turtles from 10 major nesting areas, defined six demographically independent groups: (1) North and South Carolina, Georgia and Northeast Florida, US, (2) Southern Florida, US, (3) Northwest Florida, US, (4) Quintana Roo, Mexico, (5) Bahia, Brazil, and (6) Peloponnesus Island, Greece.

At that time, these authors suggested that climate, natal homing, and rare dispersal events defined the loggerhead biogeographic scenario. Other studies, also based on 380 bp fragment of the mtDNA, have demonstrated genetic partitioning within the Northwest Atlantic (Shamblin et al. 2011), Southwest Atlantic (Reis et al. 2010a), and Mediterranean (Carreras et al. 2007). Despite clear indication of genetic structure through significant frequency differences, widespread haplotype sharing across ocean basins has limited the utility of the 380 bp sequences as a population marker in mixed stock analysis.

Recently, Wallace et al. (2010) have proposed the definition of nine Regional Management Units (RMUs) for loggerhead turtles, based on the integration of multiple tools and techniques, including genetic analyses (mtDNA and nDNA), site-based monitoring, mark-recapture studies and telemetry. Studies using longer sequences (~800 bp) have currently confirmed six RMUs and recognized at least 18 demographically independent management units (MUs), based on female natal homing (Shamblin et al. 2014). In the present chapter, we intend to review information on (1) the population genetic composition of Brazilian loggerhead rookeries, foraging aggregates and bycatch reports, (2) the phylogeography of this species and (3) hybridization cases. For this propose, we are revisiting the results described by Reis et al. (2009, 2010a, 2010b), Vilaça et al. (2012) and Shamblin et al. (2014). Reis et al. (2010a) analyzed 204 female loggerheads from rookeries in Rio de Janeiro ( $N = 64$ ), Espírito Santo ( $N = 50$ ), Bahia ( $N = 39$ ), and Sergipe ( $N = 51$ ) states, during the nesting seasons (September to March) of 1996/1997, 2003/2004, 2004/2005 and 2005/ 2006. These authors also sampled 125 loggerheads captured at Elevação do Rio Grande (ERG) as incidental take in the longline fishery. Complementarily, Reis et al. (2009) analyzed samples from one unusual loggerhead nesting specimen from Rio Grande do Norte and from five specimens that were incidentally captured in fisheries in Rio de Janeiro ( $N = 2$ ), Sergipe  $(N = 1)$ , Rio Grande do Norte  $(N = 1)$  and Ceará  $(N = 1)$  states. For both studies, a 627 bp consensus sequence was produced, but only a fragment length of 380 bp was used for comparisons with data from other Atlantic and Mediterranean rookeries and foraging aggregations.

Shamblin et al. (2014), through the establishment of an international working group, brought together data of loggerhead turtle rookeries in the Atlantic, Mediterranean and western Indian Ocean, combining information on 380 bp and ~800 bp control region sequences from the literature or generated from novel samples (as from Brazil: Rio de Janeiro  $N = 49$ , Espírito Santo  $N = 23$ , Bahia  $N = 32$  and Sergipe  $N = 27$ ; Cape Verde; Oman; and South Africa). Finally, Reis et al. (2010b) presented the distribution and frequency of interspecific hybrids within loggerhead nesting beaches in Sergipe state (Abaís, Pirambu and Ponta dos Mangues;  $N = 51$ ) based on mtDNA analyses, and Vilaça et al. (2012) discussed the high frequency of hybridization and introgression among sea turtle species on the Brazilian coast through mitochondrial and nuclear markers.

#### **Brazilian Rookeries**

Four distinct loggerhead control region haplotypes of 380 bp were observed among the 204 turtles sampled from Brazilian rookeries: CC-A4 (86.3%), CC-A24 (6.4%), CC-A25 (0.5%), and CCxLO (6.8%) (Figure 1, Table 2).

Data from Reis et al. (2010a).

Figure 1. Surveyed locations on the Brazilian coast and loggerhead turtle mtDNA haplotype frequencies for rookeries of Rio de Janeiro (RJ), Espírito Santo (ES), Bahia (BA) and Sergipe (SE), and for the foraging aggregation of Elevação do Rio Grande (ERG).

Endemic haplotypes (CC-A4, CC-A24, CC-A25), found only in Brazilian rookeries, create a unique Brazilian haplotype profile (Reis et al. 2010a). The CCxLO haplotype, only found in Sergipe, was attributed to specimens considered hybrids because they have the typical *Lepidochelys olivacea* mtDNA haplotype, but the external morphology of loggerheads (64.29%) or a mixture between loggerheads and *L. olivacea* (35.71%; Reis et al., 2010b). Brazilian rookeries have low values of genetic and nucleotide diversity (Table 5).

The genetic diversity of the Brazilian rookeries decreased from north to south. Sergipe had higher values with three different 380 bp haplotypes, Bahia had two haplotypes, Espírito Santo also had two different sequences, but one of them at a low frequency, and finally Rio de Janeiro had only one haplotype (Figure 1; Table 3; Reis et al. 2010a).

When considering the mtDNA fragments of  $\sim 800$ bp, CC-A4 haplotype was subdivided into three variants: CC-A4.1, CC-A4.2 and CC-A4.3 (Table 4; Shamblin et al., 2014). Rio de Janeiro rookery showed only two haplotypes and lower values of haplotype diversity, while Espírito Santo, Bahia and Sergipe, three haplotypes each and close values of haplotype diversity (Table 4; Shamblin et al. 2014).

A TCS network with all loggerhead 380 bp haplotypes from Brazil and Atlantic-wide rookeries revealed that the rookery haplotypes from Brazil and some from US were closely related (Figure 2). These US haplotypes included CC-A1 (the most frequently detected haplotype in western North Atlantic rookeries), CC-A11, and CC-A14 (Reis et al. 2010a).

Haplotypes	Rookeries					Foraging aggregation	<b>Bycatch</b>

**Table 2. 380 bp mtDNA control region haplotypes from loggerhead sea turtles found at Brazilian rookeries (including an uncommon nesting site\*), foraging grounds and bycatch**

Locations: Rio de Janeiro (RJ), Espírito Santo (ES), Bahia (BA), Sergipe (SE), Rio Grande do Norte (RN\*), Ceará (CE) and Elevação do Rio Grande (ERG). Data from Reis et al. (2009, 2010<sup>a</sup>, 2010b).

#### **Table 3. Standard diversity indices (mean +/- SD) calculated for Brazilian rookeries and foraging grounds based on 380 bp of the mtDNA**

CCxLO hybrids from Sergipe ( $N = 14$ ) were not included in the calculation.  $N =$  sample size,  $h =$  haplotype or genetic diversity,  $\pi$  = nucleotide diversity. Data from Reis et al. (2010a).

# **Table 4. 800 bp mtDNA control region haplotypes from loggerhead sea turtles found at Brazilian rookeries and corresponding standard diversity indices**

Locations: Rio de Janeiro (RJ), Espírito Santo (ES), Bahia (BA) and Sergipe (SE). Data from Shamblin et al. (2014).

Circles/ovals are approximately proportional to haplotype frequencies. Brazilian rookeries: Rio de Janeiro (RJ), Espírito Santo (ES), Bahia (BA), and Sergipe (SE). Other rookeries: Mexico (MX), southern United States (USAs), southern and northern United States (US\*), Greece (GR), and Turkey (TR). Data from Reis et al. (2010a).

Figure 2. TCS network of loggerhead turtle mtDNA haplotypes from Atlantic and Mediterranean rookeries. Lines between haplotypes represent one mutational step; small black circles are hypothetical haplotypes; the rectangle identifies the most probable ancestral haplotype according to the coalescent theory.

Pairwise  $F_{ST}$ , estimates of maternal gene flow  $(Nm)$  and the exact test of population differentiation (see Reis et al. 2010a) revealed that Rio de Janeiro and Espírito Santo rookeries were significantly different from those of Bahia and Sergipe, and no significant difference was found between Rio de Janeiro and Espírito Santo, or between Bahia and Sergipe. These results suggested that Brazil has two loggerhead genetic population units: one represented by Rio de Janeiro and Espírito Santo (Southern stock), and the other by Bahia and Sergipe (Northern stock). AMOVA global  $F_{ST}$  (see Reis et al., 2010a) indicated significant genetic structuring among the Brazilian sampled rookeries. However, AMOVA F-statistics did not confirm this two-stock structure. Due to the limited information provided by mitochondrial DNA markers (especially with shorter fragments), complementary studies based on larger sequences of mtDNA and biparentally inherited nuclear markers were then recommended to confirm and better understand the genetic structure of Brazilian loggerhead populations. In fact, Shamblin et al.  $(2014)$ , analyzing ~800 bp mtDNA haplotypes, suggested that the strongest demographic partitioning within the Brazilian nesting aggregation may occur between the rookeries of Rio de Janeiro relative to all others in the country. Analyses based on the 380 bp haplotypes and using the combined sample sets from Reis et al. (2010a) and Shamblin et al. (2014) supported recognition of Northern and Southern Brazil MUs with a break between Bahia and Espírito Santo.

So, based on these results, Shamblin et al. (2014) proposed the recognition of three MUs within the Southwest Atlantic RMU: Northern coast (Sergipe and Bahia), Espírito Santo and Rio de Janeiro. In light of the subdivision of CC-A4 obtained with the expanded control region fragments, analysis with larger sample sizes from the Brazilian rookeries is warranted to better resolve the number of MUs and their boundaries.

Neutrality tests and mismatch distribution analyses (see Reis et al. 2010a) suggested that Brazil has experienced recent demographic and spatial expansions, resulting from bottlenecks or founder effects.

## **Brazilian Foraging Aggregation**

Elevação do Rio Grande (ERG) is a seamount chain located ca. 800 km off the south coast of Brazil that rises to within 350 m of the sea surface. Similar to the Azores Archipelago in the North Atlantic (Bolten et al. 1998), ERG is an important foraging ground and oceanic developmental habitat for immature loggerheads in South Atlantic waters (Marcovaldi et al. 2006; Sales et al. 2008). Among the 125 loggerhead turtles sampled from the foraging aggregation atERG, six distinct haplotypes were found: CC-A2 (10.4%), CC-A4 (47.2%), CC-A11 (15.2%), CC-A33 (14.4%), CC-A34 (12%), and CC-A35 (0.8%) (Figure 1; Table 3; Reis et al. 2010a). For the first time, CC-A2, CC-A11, CC-A33, CC-A34 and CC-A35 haplotypes were reported for a Brazilian foraging aggregation (ERG). CC-A2 and CC-A11 have been reported from northwestern Atlantic rookeries (Bolten et al. 1998; Bowen et al. 2004; Reece et al. 2006; Shamblin et al. 2012a), and CC-A2, also from Mediterranean rookeries (Carreras et al. 2006; Yilmaz et al. 2011; Casale et al. 2013; Garofalo et al. 2013). CC-A33 is identical to CC-P5, already registered for rookeries of Western Australia, Queensland and New Caledonia (FitzSimmons et al. 1996; Boyle et al. 2009) and CC-A34 is identical to CC-P1, also registered for these same rookeries (Bowen et al. 1995; Boyle et al. 2009) and for Japan (Watanabe et al. 2011). CC-A35 represented an orphaned haplotype

since its source rookeries are still unknown. The foraging aggregation (Elevação do Rio Grande) had high haplotype diversity and a moderate nucleotide diversity (Table 3) compared with other Atlantic-wide foraging aggregations. Generally, foraging aggregations also show higher diversity indices than rookeries because rookeries host philopatric females while foraging aggregations can receive individuals from many source rookeries.

Mixed Stock Analysis (MSA) indicated a major contribution to the ERG foraging aggregation from Brazil (mean 59.5%) and a non-significant contribution from the US, Mexico, and Turkey (see Reis et al. 2010a). This result is expected due to the presence of the Brazilian exclusive haplotype (CC-A4) in 59 out of 106 individuals from the foraging aggregation used for the MSA. The second highest contribution detected by MSA was from Australia (28.5%), because haplotype CC-A34 has only been reported from Australian rookeries. Another significant contribution was also detected from Greece, due to the presence of CC-A2 among the Brazilian foraging aggregation, which is present at high frequencies in Greece. Although CC-A2 is also frequently observed in US, the MSA takes into account that the contribution from a particular rookery should include all of the most frequent haplotypes (Reis et al. 2010a). The occurrence of CC-A4, an endemic Brazilian haplotype, in the ERG aggregation indicates that those turtles belong to the Brazilian loggerhead genetic stock, which was corroborated by the MSA results. However, the ERG aggregation is a mixed stock with haplotypes from worldwide rookeries. The haplotypes CC-A33, CC-A34 and CC-A35 form an independent cluster in phylogenetic reconstructions and probably have a common origin. The MSA results must be interpreted with care, since this analysis assumes that all source rookeries are known, but African and Indo-Pacific rookeries have been very poorly surveyed.

Thus, the proposed contributions from Australia and Greece may well derive from rookeries on the west coast of Africa or Indo-Pacific rookeries (Reis et al. 2010a). Dispersal patterns for oceanic juveniles modeled under the assumption of passive drift supported the likelihood of dispersal of South African juveniles into the South Atlantic but did not indicate connectivity between the South Atlantic and more distant rookeries in the Indian Ocean basin (Mansfield & Putman 2013).

Nonetheless, confirmation of CC-A2.1 from South Africa and CC-A11.6 from Oman (Shamblin et al. 2014) warrants reconsideration of the possibility of long distance migratory connectivity between the South Atlantic and Indian Ocean basins (Figure 3).

Furthermore, Caraccio et al. (2008), analyzing 14 loggerheads incidentally captured by coastal trawl and 29 by pelagic longline fisheries in Uruguayan waters, found the same haplotypes identified among the ERG samples:  $CC-A2$  (N = 6, 14%),  $CC-A4$  (N = 32, 74%), CC-A11 (N = 1, 2.3%), CC-A33 (N = 2, 4.6%) and CC-A34 (N = 2, 4.6%), with genetic diversity (*h*) equal to 0.4319 +/- 0.0872 and nucleotide diversity ( $\pi$ ) equal to 0.014616 +/-0.007978. All turtles analyzed from the Uruguayan continental shelf ( $N = 14$ ), classified as adults or late maturing juveniles, showed CC-A4 haplotype, which is only found at Brazilian rookeries. On the other hand, turtles studied from the oceanic area  $(N = 29)$ , classified as juveniles, were genetically diverse and presented haplotypes that pertained to distance nesting colonies: CC-A2 (present in the US, Mexico, Mediterranean and South African rookeries), CC-A11 (present in the US and Oman), CC-A33, CCA34 (found in the Indo-Pacific Ocean), and also CC-A4. These data suggested that some adult individuals move on the continental shelf carrying out feeding migrations from the nesting beaches in Brazil towards higher latitudes.

BRZ is combined Brazilian rookeries (Reis et al. 2010a); NAT is Natal, South Africa (Shamblin et al. 2014); MAS is Masirah Island, Oman (Shamblin et al. 2014); WA is Western Australia (FitzSimmons et al. 1996), QLD is Queensland, Australia rookeries (Boyle et al. 2009). The arrows indicate directionality of major surface currents: orange represents the Leeuwin Current; blue indicates the Western Australia Current, and red, the Agulhas Current. Data compiled by Shamblin et al. (2014).

Figure 3. Loggerhead turtle haplotype distribution for an oceanic foraging aggregation and major Indian Ocean rookeries. Control region haplotype (380 base pair) frequencies for the oceanic juvenile foraging aggregation from the Elevação do Rio Grande (ERG) and adjacent ridge and slope of the continental shelf in the South Atlantic Ocean (Reis et al. 2010a) and the RMUs in the South Atlantic, Indian, and South Pacific Ocean basins.

However, juvenile turtles that pertain to diverse nesting colonies carry out feeding migrations towards areas of high productivity in open waters of the southwestern Atlantic Ocean. Prosdocimi et al. (2015), analyzing 24 samples of bycatch and 37 samples of stranded loggerhead sea turtles (all of them classified as adults or sub-adults) on the coast of the province of Buenos Aires, Argentina, have found similar results. Both shorter (380 bp) and longer (760 bp) mtDNA sequence analysis showed that in the foraging grounds of the Argentinean coast only haplotypes from Brazilian nesting areas (CC-A4 = 98% and CC-A24  $= 2\%$  for shorter sequences, and CC A4.2 = 81%, CC A4.1 = 17% and CC A24.1 = 2% for longer sequences) were found. The homogeneous stock located relatively close to the rookery where individuals originated contradicts the paradigm of immature loggerhead sea turtles forming mixed stocks in foraging and developmental areas. The conservation of the stock in coastal areas of Argentina could benefit the nesting population in the nearby Brazilian rookeries, and could be achieved by conservation actions between these two countries, as well as Uruguay in between.

#### **Additional Reports: Bycatch and Uncommon Nesting Site**

Finally, among the samples from bycatch  $(N = 5)$  and an uncommon nesting site  $(N = 1)$ , five distinct control region haplotypes were observed:  $CC-A1$  ( $N = 1$ , unusual nesting report for Rio Grande do Norte), CC-A2 ( $N = 1$ , Rio Grande do Norte bycatch report), CC-A4 ( $N =$ 2, Rio de Janeiro bycatch reports), CC-A17 (Ceará bycatch report) and CCxLO (Sergipe bycatch report) (Table 4; Reis et al. 2009). For the first time, CC-A1 and CC-A17 haplotypes were reported for the Brazilian coast. The loggerhead sampled in Rio Grande do Norte

(6°13'39"S 35°03"01"W) is an unusual report because in Brazil the northern-most regular nesting region for this species is Sergipe. CC-A1, found for this sample, is a characteristic haplotype from north western Atlantic nesting and feeding grounds (Bowen et al. 2004; Reece et al. 2006; Shamblin et al. 2012a). But it has also been reported for Cape Verde rookery, as well as for feeding aggregations in the eastern Atlantic and Mediterranean Sea (Carreras et al. 2006; Monzón-Argüello et al. 2009, 2010; Garofalo et al. 2013). CC-A17, from a bycatch sample of Ceará (3°43'06"S 38°32'02"W), is typically found in juvenile aggregations from Andalusia, Madeira and Canary Islands and has recently been reported for Cape Verde rookery (Bolten et al. 1998; Monzón-Argüello et al. 2009, 2010). In fact, Ceará has been pointed through telemetry data as an important foraging ground for loggerheads in the northern coast of Brazil (Marcovaldi et al. 2010). The occurrence of these haplotypes (CC-A1, CC-A2 and CC-A17) suggests transoceanic migratory behavior of *C. caretta* and a possible origin for the Brazilian rookeries colonization. The natal homing behavior of *C. caretta* is also confirmed by the fact that there are some in-water loggerheads with haplotypes (CC-A2 and CC-A17) that are not found in Brazilian rookeries, suggesting these animals would return to their natal nesting areas for reproduction.

#### **Brazilian Demography History**

The CC-A4 haplotype is common to all Brazilian rookeries and foraging areas (Figure 1). This fact, associated with the Brazilian low nucleotide diversity (Table 3) and phylogenetic proximity among rookery haplotypes (Figure 2), suggested a common origin, with CC-A4 the probable ancestral haplotype of Brazilian populations (Reis et al. 2010a). These data indicate that Brazilian rookeries may have had the same origin. Because the Brazilian rookeries also show low genetic diversity values and low divergence between those haplotypes, the Brazilian populations were probably colonized recently, as also suggested by neutrality tests and mismatch distribution analyses (see Reis et al. 2010a). As genetic diversity decreases from northern to southern Brazil (Figure 1; Table 3), the authors suggested that colonization of the rookeries followed a north to south route along the coastline, probably influenced by the Brazilian warm current which flows from north to south. In fact, neutrality tests indicated that the Brazilian southern stock is more recent than the northern one. At times of glacial retreats, loggerhead nesting and foraging habitats expanded into higher latitudes. Encalada et al. (1998) suggested that, during these interglacial periods, an equatorial lineage may have colonized northern latitudes along the Florida peninsula, which explains the existence of different phylogenetic lineages in US.

Reis et al. (2010a) believe that colonizations in Brazil followed the same pattern. This hypothesis is supported by the fact that loggerheads show the propensity for occasional longdistance colonization, as indicated by the widespread distribution of some haplotypes. As maritime current dynamics have changed through the years; this colonization hypothesis should be re-evaluated considering paleogeography and paleocurrents.

Reis et al. (2009, 2010a) also hypothesized that, considering the phylogenetic proximity between CC-A1 and CC-A4 haplotypes (380 bp), the colonization of Brazilian rookeries could have been from the US stock, especially from the south. However, with expanded sequences (~800 bp) it is clear that the Brazilian haplotypes appear basal among haplogroup

IB lineages (see Shamblin et al., 2014 for details). Thus, the Brazilian rookery harbors lineages older than those nesting in the southeastern United States (Shamblin et al. 2014).

## **Global Population Structure and Phylogeography**

Parwise F<sub>ST</sub>, exact test of population differentiation, *Nm* estimation, and AMOVA (see Reis et al. 2010a) indicated strong genetic structuring among global rookeries. These data corroborate the natal homing behavior of loggerheads on a global scale. If female loggerheads return to natal sites for nesting, then rookeries would show pronounced differences with respect to female-transmitted genetic markers such as mtDNA (Bowen et al. 1994). However, natal homing in loggerhead turtles cannot be absolute, because new rookeries must be colonized by turtles hatched elsewhere.

Results of the Mantel test (see Reis et al. 2010a) supported the isolation by distance model between western Atlantic (northern and southern US, and Brazil) and Mediterranean (Greece and Turkey) rookeries. This model results from spatially limited gene flow with gene dispersal only between adjacent areas. However, long distance colonization is essential to explain the current global distribution of loggerhead rookeries. Despite the great migratory capacity of loggerheads, isolation by distance is a result of their philopatric behavior. As females tend to return to their natal region to nest, it is expected that new colonizations would occur in adjacent areas. Data also suggested that the most recently colonized rookeries are Greece and Brazil. Colonization into the Mediterranean Sea was most likely accomplished within the last 10,000 years, after the Wisconsin glaciation (Encalada et al. 1998).

Recently, Clusa et al. (2013), based on the new data available to the Mediterranean Sea (by Carreras et al. 2007; Garofalo et al. 2009; Yilmaz et al. 2011), suggested that loggerhead rookeries in the Mediterranean would be the result of at least two colonization events from the Atlantic, the oldest one in Libya and a most recent in Calabria, combined with local extinctions during Pleistocenic glaciations and re-colonizations from glacial refugia in Libya, eastern Turkey and western Greece.

Based on ~800bp mtDNA sequences, Shamblin et al. (2014) suggested the invasion of the Atlantic by Indo-Pacific loggerhead lineages via southern Africa, as demonstrated in the case of the haplogroup I. These authors also suggested that inter-oceanic exchange of loggerhead lineages likely occurred multiple times and in both directions.

## **Hybridization**

Although hybridization events have previously been reported for marine turtle populations (Conceição et al. 1990; Bowen et al. 1992, 1994; Karl et al. 1995; Bass et al. 1996; Bowen & Karl 1996; Lara-Ruiz et al. 2006), hybrids between *C. caretta* and *L. olivacea* were reported for the first time on the Brazilian coast by Reis et al. (2009, 2010a, 2010b). Fossil evidence suggests that time of separation among these two species is around 10-20 million years ago (Zangerl 1980; Dodd & Morgan 1992). Sea turtles are likely the most ancient vertebrates hybridizing under natural conditions, since hybrids exist between *Caretta* and *Chelonia* genera, which were separated about 50 million years ago (Bowen et al. 1992,

1994; Karl et al. 1995). The capacity of sea turtles to generate fertile hybrids seems to be related to the slow chromosomal and anatomic evolution.

The maintenance of chromosomal number and structure may allow genomic compatibility among species (Bickham 1981). The fitness success of the carapace and accompanying morphological adaptations should favor interspecific mating. Moreover, a dearth of behavioral barriers to hybridization may be an issue, as well as the fact that male turtles are notably indiscriminate in mating preferences (Bowen 2003).

*C. caretta x L. olivacea* (CCxLO) hybrids were identified into the loggerhead nesting population ( $N = 14$ , 27%) and bycatch ( $N = 1$ ) of Sergipe (Table 3). From the 14 individuals genotyped as CCxLO hybrids, nine (64%) presented *C. caretta* external morphology and five (36%), mixed morphological characteristics from both *C. caretta* and *L. olivacea*. In this last case, specimens show a combination of morphological characteristics from both species, i.e., number of lateral scutes on the carapace and on the head, the format of the carapace and the animal's biometry. These two types of hybrids led the authors to suppose that at least two hybridization events may have occurred between these two species, but both of them involving the same *L. olivacea* haplotype. Thus, even if more than one hybridization event had taken place, they involved the same *L. olivacea* mtDNA haplotype. An ancient event resulted in individuals with *L. olivacea* mtDNA haplotypes without morphological vestiges of this species. In this case, hybrids will most likely be  $F2$  or  $>F2$  and introgression probably occurred by backcrossing of female hybrids with *C. caretta* males. A second more recent event resulted in individuals with mixed morphological characteristics from both *C. caretta* and *L. olivacea*, possibly from direct interspecific coupling, therefore, F1. This scenario, however, cannot be distinguished from an ongoing process of hybridization over the last few millennia without nuclear DNA data.

An additional hypothesis considers the CCxLO hybrids as a result of a long and antique process of introgressive hybridization, although it predicts a morphological gradient of characteristics which was not observed in the present scenario. However, Vilaça et al. (2012), through the complementary analyses of 12 nuclear markers, indicated that most of these individuals in the crossings *C. caretta* x *L. olivacea* were F1 hybrids. Thus, some sort of reproductive barrier might be present affecting the fertility of the progeny.

Reis et al. (2010b) only observed hybrids between females *L. olivacea* and males *C. caretta* (see also Hahn et al. 2007). This suggests that only unidirectional hybridization and subsequent backcrossing occurred between these two species. Karl et al. (1995) suggested that a numerical predominance of hybrids with mothers from the more common species is due to a constant "error" rate in the choice of mate per female. Nonetheless, Vilaça et al. (2012) reported a unique hybrid between a female *C. caretta* and a male *L. olivacea*, from a bycatch sample of São Paulo state previously classified by morphology as a loggerhead, but identified by mtDNA as an olive ridley. It suggested that mating occurred in either direction, as hybrids with mitochondria of either parental species were detected.

The incidence of hybridization between loggerheads and olive ridleys in Sergipe, that hosts the largest Brazilian nesting population of *L. olivacea* (Silva et al. 2007), may be related to an overlap in the reproduction period and area of both species. Recalling that the *L. olivacea* nesting population is larger than the *C. caretta*, we assumed that the same proportion is maintained at the reproduction colony. Naturally, the availability of *L. olivacea* females was superior to *C. caretta*, favoring the interspecific mating of loggerhead males with olive ridley females. The scenario is even more severe since the sex ratio is female biased

(Marcovaldi et al. 1997). This may also be associated to global warming since it might alter the sex ratio of sea turtles, thus facilitating interspecific mating. Because of that, it is important to evaluate natural sex proportion in those species. Moreover, the monitoring of natural temperature changes is crucial to better understand this ongoing hybridization process.

The unusually high proportion of hybrids between *C. caretta* and *L. olivacea* in Sergipe (almost 30%), as well as in related hybridization events between *E. imbricata* and *C. caretta* or *E. imbricata* and *L. olivacea* in Bahia (Lara-Ruiz et al. 2006), and between *C. caretta* and *C. mydas* also in Bahia (Bowen et al. 1992, 1994; Karl et al. 1995), represents a serious concern for the conservation of these species in Brazil, which raises a controversial issue about conservation efforts focusing on hybrid populations (Allendorf et al. 2001).

Although hybrids are rare in populations, a few hybrids may form a bridge which allows a trickle of alleles to be transferred between species; thus, if species that hybridize are common, even low rates of hybridization per individual can have important evolutionary consequences (Mallet 2005).

Vilaça et al. (2012) suggested that hybridization on the Brazilian coast is a recent phenomenon, spanning at least two generations or approximately 40 years. These authors also suppose that sea turtle hybridization occurring in Brazil may be linked to overhunting and local warming of beaches due to coastal deforestation (Matsuzawa et al. 2002). These could be the direct causes of the recent decline of sea turtle populations, reaching its climax in the 1970s in Brazil, which could have triggered an increase in interspecies hybridization.

In fact, frequent examples of hybridization in nature are often attributed to environmental degradation (Mallet 2005). Therefore, the occurrence of hybrids among sea turtle species may point to the existence of anthropogenic pressure that needs to be investigated.

Equally, if we consider that the process of hybridization has important evolutionary consequences, it becomes essential to evaluate its impact on the genetic diversity and identity of those species.

#### **Conservation Perspectives for** *Caretta caretta*

Reis et al. (2009, 2010a, 2010b) have not distinguished new mtDNA haplotypes with the longer sequences of 627 bp. However, Shamblin et al. (2014) have subdivided CC-A4 into three variants based on ~800 bp fragments. Indeed, over the past few years, expanded mitochondrial control region sequences of about 760 to 817 bp has been used to increase resolution of population structure and mixed stock analysis (e.g., Monzón-Argüelo et al. 2010; Shamblin et al. 2012a, 2014; Garofalo et al. 2013). Up to now, results have been promising and novel polymorphisms have been detected. Nevertheless, additional data are needed from major Atlantic rookeries (including Brazilian ones) to evaluate the utility of the expanded sequences to improve resolution of those analyses.

The variation uncovered in CC-A4 from Brazil should be further explored in two directions: i) analysis with larger sample sizes from the Brazilian rookeries is warranted to better resolve the number of MUs and their boundaries, and ii) reanalyzing Brazilian oceanic juvenile samples for the longer control region fragment should be also investigated to let testing juvenile natal homing along the Brazilian coast.

Therefore, in a global scale, phylogeographycal and mixed stock analyses should be redone considering the recent data available for western Atlantic (Ruiz et al. 2008; MonzónArgüello et al. 2010; Shamblin et al. 2011, 2012a, 2014), eastern Atlantic (Monzón-Argüello et al. 2009, 2010), Mediterranean (Carreras et al. 2007, 2011; Garofalo et al. 2009, 2013; Chaieb et al. 2010; Yilmaz et al. 2011; Saied et al. 2012; Casale et al. 2013), and Indo-Pacific (Boyle et al. 2009; Watanabe et al. 2011; Shamblin et al. 2014). Additionally, due to the limited information provided by mitochondrial DNA markers (especially shorter fragments), complementary analyses based on larger sequences of the mtDNA, and biparentally inherited nuclear markers are also recommended to confirm and better understand the genetic structure and demographic history of loggerhead populations.

The existence of three loggerhead genetic population units in Brazil, as well as evidence of extensive hybridization between *C. caretta* and *L. olivacea*, will influence the development and implementation of appropriate management strategies in the country. The extent of hybridization between different species of the Family Cheloniidae must be investigated to understand the implications and causes of such events, and its impact on the genetic diversity and identity of those species. Natal homing in loggerhead females, which was corroborated by these data, means that each regional nesting population comprises an independent stock or an Evolutionary Significant Unit (ESU). Thus, an extirpated rookery will not be reestablished over a timescale compatible with human interests. Although new nesting beaches must be occasionally colonized, the frequency of such events is low. It reinforces the need of an adequate management plan for each ESU, designed to meet its specific needs, in order to guarantee the maintenance and conservation of loggerhead populations. Recently, Wallace et al. (2010) have proposed the definition of Regional Management Units (RMUs), based on genetic, demographic, geographic, and oceanographic considerations, to organize marine turtles into global units of protection.

For loggerheads, nine significant nesting aggregations have been globally recognized as RMUs: (1) Northwest Atlantic Ocean, (2) Southwest Atlantic Ocean, (3) Northeast Atlantic Ocean, (4) Mediterranean Sea, (5) Southwest Indian Ocean, (6) Northwest Indian Ocean, (7) Southeast Indian Ocean, (8) North Pacific Ocean, and (9) South Pacific Ocean. A tenth putative RMU has been also proposed for the Northeast Indian Ocean, but genetic and biological data are still lacking.

Additionally, Wallace et al. (2011) developed a new assessment framework that allows evaluating, comparing and organizing these RMUs according to categories of paired risk and threats scores, also highlighting important gaps in available information. The definition of RMUs and this risk and threats framework provide valuable guidance to the research, management and conservation of sea turtle species, including loggerheads.

#### **Perspectives for Genetic and Conservation of Sea Turtles**

The importance of a profound knowledge on endangered species biology is unquestionable to create management strategies that fit the excepted species behaviors. This genetic data chapter, made for three sea turtles species found within widespread geographic range, shows that studies on leatherbacks are less frequent. For example, only three studies on MSA of feeding aggregations were published (Vargas et al. 2008, 2013; Prosdocimi et al. 2014) compared with many (more than ten) for the other species (Jensen 2010; Table 5).

Scarce studies on phylogeography (Dutton et al. 1999, 2007, 2013; Molfetti et al. 2013; Vargas et al. 2008) and multiple paternity (Crim et al. 2002; Stewart & Dutton 2011) were

found. We did not find studies comparing data among different life cycles stages for leatherbacks, despite its great importance to better understand the combinations of forces that can affect the construction of genetic diversity, the spreading, the recruitment and the migratory behavior on all life-history stages of marine species (see Velez-Zuazo et al. 2008 for an example in *Eretmochelys imbricata*).

Adapted from Jensen 2010.

Despite most of the paper reviewed in this chapter had the mtDNA control region and/or the microsatellites as the molecular marker of choice, new tools and methods such as single nucleotide polymorphisms (SNPs) and mitogenomics can disclose important accompaniments to the molecular database that promise to overcome some of the constraints of previous studies (Jensen et al. 2013) for all marine turtle species.

# **CONCLUSION**

To choose a molecular marker for conservation genetics analysis is very important, because a selection of inappropriate markers will result in incorrect conservation actions, so the choice of technique depends on the objective and preliminary information. Molecular techniques provide information to different taxonomic levels. All have their limitations and

application will be determined largely by the information been looked in the study and the availability of resources to the development of these techniques. Genetic data have provided important information on the distribution and migratory patterns of sea turtles in the southwestern Atlantic, reaffirming the importance of international cooperation in the management of this species.

## **ABSTRACT**

Wild animals, such as sea turtles, are becoming more common at clinics and veterinary practices. Diagnostic methods for these species are under development and more work is needed, including hematologic diagnosis and blood cytology procedures. The work presented here explores variable studies describing blood cells of sea turtles. Within red blood cell series, we present the following red cell types (erythrocytes), hemoglobin (Hb), Hematocrit (HCT), erythrocytes levels, mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC). Within white blood cell series, we present the following: heterophils, eosinophils, basophils, monocytes, azurophils and thrombocytes.

 $\overline{a}$

<sup>†</sup> Corresponding Author's Email: www.ProFauna Baja.org.

Hematologic values such as hematocrit, total counts, and hemoglobin and erythrocytes levels are also presented. Hematologic and blood cytology interpretation provide an excellent diagnostic tool for sea turtle health given cytological parameters of main blood cells. At the same time techniques for cell count and evaluation are detailed, with an interpretation of pathologies and physiological alterations. This work is aimed at biologists, veterinarians, cytologist and pathologist to assist examination of blood frotis between different sea turtle species.

## **INTRODUCTION**

Mexico is one of the few places in the world where six out of the seven species of sea turtles nest (Márquez 2002), of which all are considered endangered. Sea turtles serve as good indicators of ecosystem contamination, mainly due to their long lifespan and broad distribution. Therefore, the understanding of their health could also be used as a proxy to determine ecosystem health.

Due to the level of research conducted on the green sea turtle (*Chelonia mydas*) in terms of conservation, this species is probably the most understood due to its historical value. This species is listed as endangered by national Mexican and international laws and treaties.

Hematological and cytological reference values can aid wildlife conservation efforts, especially to threatened and endangered species, such as sea turtles as in the case of this study. Health determination and possible afflictions of individuals from blood metabolite levels aid in the selection of more precise treatments, prevention and control of various pathologens. Results prevent speculation about the reasons behind depletion of health, such as when clinical observations are the only available information.

The best available hematological and biochemical reference levels are currently only available from countries other than Mexico. *Chelonia mydas*, is one species of sea turtle that nests along the Yucatan, Mexico coastline. The present study was performed using a practical manual sampling design, whose objective was to obtain blood samples to serve as reference values, and to find differences between apparently healthy and sick turtles. We compared our study to relative studies performed on a global scale to better understand the application of our results on this vastly migratory species. The present work recommends research techniques to establish reference levels to improve treatment efficacy by using levels closer to the reality of sea turtle populations in Mexican waters. The aim of this paper is to provide a relevant tool using manual blood parameter evaluations for people interested and involved not only on sea turtle conservation but also on wildlife in general.

#### **Hematology**

Every single cell of the analyzed blood components has a particular relevance because they are involved in different metabolic paths for carbohydrates, proteins and lipids. These metabolic routes are active on different levels in accordance to the associated organ. Therefore a modification on the metabolic route can be detected as a change on blood levels of various metabolites and consequently their levels within the related organ.

Enzymes are proteins that catalyze chemical reactions performed at the cell level and their level can be modified when cells decrease in activity, since intracellular components, included enzymes, are liberated. An increase in plasma concentration of certain types of enzyme can indicate variable levels of tissue damage which can alter reproductive capabilities. Therefore, the laboratory work determination of levels of metabolites can be used for the diagnosis of different pathologens.

Implementation of these diagnostic techniques can define concentration levels (reference levels) for each blood metabolite under normal conditions. References to the state of health can be determined as acceptable for each species in accordance to their gender, age, habitat, time of the year and even time of the day when samples were taken. This level of detail sets a solid baseline to measure changes in the levels of metabolites observed at any time.

It is extremely complicated to establish reference levels on wildlife fauna. Therefore, it is necessary to select a sample of various populations considered as "healthy" for each one of the sea turtle species to determine blood metabolites concentrations. This process needs to be supported by the level of experience of biologist, marine biologists, veterinarians, ecologist and chemist professionals involved on the study of wildlife health.

Limited information of sea turtle hematologic values and cytology techniques inhibits effective health diagnosis. These two parameters serve as excellent indicators for many aspects of sea turtle well being, including health and reproductive potential. Reference values among published research is not well documented in respect of providing a comparison between lower and higher limits of each chemical and hematological threshold. In this study we compare blood parameters ranges of *Chelonia mydas* to related studies in other areas with other species of sea turtles to present a hands-on approach. Blood samples can help scientists identify the ratio of healthy to sick turtles of a given population.

Blood samples can be counted by different methods, including manual and automatized counts, but problems arise due to the challenges in in differentiating erythrocytes from nucleated thrombocytes. Some studies have determined that the most reliable leucocytes count can be obtained by the use of automatized counters such as Cell Dyn 3500 and the associated computer program for veterinarians produced by Abbott Diagnostics, Abbott Park, IL. Nevertheless, it is still necessary for the researcher to modify the parameters to validate the count for each of the studied species and eliminate the variations between cellular lines. The manual analysis of blood samples must take into account various factors that are not necessary in automatic analysis.

Hematological studies of sea turtles started in the 1970´s intended on identifying correlations between diet and anemia conditions potentially present in *Chelonia mydas* (Frair 1977). From these early studies, a large number of blood value variations were documented, related to different factors such as: age, gender, stress, diet, temperature, hydration, etc., This has spurred additional research needs on this particular topic in order to understand how blood value variations might be related to certain health conditions of this endangered sea turtle species (Aguirre & Balazs 2000).

Despite the fact that hematological evaluation is a simple method where blood values are used as indicators of the health status of an individual, such as parasitic infestations (Watson 1999), no blood value research on *Chelonia mydas* have been done for nesting female turtles in Mexico.

The objective of the present study was to obtain baseline information of hematological values and compare the findings between apparently healthy and sick (parasitized) nesting *Chelonia mydas* sea turtles in the northeast coast of Yucatan, Mexico.

#### **METHODOLOGY**

#### **Blood Collection in the Field**

Methods vary on how to capture turtles to collect blood samples. Most turtles are caught manually by the use of snorkeling gear or scuba diving that result on less stress for the turtles. Yet, depending on the region, most sea turtles are captured by gillnets set in place overnight and checked every 2 to 12 hours. Individuals are then retained until a blood sample can be collected safely and precisely.

An important factor to take into consideration during blood sample collection is the injection site. Final counts and hematocrit value can differ depending on the area and method used for collection. For example, lymphatic vessels usually run in close proximity to blood vessels on reptiles, which can result in contamination of the sample from lymph fluid during extraction (Frye 1991). Therefore, the best places to collect blood samples from sea turtles are the carotid artery and the brachial plexus.

In the case for *C. mydas* population, researchers extracted blood samples by dorsal cervical sinuses puncture (Owens and Ruiz 1980); sampled was collected by a 6 or 10 ml syringe with a 22 by 1.5" needle that was introduced at a perpendicular angle at the neck. Samples were place on 5 ml Vacutainer® tubes that contained lithium heparin. Pressure was applied to the neck area after blood extraction to prevent hematoma formation and help with cauterization (Sykes and Klaphake, 2008).

#### **Manual Preparation of Blood Samples**

Samples should be diluted to a suitable concentration for counting cells. It is important to consider various aspects of using anticoagulants when analyzing blood samples of reptiles. Some anticoagulants can lead to the degradation of erythrocytes which can result in false positives of a healthy sea turtle. The three most common anticoagulants used for blood screening include: ethylenediaminetetraacetic acid (EDTA), heparin and lithium heparin. For example EDTA has been observed to cause degradation of erythrocytes in sea turtle blood samples (Muro et al. 1998) also been observed in samples from other reptiles, however it is appropriate to use for cell tinction. In contrast, lithium heparin, has been successfully used diagnostic analysis (Sykes and Klaphake 2008, Lawrence 1985) as a preservative of the blood samples collected. However, overall, EDTA is the better option for cell identification when compared to heparin. The present study was carried out during the nesting season, April to October 2008 and 2009, at northeast beaches, identified as "El Cuyo" and "Las Coloradas" in Yucatán, México. A total of 100 blood samples were collected from the dorsal cervical sinus of *Chelonia mydas* turtles using a Vacutainer system during egg laying. Physical examination and measurement of individuals were also performed during sampling.

Blood samples were placed in crystal tubes containing lithium heparin (Sykes and Klaphake 2008, Lawrence 1985). Erytrocytes (RBC) and leucocytes (WBC) were counted using the Natt and Herricks solution (Campbell 1995).

Hemoglobin (Hb), Hematocrit (Ht), Mean Corpuscular Volume (MVC), and Mean Corpuscular Hemoglobin Concentration (MCHC), were obtained using Beckman Coulter equipment. WBC differential count was carried out with stain of blood smears with Dip Quick Stain.

Individual turtles were classified as apparently healthy (AH) during clinical examination in the absence of parasites or sick (S) when parasites were present on their bodies.

The minimum/maximum values (Range) for each red and white series components was determined.

#### **Counting Cells Manually**

The Neubauer hemocytometer chamber for cell counting method is most commonly used (counting grid  $4 \times 4$  lines); the Neubauer-improved chamber (counting grid  $5 \times 5$  lines) with the application of the Natt and Herrick solution (Frye 1991); or the Unopette system (Becton-Dickinson, Rutherford, NJ) (Figure1).

- 1. Approximately 10 µl of dilution should be placed on the Neubauer chamber central area and left to rest for 5 minutes for cells to deposit.
- 2. Counts are performed on the four square sections at the corner and the central one. Square areas at the four corners are counted on addition to the central area of the chamber. The total number of erythrocytes per ml is calculated by multiplying the total count by 10,000.
- 3. Thrombocytes are counted at a Neubauer chamber with the application of Natt and Herrick solution to blood on 1:200 rate. In this case, counts include both sides of the chamber and the totality of the grid. Total number is multiplied by 1,000 to obtain thrombocytes/µl in blood.
- 4. Leukocytes are counted using same chamber and dilutant (Natt & Herrick 1952). One of the major disadvantages of the present technique is the complications to differentiate lymphocytes from thrombocytes and immature erythrocytes. Some authors suggest including the two latest cells in the final leukocytes account on the blood sample, this way the total count on the chamber can be corrected (Wilkinson 2001). Leukocytes by µl should be obtained to estimate the total leukocytes present on the 9 major fields of the Neubauer chamber. This number should be increased by 10% and the result multiplied by 200.

Unopette's technique provides better results than the Natt and Herrick system, however variation can result between species depending on the percentage of eosinophils present in relation to heterophils (Strik et al. 2007).

This method counts the number of leucocytes with 40x magnification in 10 fields; then the middle value of counts is multiplied by 1,000 and that represents the total number of leukocytes/µl, allowing to confirm the manual counts of these cells.

http://bdigital.eafit.edu.co/bdigital/PROYECTO/P660.62CDD259/anexos.pdf.

Figure 1. Neubauer-improved chamber counting grid detail (central area has a 5 x 5 lines grid).

## **Hematocrit Determination**

Blood samples were analyzed to determine the hematocrit following the microhematocrit technique. Samples were placed in test tubes using a centrifuge machine to maintain homogenization (Nutator shaker by Clay Adams, Germany).

Each capillary tube was filled ¼ths by introducing the end into the test tube with blood samples and inverting the position. The capillary tube was sealed by maintaining the tube horizontal and melting the empty side using a Bunsen burner.

The tubes were centrifuged for 5 min at 11.000 RPM (Centrifuge LW Scientific, DSC-024, 14.490 xg, China), then the cellular volume was recorded a reader for microhematocrit.

#### **Determination of Total Leukocytes and Erythrocytes**

Blood samples were homogenized (APSA, SM, Mexico) and a Thoma pipette (precision  $\pm$  3%, Germany) was filled up with the resulting solution to be diluted at 1:200 ratio. This was achieved by filling up the pipette with blood solution to the 0.5 mark and completing with Natt and Herrick's solution to the 101 mark (Natt & Herrick 1952), followed by a 20 min settling period. Pipettes were shaken for 2-3 minutes (mechanical shaker Clay Adams, Nutator, Germany).

The first four drops were released to eliminate the liquid from the capillary proportion that was not mixed with blood, followed by the normal filling of the hemocytometer (EC Brad®, Germany) and including a 20-min settling period before count.

Erythrocytes were counted within 5 small squares along the grid in the central part of a slide at 40x magnification (Primostar microscope, Carl Zeiss®, Germany).

Counts were totaled using the following equations:

Number of Red blood cell x  $mm<sup>3</sup>$  = height x dilution x area. Number Red blood cell x mm<sup>3</sup> =  $1/10$  x  $1/200$  x  $1/5 = 1/10000$ ,

Number Red blood cell x  $mm^3$  = Red blood cell counted x 10 000 to determine the total number of erythrocytes per liter.

Leukocytes were counted at 9 squares, also under a 40x magnification, then multiplied by 220 and divided by 1000. This final number was multiplied by 109 to determine the total number of leukocytes per liter.

To determine the section with the lowest superposition of cell counts, a differential leukocyte count was performed using the direct observation of a frotis sample stained with Wright solution at 10x magnification. Differential count implies the classification of 100 leukocytes that results on a percentage of the types of leukocytes present in the blood. Prepared slides were then observed at a 100x magnification (oil objective). Absolute value was obtained by multiplying the calculated differential count using the hemocitometer.

Thrombocytes were determined based on frotis stain of every 100 leukocytes using the technique by Sypek and Borysenko (Campbell and Ellis 2007).

#### **Recording Cell Measurements**

Microphotography was used to measure cells (camera Lieca DC and software 1M 1000, Germany) (Lieca Company 2005). The number of cells to be measured was determined by the Fuentes-Mascorro method which considers the percentage of the cell type present at the hemogram (Fuentes-Mascorro 2007). Frotis samples were used to perform the differential count during this process. Measurements of round cells were performed at the x and y axes juntion in accordance to the Cartesian organization, which defines length as the longest measurement. These measurements established maximum and minimum lengths (Fei-Yan et al. 2001). The morphological index (MI), was calculated by dividing the minimum by the maximum length where the length closest to 1 determine rounded shapes. Values assessed father away from 1 determine elliptical shapes<sup>1</sup>.

#### **Evaluation of Cell Morphology**

 $\overline{a}$ 

To assess the morphology of cells, blood smears should be conducted without anticoagulant and immediately after extraction, air dried and stained using the Romanowsky techniques, such as May-Grünwald Giemsa (Campbell 1998) regardless of the technique used for tinction. This technique requires some time, but provides better results for the differentiation of leukocytes, thrombocytes and immature erythrocytes. Following these recommendations we can prevent "false positives" or "false negatives," alterations on leukocyte and thrombocyte morphology problems on monocyte visualization or increase on

<sup>&</sup>lt;sup>1</sup> Note - This measurement was not obtained for monocytes and basophils due to the presence of lobulated nuclei.

lymphocyte size. Another technique used for the same purpose is the Diff-Quick<sup>2</sup>, although it may not provide the best differentiation between the types of leukocytes, and heterophils can be glued together making evaluation difficult (Muro et al. 1998). Reagent Formulae. "Diff Quick" solution I/II or kits can be purchased from IHC Store. Store Diff-Quik at 5°C to retard growth of organisms. "Diff-Quick" includes specific technical instructions: Exposure to alcohol should be as brief as possible to prevent excessive discoloration. Paraffin sections can be rehydrated using distilled water.

- 1. Using the Diff Quick" solution II stain for 30s
- 2. Counterstain (optional) with "Diff Quick" solution I for additional 30s
- 3. Rinse rapidly in tap water,
- 4. Rapidly dehydrate in absolute alcohol,
- 5. Clear and mount.

For smears/imprints using an air dry method absent of alcohol, follow these instructions:

- 1. Air-dry the smear,
- 2. Fix in "Diff Quick" Fixative (or methanol) for 30 s/drain.
- 3. Stain with "Diff Quick" solution II for 30 s/drain.
- 4. Counterstain (optional) with "Diff Quick" solution I for 30 s/drain.
- 5. Rinse in tap water to remove excess stain,
- 6. Rapidly dehydrate in absolute alcohol,
- 7. Clear and mount

l

## **Color Reference of Blood Cell Types Using Diff Quick**

<sup>&</sup>lt;sup>2</sup> "Diff-Quick" is a proprietary brand of a Romanowski stain. The Romanowski group of stains are defined as being the black precipitate formed from the addition of aqueous solutions of methylene blue and eosin, dissolved in methanol. The variants of the Romanowski group differ in the degree of oxidation (polychroming) of the methylene blue stain prior to the precipitation. The stain class was originally designed to incorporate cytoplasmic (pink) staining with nuclear (blue) staining and fixation as a single step for smears and thin films of tissue (spread preparations of omentum). Minor modifications of working stain concentration and staining time have been made over the years for fixed tissue sections.

## **RESULTS**

Blood samples were taken from 100 individual sea turtles (*C. mydas*), during egg deposition on Yucatan beaches. Individuals were categorized as apparently healthy  $(N = 84)$ , and sick turtles ( $N = 16$ ). Sick turtles were categorized when ectoparasites were present on their bodies.

The range of blood values between apparently healthy turtles and sick turtles are presented below (Table 1). Differences between the minimum range blood values, except monocytes, from the two animal groups were noted. It is important to mention that these blood values represent the first baseline information from this species in the area.

#### **Table 1. Comparison of blood value ranges between healthy and sick sea turtles**

**Table 2. Comparison of blood vale ranges between sick and apparently healthy**  *Chelonia mydas* **sea turtles nesting on the northeast beaches of Yucatan, Mexico, with reference to other related studies**

Note: "Sick turtles, <sup>b</sup>apparently healthy turtles, 'Montilla et al., 2006 <sup>d</sup>Samour et al., 1998. Adult females, <sup>f</sup>Red blood cells, <sup>g</sup>Hemoglobin, <sup>h</sup>Hematocrit, <sup>i</sup>Mean corpuscular volume,. <sup>j</sup>Mean corpuscular hemoglobin concentration, <sup>k</sup>White blood cells, <sup>1</sup>Absolute values.

Based on 100 total samples, 84 were classified as apparently healthy turtles (AHT), and 16 classified as sick (ST) due to presence of parasites The blood values compared between the two turtle groups (AHT and ST) showed differences, especially the minimum range value, suggesting that the presence of parasites have an impact over these hematological variables (Table 2). The observed cells on blood smears were the following: different cell types of the red series and white series as eosinophilic leukocyte, 2) erythrocyte, 3) polychromatic erythrocyte, and 4) thrombocyte (Figures 2-5) are observed. These cells are observed in the green turtle of our work were seen eosinophilic leukocyte broken.

Figure 2. Blood smear of four types of blood cells identified: 1) eosinophilic leukocyte, 2) erythrocyte, 3) polychromatic erythrocyte, and 4) thrombocyte.

Figure 3. Red blood series cells: 2) erythrocyte, 3) polychromatic erythrocyte.

Figure 4. Cells on the red and white series: 1) eosinophilic leukocyte, 2) erythrocyte, and 4) thrombocytes.

#### **Blood Samples as Reference Values**

In order to determine reference values for nesting females in Yucatan, Mexico from the blood samples collected above, we compared our values to previous studies in other regions yet of the same species, *C. mydas*. Below we present a summary of the findings from comparable studies in Venezuela, just south of Mexico and presumably within the same population range as the sea turtles studied from Yucatan as presented above.

#### *Gulf of Venezuela, Alta Guajira (Montilla et al. 2006)*

In this study, blood samples from, thirty individual turtles  $(N = 30)$  were taken from the dorsal cervical sinuses of *C. mydas*. Researchers recorded the following blood parameters: Red Blood Cell (RBC), White Blood Cell (WBC), Packed Cell Volume (PCV), Mean Corpuscular Volume (MCV), and differential count of leukocytes. Curved carapace length (CCL) and curved carapace width (CCW) was collected from each turtle in order to estimate the age.

Results from this study included average values of the hematological parameters as follows: RBC (0.42  $\times$  106 µL), WBC (6.16  $\times$  10<sup>3</sup>µL), PCV (29.40%), MCV (730.17 fL), Heterophils (82.9% - 5.1023  $\times$  10<sup>3</sup>/µL), Lymphocytes (14.7% - 0.9081  $\times$  10<sup>3</sup>/µL), Eosinophils  $(0.47\% - 0.0236 \times 10^3/\mu L)$ , Monocytes  $(1.97\% - 0.1259 \times 10^3/\mu L)$ .

These results coincide with the reference intervals documented for the species. The variability in some of the parameters evaluated could be attributed to factors as age, sex, reproductive state, stress, temperature, and capture technique and analysis methods (Figure 5 and 6). A Mann-Whitney test concluded significant differences ( $P = 0.038$ ) between male and female based on the MCV values.

#### *The Wildlife Refuge Aves Island, Venezuela*

This area provides the main nesting area for *Chelonia mydas* in the country and the second largest breeding colony of relevant in the Caribbean (Prieto-Torres et al. 2012).

Magnification: 7000x.

Figure 5. Eosinophil cell of individual green sea turtle (*Chelonia mydas*).

Magnification: 7000x.

Figure 6. Heterophil cells of green sea turtle (*Chelonia mydas*).

Thus this study provides a good comparison to our study in Yucatan, Mexico to provide reference values. In this study, researchers determined hematological values from July and September 2010 based on blood samples of 64 turtles (52 females and 12 males) collected from the dorsal cervical sinus. A complete hematological study was performed using the following parameters: Red Blood Cell (RBC), White Blood Cell (WBC), Hematocrit (Hct), Hemoglobin (Hb), Mean Corpuscular Volume (MCV), Mean Corpuscular Hemoglobin (MCH), Mean Corpuscular Hemoglobin Concentration (MCHC) and Leukocytes differential count Researchers measured curved carapace length (CCL), curved carapace width (CCW) of all 64 turtles and tail length (LT), each male turtle, to estimate the minimum sexual maturity. Due to working conditions at the study area, samples were placed on ice and refrigerated for 30-60 min ice then processed at the scientific laboratory at the Simón Bolivar navy base RFSIA. The differential leukocyte count was performed on two frotis samples that were stained with a Dip-Quick solution, resulting in absolute values as percentages (Montilla et al. 2006). Results from this study included average values of the hematological parameters as follows, noting below turtles identified in the "sick" category: RBC  $(457.187 \times 103^{3} \mu L)$ , WBC  $(3.66 \times 10^3 \mu L)$ , MCV  $(727.83 \text{ ft})$ , Heterophils  $(52.3\% - (1.990 \times 10^3/\mu L))$ , Lymphocytes (36% - 1.297  $\times$  10<sup>3</sup>/µL), Eosinophils (7.4% - 0.234  $\times$  10<sup>3</sup>/µL), Monocytes  $(3.8\% - 0.123 \times 10^3/\mu L)$ , basophils 0.4%  $(0.0097 \times 10^3/\mu L)$ , Ht 30.77%, Hb 9.60 g/dL, MCHC 31.21 g/dL. Figure 7 below shows the differences of various cell types reported from this study that were used as baseline comparison model for the current study in Yucatan, Mexico. In this study, researchers noted emerging fibropapilloma disease present on front flippers and the cervical region of two of the female turtles. Mean CCL and CCW for nesting females was 112.1 cm and 101.4 cm, respectively. Recorded average measurements for males was 105.6 cm CCL, 96.2 cm CCW and 34.3 cm LT.

## **CONCLUSION AND DISCUSSION**

It is imperative to create reference values for studies involving blood samples to determine the health status of wildlife populations. In the case presented here using sea turtles, reference values are applied when analyzing condition of nesting females and foraging populations. Based on results, researchers can then adapt conservation strategies in accordance to environmental conditions present in various regions.

Correlations between sea turtle morphology and hematological variables are important, in as well as differences between nesting females, hatchlings and migrating individuals. It is a general agreement that differential counts vary from previously reported literature, mainly due to the lack of standardized criteria to measure and differentiate types of leukocytes (Aguirre et al. 1995). Various publications describe the presence of erythrocytes, eosinophils, basophils, azurophils, neutrophils, lymphocytes, monocytes and thrombocytes on frotis samples from green sea turtles (*Chelonia mydas*), with the help of light microscopes (Work et al. 1998). For example, Aguirre et al. (1995) used the same methodology but classified leukocytes as heterophils, neutrophils, lymphocytes, eosinophils and basophils. Differences in cell classification are a result of the lack of identification using cytochemistry and/or the analysis of ultrastructure by electronic microscopy to corroborate results.

Figure 7. Blood cells observed from green nesting females (*Chelonia mydas)* at the Wildlife Refuge from Isla de Aves, during the 2010 nesting season. A) heterophil (7000x); B) reactive lymphocyte (6000x); C) reactive lymphocyte (7000x); D) eosinophil (6000 x); E) monocyte (5000x) and F) basophile (7000x).

Some authors describe the presence of neutrophils on reptiles, same that are reported as heterophils by others and that play the same role as neutrophils in mammals (Aguirre et al. 1995; Montilla et al. 2006; Work et al. 1998). Heterophils are defined as polymorphic-nuclear cells that are most frequently present on bird and reptile blood samples (Myers et al. 2004; Montilla et al. 2006; Flint et al. 2010).

The influence of climatic or environmental variations over the hematological values on reptiles is still controversial (Campbell 1995; Fuentes-Mascorro 2007; Work et al. 1995).

Studies to resolve this question occur in different times and are run for short periods, factors that can temper the observed results.

Some authors have pointed out that no significant differences exist between hematological values between males and females from some species (Rossini 2002). Nevertheless it has also been mentioned that difference on sizes, sex, temperature, corporal hydration and reproductive state may be responsible of the observed variations on hematological parameters (Bolten & Bjorndak 1992; Campbell 1995; Christopher et al. 1999; Rosskopt 2000). It is hard to compare the results from this study to those mentioned above, because most samples were obtained from juveniles where sex differentiation has not been achieved. This chapter presents findings from Yucatan, Mexico of 100 sampled nesting females in comparison to related studies from Venezuela in order to provide future studies a range reference values.

### **ABSTRACT**

The supply of wild fry of coral reef fishes for aquaculture has resulted in the deterioration of their natural stock status, causing public concern. Through a series of studies on the establishment of artificial-fry production technologies for coral reef fishes, we found that ovary, testis, eggs and fry of coral reef fishes have high or intermediate levels of arachidonic acid (ArA), which is a relatively minor component in temperate and cold-water species. In gonadal polar lipids of selected coral reef, in particular demersal fishes (19 species), ArA, eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) levels ranged from 6.0% to 19.4%, from 0.9% to 6.2%, and from 7.9% to 27.8%, respectively. It is notable that the major highly unsaturated fatty acids (HUFA) of polar lipids in all coral reef fish gonads are DHA and ArA (not EPA) in a ratio of about 2:1. This result allowed us to speculate that not only DHA but also ArA may be nutritionally much important for egg development and larval growth in coral reef fishes.

Thus, feeding trials were conducted to investigate the effects of dietary ArA supplementation on reproductive performance of coral reef rabbitfish (*Siganus guttatus*) broodstock. The number of spawning and the number of hatched larvae tended to be better in broodstock fed diets with ArA than in those fed a diet without ArA. Next, larval rearing tests were conducted to investigate survival and growth in rabbitfish fry fed live rotifers which had been enriched with or without ArA. Fry fed the rotifers enriched with a combination of DHA Protein Selco (Inve Aquaculture, Baasrode, Belgium) + 5% ArA (VEVODAR CRUDE ARACHIDONIC OIL, DSM Food Specialties, Delft, the Netherlands) showed significantly the best survival  $(44.4\pm4.5\%$  for Day17 fry), although growth was not different among treatments. The present study indicates that ArA is not a minor component in coral reef fishes, and that dietary ArA is very promising for the improvement of fry production technologies of the coral reef fishes.

**Keywords:** arachidonic acid (ArA), DHA, EPA, coral reef, fry production, aquaculture

### **INTRODUCTION**

Coral reefs are not only biologically but also economically productive waters, and in fact coral reef fishes such as grouper, snapper and rabbitfish are high marketable fish (Johnson, 2007). An increasing demand for such high value fish has intensively developed aquaculture of these species during these few decades, which has provided excellent food fish as well as the means to rise revenue for coastal communities around the waters. Aquaculture appears a semi-sustainable activity which allows for avoiding overfishing and destructive fishing practices such as dynamite fishing. However, aquaculture of coral reef fishes is based on wild-caught fry, that is, the industry still relies largely on the natural capture of seed fish in the wild, because of the shortage of artificial seed fish produced in hatcheries. The heavy supply of wild fry of coral reef fishes for aquaculture may lead to the deterioration of the natural stock status, causing public concern as a new threat.

Fry supply is the most important component in aquaculture, but the fry needed for aquaculture still come mostly from the wild as mentioned above, and thus due to poor production of the artificial fry, their availability is a major constraint in the development and extension of aquaculture not dependent on wild fry (Marte, 2003). Although hatcheries should have the responsibility to stably produce and supply healthy fry to famers, fry production of coral reef species remains variable due to poor fecundity of broodstock and low survival of hatched larvae. The nutritional condition of broodstock is one of the first determinants of egg and larval quality, and diet quality and nutrients have been shown to have a profound effect on egg nutritional composition and subsequent gonadal development, fecundity (total number of eggs produced), fertilization rate, normal embryo development, hatching rate and survival rate of hatched larvae (Izquierdo et al., 2001). However, nutritional information on broodstock is limited to a few species, and little information is available in coral reef fishes. In order to improve egg production/quality and larvae/fry quality through dietary manipulation, we have conducted a series of studies that was aimed at developing advanced artificial diets for coral reef fishes.

Through a study to investigate a difference in nutritional components between mangrove red snapper (a coral reef species) (*Lutjanus argentimaculatus*) and cold/cool-water species, we found that the EPA: ArA ratios were interestingly around 1 based on analyses of eggs and newly hatched-larvae of mangrove red snapper. The EPA:ArA ratios are 7.5 in Atlantic

salmon *Salmo salar* (cold water species) eggs (Cowey et al., 1985), and 11.5 in Japanese flounder *Paralichthys olivaceus* (cool water species) eggs (Furuita et al., 2000), respectively (Figure 1). In the "Research & Development" of fry production technology, the most innovative finding is that marine fish require essential fatty acids, or dietary docosahexaenoic acid (DHA) and EPA for the developments of gonads in broodstock and the normal growth and development in embryo/larvae. Practically, dietary EPA and DHA have successfully improved reproductive performance and egg/larvae quality such as fecundity, embryo development, hatchability and survival in several species (Watanabe et al., 1984; Izquierdo et al., 2001). In contrast, although ArA also is an essential fatty acid in higher vertebrates, the acid is a minor component in cold/cool-water species, and thus little attention was paid to the function of ArA in marine fish. Considering together the practical importance of essential fatty acids in hatcheries and the existence of ArA in an amount almost equal to EPA in the snapper's eggs, it has been highly speculated that ArA may be nutritionally much more essential for reproduction and larvae growth in coral reef fishes than in cold/cool water fishes. Thus, our efforts have been directed toward demonstrating the efficacy of ArA in the advancement of artificial diets for fry production of coral reef fishes. The present paper describes I: the wide distribution of ArA as a major fatty acid component in coral reef associated, in particular demersal fishes; II: the effects of dietary ArA supplementation on reproductive performance of rabbitfish broodstock; and III: the effects of DHA/ArA-enriched rotifers on survival and growth of rabbitfish fry.

## **1. WIDE DISTRIBUTION OF ARACHIDONIC ACID AS MAJOR FATTY ACID COMPONENT IN CORAL REEFASSOCIATED FISHES**

The details of sample species analyzed and fatty acid analysis are described in our previous papers (Ogata et al., 2004; Suloma and Ogata, 2011).

#### **1.1. Coral Reef Associated, Demersal Fishes**

Tables 1-17 list fatty acid composition of coral reef associated, demersal fishes in Philippines and Ishigaki Island, Japan. Grouper's data are shown in Tables 1-3, *Lutganidae* in Tables 4-10, *Siganedae* in Tables 11-15, and *Lethridae* in Tables 16-17. The most striking result is that ArA level is higher than EPA level in polar lipids of most wild fishes (gonads and muscle). In ovarian polar lipids, ArA levels ranged from 6.0% (*Epinephelus areolatus*) (Table 2) to 19.4% (*Lethrinus. atkinsoni*) (Table 16), while EPA levels ranged from 0.9% (*Sigunus virgatus*) (Table 15) to 6.2% (*Pristipomoides argyrogrammicus*) (Table 13). ArA in ovarian polar lipids was one of the top three fatty acid components in *Cephalopholis argus* (12.6%, Table 2), *E. quoyanus* (15.2%, Table 3), *Epinephelus. sp.*-1 (11.4%, Table 3), *Epinephelus sp.*-2 (11.7%, Table 3), *Lutjanus decussatus* (16.5%, Table 5), *L. erythropterus* (17.5%, Table 5), *Plectropomus leopardus* (Ishigaki, Japan) (19.2%, Table 10), *L. gibbus* (12.3%, Table 4), *L. miniatus* (17.3%, Table 16), *S. canaliculatus* (Ishigaki, Japan) (9.9%, Table 13), *L. atkinsoni* (19.4%, Table 16), *S. guttatus* (12.7%, Table 11) and *S. virgatus* (8.9%, Table 15). Irrespective of the maturity (see Suloma and Ogata, 2011), ovarian polar lipids had higher levels of ArA than EPA levels. DHA was also one of the top three fatty acid components in ovarian polar lipids. Ovarian DHA level in polar lipids was always higher than EPA in almost all of the species analyzed, ranging from 7.9% (*S. virgatus*, Table 15) to 27.8% (*S. canaliculatus*, Table 14).

Surprisingly, ArA was the top fatty acid component in testis polar lipids of *L. ornatus* (22.9%, Table 17), *L. nebulosus* (22.5%, Table 17) and *L. atokinsoni* (21.4%, Table 16). ArA levels in testis polar lipids of two *Siganus* species were intermediate but higher than EPA levels (Tables 11 and 15). Testes of the five species of coral reef fishes had average ratios of: ArA/EPA of 9.8, DHA/EPA of 6.5 and DHA/ArA of 0.8 in polar lipids and ArA/EPA of 5.5, DHA/EPA of 3.4 and DHA/ArA of 0.6 in neutral lipids, respectively. This result suggest that since the average DHA/ArA ratio was smaller in the testis than in the ovary, the optimum dietary ratio of HUFA during gonadgenesis might be different between males and females, and moreover that the degree of the physiological essentiality of ArA might be greater in testis than in ovary.

The characteristics of ArA, EPA and DHA distribution of the gonads in the coral reef demersal fishes are shown in Figures 2 and 3. In the present study, ovaries of 19 species of coral reef fishes had average ratios of: ArA/EPA of 4.8, DHA/EPA of 6.2 and DHA/ArA of 1.7 in polar lipids and ArA/EPA of 2.5, DHA/EPA of 3.8 and DHA/ArA of 2.5 in neutral lipids, respectively. This result indicates that unlike cold water species in the northern hemisphere, ovarian DHA/ArA ratio, not DHA/EPA ratio, is about 2 in tropical and coral reef fishes, suggesting that the DHA/ArA (not EPA) ratio of around or more than 2 may be optimum for broodstock diets, especially for ovary development in coral reef fishes. It should be again mentioned that the major HUFA are DHA and ArA for the coral reef group, and DHA and EPA for the cold/temperate group in about 2:1 of DHA-to-ArA or -to-EPA ratio in each group. We recommend a dietary ratio of DHA/ArA (not EPA) of about 2 or greater as an ideal for broodstock diets of coral reef fishes. In this connection, it is quite interesting that ArA, EPA and DHA levels and ArA/EPA ration of wild goose eggs was respectively 9.3%, 1.8%, 4.8% and 3.9 (Speake et al., 1999), namely the pattern of gonadal essential fatty acids in the coral reef fishes is similar to that in the goose rather than that in the cold/cool-water fishes.

Figure 2. Levels (%) of ArA, EPA and DHA of ovaries in coral reef demersal fishes.

Figure 3. Levels (%) of ArA, EPA and DHA of testes in coral reef demersal fishes.

As an overall trait, ArA, EPA and DHA levels in neutral lipids were lower than those in polar lipids due to relatively high levels of 16:0, 18:0 and 18:1n-9 fatty acids in neutral lipids in gonad tissues. Yet, in neutral lipids, ArA levels were entirely higher than EPA levels throughout all the species.

#### **1.2. Tropical Pelagic Fishes**

For tropical pelagic fishes including coral reef waters, Table 18 shows the gonadal fatty acid composition of two *Trachurus* species and Tables 19-21 do the whole-body fatty acid composition of six pelagic species. Most important feature to be noted is that in the polar lipid fraction, EPA level ranging 4.1% to 9.6% was always higher than ArA level ranging 2.6% to 6.6% excluding the cases of *Trachurus* sp.-2 (testis) (Table 18) and *Rastrelliger* sp. (whole body) (Table 21). The polar lipid fraction had ArA level lower than EPA level even in the ovary of the two *Trachurus* species (Table 18). It should also be noted that DHA ranging 11.7% to 26.5% was always the top or second-top fatty acid component in the polar lipid fraction. Thus, there was a difference in the ArA distribution between the coral reef demersal fishes and the tropical pelagic fishes.

#### **1.3. Possible Origin of ArA in Coral Reef**

EPA and DHA in fish have been known to be derived from the pelagic food chain from phytoplankton to accumulate in higher order carnivores, especially in pelagic species and deeper offshore demersal species (Sargent and Whittle, 1981). Thus, planktonic microorganisms may be not the primary source of ArA even in tropical waters. This appears to reflect in the ArA distribution of the tropical pelagic fishes in the present study. On the other hand, all the demersal species investigated in the present study were coral reefassociated species. *Serranidae*, *Lujanidae*, *Lethridae* and *Labridae* are carnivores, which feed on smaller fishes, crabs, shrimps, cephalopods, polychaeta worms, gastropods and urochordates. *Sigaidae* are herbivores, which feed mainly on benthic macroalgae. Dunstan et al. (1988) found that in temperate marine fish from Southern Australian coastal waters, demersal omnivore species (macroalgae consumers) have relatively high ArA/EPA ratio (0.9) compared to demersal carnivores (0.6) and pelagic carnivores (0.2). ArA may be provided primarily from some organisms existing in/on benthic substrate and benthic detritus rather than pelagic organisms. Little information is available on fatty acid composition of benthic organisms as an ArA source in the tropical marine food chain. The present result, high ArA levels in coral reef demersal fishes, suggests that the existence of an ArA-rich food chain may be widespread in coral reef areas, and that the widespread existence of ArA-rich food chain may lead to comparatively higher ArA contents in the coral reef demersal fishes. However, the issue of ArA origin in the coral-reef food web is still unclear. In this connection, see another chapter of the present text book "Coral Reefs: Ecosystems, Environmental Impact and Current Threats."

#### **1.4. Rabbitfish**

Tables 11-14 show fatty acid composition of ovaries of *S. guttatus* (wild-caught and hatchery-produced) and *S. canaliculatus* (wild-caught). Rabbitfish (*S. g.* and *S. c.*) ovaries also showed that in the polar lipid fraction, ArA levels were always higher than EPA levels, irrespective of the difference in species and in sample source (wild and hatchery). It should also be noted that *S. g.* ovary contained a relatively high linoleic acid (18:2n-6) level, irrespective of the source and lipid class (Table 12), compared to *S. c.* ovary. In wild *S. g.* and *S. c.*, linoleic acid levels of the ovarian polar lipids were 6.9 and 0.9%, respectively. The whole-body fatty acid composition (%) of wild-caught *S. g.* fry or hatchery-produced *S. c.* fry is shown in Tables 12 and 14, although direct comparison in fatty acid composition is not appropriate due to the difference in species and sample source. ArA, EPA, DHA levels and the ratios of wild *S. g.* fry were 4.0, 2.7, 23.9% and 1.5/1.0/8.8, while those of hatcheryproduced *S. c.* fry were 1.4, 2.1, 13.4% and 0.7/1.0/6.5, respectively (Figure 4). ArA/EPA ratio of hatchery-produced *S. c.* fry was less than 1.0.

**ArA** level and ArA/EPA ratio of wild ( $\blacksquare$ ) and hatchery ( $\blacksquare$ ) fry

Figure 4. Comparison of ArA level and ArA/EPA ratio between wild and hatchery fry.

The information in the present study can be used as a guideline for development of appropriate broodstock and larval diets, to ensure high egg and larval quality of sustainable hatchery production in coral reef areas. We have conducted follow-up studies on the effects of dietary ArA on reproductive performance and larval/fry quality in coral reef rabbitfish.

# **2. EFFECTS OF DIETARY ARACHIDONIC ACID SUPPLEMENTATION ON REPRODUCTIVE PERFORMANCE OF RABBITFISH BROODSTOCK**

Feeding trials were conducted to investigate the effects of dietary ArA supplementation on reproductive performance of rabbitfish (*Siganus guttatus*) broodstock.

### **2.1. First Trial**

Five females and five males (340g—810g) of rabbitfish broodstock were each stocked in 5-ton-concrete tanks at Tigbauan Main Station, the Aquaculture Department of the Southeast Asian Fisheries Development Center (SEAFDEC/AQD) (Iloilo, Philippines). Fish have been fed each of the three test diets (Table 22) twice a day at a rate of 4% of biomass/day from July. Diet 1 was a basal diet with 1% of soybean oil + 6% cod oil, in diet 2 the soybean oil was replaced with 0.75% of ArA (VEVODAR CRUDE ARACHIDONIC OIL (DSM Food Specialties, Delft, the Netherlands)), and in diet 3 all of the soybean oil and a part of cod oil was replaced with 1.5% of ArA. Fish meal, soybean meal, acetes and squid meal were the protein sources and wheat flour and corn starch were the carbohydrate sources. The mixture was pelleted using a twin-screw extruder.

To induce natural spawning, pairs of one female and one male of each dietary treatment were separately transferred to spawning tanks just before first quarter moon when it is the time for *S. guttatus* to spawn (natural spawning of this species follows a lunar cycle) (Duray 1998). Since eggs spawned from *S. guttatus* are demersal and strongly adhesive (Duray 1998), and indeed the sticky eggs were attached to the wall of the spawning tank, we were not able to collect and count the number of spawned eggs. In the present report, we show only the number of spawning and the total number of hatched-larvae in each dietary treatment.

Ingredients (%)	Diet 1	Diet 2	Diet 3
Fish meal (Peruvian)	25	25	25
Soybean meal	25	25	25
A <b>c</b> etes <sup>1</sup>	8	8	8
Squid meal	1.5	1.5	1.5
Soybean oil	1.0	0.25	$\mathbf{0}$
Cod oil	6.0	6.0	5.5

**Table 22. Composition of test diets fed to rabbitfish broodstock (first trial)**

<sup>1</sup> Shrimp meal.<sup>2</sup> Imported vitamin. mixture.<sup>3</sup> vitamin mixture for poultry.

The number of spawning, the number of hatching and the total number of hatched-larvae are shown in Table 23 without statistical treatment. The broodstock spawned three times for diets 1 and 3 and four times for diet 3 during the period from July to December. The total numbers of hatched-larvae were 500,000 for diet 1, 1,548,000 for diet 2 and 0 for diet 3. Diet 3 with 1.5% of ArA supplementation appeared to affect negatively the reproductive performance of *S. guttatus* broodstock, perhaps due to the excessive supplementation. Similar results were observed, that is, reproductive performance of Japanese flounder was improved by ArA supplementation with 0.6  $g/100 g$  diet but was adversely affected by that with 1.2 g/100 g diet (Furuita et al., 2003).

#### **2.2. Second Trial**

Diet 1 was a basal diet with 1% of soybean oil  $+ 6\%$  squid oil  $+ 4\%$  cod oil (Table 24). The soybean oil was replaced with 0.3% (for diet 2) or 0.6% (for diet 3) of ArA (*Vevodar Crude Arachidonic Oil*, DSM Food Specialties, Delft, the Netherlands). Fish meal, soybean meal, acetes and squid meal were the protein sources and wheat flour and corn starch were the carbohydrate sources. The mixture was pelleted using a twin-screw extruder.

Two sources of broodstock, hatchery-bred broodstock and wild-caught broodstock, were employed in the 2nd feeding trial. The hatchery-bled broodstock were raised from eggs that were spawned at Tigbauan Main Station, and the wild-caught broodstock were purchased from local dealer. Three females and three males from each source were each stocked in six 5-ton-concrete tanks at Tigbauan Main Station (two sources per each dietary treatment x three dietary treatments and three pairs in each tank) (Table 25). Fish have been fed each of the three test diets (Table 24) twice a day, six days a week at a rate of 3% of biomass/day from March. To induce natural spawning, pairs of one female and one male of each dietary treatment were separately transferred to spawning tanks (18 tanks: three pairs x three dietary treatments x two sources) just before first quarter moon when it is the time for rabbitfish *S. guttatus* to spawn (natural spawning of this species follows a lunar cycle) (Duray, 1998). Since eggs spawned from *S. guttatus* are demersal and strongly adhesive, and indeed the sticky eggs were attached to the wall of the spawning tank, we were not able to collect and count the number of spawned eggs. Again, we show only the number of spawning and the total number of hatched-larvae in each dietary treatment.

The number of spawning and the number of hatching during the period of May through January of the next year are shown in Table 26. Table 27 lists the total number of hatchedlarvae, the average number of hatched larvae per pair, the total number of normal larvae and the average number of normal larvae per pair. Table 28 also shows average % of normal larvae. There were no differences between hatchery-bled and wild broodstock in any indices.

The broodstock spawned 13 times for diet 1, 14 times for diet 2 and 17 times for diet 3 during the period May through Jan 2of the next year. The numbers of hatching were 10 of the 13 spawning for diet 1, 11 of the 14 spawning for diet 2 and 14 of the 17 spawning for diet 3, respectively. The total numbers of hatched-larvae were  $3,818x10^3$  for diet 1,  $4,391x10^3$  for diet 2 and 4,597x10<sup>3</sup> for diet 3. The average numbers ± S.E.  $(x10^3)$  of hatched larvae were  $636\pm216$  for diet 1,  $878\pm257$  for diet 2 and  $766\pm213$  for diet 3, respectively. The total numbers of normal larvae were  $3,322 \times 10^3$  for diet 1,  $3,700 \times 10^3$  for diet 2 and  $3,876 \times 10^3$  for diet 3. The average numbers ± S.E.  $(x10^3)$  of normal larvae were 554 ± 183 for diet 1, 740 ± 243 for diet 2 and 646±183 for diet 3, respectively. Thus, broodstock fed diet 2 or 3 with ArA supplementation tended to show better performance in spawning and hatching, but with big variations. Percent of normal larvae (average $\pm$ S.E.) was as: 76.3 $\pm$ 6.4% for diet 1, 79.3 $\pm$ 6.1% for diet 2 and 79.2±5.8% for diet 3. The % of normal larvae did not differ among dietary treatment. Considered together with the adverse effects of ArA over-supplementation (Furuita et al., 2003) and the results of the 1st trial, the optimum supplementation level of ArA in broodstock diets may be 0.5% to 0.7%.

# **3. EFFECTS OF DHA/ARACHIDONIC ACID-ENRICHED ROTIFERS ON SURVIVAL AND GROWTH OF RABBITFISH FRY**

Feeding trials were conducted to investigate the effects of DHA/ArA-enriched rotifers on survival and growth of rabbitfish (*Siganus guttatus*) fry.

## **3.1. Preliminary Studies**

Our preliminary studies showed that rotifers (a live food) were enriched with emulsified triacylglycerol-type ArA, that EPA and DHA levels in the rotifers decreased as the increment of the amount of ArA in culture media, and that the optimum level ArA supplementation to the culture media appeared at 5% or lower.

#### **3.2. Materials and Methods**

Rabbitfish eggs used in this experiment came from rabbitfish broodstock maintained at Tigbauan Research Station of SEAFDEC/AQD. Rabbitfish eggs were naturally spawned. The eggs were incubated according to standard practice at SEAFDEC/AQD.

Rotifers *Brachionus sp*. were first cultured in 20 cubic meter outdoor concrete tanks fed with *Nannochloropsis sp.* for five days. The rotifers were harvested and were intensively cultured in four different 30 *l* cylindrical-conical fiberglass tanks by feeding an artificial rotifer-diet (Culture Selco (CS), Inve Aquaculture, Baasrode, Belgium) for 24 h. Subsequently, the rotifers were cultured with various combinations of artificial rotifer-diets and ArA. Rotifers in the first group were enriched with Culture selco, the second group was enriched with Culture Selco + 5% ArA, the third group were enriched with DHA Protein Selco (DHAPS) and the fourth group were enriched with DHA Protein Selco + 5% ArA. The enrichment of rotifers with each treatment was performed twice a day (9-10 AM and 7-8 PM), and the rotifers were harvested after 24 h. Prior to the enrichment, rotifer density in each tank was determined to calculate the amount of each supplement to the tank. For the second and fourth group an addition of 5% ArA by weight were made.

Newly hatched (Day 0) rabbitfish were stocked (30 larvae/*l*) in circular, conical-bottom fiberglass tanks filled with 200 *l* filtered seawater. Larval rearing protocol followed the method described by Gapasin & Marte (1990) with modifications.

The four treatments (in a completely randomized design with 4 replicates) were:

- Treatment I: larvae fed rotifers cultured on Culture Selco
- Treatment II: larvae fed rotifers cultured on Culture Selco  $+5\%$  ArA
- Treatment III: larvae fed rotifers cultured on DHA Protein Selco, and
- Treatment IV: larvae fed rotifers cultured on DHA Protein Selco + 5% ArA.

Treatment I was a control, which is standard procedure of rabbitfish larvae practiced at SEAFDEC/AQD. Larval culture for all treatments was conducted using greenwater (*Nannochloropsis sp*) with a density of  $5-10 \times 10^4$  cells/ml. Temperature (27-29°C), salinity (29-31‰) and standing food count were monitored prior to water exchange and feeding.

#### **3.3. Survival and Growth**

The feeding trials were terminated on day 17. Larval survival was determined, and 10 samples from each tank were measured for total length and body weight.

Survival of D17 rabbitfish fry (Figure 5) was significantly improved. The average survival±S.E. was 16.4±4.1% for CS, 31.2±3.7% for CS+5% ArA, 23.9±7.4% for DHAPS, 44.4±4.5% for DHAPS+5% ArA. Surprisingly, of DHAPS+5% ArA group, the best survival value recorded 58.8%. The body length (mm) and the body weight (mg) were 5.44±0.38 and 2.0±0.3 for CS, 6.20±0.34 and 2.5±0.5 for CS+5%ArA, 6.05±0.53 and 2.6±0.5 for DHAPS, and 6.23±0.27 and 2.4±0.3, respectively. Growth was not different among treatments. Thus, although dietary ArA supplementation would help advance fry production technologies in coral reef fishes, it should be noted that excessive feeding of ArA also causes adverse effects to fry and juvenile performance (Zeng et al., 1996; Xu et al., 2010). Since DHA level in rotifers is decreased by over-supplementation of ArA as shown in our preliminary studies, the dietary balance between DHA and ArA should be considered.

DHAPS+5%ArA improved survival of rabbitfish fry.

Figure 5. Survival and total length in larval rearing test – DHAPS+5%ArA improved survival of rabbitfish larvae (Day 17).

## **CONCLUSION**

ArA was not a minor HUFA but an essential component in gonads of coral reef, demersal fishes with 2:1 of DHA-to-ArA ratio.

The number of spawning and the number of hatched larvae tended to be better in rabbitfish broodstock fed diets with ArA enrichment than in those fed a diet without ArA enrichment. The optimum level of ArA incorporation in broodstock diets appears between 0.5% and 0.7%.

Rabbitfish fry fed ArA-enriched rotifers showed significantly improved survival.

The present paper indicates that dietary ArA supplementation is very promising for the advancement of fry production technologies in coral reef fishes.

#### **ACKNOWLEDGMENTS**

The present study was financially supported by the collaborative project titled "Studies on Sustainable Production Systems of Aquatic Animals in Brackish Mangrove Areas" between Japan International Research Center for Agricultural Sciences, Japan and the Aquaculture Department, SEAFDEC, Philippines.

# **ABSTRACT**

Although reef-building corals engaged in mutualistic relationships with dinoflagellates of the genus *Symbiodinium* are threatened by global climate change, many anthozoan-dinoflagellate endosymbioses display a marked capacity for acclimation with respect to temperature changes. For instance, specimens of the Indo-Pacific reef coral *Seriatopora hystrix* from Southern Taiwan were found to readily acclimate to temperatures that fluctuated from 23 to 29ºC over six hours, a periodicity aimed to

simulate local upwelling events that are common during boreal summer spring tides. To gain greater insight into the molecular mechanisms underlying this ability to acclimate to a variable temperature regime, proteins from corals exposed to both stable (26ºC) and variable temperatures for one week were electrophoresed across two dimensions, and differentially expressed proteins were sequenced with mass spectrometry. Seventy-five (64%) and forty-two (36%) proteins were expressed at higher levels by coral hosts and their *Symbiodinium* populations, respectively, of the stable temperature treatment. This suggests that a number of cellular pathways, including lipid body stabilization and metabolism in the *Symbiodinium* cells, are down-regulated upon exposure to variable temperature, and the potential shift in energy modulation implied by these findings may play a role in the restoration of homeostasis necessitated by exposure to such highly variable temperature conditions.

## **INTRODUCTION**

Most current global climate change (GCC) models assume that reef-building corals are unable to acclimate to changes in their abiotic environment [1]. Although it is true that many corals are known to live near the upper threshold of their thermotolerance and readily bleach in response to sustained temperature increases [2-3], recent studies have revealed that not only can corals readily acclimate to elevated temperature, salinity, and  $pCO<sub>2</sub>$  [4-7], but they can thrive under such conditions [8-10]. For instance, corals from Houbihu, Taiwan (Figure 1A) are readily exposed to episodic, spring tide upwelling during the boreal summer, periods during which temperatures may change up to 9-10ºC within several hours [11]. Corals from these upwelling habitats have proven to be markedly resilient to both short- [12] and longterm [13] increases in temperature, as has been predicted to occur based on studies of intertidal organisms [14].

In order to gain insight into how corals from these upwelling sites acclimate to such dramatic temperature changes, an experiment was conducted in which corals from not only Houbihu, but also a nearby, non-upwelling site, Houwan, were exposed to either a variable (23-29ºC over a 6-hr period) or stable (26ºC) temperature profile for seven days [15-17]. *Seriatopora hystrix* (Figure 1B-C) was chosen as the model coral for such laboratory-based studies, given its 1) widespread distribution across the Indo-Pacific [18-19], 2) propensity for bleaching under periods of elevated temperatures [20], and 3) modest existing understanding of its molecular eco-physiology [21-22]. In general, even *S. hystrix* specimens that were never exposed to upwelling *in situ* readily acclimated to variable temperature conditions (Table 1), and an effort was made to develop both a physiological and a sub-cellular understanding of how such acclimation occurred in the samples from this "*Seriatopora hystrix* variable temperature study" (SHVTS; [15-17]).

Given recent success in employing molecular biology-driven approaches to answering an array of both fundamental [23-27] and stress/environmental biology [28] questions in the field of anthozoan-dinoflagellate endosymbiosis, the expression of a series of gene mRNAs was measured in samples of the SHVTS [15, 17]. Although several genes encoding proteins involved in photosynthesis were differentially expressed between the stable and variable temperature treatments (TT; [15, 17] and Table 1), the variation was generally modest, and it was, furthermore, unclear whether such changes in mRNA expression would actually lead to altered levels of translation of the respective proteins; indeed, in the few studies that have

looked at both gene and protein expression in the same anthozoan-dinoflagellate sample [7, 26], there was not always a significant, positive correlation between gene and protein expression [7]. Therefore, a whole-proteome-based approach employing two-dimensional (2D) electrophoresis followed by protein sequencing via mass spectrometry (MS) was taken herein in order to better unravel the molecular means by which *S. hystrix* and its endosymbiotic *Symbiodinium* populations acclimate to a variable temperature regime.

Figure 1. The upwelling field site Houbihu, the model coral *Seriatopora hystrix*, and an analytical flowchart of the proteomic analyses. (A) Houbihu, the upwelling site from which half of the *Seriatopora hystrix* specimens used in the variable temperature study were sampled (photograph taken by Dr. Pi-Jen Liu, National Museum of Marine Biology and Aquarium, Taiwan). (B) An adult *S. hystrix* colony. (C) Proteins were extracted from each of two technical replicates (*i.e*., nubbins) from each of the 12 experimental aquaria after a 7-d exposure to either variable (23-29 $^{\circ}$ C over a 6-hr period; n = 6 aquaria) or stable temperature ( $26^{\circ}\text{C}$ ; n = 6 aquaria). (D) The expression of RBCL was quantified in the 12 samples dissolved in SDS-PAGE sample buffer. (E) For the second technical replicate from each aquarium, proteins were prepared for 2-dimensional gel electrophoresis as described in the text. Proteins were pooled across sites of origin (SO; *i.e*., proteins from Houbihu were mixed with those of Houwan) for each of the two temperature treatments (TT) given the fact that *only* a TT effect on protein expression was of interest herein. The numbers on the arrows represent the respective experimental steps in E, and the scale bars in A, B, and C represent 500, 50, and 5 mm, respectively.

treatment (TT), and interaction effects were deemed statistically significant at  $\alpha < 0.05$  (denoted by "\*") in the respective cells). **treatment (TT), and interaction effects were deemed statistically significant at α < 0.05 (denoted by "\*" in the respective cells).**  Table 1. ## **MATERIALS AND METHODS**

#### **SHVTS**

The SHVTS was discussed in previous works [15-17]. Briefly, six *S. hystrix* colonies from both the upwelling (Houbihu; Figure 1A) and non-upwelling (control) sites (Houwan) were collected, acclimated in indoor aquaria to allow for recovery from transplantation [16], fragmented into nubbins, acclimated again for several weeks, and randomly assigned to 1 of 12 experimental aquaria: 3 for each site of origin (SO) x TT combination. For protein work,  $\sim$ 100 mg pieces/branches from each nubbin (n = 2 pseudo-/technical replicates per aquarium) were immediately immersed in TRIzol® (Life Technologies, USA) after a 7-d exposure to either a stable (26°C, n = 6 aquaria) or variable TT (23-29°C over a 6-hr period, n = 6 aquaria), with time 0 samples  $(\sim 100 \text{ mg}; \text{ n = 2 pseudo-replicated nubbins/aquarium})$  taken just before the temperature began to fluctuate in the variable temperature aquaria; such samples ( $n = 6$  for each SO) were collected to uncover SO, rather than TT (the focus of this work), differences and are not discussed further herein. Samples were frozen in TRIzol at - 20ºC until the day of extraction. The remainder of each of the 48 nubbins (2 nubbins/aquarium x 12 aquaria [3 for each of 4 SO x TT interaction groups]  $x$  2 sampling times  $[t = 0$  and 7 dl) was used for a variety of additional molecular and physiological analyses discussed in Table 1 and in prior works [15-17]. RNAs and DNAs were isolated from the same 100-mg fragments from which the proteins, discussed below, were isolated, as TRIzol permits the extraction of high quality RNA, DNA, and protein from the same biological sample [12].

#### **Protein Extraction**

Proteins were extracted from ~100-mg fragments from each of the 24 nubbins sampled at the t = 7 d sampling time (2 pseudo-replicates/aquarium x 12 aquaria) with TRIzol as recommended by the manufacturer except with 10-min sonications on ice between the washes with "protein wash I." As mentioned above, the respective RNAs and DNAs from each of the same 24 samples were already purified and analyzed [15-17]. For one of the two technical replicates from each aquarium (Figure 1C), the proteins were dissolved in 100-200 µl Laemmli sample buffer [29] without the additional of bromophenol blue (Figure 1D), boiled, spun at 12,000 *xg* for 10 min at 4ºC, and the supernatants were transferred to a new 1.5-ml microcentrifuge tube. Approximately  $20-25 \mu l$  of protein were quantified with the 2D Quant kit (Amersham Biosciences, USA), as recommended by the manufacturer. For the second of the two technical replicates from each aquarium (Figure 1E), the proteins were purified as described above except they were dissolved in rehydration buffer (8 M urea, 2% CHAPS; *i.e*., "urea/CHAPS buffer" of Figure 1E) at room temperature (RT) for 2-3 hr, with constant, vigorous agitation. Approximately 20-25 µl of protein were quantified as described above, and proteins were frozen at -80ºC.

Given that the temperature regime itself, rather than the SO, was found to have a greater influence on coral physiology based on previous analyses (Table 1), proteins to be electrophoresed across two dimensions were pooled across SO. Given the oceanographic

differences between Houbihu and Houwan, future work should, however, seek to look at SO differences in addition to TT alone, as was done herein, in order to uncover how environmental history drives the future physiological response to altered abiotic conditions. After several days of storage at -80ºC, proteins dissolved in the initial urea/CHAPs buffer were thawed, and three samples (one from each aquarium) from each of the two SO from the same  $TT$  ( $n = 6$  protein aliquots/ $TT$ ) were mixed in equimolar concentrations:

- Sample 1: 3 Houwan-stable TT samples + 3 Houbihu-stable TT samples = *1 stable TT* sample pooled across SO to be analyzed by  $2D + MS$ .
- Sample 2: 3 Houwan-variable TT samples + 3 Houbihu-variable TT samples = *1 variable TT* sample pooled across SO to be analyzed by 2D + MS.

These two, pooled protein samples were precipitated with 2 ml acetone supplemented with 0.07% beta-mercaptoethanol (BME) at -80°C for 1 hr. Protein pellets from the stable and variable TT samples were washed thrice with acetone-BME, dried on the benchtop at RT, and dissolved in 150 µl of the rehydration buffer recommended by Jacobs et al. [30]: 9.5 M urea, 2% CHAPS, 0.5% carrier ampholytes (GE Healthcare, USA), and 65 mM dithiothreitol (DTT). Samples in this "urea rehydration buffer" (Figure 1E) were vortexed vigorously for several minutes, spun at 12,000 *xg* for 10 min at 4ºC, and the supernatants were transferred to new tubes and quantified (20-25 µl aliquots) as described above.

The remaining, un-solubilized protein pellets were dissolved in 150 µl of the "thiourea rehydration buffer" (Figure 1E) described by Jacobs et al. [30]: 2 M thiourea, 7 M urea, 4% CHAPS, 0.5% carrier ampholytes, and 65 mM DTT. In general, this allowed the remaining proteins to be solubilized. Then,  $20-25 \mu l$  of these proteins were quantified as described above. Because preliminary experiments found that urea and thiourea rehydration bufferdissolved proteins presented different profiles on 2D gels (data not shown), approximately 200 µg protein from each TT and solubilization buffer were mixed to yield 400 µg protein in urea + thiourea buffer for each of the two TT, a sufficient quantity for running  $4\ 100$ -µg 2D gels (*i.e*., four technical replicates/sample) for each of the two pooled protein samples.

#### **2D Gel Electrophoresis 1st Dimension-Isoelectric Focusing**

Isoelectric focusing (IEF) was used for the first dimension of the 2D gel with the Ettan IPGphor IEF system (Amersham Biosciences). Four gels were run for each of the two TT: stable and variable, and approximately 100 µg protein were loaded into each of the eight gels. Samples, which represented a mix of proteins from samples of both SO, as well as a mix of both urea and thiourea-based buffers, were diluted to 125 µl with the addition of thiourea buffer and, if necessary, additional carrier ampholytes to where the latter was at a final concentration of 0.5%. Proteins of each of the two TT were focused at the same time on different IEF strips (*i.e.,* one of the four stable TT protein samples was run at the same time as one of the four variable TT protein samples). Along the center of the bottom of the IEF strip holder, proteins (100  $\mu$ g/TT; 125  $\mu$ ) were loaded evenly from left to right, while simultaneously ensuring that there were no air bubbles. The protective membrane was removed from the IEF strip (pH 4-7, 7 cm, Amersham Biosciences), which was then placed into the strip holder with the gel side down. Then,  $200 \mu l$  of dry strip cover fluid were

aliquoted over the strip, and the lid was placed over the strip holder. The two strip holder units (one for each of the two co-run samples) were placed in the Ettan IPGphor IEF electrophoresis chamber (Amersham Biosciences), and the following program was run at 20ºC: 50 V for 12 hr (rehydration), 300 V for 60 V-hr along a gradient, 600 V for 120 V-hr along a gradient, 1000 V for 500 V-hr along a gradient, 2000 V for 1000 V-hr along a gradient, 5000 V for 6000 V-hr, and 50 V for 10 hr. The same protocol was used on the three additional pairs of stable and variable TT samples, which were electrophoresed on different days.

#### **2D Gel Electrophoresis 2nd Dimension-SDS-PAGE**

Chromatography paper (Whatman, USA) was cut to a 1 x 0.5 cm size and overlaid with 5 µl protein marker (Fermentas PageRuler™ prestained protein ladder, Life Technologies). Then,  $\sim$  1 ml of 1% agarose was aliquoted onto a smooth sheet of plastic wrap, and the chromatography paper was placed over the agarose. An additional 1 ml of 1% agarose was then overlaid on the chromatography paper. After the agarose solidified, the chromatography paper was removed from the agarose to where a 1 mm distance was maintained around the paper. Meanwhile, the IEF strips were immersed in equilibration buffer (6 M urea, 2% SDS, 30% glycerol, 50 mM Tris-HCl [pH 8.8], 0.002% bromophenol blue, and 1% DTT) at RT for 15 min. Then, strips were transferred to the same buffer, except with 1% iodoacetamide (IAA) instead of 1% DTT, for 15 min at RT, washed with SDS-PAGE running buffer to remove residual IAA, and placed on top of a 5-14% stacking-separating Tris-glycine SDS-PAGE gel. Electrophoresis was conducted on ice at 70 V for  $\sim$ 30 min and 120 V for 1-2 hr in a Mini-PROTEAN® Tetra cell (BioRad, USA), with two samples (one stable and one variable) run at the same time. In total, eight 2D gels were run (four technical replicates for each of two TT), though only two gels were run at any given time (*i.e*., four days were required to run all eight gels).

Each of the eight gels was fixed in 50% methanol and 7% acetic acid for 30 min after removing the stacking gel. Then, the gels were stained with SYPRO® Ruby (Life Technologies) on a shaker table in the dark overnight. The gels were then destained in 10% methanol and 7% acetic acid for 30 min and imaged with a Typhoon Trio<sup>™</sup> scanner (GE Healthcare) at 312 nm (aperture  $= 2.8$ , exposure time  $= 2.4$  s). In general, there were no unique protein spots between the stable and variable TT (Figure 2A-B), though this could be due to the low amount of protein loaded (100 µg per gel). Since *Symbiodinium* density was similar between TT (Table 1), the protein spot intensity values of each of the eight gels (data not shown) were *not* normalized to a genome copy proportion (GCP) prior to the subtraction step (described below). In contrast, the target protein (RBCL) data, described below, warranted the use of a GCP given that both SO and TT effects were tested in that analysis, and a difference in *Symbiodinium* density between SO was documented previously (Table 1 and [15]).

Image analysis software (ImageQuantTL) provided with the scanner was used to perform a "subtraction" whereby the gel image of one stable TT replicate sample was overlaid on the variable TT replicate run and processed simultaneously to better portray differentially expressed proteins (Figure 2C-D). This subtraction was performed on the four pairs of stable vs. variable TT run on four different days. Because no unique spots were evident in any of the

four pairs of gels, proteins found to be expressed at significantly higher quantities by ImageQuantTL in the stable temperature gel were instead targeted, and 10 protein spots that were found to be over-expressed in all four stable TT gels (*i.e*., all technical replicates; Figure 2C) relative to their variable temperature counterparts were excised from a representative stable TT gel (Figure 2D) with sterilized 200-µl pipet tips and placed into 1.5-ml microcentrifuge tubes.

Figure 2. 2-dimensional gel electrophoresis of proteins expressed by *Seriatopora hystrix* specimens exposed to either a variable or stable temperature regime for seven days. Proteins dissolved in a urea + thiourea-based buffer were pooled between the two sites of origin (SO), Houbihu (upwelling site) and Houwan (non-upwelling site), and electrophoresed across two dimensions as described in the text. A representative 2D gel out of the four that were run for each temperature treatment (TT) has been shown for both stable (A) and variable (B) temperature specimens. Although no proteins appeared to have been solely expressed by one treatment, a total of 10 protein spots (circled in C) were found to be overexpressed by samples of the stable TT by image analysis software, and these protein spots were extracted from the gel with sterilized pipet tips (D), processed as described in the text, and submitted for sequencing by mass spectrometry (MS). The y-axis labels in (A) and (C) are shared with (B) and (D), respectively, while the x-axis labels in (C) and (D) are shared with (A) and (B), respectively. "Before" and "after" refer to before and after removing the protein spots, respectively, with sterilized pipet tips.  $pI = isoelectric point. kDa = kilodalton.$ 

The ten excised protein spots were destained and in-gel digested as follows. First, the protein + gel slabs were washed in 50% acetonitrile in 25 mM ammonium bicarbonate (pH 8.5). Then, they were incubated in 100  $\mu$ l of the same acetonitrile solution for 15 min and spun at 10,000 *xg* for 1 min. The supernatant was removed and replaced with 100 µl of 100% acetonitrile, and the samples were incubated for 5 min. The samples were spun again as above, and the supernatant was removed. The gel bits were allowed to dry for 5 min before incubation with 30  $\mu$ l trypsin (a 2  $\mu$ g aliquot that had been re-suspended in 1 ml water and 1 ml 50 mM ammonium bicarbonate) at 37ºC overnight. The next day, samples were centrifuged at 10,000 *xg* for 1 min, and the supernatant was transferred to a new microcentrifuge tube. Then, 50  $\mu$ l of 50% acetonitrile and 5% trifluoroacetic acid (TFA) were added to the remaining samples, which were then sonicated 10 times (10 s each time). Samples were centrifuged again at 10,000 *xg* for 1 min, and the supernatant was combined with the supernatant from the first spin. Another round of 50% acetonitrile/5% TFA incubation followed by sonication/spinning/supernatant collection was conducted, and the third supernatant was combined with the previous two. The supernatant was dried for 1-2 hr prior to shipping to the MS facility at Kaohsiung Medical University's (KMU) Center for Research Resources and Development's Core Proteomics facility, where the 10 protein spots were analyzed by MS, as described below.

### **MS**

After trypsin digestion,  $2 \mu l$  of the digested peptides were injected into the nano-liquid chromatography (LC) system and detected by an LTQ Orbitrap Discovery Hybrid Fourier Transform Mass Spectrometer (FTMS; Thermo-Fisher, USA) at a resolution of 30,000 coupled with a nanospray source that was executed in the positive ion mode. The Nano-UPLC system (nanoACQUITY UPLC) was purchased from Waters (USA), as were the desalting (Symmetry C18, 5  $\mu$ m x 180  $\mu$ m x 20 mm) and analytical (BEH C18, 1.7  $\mu$ m x 75 μm x 150 mm) columns. The peptide eluate from the column was directed to the nanospray source, and the MS was operated in positive ion, data-dependent mode.

#### **MS Data Analysis**

Raw data files (mascot generic format [.mgf]) were processed with Mascot distiller software (version 2.2, Matrix Science, USA) and then uploaded onto the Mascot server hosted by KMU. Several Mascot protein databases (Tables 3-4) were queried using Mascot's default search parameters. Comparison of MS data against the NCBI's nr database via Mascot yielded mainly common protein contaminants (human keratins, actins, etc.). However, upon comparing spectral data against the *Hydra magnipapillata* and *Acropora digitifera* (coral) proteomes, as well as a suite of others, a variety of both host coral and *Symbiodinium* peptides were identified. The *A. digitifera* proteome was conceptually translated previously and converted into a Mascot searchable database by Li et al. [31] and is referred to as "NMMBA" in Tables 3-4.

One of two criteria was required to have been met to determine verification of "presence" of a protein: either 1) 15 consecutive amino acid (AA) residues were sequenced or 2) two unique peptides mapping to the same protein were sequenced, and the total length of both peptides was 15 AA or more. After using Mascot to determine the likely identity of each protein, individual peptide sequences were BLASTed (BLASTp) against the NCBI database to further verify the identities of the sequenced proteins. Proteins fulfilling the minimum criteria established *a priori* were assigned a functional category from the "Pfam" database, and 2-sample proportion tests were used to determine whether proportional differences existed between compartments (coral vs. *Symbiodinium*) in the functional categories in which the identified proteins were grouped. Two-sample proportion tests were also used to determine whether was compartment was over-represented in each of the 10 spots. Bacterial proteins were excluded from analysis, though should be more carefully considered in future works given the importance of probiotic microbes in maintaining coral health.

#### **Western Blotting**

Given that significant differences in ribulose-1,5-bisphosphate carboxylase/oxygenase large subunit (*rbcL*) gene expression were documented across TT in the SHVTS [15], the respective protein, RBCL, was targeted herein for expression analysis with western blotting with a commercially available antibody from Agrisera (Sweden). Proteins (20 µg) representing one sample from each of the 12 experimental aquaria ( $n = 3$  for each of the four SO x TT groups), as well as positive controls (30 µg protein from *Pocillopora damicornis* larvae exposed to ambient temperature and  $pCO<sub>2</sub>$  from Putnam et al. [7]), were electrophoresed on two 4-10% SDS-PAGE gels as in Mayfield et al. [12]; one SDS-PAGE gel was stained with SYPRO Ruby as described above for staining of the 2D gels and visualized on a Typhoon Trio scanner for assessment of protein quality. Proteins within the second gel were transferred to a polyvinylidene fluoride (PVDF) membrane on ice at 100 V for 75 min. Afterwards, the protein-laden membrane was stained with Ponceau S (Sigma, USA) according to the manufacturer's recommendations in order to visualize degree of protein transfer.

De-stained PVDF membranes were blocked in 5% skim milk (w/v) in Tris-buffered saline with Tween-20 (TBST; 100 mM Tris-HCl, 150 mM NaCl, 0.05% Tween-20) for 1 hr at RT. The blocking buffer was decanted, and 10 ml of a 1:5000 dilution of a RBCL primary antibody (forms I and II, Agrisera) in 5% skim milk  $(w/v)$  in TBST were added to the membranes, which were then incubated for 2 hr with gentle agitation at RT. This antibody has been used successfully for detection of the RBCL of *Symbiodinium* [26], as well as other dinoflagellates [32-33]. Membranes were washed thrice (10 min each) with TBST and then incubated in 10 ml of a 1:5000 dilution of goat anti-rabbit secondary antibody (Millipore, Germany) in TBST for 5 min and washed with TBST as above. Membranes were then stained with 400 µl SuperSignal® West Pico Chemiluminescent Substrate Kit chemiluminescent reagent (Thermo-Scientific), and the chemiluminescent signal was immediately visualized on a Fusion FX7 (Vilber Lourmat, France) gel doc under the chemiluminescence setting.

ImageJ (National Institutes of Health, USA) was used to quantify RBCL protein band intensity, and values (arbitrary units) were first divided by the intensity of the positive control band on the respective gel. These gel-normalized values were then divided by the respective *Symbiodinium* GCP for each sample, which was previously calculated [15] and is routinely used to control for variable ratios in host: *Symbiodinium* biological material between samples [34]. The effects of SO, TT, and the SO x TT interaction on GCP-normalized RBCL expression were tested with a 2-factor ANOVA, which was performed with JMP® (ver.

11.1.1, SAS Institute, USA) after having log-transformed the data due to lack of normality. Then, JMP was used to determine the statistical significance of the correlation between *rbcL* mRNA expression (measured previously [15] in the same samples from which proteins were extracted herein) and the RBCL protein expression quantified herein. It was hypothesized that a significant, positive, linear relationship would be documented between expression levels of these two molecules for both TT ( $n = 6$  protein samples/TT), as well as across the dataset as a whole (n = 12 protein samples), and an  $\alpha$  level of 0.05 was set for all aforementioned statistical tests.

## **RESULTS**

#### **Differentially Expressed Proteins Uncovered by a 2D + MS-Based Approach**

It is evident from Tables 3 and 4, as well as Figure 3, that a number of different cellular processes were affected by exposure to variable temperature. Of the coral host's differentially expressed proteome (DEP; Tables 3 and S1), 18 Pfam categories could be identified, and these groupings encompassed 62 of the 75 proteins identified (83%). The only functional categories in which more than five proteins were identified with confidence (Figure 3) were DNA binding/transcription factor (n = 8; 10.7%), metabolism (n = 8; 10.7%), and mRNA processing  $(n = 15; 20%)$ . In contrast, only one transcription factor  $(2%)$  was under-expressed in *Symbiodinium* samples of the variable TT (Tables 4 and S2), and this zinc finger transcription factor was one of only two proteins found in the DEPs of both compartments (the other being the pre-mRNA splicing factor CWC22). However, the degree of homology of these proteins across compartments could not be ascertained due to the short nature of the sequenced peptides (17-20 AA).

There were only two functional categories that encompassed multiple proteins and were represented in each of the two eukaryotic DEPs of this association: metabolism and mRNA processing. Regarding the latter, although mRNA processing is surely a cellular process that could be hypothesized to undergo differential regulation during periods of temperature change, the fact that the majority of the proteins aligned most closely to published fungal proteins precluded the ability to confidently ascribe them to one compartment; in fact, many were equally homologous to bacterial proteins (see annotations in Tables 3-4.). Therefore, while these mRNA processing proteins are *likely* involved in the coral and/or *Symbiodinium* response to variable temperatures, their relative importance has been downplayed in this manuscript until longer peptide sequences can be obtained and the compartment of origin more confidently assigned.

Regarding the second functional category that featured multiple proteins for both eukaryotic compartments of this reef-building coral, eight and nine metabolism-targeted proteins were over-expressed in stable TT samples of the host coral and *Symbiodinium* compartments, respectively (Figure 3), and one such *Symbiodinium* protein, lipoxygenase, is known to play a role in lipid metabolism. Also pertaining to lipids/lipid metabolism, one process that was over-represented in the *Symbiodinium* DEP relative to the host coral one was lipid bodies (LBs); nearly 1/3 of the *Symbiodinium* DEP (Figure 3) was comprised of proteins involved in stabilization and metabolism of LBs, notably oleosins and caleosins.

Figure 3. Functional distribution of the host coral and *Symbiodinium* differentially expressed proteins. Percentage breakdown of Pfam functional groups encompassing the 75 host coral (outer pie graph) and 42 *Symbiodinium* (inner pie graph) proteins that were over-expressed in samples exposed to a stable temperature regime. Functional categories that were over-represented in the *Symbiodinium* differentially expressed proteome (DEP) relative to the host DEP (2-sample proportion test,  $p < 0.05$ ) have been marked with an asterisk (\*).

### **RBCL Western Blot**

The *Symbiodinium* populations (clade C only [15, 17]) housed within corals exposed to the variable TT for seven days expressed the RBCL protein (Figure 4) at similar levels between the four SO x TT groups ( $n = 3$ ; Figure 4B-C), and, furthermore, there was no significant, positive correlation between *rbcL* mRNA and RBCL protein expression across the 12 samples of the SHVTS collected after seven days of treatment exposure (Figure 4D).

Figure 4. RBCL protein expression. Proteins were electrophoresed as described in the text, and a representative SDS-PAGE gel including a ladder, a positive control sample (30 µg of soluble protein from *Pocillopora damicornis* larvae [7]), and several proteins from each of the two sites of origin (SO) have been shown (**A**). A 55-kDa protein was detected with an RBCL (forms I and II) antibody, and representative bands from different SO and temperature treatments (TT) have been shown (**B**). The positive control sample also yielded a ~55-kDa band (data not shown). RBCL expression was normalized to a proxy for *Symbiodinium* density within samples, the genome copy proportion (GCP), and normal quantile plots (with averages connected by solid diagonal lines) for samples of both SO and TT have been shown  $(C)$ . Error bars represent standard error of the mean  $(n = 3$  for each SO x TT group), and the 2-way ANOVA (SO x TT) *p*-values have been presented on the figure. The global (pooled across SO) variable and stable TT expression levels have been plotted as horizontal solid and dotted lines, respectively. Expression of the RBCL protein (normalized to the *Symbiodinium* GCP) was plotted against expression of the respective *rbcL* mRNA (normalized to both the Solaris® [Thermo-Scientific] RNA spike and the *Symbiodinium* GCP), which was measured in a previous study [15], and best fit lines have been plotted for data of both the variable (solid line) and stable (dotted line) TT (**D**).

#### **CONCLUSION**

Curiously, no proteins were uniquely expressed by one treatment and not the other, nor were any proteins expressed at higher levels in samples of the variable TT. One explanation for this could be the low quantity of protein loaded; mini-gels  $(\sim 10 \times 10 \text{ cm})$  were used herein with 100 ug protein, and many spots on the gels were fairly faint. This may have limited the ability to detect proteins that were over-expressed by the variable TT samples, and future studies attempting to look at proteome-scale differences between experimental coral samples may consider loading larger quantities (*e.g.,* 500 µg) of protein into the gels. Furthermore, proteins were pooled across two SO of differing environmental history; although preliminary data revealed that the effect of TT led to greater variation in the *S. hystrix*-*Symbiodinium* physiological response than did the SO (Table 1; [15-17]), future work should nevertheless seek to determine the extent to which environmental history drives the ability of this common, widely distributed coral species to acclimate to future changes in temperature, using samples collected both before and after experimentation. Corals from Houwan, a site that never experiences upwelling *in situ*, were, in contrast to what had been hypothesized, readily able to acclimate to a temperature regime that fluctuated from 23 to 29ºC over a 6-hr period; it would be interesting to know if the protein-level acclimation response differed between these corals and those of Houbihu, which *do* experience such highly variable temperatures *in situ*.

Despite the potentially low resolution of the approach utilized herein, 117 proteins were nevertheless found to be expressed at higher levels in samples exposed to a stable TT for one week relative to those exposed to a variable TT for this same duration. The majority of these proteins (64%) were from the coral host, with the remaining 36% from the *Symbiodinium* populations housed within these samples. This  $\sim$ 2:1 ratio of host/endosymbiont agrees well with biological composition estimates made with other pocilloporids [13]. It should be noted that the fact that the coral host comprises a greater fraction of the holobiont means that differentially expressed proteins will be more readily documented for this compartment due to having loaded a larger quantity of coral protein *(i.e.*, ~64 µg coral host protein/100 µg total holobiont protein) into the gels.

Although *rbcL* mRNA expression was significantly higher in *Symbiodinium* populations harbored within *S. hystrix* colonies of the variable TT [15], the expression of the respective protein was not only similar between TT, but also between SO. As such, it was unsurprising that RBCL was *not* found to be differentially expressed between TT by 2D + MS analysis. Furthermore, *rbcL* gene expression did not correlate positively with RBCL protein expression to a significant degree across the 12 samples. This lack of correlation may suggest that inferring protein expression differences based only on mRNA-scale data, as is common in the coral biology field (e.g., [9-10, 35]), is risky. Additionally, the respective proteins of none of the differentially expressed genes identified in these same samples [15, 17], such as photosystem I (*psI*), were sequenced herein, further pointing to an absence of significant, positive correlation between gene and protein expression in this coral-*Symbiodinium* holobiont. As a final example, expression of no heat shock protein (*hsp*) mRNA was found to be affected by variable temperature exposure in these samples [15, 17], yet a small HSP was found by 2D gel electrophoresis to be down-regulated in host corals exposed to variable temperatures for seven days.

Although next generation mRNA sequencing has yielded marked insight into the molecular biology of cnidarian-dinoflagellate endosymbioses [13], the observation made herein that there is not always a positive association between mRNA and protein expression suggests that researchers should heir on the side of caution when attempting to use their mRNA data to make predictions about how corals will respond to environmental change. Rather than an end-all, such RNA Seq-based endeavors may be better seen as a means to target specific *proteins*, rather than gene mRNAs, for future, molecular characterization studies. Though not without their own limitations,  $2D + MS$ -based methods yield direct insight into the molecules that actually carry out essential cellular processes; such proteins, of which several are discussed below, may better serve as biomarkers of the coral response to environmental changes, and notably GCC.

Upon a comprehensive look at the proteins that were down-regulated after seven days of exposure to variable temperature in the *S. hystrix-Symbiodinium* holobiont, it appears that different cellular processes were affected in each compartment. From an evolutionary perspective, eukaryotic cells are expected to respond similarly to changes in temperature [14, 36]. However, given the extensive evolutionary divergence between cnidarians and protozoans, it is unsurprising that some unique pathways were differentially affected by variable temperature exposure between the two endosymbiotic constituents. One group that merits further mention is the LB-associated proteins, oleosin and caleosin. The former is an abundant structural protein that acts to stabilize LBs, which are absent from asymbiotic or aposymbiotic cnidarians, by preventing their coalescence [37]. Caleosin is thought to play a role in the degradation of LB lipids in higher plants [38], though its ancestral role appears to be as another structural protein found on/in the coat of LBs [39]. As caleosin and oleosin are plant proteins, they were almost surely synthesized by the *Symbiodinium* cells. However, it cannot be ruled out that these proteins migrate alongside the LBs as they flow between compartments (discussed in more detail below). For the sake of argument, the remainder of this discussion will assume that these proteins are ultimately of dinoflagellate origin.

Endosymbiotic anthozoan LBs are thought to be involved in the metabolic dialogue between host anthozoans and their *in hospite Symbiodinium* populations [27, 37]; these organelles have been shown to flow back and forth between hosts and endosymbionts as a means of transferring lipids [24]. It seems reasonable to speculate, then, that the decrease in oleosin and caleosin expression in *Symbiodinium* within corals exposed to variable temperature for seven days may suggest that LB metabolism differed fundamentally between TT; perhaps the down-regulation of these two proteins under variable temperatures insinuates that LBs were being metabolized, since proteins that catabolize LB lipids could more readily interact with LBs upon the absence of these integral coat proteins. This presumed upregulation of LB metabolism may have allowed for these *Symbiodinium* populations to sustain sufficient energy levels to maintain homeostasis under periods in which cellular energy demand could be hypothesized to be high due to, for instance, elevated rates of protein turnover brought on by these rapid temperature changes.

However, it should be noted that caleosin and oleosin are also known to have roles in lipid metabolism [40-41], and so their down-regulation, alongside a decrease in expression of another lipid-metabolizing protein, lipoxygenase, at variable temperature could, in contrast, suggest a decrease in LB metabolism. Indeed, the overall down-regulation of proteins involved in a variety of cellular pathways, notably metabolism, at variable temperatures in both compartments of this endosymbiosis may ultimately speak to this need to conserve energy for growth, which was similar between temperature regimes (Table 1 and [15]), by suppressing certain metabolic pathways. As evidence for this, *Symbiodinium* have been found to actually *accumulate* lipids and LBs when deprived of nitrogen [42]. Future work should, then, seek to uncover the role of proteins involved in LB stabilization and metabolism in the response of *in hospite Symbiodinium* populations to environmental change; without further immuno-localization studies, it is premature to conjecture where these LB metabolic changes, in fact, took place, within the host coral or within the *Symbiodinium* cells. Such studies should also attempt to observe LB metabolism during stress events in order to determine whether they are more likely to be synthesized/accumulated, as when undergoing nutrient stress, or catabolized at such times. The ensuing data could help to develop a more comprehensive cellular model of how reef-building corals acclimate to highly variable temperature exposure both *in situ* and in the laboratory.

#### **ACKNOWLEDGMENTS**

This work was funded by the National Science Foundation (NSF) of the United States of America via an international postdoctoral research fellowship to A.B.M. (OISE-0852960). A.B.M. was also supported by a postdoctoral research fellowship from the Khaled bin Sultan Living Oceans Foundation. Dr. Tung-Yung Fan and Ms. Pei-Hsun Chan are thanked for their assistance with the collection of the samples and the performing of the experiment. Gratitude is also given to Dr. Shao-En Peng for his assistance in introducing us to the proteomics facility. The Research Center for Environmental Medicine of KMU (KMUTP103) is appreciated for instrument support. Finally, thanks are given to Dr. Pei-Ciao Tang, who helped to conduct the western blots, and to Dr. Hollie Putnam for fruitful discussions pertaining to the dataset.

#### **AUTHOR CONTRIBUTION STATEMENT**

A.B.M. conducted the experiment, processed the samples, analyzed the data, and wrote the manuscript. Y.-J.C. and C.-Y.L. ran the 2D gels and sequenced the proteins, respectively. C.-S.C. provided laboratory space, facilities, and reagents that were instrumental to the success of the project. A.B.M. declares that the authors have no competing interests.

# **ARACHIDONIC ACID DISTRIBUTION IN SEAWEED, SEAGRASS, INVERTEBRATES AND DUGONG IN CORAL REEFAREAS**

## *A. Suloma<sup>1</sup> , H. Fruita<sup>4</sup> , D. R. Chavez<sup>2</sup> , E. S. Garibay<sup>3</sup> and H. Y. Ogata<sup>4</sup>*

<sup>1</sup>Animal Production Department, Faculty of Agriculture, Cairo University, Giza, Egypt 2 INVE Asia Services Ltd., Tambon Bangpood, Amphur Pakkred, Nonthaburi, Thailand (the former affiliation) <sup>3</sup>Aquaculture Department, Southeast Asian Fisheries Development Center, Iloilo, Philippines <sup>4</sup>National Research Institute of Aquaculture, Fisheries Research Agency, Mie, Japan

#### **ABSTRACT**

Fatty acid composition was determined in seven species of seaweed, four species of seagrass, 17 species of invertebrates and dugong (mammal) sampled in coral reef areas in the Philippines. The data obtained indicated that Arachidonic acid (ArA) was not a minor component, and ArA distributes widely in coral reef organisms. Seagrass had high linoleic acid and linolenic acid levels with low ArA, EPA and DHA levels, while some species of seaweed had intermediate or high ArA levels (5% to 12%). In starfish, sea cucumber and some species of corals, ArA was the first major fatty acid (20% to 30%), but DHA levels were very low. Bivalves, abalone and shrimps had intermediate ArA levels. Total lipids of abdominal muscle and liver of dugong had respectively ArA levels of 7.8% and 11.0%, which were higher than EPA levels (2.4% and 1.6%), but DHA levels (0.4% and 2.3%) were low. It is clear that ArA is a major fatty acid in coral reef animals. Thus, intermediate or high ArA levels appear to be universally found in coral reef animals. However, the origin of ArA is not still clear. Micro-organisms on the bottom or in the soil and/or macro-algae may be the sources. Although it is highly speculative, the present results suggest that the existence of an ArA-rich food chain may be widespread in coral reef areas, and that the widespread existence of ArA-rich food

chain may lead to intermediate or high ArA contents in coral reef species. This speculation does not rule out the possibility that coral reef animals might have the ability to convert linoleic acid to ArA.

**Keywords:** fatty acid, arachidonic acid, DHA, EPA, coral reef, seagrass, seaweed, invertebrates, dugong

#### **1.INTRODUCTION**

Marine fish and invertebrate fatty acid signatures will be affected mainly by diet, as well as to some degree by the biosynthesis of certain fatty acids. Diets within and among fish and invertebrate species will in turn reflect characteristics of the prey field as well as morphological constraints and life style of the predators. Lipids, and especially fatty acids, have long been used as biological markers and general indicators of diet in marine ecology (Sargent et al. 1988). Animals can biosynthesize a relatively limited number of fatty acids (Cook 1985). These biochemical restrictions, coupled with the fact that fatty acids in the marine food web are exceptionally complex and diverse, provide the opportunity to use fatty acids for understanding food habits and nutrients requirements for marine fish.

Arachidonic acid (ArA) is an essential fatty acid but a minor component especially in cold and temperate water species. The abundance of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) in marine animals has been emphasized in view of the importance in aquaculture, while little attention has been given to the existence and importance of ArA. However, preliminary studies, which aimed at developing advanced diets for improving fry production technologies of tropical fish, ovaries, eggs and fry of mangrove red snapper were unexpectedly found to have intermediate or high ArA levels and relatively low EPA levels (Ogata et al. 2004; Suloma and Ogata 2011). This phenomenon was also found in two species of rabbitfish, coral trout and striped jack sampled in the Philippines (Ogata et al. 2004). The result suggests that ArA may be much more important in fry production of coral reef associated species compared with cold/temperate species. Together with a series of feeding studies on dietary ArA and reproduction/larval quality, we have investigated the distribution of ArA in mangrove and coral reef. In the present chapter, data of fatty acids distribution in seaweed, seagrass, invertebrates and dugong in coral reef areas *will be presented to speculate the possible source of ArA in coral reef food-web*.

#### **2. METHODOLOGY**

Samples from invertebrates (Crustaceans, Mollusks, Echinoderms, Cnidarians and Poriferans) and aquatic plant (Seaweeds & Seagrass) were collected from coral reef areas in the Philippines. Table 1 lists common names, scientific names, sampling places and the time of samplings. Abdominal muscle and liver tissues of dugong were provided from a local fisherman who found a dead dugong on a beach (Pandan, Antique). Fatty acid composition of total lipids was determined for seaweed, seagrass, acetes and dugong. Fatty acid compositions of both polar (PL) and neutral (NL) lipids were determined for other invertebrate species. All the samples were freeze-dried and stored at-80℃ until lipid extraction. The extraction of lipids from freeze dried samples was carried out with a mixture of chloroform and methanol (2:1, v/v) containing 0.01% butylhydroxytoluene (BHT). Total lipids were separated into polar and neutral lipids with a silica cartridge. Fatty acid methyl esters (FAME) were prepared and purified with thin-layer chromatography. FAME were analyzed on a gas liquid chromatography. Individual FAME were identified using reference standards.

#### **3. FATTY ACID COMPOSITION**

#### **I. Invertebrates**

In general, linoleic acid and linolenic acid in both neutral and polar lipids were trace components in all the invertebrate species examined. ArA in all invertebrate samples showed higher levels especially in PL, and ArA was superior to EPA in all samples, and in some samples superior to DHA. ArA levels ranged between 1.26 %- 30.18 % in polar lipid and 0.83%-5.63% in neutral lipids. High or intermediate ArA levels were found in polar lipids of jellyfish (9.3%), sponge (5.9%), starfish (28.7%), sea urchin gonads (10.0%) and sea cucumber (17.4%). ArA was the first major fatty acid in starfish, *Asterias sp*. In sea cucumber, EPA (not detected) and DHA (0.7%) levels were very low. ArA content is remarkably higher in tropical holothurians than in the temperate species (Svetashev et al. 1991). DHA was not detected in starfish, and DHA level was very low in sea urchin gonads (0.70%). These invertebrate species may be good sources of ArA, but it should be noted that the balance of DHA and ArA is poor in these species.

#### *Corals*

Two species of corals, *Sarcophyton* sp. (22.7%) and *Dendronephthya* sp. (30.2%), had very high ArA levels in their polar lipid fraction (Tables 3 and 4). By contrast, ArA levels in *Millepora platyphylla* (2.3%) and *Nephthya* sp. (3.5%) were not high. At present, we cannot explain the reason for the extreme difference in ArA level among the coral species. *Nephthya sp*. also had low EPA (0.9%) and DHA (0.9%) levels (Table 2). In other coral species, EPA and DHA levels ranged from 1.9% to 6.1% and from 6.1% to 9.4%, respectively.

#### *Crustaceans*

In four crustacean species (torpedo shrimp, mantis shrimp and swimming crab for polar lipids and *acetes* for total lipids), ArA levels (3.7% to12.3%) were always lower than EPA levels (9.5% to15.0%) (Tables 4 and 5). However, ArA levels in these crustacean species were not low compared to cold/temperate water species. Especially ArA level of swimming crab was 12.3%. DHA levels ranged from 6.5% to16.6% in polar lipid of these crustacean species.

In tropical paracalanid copepods, EPA level is higher than ArA level with DHA/EPA/ArA ratios of 14:3:1 for Acartia sinjiensis, 20:9:1 for Parvocalanus crassirostris and 25:6:1 for Bestiolina similes, respectively (McKinnon et al. 2003). Thus, planktonic crustaceans do not appear to be the primary source of ArA.

#### *Shells*

Abalone had a high ArA level (13.8%) and low EPA (2.3%) and DHA (0.4%) levels (Table 6) in polar lipids. Scallop had a high DHA level (22.0 %) and intermediate ArA (4.8%) and EPA (4.9%) levels in polar lipids. ArA, EPA and DHA levels were 6.5%, 5.8% and 11.6% for mussel in polar lipids. ArA levels were equivalent to or higher than EPA levels in the shells in coral reef areas.

**Table 8. Fatty acid composition of coral reef associated invertebrates**

## **Table 9. Fatty acid composition of coral reef associated seaweeds**

## **Table 10. Fatty acid composition of coral reef associated seaweeds**

## **Table 11. Fatty acid composition of coral reef associated sea grass and dugong**

#### **II. Aquatic Plants**

Fatty acid composition of aquatic plants samples showed low ArA, EPA and DHA levels compared to invertebrates samples. The seagrass samples had low levels of ArA compared to seaweeds samples.

#### *Seaweed and Seagrass*

Substantial levels of ArA (3.2 % to 12.9%) in the total lipids were detected in seaweed excluding *Ulva faciata* (Table 9). A species of *Corallinaceae* contained 12.9% of ArA in the total lipid. Aquaculture species, *Kapaphycus* and *Gracillaria*, had ArA levels ranging 5.1% to 6.8% and EPA levels ranging 1.8% to 8.5%, and very low DHA levels (Table 10). Linoleic acid (0.3% to 5.6%) and linolenic acid levels in seaweed were low compared to those of seagrass. *Kapaphycus* and *Gracillaria* might be useful as feed ingredients to provide ArA and EPA.

Four species of seagrass had high linoleic acid (LA: 7.5% to 22.2%) and linolenic acid (LNA: 13.9% to 16.5%) levels with low ArA (0.3% to 2.3%), EPA (0.4% to 3.6%) and DHA (0.2% to1.3%) levels in the total lipids (Table 11). Other major fatty acids in seagrass were 16:0 (21.3% to 29.5%) and 16:1n-7(10.8% to13.7%).

Renaud et al. (1999) investigated fatty acid composition of 18 species of tropical Australian microalgae. Only two pelagic species, *Nitzschia* sp. and *Fragilarias* sp. had relatively high ArA levels equivalent to EPA levels, but in the remaining 16 species, EPA was the major HUFA and ArA level was low. EPA was also the major HUFA in tropical phytoplankton sampled from coastal waters of the South China Sea during one year cycle (Shamsudin, 1998). Thus, planktonic microorganisms do not appear to be the primary source of ArA even in tropical waters. High ArA levels are found in some species of marine red and brown seaweeds from both temperate and tropical waters, although this phenomenon is not always limited to tropical areas (Johns et al. 1979; Dembitsky et al. 1991; Vaskovsky et al. 1996). Nevertheless, red and brown seaweeds may be at least one of the sources.

#### **III. Dugong**

The total lipids of abdominal muscle had linoleic acid of 5.2%, linolenic acid of 1.4%, ArA of 7.8%, EPA of 2.4% and DHA of 0.4%, respectively (Table 11). The total lipids of liver had linoleic acid of 8.3%, linolenic acid of 1.2%, ArA of 11.0%, EPA of 1.6% and DHA of 2.3%, respectively. Other major fatty acids in the muscle and liver were 16:0 (17.8% and 16.8%), 16:1n-7 (8.1% and 3.6%), 18:0 (9.9% and 15.3%), 18:1n-9 (26.2% and 20.2%) and 22:5n-3 (2.6% and 3.8%).

ArA–derived eicosanoids have been identified in many fish species and have a wide range of physiological functions including control of fluid and electrolyte fluxes, the cardiovascular system, reproductive function and control of the neutral system (Mustafa and Srivastava 1989 and Johnston et al. 1983). Suloma and Ogata (2011) suggested that coral reef, in particular demersal fish appear to have a comparable ArA/EPA ratio with freshwater fish rather than cold and temperate water marine fish. Suloma and Ogata (2011) reported that the

testes of the coral reef fish have higher ArA levels and ArA/ EPA ratios than those of cold and temperate water species. This may imply that ArA is more important for coral reef fish.

The present data provide an insight into fatty acids flow through the coral reef community. It is widely accepted that fatty acid composition of fish tissues reflects dietary fatty acid composition. Our previews results suggest that muscles and gonads from carnivore species tend to contain ArA acids more than those from herbivores species in coral reef waters (Suloma & Ogata 2011 and Ogata et al. 2004). Thus the fatty acids profile of invertebrate and aquatic plants samples in the present study might answer why there are differences in ArA levels of coral reef fish families. Lutjanida, *Lethrinidae*, *Serranidae* and *Labridae*, which are carnivore species, had higher ArA levels compared to Siganidae species which are a browsing herbivore.

Scarce data are available on fatty acid composition of benthic prokaryotes and eukaryotes, bacteria, fungi and protozoa towards the beginning of ArA source in tropical marine food chain. The present result, high ArA levels in coral reef fish, suggests that the existence of an ArA-rich food chain may be widespread in coral reef areas, and that the widespread existence of ArA-rich food chain may lead to comparatively higher ArA contents in the coral reef fish. However, the origin of ArA in the coral-reef food web is still unclear.

## **CONCLUSION**

From our previous and present studies we found that in general ArA was high and superior to EPA in coral reef fish compared to cold and temperate fish in all tissues studied. However, the origin of ArA is not still clear. Micro-organisms on the bottom or in the soil and/or macroalgae may be the sources. Although it is highly speculative, the present results suggest that the existence of an ArA rich food chain may be wide spread in coral reef areas, and that the wide spread existence of ArA-rich food chain may Lead to intermediate or high ARA contents in tropical species. This speculation does not rule out the possibility that coral reef animals might have the ability to convert linoleic acid to ArA. The information in the present study would be suggestive for development of appropriate grower and broodstock and larval diets, to ensure high egg and larval quality of sustainable hatchery production in coral reef areas.

#### **ACKNOWLEDGMENTS**

The present study was financially supported by the collaborative project titled "Studies on Sustainable Production Systems of Aquatic Animals in Brackish Mangrove Areas" between Japan International Research Center for Agricultural Sciences, Japan and the Aquaculture Department, SEAFDEC, Philippines. A part of this study was supported by the Tsukuba Visiting Researcher Invitation Program of JIRCAS (Ashraf Suloma, Dec., 2004 to Nov., 2005, Cairo University, Egypt).

# **CORAL SKELETONS AS A RECORDER OF METAL POLLUTION: ENVIRONMENTAL MONITORING IN THE GULF OF THAILAND**

## *Shigeru Ohde1,\* , Kentaro Tanaka<sup>1</sup> , Monthon Ganmanee<sup>2</sup> and Cameron W. McLeod<sup>3</sup>*

<sup>1</sup>Faculty of Science, University of the Ryukyus, Nishihara, Okinawa, Japan <sup>2</sup>Faculty of Agricultural Technology, King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand <sup>3</sup>Centre for Analytical Science, Department of Chemistry, University of Sheffield, Western Bank, Sheffield, United Kingdom

## **ABSTRACT**

Coral skeletons provide useful information on aquatic environments in which corals grew, and they also offer to use as recorders of pollution history from urbanized hinterlands to coral reefs. In order to monitor pollutant discharges from urban areas to the Gulf of Thailand since the 1980s, we collected *Porites* corals from Khang Khao Island about 50 km southeast of Bangkok in 1985, 1998, 2001 and 2008. The coral collection periods since the 1980s coincided with a series of laws enacted by the Thai government to curb environmental pollution. To determine the skeletal growth of the samples, oxygen isotopes ( $^{18}O/^{16}O$  as  $\delta^{18}O$ ) in coral aragonite was measured by stable isotope mass spectrometry. A cyclical change in  $\delta^{18}O$  is observed to record an annual change in seawater salinity, and then the coral growth rate is estimated at  $\sim$ 18 mm/year on average. Using the skeletal  $\delta^{18}O$  method, the coral chronology was established in the Gulf of Thailand. Nest we used a recently developed laser ablation inductively coupled plasma

 $\overline{a}$ 

<sup>\*</sup> Corresponding Author's Email: sohde@sci.u-ryukyu.ac.jp.

mass spectrometry (LA-ICP-MS) method to assess the impact of metal pollution on coral skeletons taken from the Gulf of Thailand since the 1980s. The extent of anthropogenic contribution by riverine input to the gulf, including aerosol deposits, was assessed by comparing metal-calcium (Me/Ca) ratios of Khang Khao corals to those of Rukan-sho, a relatively unpolluted coral reef, Okinawa. In this comparison, high riverine inputs of Ba, V, Cd and Pb were observed from the Me/Ca values in the Thai coral samples. Since Ba concentration in seawater around Khang Khao Island largely depends on input from the rivers, especially the Chao Phraya River, the Ba/Ca ratios in Khang Khao corals reflect by the high concentrations of riverine input, showing cyclical variations like those of oxygen isotopes in the coral samples. The V/Ca ratios of Khang Khao corals showed a higher average value than that of the Rukan-sho coral, suggesting anthropogenic vanadium inputs due to fuel oil pollution in the Gulf since the late 1990s. Higher Cd/Ca ratios were observed in Khang Khao corals compared to that of Rukan-sho coral, indicating that the Cd concentration in the Gulf continuously suffered from anthropogenic input since 1983. The levels of Cd in the coral indicate a gradual decrease in the Gulf in the late 1990s, with a drastic drop in concentration from the 1980s. The historical variation in Pb/Ca ratios recorded in the coral skeletons suggests the Gulf of Thailand suffered from anthropogenic lead from 1985 to 2001. The Pb/Ca values recorded in Khang Khao Island corals suggest that the Gulf has been polluted by anthropogenic Pb from the early 1990s. After the use of leaded gasoline was banned in Thailand since 1995, the Pb/Ca in the Khang Khao Island corals showed a remarkable decrease, indicating that regulatory control has limited anthropogenic Pb inputs to the Gulf of Thailand. In conclusion, the coral archival record of the metals (V, Cd, Hg and Pb) strongly suggests the success environmental of the laws and regulations by the Thai Government introduced since the middle 1990s.

#### **1.INTRODUCTION**

Sediments are chemical fossils that record global and local environmental changes in water media. However, the record from sediment data could be altered by human activities such as dredging and processes like remineralization and recrystallization. Compared to sediments, coral aragonite  $(CaCO<sub>3</sub>)$  is a better proxy tool and remarkably provides a more faithful representation of environmental metal loads. Corals are deemed to be very useful indicators of pollution level because their skeletons assimilate records of certain metals over hundreds of years (Esslemont, 1999). The composition of coral skeleton reflects the extent of pollution caused by heavy metals or nuclear wastes (Scott, 1990). *Porites* corals, for example, can function as recorders of mining and environmental impacts (Fallon et al., 2002; David, 2003; Edinger et al., 2008). A comparison with the natural background of the area could then provide the basis for identifying influences of local human activities on coral reefs.

During the formation of  $CaCO<sub>3</sub>$ , metal ions are taken up by the aragonite lattice, according to an ion-exchange reaction, i.e.,  $CaCO_3 + Me^{2+} = MeCO_3 + Ca^{2+}$ . The metal-tocalcium (Me/Ca) ratio of coral aragonite is mainly controlled by three factors: (1) the distribution coefficient of the metal ion between aragonite and seawater, (2) the  $\text{Me}^{2+}/\text{Ca}^{2+}$ ratio of the surface oceanic water, and (3) biological effects. Biological effects are possibly negligible when the same coral species is used.

Certain Me/Ca ratios in corals have been well documented as a mean to evaluate aquatic environmental conditions in which the corals grew. For instance Sr/Ca in seawater is uniformly distributed in the world's oceans. Because Sr distribution coefficients are controlled by temperature, Smith et al*.* (1979) clarified that Sr/Ca ratio in coral skeleton could be used as a thermometer. This Sr/Ca thermometer is now currently used to track sea surface temperature (SST). There is also the promise of using the Mg/Ca ratio along with the  $Sr/Ca$ ratio because the former varies with SST change about four times greater than that of the coral Sr/Ca ratio (Mitsuguchi et al., 1996). As a coral recorder for pollution use, Shen and Boyle (1987) showed that Pb/Ca in coral skeleton increased in the 1940s due to the use of leaded fuels for motor vehicles. Bastidas and Garcia (1999) have also confirmed that Pb/Ca ratio could be applied as a recorder of marine pollution from anthropogenic activities. In order to assess lead contamination due to rapid development near a coastal area, Bangkok, Tanaka et al*.* (2010) measured Pb/Ca in *Porites* coral. Similarly, other Me/Ca ratios in corals might be used to extend the pollution assessment to other metals present in the ambient seawater (Tanaka et al., 2013).

As is well known, the ecological balance is disturbed by land-use changes and associated river discharges (West and van Woesik, 2001) that contain sediments contaminated by trace metals (Elbaz-Poulichet et al., 1984; Bastidas et al., 1999). Rivers are subject to discharges of wastewater as an inevitable result of urbanization. Untreated sewage coming from domestic and industrial sources is transported from the rivers to the estuary, carrying pollutants like heavy metals. The adverse effects of these pollutants is evident in the coastal environment, e.g., reduced biodiversity, diminished productivity and even the death of certain corals. Although there are marine species that can thrive under relatively high metal concentrations (Miao et al., 2001), the difference in species-specific response due to biochemical utility or toxicity (Esslemont et al., 2000) may prove deleterious to other life forms in which low metal concentrations can significantly affect the fertilization process (Reichelt-Brushett and Harrison, 1999). Pollution from sewage and heavy metals might contribute to the collapse of reef ecosystems adjacent to the river mouth and lead to the loss of estuarine habitats (Zann, 2000).

Riverine transport is regarded as an important pathway for input of nutrients to the coastal environment. Riverine nutrient loads of nitrogen, phosphorus and silica have been known to limit biological primary production in coastal areas. For example, phosphate deficiency in coastal areas could preclude the dominance of diatoms in the phytoplankton community (Egge, 1998). In some cases, nutrient input may generate eutrophication which enhances photoplankton growth. Because river discharge is a major source of both nutrients and heavy metal pollutants, it is appropriate to measure the chemical composition of rivers and estuarine areas, in the interest of pollution monitoring. Several studies have been carried out to assess the metal content of river water, colloidal particles and sediments in estuary (e.g., Banat and Howari, 2003; Ramos et al*.*, 2004; Wijaya et al*.*, 2012; 2013). To better understand the anthropogenic impact of metals in the coastal environment, it is therefore critically important to study river transport and discharge to the estuary and to monitor the metal contents in reefs adjacent to the river mouth.

Coral reefs are widely distributed along the coasts of the Gulf of Thailand. This region, which includes the capital of Thailand, Bangkok, has experienced rapid urbanization and industrialization in the last two decades. The impact of heavy metal pollution in Bangkok has been studied to assess the effects of urbanization and industrialization on the environment

(Mukai et al., 1993; Cheevaporn et al., 2004). Lead isotopes in airborne particles collected from Bangkok suggest that the main source of Pb has been the use of leaded gasoline (Mukai et al., 1993). Since four rivers discharge into the northern coast of the Gulf after running through the urbanized and industrialized areas, the impact of heavy metal pollution on aquatic environments in Thailand has also been investigated (Hungspreugs et al., 1989; Cheevaporn and Menasveta, 2003). The Chao Phraya River, the largest river in Thailand, is heavily affected by a variety of anthropogenic activities along its length. There are numerous sources of domestic and industrial effluents that lead to heavy metal enrichment in water and sediments. Indeed, at the mouth of the Chao Phraya River, which runs through Bangkok, a relatively higher heavy metal concentration was observed from river water and sediments (Hungspreugs et al., 1989; Wijaya et al., 2013).

To date, only a few studies have assessed the impact of metal pollution in Thai coral reefs (Hungspreugs et al., 2002; Tanaka et al., 2010; 2013). Corals are often chosen as samples in such studies as their colonies live for long periods of time and their aragonite skeletons often have growth bands that show a clear chronology of their lifetime. Using such skeletons, laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) has been used to measure heavy metals to understand trends in historical pollution in coastal areas (Alibert et al., 2003; Edinger et al., 2008; Tanaka et al., 2013). The coralline archival approach is now viable because newly developed LA-ICP-MS methodology makes it possible to measure onedimensional and two-dimensional trace metals' distribution in coral carbonates. Here we present recent changes in heavy metal distribution in corals from Khang Khao Island examining the period from 1982 to 2008. The coral archive provides a means to examine the health status of the current coastal environment in the Gulf of Thailand such that it can be preserved for the benefit of the Thai people.

## **2. MATERIALS AND METHODS**

#### **2.1. Study Location**

The Gulf of Thailand is located in the southwest of the South China Sea (Figure 1a), with its upper portion bounded by the Thai coast (Figure 1b) and characterized by limited water exchange with the open ocean (Hungspreugs and Yuangthong, 1983). Four rivers (the Chao Phraya, the Mae Kong, the Ta Chin, and the Bang Pakong) flow into the northern coast of the Gulf; the largest among them being the Chao Phraya River, which has a drainage area of ~177,000 km<sup>2</sup> and an annual average flow rate of >1000 m<sup>3</sup> s<sup>-1</sup> (Hungspreugs et al., 1989) and it runs through both urbanized and industrialized areas in Bangkok before it discharges into the Gulf. The suspended matter concentration in the river mouth has been estimated to be over 100 mg/L (Cheevaporn and Menasveta, 2003). The sampling site, Khang Khao Island (13˚09′N, 100˚48′E), is located in the upper Gulf about 40 km southeast of the river mouth of the Chao Phraya and directly south of the island of Ko Sichang (Figure 1b). Sea surface temperature (SST) was measured using a standard mercury thermometer (minimum unit: 0.1°C, precision:  $\pm$  0.05°C) at the sampling site (water depth: ~0.5 m) of Khang Khao Island when we collected the coral samples from 1998 to 2008 (see Figure 1b). On 10 November 1999, a Tidbit temperature logger (Stow Away, USA) was also set up at the study site to

record *in situ* seawater temperature every 1 hour. The logger was collected on 15 March 2001 and the recorded SST's were downloaded at the laboratory.

To serve as a reference for the relatively pristine, un-contaminated coral community, a sample was also taken from Rukan-sho (26˚06′N, 127˚32′E; see Figure 1a), Okinawa, Japan. Rukan-sho, an isolated and beautiful Okinawan island, is a small atoll that has a rich coral reef fauna and flora (Ohde and van Woesik, 1999).

Figure 1. Map showing sampling locations. (a) The Gulf of Thailand and Rukan-sho, Okinawa, (b) the Chao Phraya River estuary and Khang Khao Island in the Upper Gulf of Thailand (inset) and the sampling site off of Khang Khao Island.

#### **2.2. Sampling**

The sampling site for both seawater and coral was located approximately 30 m off of the southern coast of Khang Khao Island (Figure 1b). This fringing reef was located underneath a cliff that sloped down towards the north side of the island, making groundwater contamination negligible. Seawater samples were collected from approximately 0.5 m below the surface and stored in 250 mL plastic bottles. Within several days, salinity was measured using a salinometer (601 MKIII, YEO-KAL Electronics, Australia) after calibrating it with an IAPSO standard seawater (Salinity: 34.996 psu,  $K_{15}$ : 0.99990) (precision:  $\pm$ 0.003). Four *Porites* coral samples were collected from the reef approximately 5 m below the surface, within an approximate 10 m radius of the sampling site. In order to check metal pollution as far back as the early 1980s, we collected a coral sample (size,  $\phi$ : ~15 cm, h: ~10 cm) in the years of 1985, 1998, 2001 and 2008, hereafter referred to by sample numbers, KK-85, KK-98, KK-01 and KK-08, respectively. After being stored in polyethylene bags, the samples were washed several times using deionized water (MQ water). In preparation for analysis, the samples were cut into slabs of approximately 5 mm thickness along the growth axis using a diamond saw. For stable isotope and trace element analyses, the slab was cut into a small fragment  $(\sim)$  x 40 mm) in order to fit into the experimental LA cells of the mass spectrometer

(LA-ICP-MS). It was then cleaned with MQ water in an ultrasonic bath before being dried in an air oven  $({\sim}60^{\circ}C, 7h)$ .

For the purposes of registering baseline metal data, we used a relatively unpolluted *Porites* coral sample collected from the reef at Rukan-sho (Figure 1a) on 3 November 1987 (RS-87). In Japan, the use of leaded gasoline has been prohibited since 1980, while it was used up until the late 1990s in Thailand. Considering these time periods, we used a *Porites* sample collected from Rukan-sho in the year 1987 (RS-87).

#### **2.3. Preparation of CaCO<sup>3</sup> Matrix Standard**

A series of calcium carbonate (aragonite) matrix standards (Std-0, Std-1, and Std-2) were prepared for LA-ICP-MS by using a mixed solution of a multi elemental standard solution containing 100 mg/L of V, Cd, Ba, and Pb (SPEX, XSTC-22, USA) (see Table 1). This multi elemental standard and 1 M HCl (10 mL) were added to a 1 M CaCl<sub>2</sub> solution (40 mL), which was then diluted to 140 mL with MQ water and then heated. With gentle boiling, a 1.5 M  $Na<sub>2</sub>CO<sub>3</sub>$  solution (60 mL) was added into the solution, producing a CaCO<sub>3</sub> (aragonite) precipitate. Use of higher temperature makes it possible to precipitate aragonite crystal from aqueous solution rather than calcite. After stirring and heating for 2 minutes, the suspension was then kept at 15 $\degree$ C for 4 hours, before the CaCO<sub>3</sub> was removed from the suspension through filtering. The parent solutions for synthesized Std-1 and Std-2 contained the metals (V, Cd, Ba and Pb) as concentrations of 1.19 mg/L and 2.91 mg/L at the initial stage of the experiments. The precipitate was dried at 50 $^{\circ}$ C for 14 hours, and then pressed into a pellet ( $\phi$ : 10 mm, ~3 mm thickness). Calcium carbonate was also synthesized in the absence of the multi-elemental standard solution and served as a low concentration standard (Std-0). Calibration for V/Ca, Cd/Ca, Ba/Ca, and Pb/Ca in coral samples was based on the use of the synthetic CaCO<sub>3</sub> standards (Table 1). A coral aragonite reference material, JCp-1 (Okai et al., 2002), was pressed into pellet form to facilitate determination of B/Ca in the coral samples by LA-ICP-MS. These solid standards were then dissolved in 3% nitric acid and analyzed for V/Ca andCd/Ca by ICP-AES (Spectro Arcos, Spectro, Germany) at Sheffield University, and for Ba/Ca and Pb/Ca by ICP-MS (HP-4500, Hewlett Packard, Japan) at Ryukyu University.

## **Table 1. Added amount of multi-elemental standard, XSTC-22, and count ratio for V/Ca, Cd/Ca, Ba/Ca and Pb/Ca of the standard measured by LA-ICP-MS. The parent solution of synthesized standard, Std-1 and Std-2, contained metals (V, Cd, Ba and Pb) of 1.19 and 2.91 ppm, respectively. Molar ratio of the standard was determined by ICP-AES and ICP-MS as described in the text**

#### **2.4. LA-ICP-MS Analysis**

The LA-ICP-MS system at Sheffield consisted of a Nd:YAG laser (UP266 MACRO, New Wave Research, USA) connected to an ICP-MS (HP-4500, Agilent Technologies, Japan). One-D and 2-D (imaging) analyses were carried out on coral skeletons and synthetic metal standards prepared in the  $CaCO<sub>3</sub>$  matrix. Main laser operating parameters were wavelength, 266 nm; beam diameter, 155 µm; laser energy, 2 mJ; repetition rate, 10 Hz. Prior to analysis, the coral section was first subjected to laser ablation along the line that would be used for laser sampling as a means of pre-treatment for the sample surface cleaning. Acquisition times for measurement of <sup>11</sup>B, <sup>51</sup>V, <sup>111</sup>Cd, <sup>137</sup>Ba, <sup>202</sup>Hg, and <sup>208</sup>Pb were 100 ms and 10 ms for  $42$ Ca. The isotope  $42$ Ca was used as the internal standard, as measurement precision was lower than that for  ${}^{43}$ Ca. For coral samples, the sample translation stage was moved at a constant speed of 10  $\mu$ m s<sup>-1</sup> to create an ablation track along the growth axis of the skeleton. The LA tracks for samples KK-85, KK-98, KK-01, KK-08, and RS-87 were 36.5, 38.8, 42.3, 36.6, and 34.1 mm in length, respectively. For the synthetic metal standards prepared in the  $CaCO<sub>3</sub>$  matrix, each pellet was subjected to three consecutive and parallel line rasters of 9 mm in length with a spacing gap of 400 µm between each ablation track. The data obtained from the analyses were relatively noisy; hence a noise-reduction filtering procedure (Sinclair et al., 1998) was also utilized. The precisions (external) for the LA-ICP-MS measurement of B/Ca, V/Ca, Cd/Ca, Ba/Ca, and Pb/Ca, were 8.5%, 1.4%, 6.0%, 2.1%, and 6.0%, respectively.

#### **2.5. Stable Isotopic Analysis**

For the stable isotopic analysis of oxygen and carbon, a vertical bar  $(\sim 40 \times 4 \times 3 \text{ mm}^3)$ was cut along the major growth axis of the coral sample using a fine diamond saw. The sample was cleaned ultrasonically and dried up. Approximately 1 mm of aragonite coral was gradually shaved from the top of the bar as a sub-sample using a dental drill. A sub-sample depth was measured by an Absolute Digital Solar Caliper (CD-S20C, Mitutoyo, Japan) after shaving. The shaved sample  $(\sim 0.15 \text{ mg})$  was dissolved with 100% phosphoric acid at 70°C for isotopic analysis. The reaction occurred in an automated individual carbonate reaction device (Kiel device), and oxygen and carbon isotopes were measured using a mass spectrometer (Finnigan MAT251 or Delta V, Thermo Fisher, Germany) (Hossain et al., 2008). The isotope ratios are presented in conventional  $\delta$  notation relative to the isotope ratio of  $CO<sub>2</sub>$  gas derived from the PDB standard through NBS-19. Isotope values for the coral skeleton are expressed in per mil (‰) as follows:

$$
\delta^{18}O = 1000 \times \{(1^8O/^{16}O)_{sample} / (1^8O/^{16}O)_{standard} - 1\}.
$$

Skeletal  $\delta^{13}C$  data are measured simultaneously in term of the  $^{13}C^{12}C$  ratio. For seven replicate measurements, the precision of internal standard was calculated at 0.18 and 0.12‰ for  $\delta^{18}$ O and  $\delta^{13}$ C, respectively.

In addition,  $\delta^{18}$ O values for 15 seawater and 8 river water samples were measured using the same mass spectrometer (MAT 251). Most of the samples were measured twice. A 2 mL

of the sample was taken into a syringe and equilibrated with 4 mL of  $CO_2$  of known  $\delta^{18}O$  by shaking it at  $25 \pm 0.1$  °C for 12 h. The equilibrated CO<sub>2</sub> gas was then pushed through the vacuum line of the spectrometer for  $CO<sub>2</sub>$  extraction and the value was measured. Seawater δ <sup>18</sup>O are also expressed in per mil (‰) relative to the Vienna-Standard Mean Ocean Water (V-SMOW) standard as follows:

$$
\delta^{18}O_w = 1000 \times \{(^{18}O^{/16}O)_{sample} / (^{18}O^{/16}O)_{SMOW} - 1\}.
$$

## **3. RESULTS**

#### **3.1. Seawater Temperature, Salinity, and Oxygen Isotope**

The salinity and SST data including seawater  $\delta^{18}O_w$  observed at Khang Khao Island are given in Table 2. The SST was nearly constant between 27.1 and 31.0 ˚C, with an average SST  $(\pm 1\sigma)$  of 29.4  $\pm$  1.0 °C (Table 2). The SST for the location (11.5-13.5°N, 99.5-101.5°E) was also obtained from data acquired by NOAA (http://iridl.ldeo.columbia.edu) (see Figure 2c). Salinity varied largely between 21.129 and 32.515 psu. During the wet season (June - October), relatively lower salinity  $(21.129 - 30.412 \text{ psu})$  was observed, whereas higher salinity (31.260 - 32.515 psu) was observed during the dry season (November - April)(see Table 2). Similarly, seawater  $\delta^{18}O_w$  varied between -1.609 and -0.232‰ (SMOW). As listed in Table 2, during the wet season (June - October), relatively lower  $\delta^{18}$ O<sub>w</sub> (-1.609 and -0.537‰) was observed, whereas higher  $\delta^{18}O_w$  (-0.365 and -0.232‰) was observed during the dry season (November - April).

**Table 2. Salinity, sea surface temperature (SST) and seawater δ <sup>18</sup>O observed at Khang Khao Island from 1998 to 2008**

Sampling date (e.g., 2008.9.5: 5 September 2008)

In order to understand the annual variation in seawater  $\delta^{18}O_w$  at Khang Khai Island, river water was collected from the Chao Phraya River near Shangri La Hotel, Bangkok in July, September and November, 2000, and July 2001. River water  $\delta^{18}O_w$  varied between -6.60 and -4.10‰. Relatively lower  $\delta^{18}O_w$  was observed at -6.14 and -6.60‰ in September and November 2000, while higher  $\delta^{18}O_w$  was observed at -4.81 and -4.10‰ in July 2000 and July 2001. In addition, we also collected river water samples from the Mekon River near Golden Triangle, Thailand. The Mekon River water  $\delta^{18}O_w$  showed lowest value at -11.0 ( $\pm$ 0.070)‰ as  $\delta^{18}O_{\rm w}$ .

#### **3.2. Oxygen and Carbon Isotopes in Coral**

The coral sample KK-98 collected on 17 November 1998 from the Khang Khao Island reef showed that two pairs of density bands were observed for a single year's growth (Hossain et al., 2008). This fact makes determining the chronology of the sample unreliable. In the absence of a clearly defined sclerochronology, the oxygen isotope data are used, instead, to determine the chronology and growth rate. The  $\delta^{18}$ O data (Figure 2a) permitted the determination of the growth rate based on the cyclic changes of the sample, and this in turn contributed to the definition of the chronology. In addition, skeletal  $\delta^{13}$ C values also shows the changes during the study (Figure 2b). The changes occur due to the changes in light intensity and water chemistry, especially carbon dioxide and nutrients in ambient seawater.

To examine the relationship between the coral skeletal  $\delta^{18}$ O and precipitation, rainfall data in the periods of 1981 - 1985, 1996 - 2001, and 2006 - 2009 were acquired from the Thai Meteorological Department, and compiled for the Bangkok Metropolitan Area (Figure 2d) and the island of Ko Sichang (Figure 2e); Sichang is nearest to the Khang Khao Island sampling site (see Figure 1b). The total monthly rainfall data are presented for the years 1981 to 1985, 1996 to 2001, and 2006 to 2009 (see Figures 2d and 2e). From these data it is clear that precipitation around the Gulf of Thailand is generally cyclical in nature. The greatest amount of rainfall appears to occur in the months of August, September, and October, with the months of January, February, March, and December receiving little to no recorded rainfall in either Bangkok or Ko Sichang Island.

#### **3.3. Me/Ca in Coral**

Using the LA-ICP-MS data, the calibration curves for V/Ca, Cd/Ca, Ba/Ca, and Pb/Ca (Table 1) were calculated to have correlation coefficients (*r*) of 0.996, 0.995, 0.981, and 0.991, respectively, which were then used to determine the Me/Ca ratios in the coral samples. The measured values of B/Ca, Ba/Ca V/Ca, Cd/Ca, Pb/Ca (µmol/mol), and Hg/Ca (cps/cps) in the coral skeletons from Khang Khao Island are shown in Figures 3a-f, respectively, with the averages and standard deviations listed in Table 3. The average ratios found in the Rukansho sample (RS-87) are represented by a dashed line in the figures. In evaluating the Me/Ca values in the coral samples' tissue layer  $(\sim 5 \text{ mm from the surface of the sample})$ , the ratio values in the surface layer were calculated to be much higher compared to the ratios found in the remaining skeletal layers. As it has been found that corals seem to have higher concentrations of these trace metals in the surface layer due to an as yet unidentified factor,

the tissue layer was has not been discussed in this study. For our model, interspecies variations are considered negligible.

Figure 2. (a) Oxygen isotopes ( $\delta^{18}O$ ) and (b) carbon isotopes ( $\delta^{13}C$ ) in corals from Khang Khao Island, (c) SST (NOAA satellite data near the Khang Khao site described in the text), and total monthly rainfall for (d) Bangkok and (e) Sichang Island, Thailand.

Figure 3. Metal-to-calcium molar ratio (cps/cps for Hg/Ca) in corals from Khang Khao Island. (a) B/Ca, (b) Ba/Ca, (c) V/Ca, (d) Cd/Ca, (e) Pb/Ca, and (f) Hg/Ca. Dashed line shows average value observed in the Rukan-sho sample.

## **4. DISCUSSION**

## **4.1. Salinity and δ<sup>18</sup>O<sup>w</sup> in Seawater, and Oxygen and Carbon Isotopes in Coral**

Salinity in the Gulf of Thailand is primarily dependent on the influx of freshwater as a result of the annual monsoon cycle. The wet season from late May to October causes a decrease in salinity, and the lack of rainfall in the dry season from November to April causes the salinity to increase (see Figures 2d-e). Table 2 clearly shows such a cyclical pattern to the salinity in the Gulf. The SST data (Figure 2c) show an annual cyclical change with a pair of quartic maxima. Such quartic maxima peaks (Figure 2c) may be explained from three seasons that include hot dry, hottest dry and hotter wet cycles of the annual climate change. These fluctuations in SST and salinity are then reflected in the  $\delta^{18}$ O in the carbonate skeletons (Dettman et al., 2001). Sun et al. (2005) have previously measured the annual monsoon season's effects on *Porites* specimens, as the rainfall including river water input, enriches the local seawater with the lighter isotope  $(^{16}O)$ , which is then reflected in the skeletons as a cyclical decrease in the  $\delta^{18}O$ .

Being a tropical area, the upper Gulf of Thailand usually receives a very heavy rainfall during the wet season. Since local precipitation and evaporation rate including river run-off affects salinity and eventually changes the seawater  $\delta^{18}O_w$  values, the corals in Khang Khao Island are likely to grow up under a large variation  $(\sim 11 \text{ psu})$  in sea surface salinity (Table 2). Moreover, there were often sudden outbreaks of floods along the Chao Phraya River in Bangkok. For example, severe flooding occurred from July to November 2011, which caused much damage and hardship to Thai people and the economy. Considering the annual seasonal change for rainfall (Figures 2d-e), there would be expected to be a correlation changes in salinity and skeletal  $\delta^{18}O$  values. In order to verify such a correlation, a calibration was established for seawater  $\delta^{18}O_w$  and salinity values using the data in Table 2. The linear correlation between seawater  $\delta^{18}O_w$  and salinity is expressed as follows:  $\delta^{18}O_w$  (‰, SMOW)  $= 0.1205 \times$  Salinity – 4.1829 (r<sup>2</sup> = 0.979, n=26). The rainfall enriches the local seawater with the lighter isotope  $(16)$  as it decreases the surface salinity, which is then reflected in the skeletons as a cyclical decrease in the  $\delta^{18}O$ . In turn, when the temperature rises, the lighter isotope is also preferred in isotopic reactions, depressing the observed  $\delta^{18}O$  (Gagan et al., 2012). The seasonality of these events results in a cyclical change in  $\delta^{18}O$  expressed in the coral skeletons, with the monsoonal rainfall first decreasing salinity and therefore  $\delta^{18}O$ , and then the hotter monsoon season's increase in SST further depresses the  $\delta^{18}O$  ratio.

On the other hand, skeletal  $\delta^{13}$ C values show slightly less clear cyclical changes compared to those of  $\delta^{18}O$  (Figures 2a and 2b). The photosynthetic rate of coral's symbiotic zooxanthallae increases with increasing in the light intensity and thereby  $\delta^{13}C$  values increase due to the uptake of  ${}^{12}CO_2$  in seawater instead of  ${}^{13}CO_2$ . Moreover, the sun photoperiod and nutrients influence δ<sup>13</sup>C in coral skeletons. As shown in Figure 2b, high δ<sup>13</sup>C values in the coral skeletons suggest the records during cool months (December to February) since low photosynthetic rate in the coral reef. The  $\delta^{13}$ C data in Figure 2b somewhat indicate variations related to the climate change due to the alternating dry and rainy season, supporting the coral  $\delta^{18}$ O record shown in Figure 2a. The  $\delta^{13}$ C data might be controlled by the primary production associated with the sunlight intensity (cloud cover) and water chemistry (nutrients and

suspended matter). Nonetheless, variations in skeletal  $\delta^{13}C$  values may be interpreted as the changes in light levels of the sample habitat during different seasons, but the  $\delta^{13}C$  values are largely affected by metabolic activities for which the values are difficult to use as a tracer of the coral chronology.

We also measured SST every 1 hour for 16 months from November 1999 at the site in Khang Khao Island and the weekly average was used for the calibration of skeletal  $\delta^{18}O$  – SST relationship. Monthly mean SST fluctuated from 26.0 to 30.60˚C and salinity varied from 21 to 33 psu during the study. The wet season in the upper Gulf of Thailand lasts from late May to October, and the dry season lasts from November to early May. The  $\delta^{18}O_w$  values in ambient seawater are extremely correlated  $(r^2 = 0.979)$  with salinity values (Table 2), indicating that seawater  $\delta^{18}$ O values are strongly affected by salinity.

As pointed out,  $\delta^{18}$ O values are lighter in river water, and the rainfall also enriches localized seawater with the lighter isotope  $(^{16}O)$  given that it decreases surface salinity, which is then reflected in the skeletons as a cyclical decrease in the  $\delta^{18}O$ . In turn, when the temperature rises, the lighter isotope is also preferred in isotopic reactions, depressing the observed  $\delta^{18}O$ . The seasonality of these events results in a cyclical change in  $\delta^{18}O$  expressed in the coral skeletons, with the monsoonal rainfall first decreasing salinity and therefore  $\delta^{18}O$ , and then the hotter monsoon season's increase in SST further depresses the  $\delta^{18}O$  ratio. Therefore, we have used  $\delta^{18}O$  for coral values to reconstruct the growth rate of the corals due to salinity and SST in the upper Gulf of Thailand.

Using a *Porites* coral from Khang Khao Island (KK-98), Hossain et al. (2008) pointed out two pairs of density bandings were observed in a *Porites* coral for one year (see Table 3 and Figure 2a). The growth rate of the *Porites* samples could not be estimated from the coral density bandings in the Khang Khao coral samples for this reason. In the absence of using the coral skeletons' density bands to determine the chronology, the cyclical manner of  $\delta^{18}O$  has been used as an alternative method (Maier and Titschack, 2010). These isotopic data allow us to establish the chronology in scenarios where density banding is unreliable. Using the cyclical changes of the isotopes, we determined the growth rate of the *Porites* samples, which is reported in Table 3.

Another factor that aided in establishing the chronology and the growth rate of the coral samples was the fact that we specifically chose four different samples over the sampling period rather than a single long core. While a single long core is normally preferred in such studies, the density banding of these samples were so poor that using a single core would have made the chronology impossible to determine. The skeletal  $\delta^{18}O$  in multiple colonies of *Porites* corals was measured to evaluate inter-colony variation of  $\delta^{18}$ O that reported that intercolony variation of the  $\delta^{18}$ O which has reported to be negligible (Matthews et al., 2008; Hayashi et al., 2013). Cadmium contents measured in multiple *Porites* colonies showed similar value among the colonies (Matthews et al., 2008). Spatial distribution of Pb in the surface water of the Pacific Ocean was investigated by measuring Pb/Ca in *Porites* corals taken from different sites, assuming negligible inter-colony variation of the skeletal Pb/Ca (Inoue et al., 2006). Based on these studies, we assume that inter-colony variation of the skeletal  $\delta^{18}$ O and metal contents is negligible in the corals taken from within a 10 m radius of the sampling site. The model used in this study to examine the heavy metals incorporated into the coral skeleton considers any such interspecies variations in ratio levels as being negligible, and instead relies on the observed cyclical differences and the observed levels of  $\delta^{18}$ O (Figure 2) to estimate the chronology. In conclusion, the cyclic change in  $\delta^{18}$ O has been

observed to record an annual change in seawater salinity, and then the coral growth rate is estimated at ~18 mm/year on average (Table 3). Using the skeletal  $\delta^{18}O$  method, the coral chronology was established in the Gulf of Thailand in order to determine the horizontal axis shown in Figure 3.

Source: Sampling date (e. g. 080905: 8 November 2008) 4.2. B/Ca in Coral.

#### **4.2. B/Ca in Coral**

The B/Ca ratios in the samples (Figure 3a) show clear cyclical variations during 1997- 1998 in the KK-98 sample, with slightly cyclical variations observed in KK-85, KK-01, and KK-08. The average B/Ca value ( $\pm 1\sigma$ ) of the Khang Khao corals was calculated to be 514  $\pm$ 87 µmol/mol (434-563 µmol/mol) shown in Table 3. The B/Ca in Rukan-sho coral varied between ~600 - 1110 µmol/mol with an average of 753 µmol/mmol. The average value of B/Ca in Khang Khao corals (434-563 µmol/mol) was lower than the Rukan-sho value.

Using secondary ionization mass spectrometry (SIMS) (Hart and Cohen, 1996) and LA-ICP-MS (Sinclair et al., 1998; Fallon et al., 1999; 2003), a narrow range of seasonal variation in B/Ca was observed in *Porites* corals. Previous studies have subsequently suggested a strong temperature-dependence such that B/Ca in corals increases with decreasing sea surface temperature (Sinclair et al., 1998; Fallon et al., 2003; Ohde et al., 2011). We also pointed out that the distribution coefficient between the seawater borate ion and the aragonite crystal might have a temperature dependency during precipitation (Ohde et al., 2011). Based on the temperature-dependence of B/Ca, the relatively higher SST for the annual average at Khang Khao Island (29.4 °C) compared to Rukan-sho (25.0 °C) can explain the observation that B/Ca in Khang Khao corals are lower than that in Rukan-sho coral (see Table 3). Further, due to the relatively narrow range of SST at Khang Khao compared to Rukan-sho, the variation in B/Ca of Khang Khao corals was smaller than that of Rukan-sho coral (Table 2). These observations agree with the prediction based on the temperature dependence of B/Ca, which shows that the ratio in the Khang Khao corals is possibly controlled by seawater temperature and has a relatively small variation because of a narrow range of SST observed in the Gulf of Thailand (Table 2).

The data in Table 3 also indicate a range of average B/Ca ratios from 434 to 563 µmol/mol, showing a slight variation in values. The variation of SST and salinity within the monsoon cycle will possibly have an effect on the B/Ca ratio, as it is dependent on these two factors, as well as a biological effects. In spite of such differences amongst the four coral samples, our model does not take into account the biological variation. The cyclical variations found in the B/Ca values in the time periods when it is evident can likely be linked to the same cyclical variations for the  $\delta^{18}$ O and precipitation values (see Figures 2a and 3a). The variation of SST and salinity within the monsoon cycle will possibly have an effect on the B/Ca ratio, as it is dependent on these two factors, as well as biological effects. In spite of such differences amongst the four coral samples, our model does not take into account the biological variation. When we use the same coral species, somewhat biological effects are possibly negligible and can be discounted.

#### **4.3. Ba/Ca in Coral**

The Ba/Ca in the Khang Khao corals varied in a range from approximately 1 µmol/mol to over 100 µmol/mol. The surface layer in the samples (KK-85, KK-98, and KK-02) was significantly more concentrated in Ba than the lower layers. Such a variation in the barium concentration has been reported previously (Sinclair et al., 1998; Alibert et al*.*, 2003); it is thought that the living tissue is concentrated in Ba through some means, either through the seawater concentration or through the organism consuming Ba-rich food, and this barium is then precipitated into the skeleton (Sinclair, 2005). The values of Okinawa sample (RS-87) showed a narrow range of variation from  $\sim$  1.5 to 3.7 µmol/mol with an average value of 2.03 µmol/mol (Table 3), which is lower than the Thai samples.

Both river water and deep seawater are enriched in barium due to silicate rock weathering and dissolution of barium-rich minerals, respectively. In surface seawater, Ba is mainly supplied from these river inputs and the upwelling of deep seawater. Because the Ba content in coral skeletons reflects the concentration in seawater (Lea et al., 1989), Ba/Ca in coral skeletons reflects both riverine input (McCulloch et al., 2003; Alibert et al., 2003; Wyndham et al. 2004; Horta-Puga and Carriquiry, 2012) and deep seawater (>1000 m) upwelling (Lea et al., 1989; Fallon et al., 1999). However, upwelling of barium-rich deep seawater is unlikely to occur in the Gulf of Thailand as the depth of the Gulf is much too shallow at  $\sim$ 45 m (Nozaki et al., 2001). Khang Khao Island is located about 40 km to the southeast of the mouth of the Chao Phraya River (Figure 1b) where Ba concentration varied from 250 to 430 nmol kg<sup>-1</sup>, while Ba in the East China Sea was approximately 40 nmol kg<sup>-1</sup> (Nozaki et al., 2001). In the upper Gulf of Thailand, seawater Ba concentration increased with decreasing salinity (Nozaki et al. 2001). Barium influx from the Chao Phraya River (250 - 430 nmol kg<sup>-1</sup>) significantly contributes to the higher Ba concentration at the inner Gulf compared to the East China Sea (~40 nmol kg-1 ), and with the higher Ba concentration being linked to increasing salinity (Nozaki et al., 2001). Thus the Ba concentration in seawater of the Gulf is formed through the mixing between the East China seawater and river water.

In addition to the Ba concentration in seawater, temperature can also influence the Ba/Ca values in coral aragonite; dissolved  $Ba^{2+}$  can be incorporated in coral aragonite as a solid solution. The temperature dependency of the distribution coefficient of barium  $(D_{\text{Ba}})$  between seawater and aragonite has been studied, defined as  $D_{Ba} = (Ba/Ca)_{\text{aragonite}} / (Ba/Ca)_{\text{seawater}}$ 

(Zachel et al., 2003; Dietzel et al., 2004). Assuming this relationship between  $D_{Ba}$  (Dietzel et al., 2004) and SST observed at Khang Khao (27.1-30.0 °C) (Table 2), the  $D_{Ba}$  value is calculated to be 1.37 and 1.27 at 27.1 °C and 30.0 °C, respectively. This variation in  $D_{Ba}$ results in a small variation in Ba/Ca in coral aragonite (less than 8%). Thus the temperature effect on the Ba/Ca values in Khang Khao corals is negligible.

Since Ba concentration in seawater around Khang Khao Island largely depends on input from the rivers, especially the Chao Phyraya River, Ba/Ca in Khang Khao coral reflects the high concentration of riverine input. In the light of such Ba influx from the rivers, the Ba/Ca ratios in the samples (KK-85 and KK-01) could show an annual cyclical change as evident in Figure 3b. Such changes might occur as a result of the monsoon cycle in Thailand.

#### **4.4. V/Ca in Coral**

The V/Ca values (Figure 3c) varied over a narrow range in the Khang Khao samples, with the average value being comparable to that of the Rukan-sho sample (Table 3). As shown in Figure 3c, the V/Ca in KK-85 varied in a narrow range  $(0.09 - 0.30 \,\mu\text{mol/mol})$  with an average value of  $0.128 \mu$ mol/mol. The V/Ca values in KK-98 (0.16-0.50  $\mu$ mol/mol) and KK-01 (0.09-0.30 µmol/mol) were higher than that for KK-85. The V/Ca in KK-08 varied between  $\sim$ 0.17-0.30 µmol/mol except for the surface layer, in which the highest V/Ca in the Khang Khao corals (1.56  $\mu$ mol/mol) was observed. The average value of V/Ca in the coral samples is given in Table 3. Although the average  $V/Ca$  in KK-85 (0.128  $\mu$ mol/mol) is comparable with that in RS-87 (0.123  $\mu$ mol/mol), the average V/Ca values in KK-98, KK-01 and KK-08 (0.255, 0.139 and 0.282 µmol/mol, respectively) are higher than that of RS-87  $(0.10 \text{ mmol/mol})$ .

Since vanadium is enriched in crude oil, it is suggested that the main source of anthropogenic input for this element is from refining operations and the burning of residual oil (Hope, 1997). Only a few studies have measured V in coral skeletons in an attempt to detect oil pollution in coral reefs (Shen and Boyle, 1988; Guzman and Jarvis, 1996). Shen and Boyle (1988) reported an almost constant V/Ca in a coral skeleton from Bermuda  $(\sim 0.1$ µmol/mol) and suggested that the variation related to anthropogenic vanadium was possibly swamped by the background concentration in seawater. Guzman and Jarvis (1996) analyzed the V/Ca ratio in a coral skeleton from a Caribbean reef and found an increasing trend from the 1960's ( $\sim$ 0.15 µmol/mol) to the 1990's ( $\sim$ 0.35 µmol/mol) due to oil pollution.

In order to assess the impact of oil pollution in the Gulf of Thailand, the concentration of petroleum hydrocarbons in marine, estuarine, and riverine environments has been studied (Wattayakorn et al., 1998; Cheevaporn and Menasveta, 2003; Boonyatumanond et al., 2006). The concentration of petroleum hydrocarbons in seawater was measured at 78 sites along the coast in the Gulf of Thailand from 1994-1995 (Wattayakorn et al., 1998). These authors found oil pollution in the coastal waters around oil refineries in Si Racha, which is located about 10 km to the east from Khang Khao Island, and suggested the sources of petroleum pollution might be spills from tankers and the waste derived from the oil refinery and associated industries in the coastal region. The concentration of petroleum hydrocarbons in sediments from the Chao Phraya River collected from 2003-2004 increased from the upper stream to Bangkok and composition profiles of hydrocarbons in sediments from the urban canals were similar to those in street dusts, indicating that street dusts in Bangkok are a

source of oil pollution in the Gulf (Boonyatumanond et al., 2006). In addition, petroleum hydrocarbon contamination was suggested by high vanadium concentrations observed in the seawater of the Gulf (Censi et al., 2006). In contrast, in the 1980s, the petroleum hydrocarbon contamination level in seawater of the Gulf of Thailand was lower than the baseline value of 100 µg/L, suggesting that oil pollution in the Gulf was negligible (Cheevaporn and Menasveta, 2003). Based on the previous studies, it is estimated that the Gulf suffered from oil pollution in the 1990s and 2000s, whilst not in the 1980s. This estimation of the historical change in oil pollution in the Gulf agrees with the variation in the average value of vanadium in corals from Khang Khao (see Figure 3c and Table 3). Therefore, the vanadium content in corals from Khang Khao Island is indicative of oil pollution in the Gulf of Thailand.

#### **4.5. Cd/Ca in Coral**

The Cd/Ca values (Figure 3d) in the Khang Khao corals show an unusually high level of Cd in the KK-85 sample, much higher than the other 3 samples, and also much higher than the Rukan-sho values (Table 3). In KK-85, Cd/Ca was significantly higher than in the other three coral samples from Khang Khao. The average Cd/Ca value of Khang Khao corals (KK-85, KK-98, KK-01 and KK-08) is calculated to be 0.202, 0.0303, 0.0442 and 0.0431  $\mu$ mol/mol, respectively, and is higher than that of RS-87 (0.0161  $\mu$ mol/mol) (Table 3).

Since cadmium concentration in surface seawater is mainly affected by anthropogenic cadmium input and upwelling of deep water enriched in Cd, coral Cd/Ca values reflect pollution and upwelling events (Shen et al., 1987; Lea et al., 1989; Matthews et al., 2008). As mentioned above, since upwelling is unlikely in the Gulf of Thailand, and as a consequence, Cd/Ca in the coral skeletons from Khang Khao mainly reflects anthropogenic cadmium input. Hungspreugs et al. (2002) measured the metal contents in a *Porites* coral core (corresponding to the growth of 1950-1984) from Khang Khao Island and reported that the Cd/Ca value (0.17 µmol/mol) in the coral after 1964 was higher than that in the coral bands before 1964 (0.08 µmol/mol). Figure 3d also shows that the Cd/Ca in Khang Khao corals had several spikes. The average Cd/Ca value in Khang Khao corals is extremely higher than that in Rukan-sho coral (Table 3). These observations indicate that the Cd level in the Gulf of Thailand was higher than that in Rukan-sho from 1983 to 2008. As the highest Cd/Ca ratio was observed in KK-85, this suggests considerable Cd input into the Gulf took place in the early 1980s and anthropogenic cadmium inputs have significantly decreased in the subsequent decades.

In Thailand, cadmium contamination in water and sediments has been monitored (Hungspreugs and Yuangthong, 1983; Polprasert, 1982; McLaren et al., 2004). A high Cd concentration was observed in the surface  $(-0.5 \text{ cm})$  of a sediment core from the Chao Phraya River estuary collected in 1982 (Hungspreugs and Yuangthong, 1983). The dissolved Cd in the Chao Phraya River water tended to increase from the upper stream to the river mouth (Polprasert, 1982). McLaren et al. (2004) reported low levels of cadmium in the waters of the Chao Phraya River, although Cd in the river water showed a temporal variation. These studies suggest that the estuary was contaminated by anthropogenic cadmium from riverine inputs in the early 1980s, but the cadmium level in the estuary seems to have become lower in the 2000s.

The release of Cd from particulate matter in estuaries has been investigated to understand the behavior of cadmium (Tang et al., 2002; Audry et al., 2007). Using estuarine waters of

different salinities  $(S = 0, 15, 15)$  and 31 psu), the mobility of cadmium into particulate matter such as urban dusts and river sediments was assessed by extraction experiments (Schäfer et al., 2009). They found the highest mobility for Cd in particle matter exposed to saline estuarine water  $(S = 31 \text{ psu})$ , for which up to 90% of Cd was desorbed. Considering that salinity ranges from 21-33 psu with an average of ~30 psu at Khang Khao Island (Table 2), cadmium from rivers seems to be present as dissolved  $Cd^{2+}$  in seawater in the Gulf. Accordingly, the cadmium content of corals from Khang Khao possibly recorded the dissolved  $Cd^{2+}$  in the Gulf of Thailand, which was mainly affected by the anthropogenic cadmium inputs.

#### **4.6. Hg/Ca in Coral**

The count ratio of Hg/Ca is shown in Figure 3f. In KK-85, the Hg/Ca values varied over a narrow range with an average value of  $0.392 \times 10^{-3}$  cps/cps, lower than that of RS-87. The Hg/Ca values for KK-98 were relatively constant with an average value of  $0.821 \times 10^{-3}$ cps/cps. KK-08 showed spiky signals for Hg/Ca between 1.6-4.7 x  $10^{-3}$  cps/cps with an average value of 2.38 x  $10^{-3}$  cps/cps. In KK-08, the Hg/Ca was lower than the average Hg/Ca of RS-87. The average count ratio of Hg/Ca in Khang Khao corals is higher in the order of  $KK-01 > KK-98 > KK-85 > KK-08$  (Table 3). These findings suggest that the Gulf of Thailand experienced relatively higher Hg contamination from 1996 to 2001, whilst for the periods 1983-1985 and 2006-2008, the Hg concentration in the gulf water was comparable with that in Rukan-sho.

Only a few studies have investigated the mercury content of coral skeletons (Guzman and Garcia, 2002; Ramos et al., 2009). These examined the correlation between Hg and tracers of terrestrial input, such as aluminum and iron content, in order to clarify the route of anthropogenic input. In this study, the highest  $Hg/Ca$  value was observed in  $KK-01$ , indicating a significantly higher Hg level in the early 2000s (Figure 3f). In KK-01, however, there is no correlation between  $Hg/Ca$  and  $Ba/Ca$ , the latter of which reflects riverine inputs into the Gulf of Thailand (Figures 3f and 3b), showing anthropogenic mercury has some other form of input into the Gulf of Thailand. In Thailand, natural gas production in the Gulf (Windom and Cranmer, 1998), amalgamation in gold mining (Umbangtalad et al., 2007), and sewage from urbanized and industrialized areas (Cheevaporn and Menasveta, 2003) would seem to be possible sources of anthropogenic mercury during 1984-2001. However, further studies are required to identify the route and source of this anthropogenic Hg into the Gulf of Thailand.

#### **4.7. Pb/Ca in Coral**

Figure 3e shows the Pb/Ca in Khang Khao corals. In 1984-1985 (sample KK-85), the Pb/Ca value was lower than the average of Pb/Ca in Okinawan coral (RS-87: 0.0679  $\mu$ mol/mol) except for the upper layer in which Pb/Ca increased to more than 0.25  $\mu$ mol/mol. The Pb/Ca in KK-98 varied between ~0.3-7.0 µmol/mol. In KK-98, the Pb/Ca ratio gradually increased from late 1996 and steeply decreased from early 1998. The Pb/Ca in KK-01 was observed to be higher than the Rukan-sho value, while the Pb/Ca level in KK-01 decreased compared to that in KK-98. The Pb/Ca in KK-08 showed lower values than the average of

RS-87 except for a single peak in late 2008. The average values of KK-85 (0.04 µmol/mol) and KK-08 (0.02  $\mu$ g/g) are lower than that of RS-87, whilst the average values of KK-98 (1.78 µmol/mmol) and KK-01 (0.17 µmol/mol) are higher than RS-87. The variation in Pb/Ca of corals from Khang Khao suggests that the Gulf of Thailand suffered from anthropogenic inputs of Pb from the 1990s to 2003, but the Gulf might contain slightly less anthropogenic Pb during the 1983-1985 and 2006-2008 periods.

The variation in Pb/Ca of corals from Khang Khao suggests that the Gulf of Thailand was polluted by anthropogenic lead inputs from 1984 to 2001, but the Gulf might contain have experienced slightly less anthropogenic lead input during the periods 1982-1983 and 2006- 2008 periods. As shown in Figure 3e, Pb/Ca in Khang Khao coral significantly decreased from the late 1990s to 2008. This trend agrees with the decreasing trend in the Pb content of airborne particles in Bangkok (Cheevaporn et al., 2004).

Global lead production dramatically increased after the Industrial Revolution (Nriagu, 1998). Moreover, lead was added to gasoline as an anti-knocking agent in the form of tetraethyl lead. Lead in corals is considered to record anthropogenic Pb inputs into coral reefs due to human activities including the use of leaded gasoline (Dodge and Gilbert 1984; Shen and Boyle 1987; Inoue et al. 2006). Hungspreugs et al. (2002) measured Pb in *Porites* coral collected from Khang Khao Island and reported Pb/Ca in the skeleton corresponding to the coral growth from 1964 to 1984 was  $\sim 0.07$   $\mu$ mol/mol. In addition, based on Pb isotopic composition and lead contents in airborne particles, the sources of anthropogenic lead were assessed in Thailand (Mukai et al., 1993; Cheevaporn et al., 2004). Mukai et al. (1993) measured the Pb isotopic composition of airborne particulate matter collected from Bangkok in 1989 and reported that leaded gasoline might be the main source of anthropogenic lead in Bangkok. The government of Thailand, however, banned the use of leaded gasoline by the end of 1995 (Lovei, 1998). The content of airborne particles was measured in Bangkok from 1990 to 2000 and a significant decrease in Pb was observed after the ban of leaded gasoline (Cheevaporn et al., 2004). Accordingly, we consider that Pb in KK-98 and KK-01 was derived from anthropogenic lead due to the use of leaded gasoline in Thailand. The Pb content of KK-08 is lower than the baseline value observed in RS-87 (Figure 2e). This observation suggests that the regulation of leaded gasoline in Thailand resulted in markedly reduced anthropogenic lead input into the Gulf of Thailand.

## **CONCLUSION**

The following tentative conclusions have been deduced from the measurement of metal contents in corals by LA-ICP-MS. Heavy metal input into the Gulf has been assessed by comparing the metal content of corals from Khang Khao Island to those of Rukan-sho, Okinawa, taken as a reference for baseline metal concentrations. The metal contents of the corals from Khang Khao Island possibly reflect the impact of metal pollution from urbanized and industrialized areas into the Gulf of Thailand.

(1) Stable isotope mass spectrometry provided the oxygen isotope ( $\delta^{18}$ O) data which revealed cyclical variations along the coral growth due to an annual change in seawater salinity. Using the skeletal  $\delta^{18}O$  method, the coral chronology was established in the Gulf of Thailand.

(2) LA-ICP-MS made it possible to determine linear and two-dimensional metal-tocalcium (Me/Ca) ratios along the coral growth for monitoring aquatic environments in which the coral grew.

(3) The average values for V/Ca in three samples (KK-98, KK-01 and KK-08) were relatively higher, suggesting discontinuous inputs of anthropogenic vanadium into the Gulf of Thailand from 1997 to 2008. The V/Ca values in the corals may reflect oil pollution since the 1990s.

(4) The Cd/Ca ratio in corals from Khang Khao showed higher values compared to Rukan-sho, indicating that the cadmium concentration in the Gulf was continuously higher than that in Rukan-sho for the period from 1982 to 2008. However not withstanding this, anthropogenic cadmium input to the Gulf decreased over time.

(5) The Pb/Ca values for Khang Khao Island corals suggested that the Gulf has been polluted by anthropogenic lead since the middle 1980s. After the use of leaded gasoline was banned in Thailand in 1995, the Pb/Ca in the Khang Khao Island corals showed a remarkable decrease since the late 1990s, indicating that regulatory control has limited anthropogenic lead inputs to the Gulf of Thailand.

(6) The coralline archival record of the metals (V, Cd, Hg and Pb) gives convincing evidence of success for the regulatory laws of the Thai Government since the middle 1990s.

We hope that our studies would contribute to an improved understanding of the aquatic environments in the Gulf of Thailand and they will aid in the preservation of future ecosystems.

#### **ACKNOWLEDGMENTS**

We would like to thank M. Hungspreugs, S. Sirirattanachai, A. Snidvongs, T. Ono, and H. Yamamoto for coral sampling in Thailand and Okinawa, A. G. Cox and R. Shinjo for LA-ICP-MS measurements, and T. Oba, M. M. Hossain, R. Uemura and R. Asami for stable isotope measurements. We are grateful to A. K. Ouchi and M. D. Cohen for critical reading of the manuscript. This paper was completed as part of exchange programs between the University of Sheffield, King Mongkut's Institute of Technology Ladkrabang and the University of the Ryukyus. This work was partly supported by the Japanese Ministry of Education and Science through JSPS (No. 23510029 and 26340051), and the International Research Hub Project for Coral Reef/Island at Ryukyu University.

## **ABSTRACT**

The chapter considers the ratio of constitutive and reparative neurogenesis in pallium of juvenile masu salmon *Oncorhynchus masou*. Since salmonid juveniles are characterized by a high level of constitutive neurogenesis, we investigated the proliferative activity and neurodifferentiation in the dorsal pallial area of juvenile masu salmon. The study of proliferative activity in pallium of juvenile masu salmon *O. masou* has allowed us to identify the superficially located periventricular proliferative zone, which corresponds to the pallial periventricular zone (PVZ) of other fish species, including the dorsal, lateral, and medial compartments. The PCNA+ cells are also identified in parenchyma of masu salmon intact brain, and their maximum concentration is observed in the medial zone. In intact brain, solitary proliferating cells were identified in parenchymal regions with their maximum concentration in the medial zone. After a mechanical injury, the zones of reparative neurogenesis — neuroepitelial neurogenic niches and zones of reactive neurogenesis surrounded by radial glial fibers—appear in masu salmon pallium. An increase in the proliferative activity is characteristic of all compartments of the PVZ (especially of the medial zone), including its deep parenchymal layers. The PVZ of juvenile masu salmon contains clusters of undifferentiated HuCD+ neurons. A change in the HuCD+ cell topography is observed in the mechanically injured masu salmon pallium, in particular, reactive neurogenic niches in the lateral zone and an increase in the cell distribution density and cell migration patterns in the medial zone. A high level of constitutive neurogenesis is characteristic of juvenile masu salmon brain. Undifferentiated HuCD+ neurons form clusters in the PVZ of intact juvenile masu salmon brain. Neurons at different stages of maturation, differing in the level of HuCD

activity, were detected in the parenchymal layers of the dorsal region. A mechanical injury of masu salmon pallium is accompanied by a change in the topography of HuCD+ cells. Formation of reactive neurogenic niches is characteristic of the lateral zone, while the medial zone displays an increase in the density of immunopositive and negative cells, as well as a distinct pattern of cell migration. HuCD and PCNA immunolabeling patterns in intact pallium suggest intensive constitutive neurogenesis in the pallial PVZ of juvenile masu salmon. After a mechanical injury, the neurogenic activity spreads to deeper layers of parenchyma. The main sources of new neurons during the reparative neurogenesis are reactive neurogenic niches.

## **INTRODUCTION**

Neuronal regeneration is the restoration of structural integrity of injured cells and fibers; it is limited by the CNS ability to produce new cells at an adult age (Kempermann, 2013). Bony fishes is a group of vertebrates that retain through adulthood the ability to produce new cells in the specialized brain regions, proliferative zones (Lema et al., 2005; Lindsey et al., 2007), which, unlike mammals, are present in many brain regions. The periventricular brain region displays the highest proliferative activity during embryogenesis, while the active neurogenesis in adults resides in the secondary matrix regions of the brain located near the external walls of different brain regions: optic tectum, cerebellum, and myelencephalon at different levels from mesencephalic isthmus to rhombencephalon (Kaslin et al., 2008).

Unlike other vertebrates, a specific everted type of hemisphere formation and development is characteristic of telencephalon in bony fishes: the intracerebral ventricles are absent, while the matrix zones are located near the external walls of the dorsal and ventral zones and are able to produce new cells both under normal conditions and after injuries (Dirian et al., 2014). The proliferative activity in pallium of adult *Danio rerio* concentrates in the dorsal proliferative zone, which corresponds to the pallial periventricular zone (PVZ), and the ventral zone, corresponding to the subpallial PVZ (Adolf et al., 2006). The preliminary studies have shown the importance of phylogenetic studies of the pallial and subpallial proliferative zones in the forebrain of the zebrafish and other fish species. Lindsey et al. (2014) demonstrated the presence of a glial-like phenotype of neural stem cells (NSCs) involved in the adult neurogenesis and the expression of various transcription factors. According to other data, PVZs contain slowly and rapidly proliferating cells generated by adult NSCs/precursor cells with radial glial-like phenotype (Adolf et al., 2006). Neuroepitelial progenitors were also recently discovered in the adult zebrafish pallium (Dirian et al., 2014). A major part of the adult pallial ventricular zone is occupied by radial glia that acts as constitutive NSCs.

The neurogenesis in adult vertebrate brain can be modulated by changing the level of cell proliferation, their survival, and/or differentiation. This is associated with different functional requirements to new neurons, such as provision of specialized functions related to sexual behavior during the mating season in songbirds (Kaslin et al., 2008; Kempermann, 2013) and emergence of new neurons in the reticular formation involved in the innervation of salmonid spinocaudal muscles, increasing in volume during individual development (Pushchina et al., 2012).
According to the lesion paradigm formulated by Zupanc et al. (1998), a high regenerative potential of the fish CNS is determined by a set of processes, including the CNS response to injury. It is currently known that the insight into regeneration-competent organisms gives a certain advantage in studying the biology of NSCs, their interaction with the cell microenvironment, and specific features of their metabolism (Berninger et al., 2006; Stocum, 2006). The neurogenesis in an adult mammalian and human brain takes place only in the subventricular zone of the lateral ventricular wall and in the subgranullar zone of the hippocampal dentate formation (Chojnacki et al., 2009; Kaneko and Sawamoto, 2009). Neurogenesis can be stimulated or inhibited by various factors, including physical activity (Kempermann, 2011), changes in environmental conditions (Lema et al., 2005), and stress (Hutton et al., 2015). These factors have multidirectional effects on the intensity of neurogenesis and determine the final success of this process.

Variations in the physiological status of the animal, beyond regenerative conditions, are important players controlling the activation state of germinal zones in the mammalian forebrain. These aspects remain understudied in fish brain. The lack of standardized animal maintenance conditions explaines the large degree of variability between animals that complicates reading of subtle effects. Several neurotransmitters and hormones were recently shown to impact on radial glia activation (Mouriec et al., 2009; Perez et al., 2013). In the paraventricular organ for example, serotonine (5HT) is necessary for proliferation of radial progenitors (Perez et al., 2013), and the projection of 5HT processes toward pallial germinal zones suggests that it may be the case in this location as well (Lillesaar et al., 2009). Aromatase B (AroB), which converts androgens to estrogen, is strongly expressed in zebrafish radial glia (Menuet et al., 2005). Blockage of the aromatase activity in adult zebrafish led to a trend increase in the number of proliferating progenitors in several brain areas, particularly in pallium, suggesting a lower proliferation of oestrogens (Diotel et al., 2013). However, it remains to be assessed whether they primarily target radial glia or nonglial proliferating progenitors. Along with a quiescence-promoting effect on radial glia, radial glia, maintaining AroB expression after injury, are not activated and presumably do not participate in the repair process (Diotel et al., 2013).

A study of the constitutive neurogenesis under natural conditions gives a large volume of information for comparative analysis (Than-Trong and Bally-Cuif, 2015). However, the balance between constitutive and injury-induced neurogenesis in brain of regenerationcompetent organisms is rather vague. Recent works considered the effect of behavioral challenges or sensory stimuli on zebrafish adult neurogenesis (Lindsey and Tropepe, 2014). As the most interesting fact, it was found that sensory stimulation (chemosensory or visual stimulations) selectively affected the neurogenic niches in the brain areas involved in processing these stimulations (Lindsey et al., 2014). Changes in the social context, such as social isolation or social novelty, also decrease the number of proliferating progenitors in sensory niches and increase the number of newborn neurons (Lindsey and Tropepe, 2014). The number and complexity of neurogenic niches in teleosts, and the complex repertoire of behaviors that a fish can exhibit, suggest that much is to be learned from this model in terms of the environmental modulation of adult stem cell pools and neurogenesis. The goal of our chapter was to observe the proliferation and neurogenesis in pallium of juvenile masu salmon *Oncorhynchus masou* before and after a mechanical injury.

### **PCNA LOCALIZATION IN THE MASU SALMON PALLIAL PVZ IN NORM AND AFTER A MECHANICAL INJURY**

PCNA was immunolocalized in the dorsal, lateral, and medial zones of pallium in juvenile masu salmon (Pushchina et al., 2017). The PCNA+ cell distribution patterns in these zones were somewhat similar: solitary proliferating cells or their small clusters were observed in the surface and subventricular layers (Figure 1A, C, E). The main specific feature in the distribution of immunopositive cells in the intact animals was the pronounced surface periventricular layer containing PCNA+ conglomerates of cells that spread over all zones of the dorsal region (Figure 1A, C, E). Another specific feature consisted in the presence of solitary PCNA+ cells in deep parenchymal layers beyond the surface proliferative zone (Figure 1A, C, E). Similar patterns of PCNA+ cell distribution have been observed in other fish species (Lindsey et al., 2007; Pushchina et al., 2007; Zupanc and Sîrbulescu, 2013). Solitary PCNA+ cells were observed in the dorsal and lateral zones (Figure 1A, C) of masu salmon pallium versus the medial zone with more abundant immunopositive cells (Figure 1E).

Earlier studies demonstrated that the proliferative activity in telencephalon of adult *D. rerio* usually concentrated in the dorsal proliferative zone, corresponding to the pallial PVZ, and ventral zone, corresponding to the subpallial PVZ (Adolf et al., 2007; Lindsey et al., 2007). Data of different researcher demonstrate the importance of phylogenetic studies of the pallial and subpallial proliferative zones in the forebrain of zebrafish and other fish species (Lindsey et al., 2007; Zupanc and Sîrbulescu, 2013). The presence of the NSCs involved in adult neurogenesis with a glial phenotype is demonstrated (Adolf et al., 2007; Kempermann, 2011). In particular, it is shown that the PVZ contains slowly and rapidly proliferating cells developing from adult NSCs/precursor cells with a radial glial phenotype (Adolf et al., 2007). A recent classification, based on detailed immunohistochemical labeling (März et al., 2010) and clonal analysis (Rothenaigner et al., 2011), distinguishes between three types of mitotically active cells (II, IIIa, and IIIb) and non-dividing type I cells. An examination of the pallial–subpallial zone of the zebrafish forebrain PVZ has shown that the precursor cells express various transcription and growth factors, such as Pax6 and FGF, and are putatively regulated by these factors (Adolf et al., 2007; Ganz et al., 2010). However, the everincreasing number of studies on the forebrain pallial and subpallial PVZs still fail to sufficiently clarify certain basic aspects in this area, including anatomical boundaries of these zones, their ultrastructural composition, and specific features in their cellular and molecular organizations.

Analysis of regeneration of zebrafish telencephalon has been a subject of several recent investigations (Kishimoto et al., 2011; Kroehne et al., 2011; März et al., 2011; Baumgart et al., 2012; Kroehne and Brand, 2012). In these studies, telencephalon was chosen as the assay system because: (1) newborn neurons are not observed in the parenchyma of the telencephalic pallial subdivision under normal conditions, thus enabling an observer to distinguish between constitutive neurogenesis and regeneration, and (2) there is hope to get an insight into functional differences of teleost and mammalian telencephalic regenerative behaviour.

Since juvenile masu salmon are in the state of active growth, the constitutive production of new cells, according to our data, is rather intensive and is observed both in the brain proliferative zones and beyond them. We believe that the phylogenetic factors, demonstrating

that salmonids belong to an evolutionarily ancient group, the teleosts, for which the uncompleted eversion of telencephalon and retained embryonic brain structural traits are characteristic in the postembryonic development, can also play an important role (Wullimann and Muller, 2009). A similar characteristic, referred to as *fetalization*, is typical of phylogenetically ancient vertebrate groups, the brain of which contains many morphogenetic zones with an increased proliferative potential (Artyukhin, 2008; Zupanc and Sîrbulescu, 2013). Our studies suggest that the cell proliferative potential of the medial zone is considerably higher as compared with the other zones of pallium. One more specific feature of the masu salmon medial zone is a pronounced depthward cell migration from the surface layers of pallium. The stratification of cell layers in this region has been traced in individual cases. Thus, our data suggest that the medial zone is the most important contributor to the constitutive morphogenesis of masu salmon telencephalon as compared with the remaining zones of the dorsal region.

Currently, the data on the embryonic origin, associated with homogeneity of the NSCs in the adult fish brain, are scarce. The studies on zebrafish demonstrate that the proliferative zone of the definitive pallium develops from two separate subtypes of embryonic precursors and comprises two NSC types involved in the adult neurogenesis (Dirian et al., 2014). The dorsomedial NSCs emerge owing to active amplification of the neurogenic radial glia in the embryonic telencephalon. The NSC population of the lateral zone is formed through constant supplementation of the pallial band from the pool of discrete neuroepithelial progenitors of the telencephalon posterior roof, activated in the postembryonic period and retained throughout the lifecycle. This dual origin of the zebrafish pallial proliferative zone implies a time-dependent construction of pallial regions as mosaic and adjacent compartments. Taking into account the results obtained from zebrafish, the data on a nonuniform distribution of the proliferating and HuCD+ cells in the masu salmon periventricular proliferative zones, and the ratio of migrating and proliferating cells in the brain parenchyma, we believe that the masu salmon pallial PVZ has a complex multicomponent mosaic structure and is most likely comprised of several formations containing NSCs.

After a mechanical injury of masu salmon pallium, we observed considerable changes in the cell proliferative activity in both the pallium proliferative zones and parenchyma. The most pronounced changes in the topography of proliferating cells were associated with the structural remodeling of the integrated proliferative, superficially located in the periventricular layer, and formation of the local zones of induced neurogenesis (Figure 1B, D). It should be noted that the periventricular zone as a rule was not verified. Formation of local cell clusters containing both PCNA+ elements and numerous PCNA- cells in *reactive neurogenic niches*, as well as vast populations of migrating cells and weakly labeled radial glial fibers, were observed (Figure 1B, D). These changes appeared after a mechanical injury, suggesting that they can be regarded as repair rearrangements.

Another specific feature in the post-traumatic morphogenesis of masu salmon telencephalon was the formation of the *secondary neurogenesis centers* (reactive parenchymatic niches) in the medial zone, which also possesses an elevated proliferative potential in norm (Figure 1F). After the injury, numerous PCNA- cells surrounded by undifferentiated immunonegative cells were observed. The distribution density in such reactive clusters considerably exceeded that in the adjacent regions, suggesting that these clusters can be regarded as integrated functional complexes with an increased proliferative activity. According to the data by Savel'ev (2001), the centers of secondary neurogenesis are

formed in vertebrate brain when cells from the primary periventricular proliferative region migrate to deeper brain layers retaining their increased proliferative potential. Such cells continue proliferation even beyond the typical conditions of cell microenvironment in the proliferative zone and form the centers of secondary proliferation. In this process, a part of the cells continues proliferation, whereas the other part starts to differentiate. Such cell cluster outside the matrix zone typically has a higher density and heterogeneous cell composition and contains cells at different stages of differentiation. We observed these particular cell clusters in the medial zone of masu salmon telencephalon after injury.

Figure 1. Distribution of the proliferating cell nuclear antigen (PCNA) in the pallial proliferative zone and deep layers of the dorsal telencephalon in juvenile masu salmon *Oncorhynchus masou* (A, C, E) in the norm and (B, D, and F) after mechanical injury: (A) dorsal (Dd), (C) lateral (Dl), and (E) medial (Dm) zones of the masu salmon dorsal telencephalon in the control (dashed line shows the boundaries of the proliferative zone; black arrows indicate solitary PCNA+ cells in the PVZ; red rectangle encloses PCNA+ cell clusters in the dorsal and medial zones; and red arrows indicate PCNA+ cells in parenchyma) and (B) dorsal, (D) lateral, and (F) medial zones after a mechanical injury (ovals enclose neurogenic niches; rectangle in panel (F), the zone of secondary neurogenesis; red arrows indicate PCNA+ cells in parenchyma and in panel (F), in the periventricular proliferative zone; yellow arrows indicate radial glial fibers; white arrows indicate clusters of migrating cells, and black arrows indicate PCNA– cells in parenchyma). Scale bar is  $100 \mu m$ .

The studies on zebrafish have demonstrated that an injury of telencephalon induces a rapid proliferation of neural precursor cells in the PVZ of the injured telencephalon hemisphere as compared with the intact one. The NSC distribution, detected using BrdU and neurogenin, demonstrates that these cells migrate laterally and reach the injured site via subpallium and pallium (Kishimoto et al., 2011, 2012). Recent studies of the zebrafish NSCs have revealed new aspects in the physiology of the radial glia. In particular, it is shown that the radial glia is present in the fish brain proliferative zones (Grandel et al., 2006). A part of the cells forming the radial glial population possesses the NSC properties, which determines a high level of reparative neurogenesis (Zupanc, 2001; Grandel et al., 2006). Cells of the fish radial glia are spread all over the brain regions along the ventricular lumen and enhance successful regeneration of injured brain (Tozzini et al., 2012). It is known that the regenerative potential of somatic stem cells, as a rule, decreases with age of animals; thus, the intensity of constitutive neurogenesis in juvenile masu salmon individuals of different ages (Pushchina et al., 2012) suggests a proliferative potential of NSCs at different ages.

Studies on zebrafish have shown that neurogenesis and oligodendrogenesis in the ventricular zone, olfactory bulb, and parenchyma of the telencephalon weaken with aging (Edelmann et al., 2013). According to our data, pallium in juvenile masu salmon displays a high level of constitutive neurogenesis (Pushchina et al., 2017). We have earlier demonstrated that the periventricular region of masu salmon of different age cohorts have a large content of the radial glia, marked by tyrosine hydroxylase, NADPH diaphorase, and GABA (Pushchina et al., 2012). The radial glial cell population in the periventricular zone remains unchanged to a considerable degree, but immunohistochemical analysis demonstrates that such cells in more adult animals rarer enter mitosis and, consequently, produce fewer neuroblasts. The activity of neuroblasts remains rather constant with age (Adolf et al., 2006; Grandel et al., 2006); thus, neuroblasts produce the same number of postmitotic neurons. The decrease in the level of neurogenesis physiologically correlates with the increase in the radial glia quiescence (Edelmann et al., 2013). An injury activates the radial glia and induces its proliferation. However, the radial glia is to a considerably lesser degree involved in neurogenesis in adult animals as compared with juveniles, suggesting certain irreversible changes in the radial glial cells during brain aging.

Muller and Wullimann (2003) have shown that PCNA labeling of proliferative regions reflects a neuromeric organization of the brain, which has also been confirmed by autoradiography and immunocytochemical (BrdU) assays. PCNA expression in cells retains for 24 h after the completion of mitosis, but the level of its activity decreases by 30% (Wullimann and Puelles, 1999). PCNA is expressed in mitotic cells during the entire proliferative cycle and has a prevalent nuclear localization (Waseem and Lane, 1990); however, cytoplasmic localization of PCNA is also observable in some cases (Vriz et al., 1992). Specific methodical features of PCNA as a cell proliferation marker in the studies of different neurogenesis stages in fish brain has made it possible to demonstrate that this marker at the early developmental stages in zebrafish (days 1–4 after fertilization) identifies neuroepithelial cells that have a rather short cell cycle in this period (Muller and Wullimann, 2003). Nonetheless, PCNA is a convenient cell proliferation marker when studying later postembryonic neurogenesis in fish (Candal et al., 2005), since the cell cycle at subsequent stages is considerably (manifold) longer as compared with the early neurogenesis.

Various lesion paradigms have been elaborated for studying the nervous tissue regeneration of fish brain and its functional repair after CNS injury. Many studies of telencephalon injuries focus on injuries of olfactory bulbs or the dorsal region in one of the telencephalon hemispheres (Zupanc, 2001; Zupanc and Sîrbulescu, 2013). In some cases, the neural repair was studied in the lateral and dorsolateral parts of telencephalon (Ayari et al., 2010). A better insight into the bony fish brain regeneration capacities requires the knowledge of the sources for neuron regeneration in injured brain. Genetic studies involving an injury of dorsal pallium demonstrate that most of regenerating neurons originate from radial glia-type progenitor cells, while differentiation of nonneurogenic cells plays a minor role in the brain repair (Kroehne et al., 2011). A systematic neuroanatomy examination of zebrafish allowed distinguishing of 16 constitutive neurogenic domens located along the brain axis (Adolf et al., 2006; Grandel et al., 2006; Kaslin et al., 2008). As has been shown, the adult NSCs are mainly associated with the ventricular system (Tozzini et al., 2012). The NSCs in fish telencephalon have radial glia morphology and express certain molecular markers (vimentin and nestin) characteristic of the mammalian NSCs (Ganz et al., 2010; März et al., 2010). The pial and subpallial constitutive neurogenic niches, identified in fish, are now regarded as homologs of the subgranullar and subventricular proliferative zones in mammalian brain (Adolf et al., 2006; Mueller and Willimann, 2009).

Telencephalon of zebrafish mostly recovers histologically by 30 dpl and becomes indistinguishable from a non-injured telencephalon after 1 year. Besides the rapid reduction of cell death, gliosis and inflammation, the regenerative/reactive neurogenesis commences with the initial proliferative response of radial glia in the endogenous proliferation domain that produces new neurons in the damaged hemisphere (Kroehne et al., 2011). As early as at 4 dpl, pulse-chase experiments show many newborn pallial neurons in the periventricular zone (Kroehne et al., 2011; März et al., 2011), and newborn parenchymal neurons become evident in the damaged brain from the first week post injury (Kroehne et al., 2011; Baumgart et al., 2012). The parenchymally located newborn neurons, which arise from the ventricularly located radial glial cells as determined by Cre-lox lineage tracing technology, home into the lesion site only after a very long chase time (21–90 dpl) (Kroehne et al., 2011). Pallial radial glia are under the control of notch signalling (Ganz et al., 2010; Kishimoto et al., 2012) which can be monitored by transgene expression under the control of the her4.1 promoter. A transgenic conditional Cre-lox recombination approach has been used to genetically mark pallial radial glia and their progeny (Kroehne et al., 2011).

Thus, PCNA immunolabeling of masu salmon pallium demonstrates the presence of the superficially located proliferative layer and individual proliferating cells with spatially specific number and localization (Pushchina et al., 2017). In general, the distribution pattern of PCNA+ cells in the dorsal telencephalon matches the corresponding patterns of other fish species; it should be noted that an important specific feature consists in organization of the medial zone, the main characteristic of which is an increased proliferative potential. Taking into account the data on the incomplete eversion of salmonid telencephalon, we tend to believe that the medial part of telencephalon is the particular region that houses the most of cell proliferation and migration events that are decisive in telencephalon formation during persistent neurogenesis. The zones of induced neurogenesis appear exclusively in the postinjury process and, in our view, are related with the brain repair.

## **HUCD LOCALIZATION IN THE PROLIFERATIVE ZONES AND PARENCHYMA OF THE MASU SALMON PALLIAL PVZ IN NORM AND AFTER A MECHANICAL INJURY**

Most researchers regard the cells of the PCNA- brain regions as stimulated to differentiation (Candal et al., 2005) because of the presence of neural determination markers, such as Pax6, Zash-1a, Zash-1b, neurogenin, and neuroD, and neural differentiation marker HuCD (Mueller and Willimann, 2009). The newborn neurons in zebrafish pallium also expressed more mature region-specific neuronal markers such as parvalbumin and Prox1 in an appropriate manner and appeared integrated into the neural circuitry as visualized by dendritic (MAP2a+b) and synaptic markers (SV2, mGlu2). The results of HuCD labeling of pallium of juvenile masu salmon confirm these data. A comparison of the distributions of HuCD+ neurons in the dorsal, lateral, and medial zones of masu salmon pallium demonstrates that the definitive cells with a mature neuron-like phenotype, most likely involved in formation of neuronal networks, display different degrees of HuCD immunostaining. The results obtained from juvenile masu salmon differ from the data on HuCD immunolocalization after a mechanical eye injury in adult trout (Pushchina et al., 2016). The trout pallial proliferative zone also displayed a high level of HuCD activity as compared with the definitive neurons in the dorsal regions (Pushchina et al., 2016). However, neither typical neurogenic niches nor structural changes in the dorsal pallial zone, observed after an injury of pallium in juvenile masu salmon, were detectable after an optic nerve injury in adult trout. Thus, we believe that the region of brain injury, as well as the animal age, influences the pattern of postinjury repair. In particular, an injury of trout eye and optic nerve activates neurogenic niches in the optic tectum and cerebellum, but no typical neurogenic niches were detected in telencephalon (Pushchina et al., 2016). The control masu salmon juveniles displayed rather intensive constitutive neurogenesis in different parts of the pallial proliferative zone. The superficially located HuCD+ cells either formed clusters or, in some cases, even a superficial cell layer. The distribution density of immunopositive cells in the lateral zone was higher as compared with the dorsal zone; however, the most superficial layer was formed of negative cells. A high density of both HuCD+ and HuCD- cells and a moderate density of cell distribution in the proliferative region were characteristic of the medial zone.

The densitometric data for the postinjury period make it possible to distinguish between two HuCD activity levels in masu salmon pallium: intensive and moderate (Pushchina et al., 2017). Intensively labeled definitive neurons were prevalent in all the regions of the control animals. The HuCD+ neurons were surrounded by undifferentiated immunonegative cells varying in number in different zones. According to the classification by Edelmann et al. (2013), we referred these cells as to the cell population stimulated to neural differentiation but not yet expressing neural determination markers. Our studies allowed us to distinguish four types of HuCD+ cells differing in their morphology and density of HuCD immunolabeling. We believe that the differences in densitometric characteristics of HuCD+ cells may reflect the differences in the distribution pattern of this protein in the neuron cytoplasm and correspond to different degrees of neuronal differentiation of the cells formed during reparative neurogenesis. Nonetheless, we should emphasize that masu salmon brain contains neurons displaying different degrees of HuCD immunolabeling irrespective of their

differentiation stage and also the described types of neurons. We also assume that different densitometric characteristics of HuCD+ cells may result from methodological aspects, in particular, the ability of antibodies to penetrate into different depths in brain sections. However, the most apparent and grounded assumption explaining the differences in HuCD labeling intensity during reparative neurogenesis, in our view, is that the produced cells are at different stages of neuronal differentiation.

Figure 2. Distribution of the HuCD neural protein in the pallial proliferative zone and deep layers of the dorsal region in juvenile masu salmon *Oncorhynchus masou* (A, C, E) in norm and (B, D, F) after a mechanical injury: (A) dorsal (DD), (C) lateral (DL), and (E) medial (DM) zones of masu salmon telencephalon in the control (rectangles enclose regions of the periventricular zone and arrows of different colors indicate cells of types 1–4) and (B) dorsal, (D) lateral, and (F) medial regions after a mechanical injury (red arrows indicate intensively labeled neurons; white, weakly labeled; in panel (D), black arrows indicate radial glial fibers; rectangles enclose neurogenic niches containing newly formed neurons; black arrows in panel (F) indicate intensively labeled neurons in the pallial periventricular zone; white dashed line is direction of cell migration, and red line segments show different thicknesses of neurogenic layer). Scale bar is 100 μm.

The expression of HuCD protein in the pallial proliferative zones of masu salmon yearlings is rather pronounced, which agrees with the data on zebrafish (Mueller et al., 2011). The cells newly formed in dorsal telencephalon of zebrafish after an injury start to express HuCD on days 3–4 post-injury (Ayari et al., 2010; Kishimoto et al., 2011). The newly formed neurons appear both near the injury site and in the regions distant from this site. As is shown,

a small population of zebrafish cells, formed within 2 days before the injury, is involved in the repair of the injured brain region (Kroehne et al., 2011). The number of HuCD expressing cells gradually increases in the subsequent days, especially in the injured zone. An analysis of the spatiotemporal pattern of HuCD+ cell distribution in zebrafish demonstrates that the newly formed cells acquire the phenotype characteristic of the neurons during migration to the injured zone (Lam et al., 2009; Edelmann et al., 2013). These data suggest that the interactions between proliferating cells in an intact fish brain also change after the injury.

Both intensively and moderately HuCD immunolabeled cells were observed in the deep layers of the masu salmon dorsal zone on day 3 post-injury, which considerably differs from the immunolabeling pattern in the control (Figure 2A, B). In our opinion, a decrease in the HuCD immunolabeling intensity in most of definitive neurons against the background of retained intensive labeling in 25% of the cells is a manifestation of the adaptive response to a mechanical injury of pallium. A redistribution of the HuCD+ cells, forming the layer of irregular clusters with retention of the immunonegative surface layer in control animals, was observed in the proliferative region of the dorsal zone.

The ratio of intensively to moderately HuCD-labeled definitive neurons in the lateral zone was 1:2.5, differing from that in the dorsal zone. After injury, the proliferative zone underwent considerable changes (Figure 2C, D). Two zones of induced neurogenesis were observed as neurogenic niches of different morphologies and, possibly, different origins. After an eye injury in adult trout, local clusters of HuCD+ cells were observed in the lateral proliferative zone (Pushchina et al., 2016). Neurogenic niches in the lateral zone of juvenile masu salmon individuals were surrounded by weakly immunolabeled radial glial fibers. Formation of such structural complexes producing new neurons is a consequence of activated proliferation in NSCs induced by injury (Lam et al., 2009; Edelmann et al., 2013). NSCs are able to produce neurons and glia both *in vivo* and *in vitro*, although the neuronal or glial specialization is determined by the conditions of cell microenvironment and other dynamic factors (Adolf et al., 2006; März et al., 2010; Kishimoto et al., 2011). Similar to mammals, the precursor cells in zebrafish give rise mainly to neurons rather than glial cells (Hinsch and Zupanc, 2006; Mueller et al., 2011). The causes of this phenomenon in zebrafish are still unclear; however, a limited production of astrocytes in adult brain correlates with fits their total low content in brain of bony fish.

According to Kishimoto et al. (2012), the NSCs that emerge after an injury of zebrafish telencephalon differentiate into mature neurons during 1 week post-injury. Most of these cells express Tbr1, suggesting a normal adaptation of the neurons in this region, Thus, the ventricular zones of zebrafish telencephalon are involved in the repair of nervous tissue after a telencephalon injury in adult fish.

A considerable increase in the number of intensively labeled HuCD+ cells, localized to the proliferative zone and forming migratory flows of cells with neuronal specialization, was observed in the medial zone of masu salmon pallium (Figure 2E, F). This overproduction of neurons in the medial zone after injury generally agrees with the increased proliferative potential of this zone, which we revealed by PCNA labeling. As for adult trout, we observed an increased density of HuCD+ cells in the dorsal zone after an eye injury (Pushchina et al., 2016). We believe that the increased production of neurons during the postinjury period in different telencephalon zones is a species-specific feature of salmonids and may possibly reflect certain specific phylogenetic features of the repair process characteristic of this fish group.

### **CONCLUSION**

Stab injury experiments were conducted by inflicting a damage to telencephalon with a needle. This type of traumatic brain injury initiates a cascade of events. An immediate response to the stab is the formation of an oedema and a wave of neuronal cell death, both of which rapidly recede at 7 dpl and 3 dpl, respectively. Another reaction to a stab injury is the onset of gliosis and inflammation in the damaged hemisphere of masu salmon pallium. In the parenchyma of the damaged pallium, from 4 dpl on, a marked hypertrophy of GFAP-positive and vimentin-positive radial fibres is observed.

L-plastin-positive cells in pallium of adult zebrafish consist of a heterogeneous mixture of blood-derived leukocytes and resident microglia that become more numerous after a stab wound (Kroehne et al., 2011; Baumgart et al., 2012). Proliferation levels of different cell types also increase after damage to telencephalon in adult zebrafish, peaking at 3 dpl in the endogenous ventricular proliferation domain, as well as ectopically in the damaged parenchyma. In the endogenous ventricular proliferation zone, radial glial cells expressing GFAP, vimentin, nestin and glutamine synthetase specifically upregulate their proliferation upon a stab injury. In the parenchyma of zebrafish telencephalon, mostly L-plastin-positive cells contribute to the proliferating population (Kroehne et al., 2011); however, a small fraction of oligodendrocyte precursors proliferate as well (Kroehne et al., 2011; März et al., 2011). Also, proliferating endothelial cells can be observed (Kroehne et al., 2011). Slightly elevated proliferation rates can still be detected at 2 weeks post-injury but decline subsequently. Likewise, the initial early inflammatory response does not persist and neither hypertrophic radial glial processes nor a surplus of L-plastin-positive cells are detected by 30 dpl. It is important that the glial scar does not form (Kroehne et al., 2011). This is in marked contrast to the reaction of mammalian telencephalon to a damage where regeneration is hampered by gliosis, inflammation and subsequent formation of the glial scar that inhibits regeneration of neural tissue (Fitch and Silver, 2008; Sofroniew, 2009).

The study of proliferative activity of pallium in juvenile masu salmon *O. masou* has allowed us to identify the superficially located periventricular proliferative zone, which corresponds to the pallial periventricular zone (PVZ) of other fish species, including the dorsal, lateral, and medial compartments. A superficially located periventricular proliferative area with PCNA+ cells, which corresponds to the PVZ of other fish species, including its dorsal, lateral, and medial compartments, has been discovered in pallium of juvenile masu salmon. The PCNA+ cells are also identified in the parenchyma of intact masu salmon brain, and their maximum concentration is observed in the medial zone. In intact brain, solitary proliferating cells were identified in parenchymal regions with their maximum concentration in the medial zone. After a mechanical injury, the zones of reparative neurogenesis neuroepitelial neurogenic niches and zones of reactive neurogenesis surrounded by radial glial fibers — appear in masu salmon pallium. An increase in the proliferative activity is characteristic of all compartments of the PVZ (especially of the medial zone), including its deep parenchymal layers. The PVZ of juvenile masu salmon contains clusters of undifferentiated HuCD+ neurons. A change in the HuCD+ cell topography is observed in a mechanically injured masu salmon pallium: reactive neurogenic niches in the lateral zone and an increase in the cell distribution density and cell migration patterns in the medial zone. A high level of constitutive neurogenesis is characteristic of juvenile masu salmon brain.

Undifferentiated HuCD+ neurons form clusters in the PVZ of intact brain in juvenile masu salmon. Neurons at different stages of maturation, differing in the level of HuCD activity, were detected in the parenchymal layers of the dorsal region. A mechanical injury of pallium in masu salmon is accompanied by a change in the topography of HuCD+ cells. Formation of reactive neurogenic niches is characteristic of the lateral zone, while the medial zone displays an increase in the density of immunopositive and negative cells, as well as a distinct pattern of cell migration. HuCD and PCNA immunolabeling patterns in intact pallium suggest the intensive constitutive neurogenesis in the pallial PVZ of juvenile masu salmon.

The colocalization of newborn cells with the neuronal marker HuCD showed that her4.1 positive radial glia generates neurons. A two-third of the newborn neurons were located in a periventricular position close to the pallial proliferation zone that corresponds to their regular target area. A one-third of all HuCD-positive newborn neurons were found in a parenchymal position that was usually not attained by newborn neurons neither in undamaged brains nor in the control hemisphere.

Thus, the damage site specifically attracts newborn neurons from the endogenous proliferation domain that are rerouted to populate and integrate into this site (Kroehne et al., 2011). It will be important to decode the signals that emanate from the damage site, which act to trigger the regenerative response. Chemokines and their receptors have been suggested as possible candidates. They have been reported to localize to radial glia in telencephalon (Diotel et al., 2010), where their overexpression enhances the proliferative response after an injury (Kizil et al., 2012). Other, still unidentified, pathways may also funnel into a regenerative response to trigger there generative pathway at different angles (Kyritsis et al., 2012). This observation confirms the long-lasting suggestion (Kirsche and Kirsche, 1961) that periventricular progenitors of the "matrix zones" produce neuronal progeny, which are engaged in regeneration.

### **ABSTRACT**

The objective of this chapter was to study proliferation processes and the role of radial glia and neural stem cells in the event of injurious action on cerebellum of masu salmon *Oncorhynchus masou* juvenile. Using the immunoperoxidase staining of the glial fibrillary acidic protein (GFAP), doublecortine (DC) and proliferating cells nuclear antigen (PCNA), processes of proliferation and gliogenesis after mechanical trauma of cerebellum of juvenile masu salmon *O. masou* were studied. After the trauma, the intensity of proliferation and migration processes varies in different zones. Proliferation processes decrease after the trauma in lateral and basal zones, and migration increases. In the dorsal zone, on the contrary, migration processes significantly decrease and proliferation increases. In the dorsal matrix zone of cerebellum, intense cell proliferation was detected. In the dorsal, lateral, and basal zone of the molecular layer of cerebellum after traumatic injury, neurogenic niches containing PCNA and cells, as well as a heterogeneous population of PCNA- cells, were identified. At the location of neurogenic niches, fibers of radial glia and small single, intensely or moderately labeled GFAP cells were discovered. As a result of injury, GFAP+ fibers of radial glia, which form differently directed, radially oriented bundles, appeared in the dorsal matrix zone. Such structural formations were not discovered in intact animals. We suppose that, after the trauma, a structural reconstruction, connected with partial spatial reorientation of the radial glia fibers, and formation of specific directions for cells formed in this zone occur in the dorsal matrix zone. As a result of the trauma, elements of the radial glia, including both the cells possessing typical morphology and the cell fragments represented by long

radially oriented processes or cell body, containing initial fragments of radial fibers, appeared in masu salmon's cerebellum.

#### **INTRODUCTION**

Fish is quite an interesting subject for investigation of neurogenetic processes, since, during the period of their postembryonic development, the formation of brain, growth, and differentiation of integrative centers are very active (Zupanc, 2006). The peculiarity of adult neurogenesis in teleost fish is the ability to form large amounts of new cells. Studies on the fresh-water fish, *Danio rerio* and *Apteronotus leptorhynchus*, have shown that proliferation rate in these species is by 1–2 orders of magnitude higher than in mammals (Zupanc and Zupanc, 2006). A mass increase of intensity of cell proliferation is observed in bony fish as a response to brain damage. Complete recovery of neural tissue occurs due to colonization of the injured area with new neurons. In mammals, the long persistency of newborn cells, as a rule, is weakened, and their brain is restricted in its ability to recover (Zupanc and Sîrbulescu, 2011).

Сerebellar morphogenesis of zebrafish has been repeatedly investigated in recent years with a focus on progenitor migration during embryonic and early larval stages (Chaplin et al., 2010; Wullimann et al., 2011). However, since adult teleosts add large numbers of new cells to the cerebellum (Zupanc and Horschke, 1995; Grandel et al., 2006; Hinsch and Zupanc, 2006; Zupanc and Sirbulescu, 2011), it is clear that teleost cerebellar morphogenesis continues after embryogenesis. Recently, Kaslin et al. (2009) have studied the continued generation of new granule neurons during adult stages with the aim to determine the identity of progenitor/stem cells and their progeny.

The basis of this is postnatal neurogenesis, the process beginning with division of precursor cells, their subsequent migration, differentiation of newly formed cells and ending with integration of new neurons in the neural network (Kempermann, 2008). The phenomenological manifestations of neurogenesis in adult fish are similar to those in embryonic brain of birds and mammals (Levine et al., 1994). It is supposed that adult neurogenesis plays an important role in quantitative harmonization and coordination of CNS neurons in motoric brain structures. In mammals, body growth occurs due to the increase in size of muscle fibers rather than in their number. Number of muscle fibers increases throughout the lifecycle of fishes, and this probably requires corresponding increase in neuron units to control the muscle activity and for the quantitive harmonization of central neurons and peripheral sensor elements. In bony fishes, production of new neurons in association with a sufficiently long survival of their significant fraction leads to continuous growth of brain and its structures. In contrast to mammals, where central parts of sensory systems become completely formed and equivalent to the quantity of sensory receptors by the moment of birth and/or shortly after it, the growth and development of sensory projections in fish brain can continue throughout the lifecycle because of the necessity of adaptation to continuous significant increase in body size and amount of incoming sensory information. The continuous formation of new neurons in adult fish is provided by the presence of large amounts of cerebral radial glia (Onteniente et al., 1983; Pellegrini et al., 2007), which are known to perform a function of neural stem cells during embryonic neurogenesis in mammals (Noctor et al., 2002; Kriegstein and Alvarez-Buylla, 2009). In mammals, new neurons form

mainly in the following two zones of brain: (1) in the frontal part of the subventricular zone of the lateral ventricle, from which immature neurons migrate in the composition of the socalled "rostral migratory stream" to olfactory bulbs where they differentiate into granular neurons and periglomerular interneurons (Curtis et al., 2007), and (2) in the area located in the subgranular zone of the dentate gyrus from which new cells migrate for short distances to the granular layer of hippocampal cells and develop into mature granular neurons (Seri et al., 2004). In mouse brain after inflicting mechanical damage, proliferation of resting progenitor cells in cortex parenchyma was discovered (Ahmed et al., 2012). There is an increase in numbers of endogenic stem cells forming neurospheres when grown *in vitro*. Secondary spheres in case of differentiation yield three types of neural stem cells (NSC), which indicate their multipotency in the cortex and hippocampus alike (Ahmed et al., 2012).

Mature bony fish display high neurogenic potential in many cerebral areas. Zones of initial proliferation in fish are located along the brain ventricle and form 16 accumulations along the rostro-caudal axis of the brain (Ekström et al., 2001). The brain areas, where quite intense cell division takes place in adult individuals, are considered as zones of secondary neurogenesis being localized in telencephalon, optical tectum, and cerebellum, as well as in thalamus and brain axis (Zupanc and Ott, 1999).

Fish are able to regenerate neural tissue after a mechanic or chemical damage in cerebellum, telencephalon, olfactory bulbs, and retina, and this is supposedly closely allied to the processes of adult neurogenesis (Takeda et al., 2008; Kroehne et al., 2011; März et al., 2011; Diotel et al., 2013; Zupanc and Sîrbulescu, 2013). It has been proven than the neural tissue of fish regenerates after damage within a few weeks (Zupanc et al., 2003). Replenishment of a large number of cells lost as a result of damage occurs from different sources, such as radial glia, centers of initial and secondary proliferation, and neurogenic niches (Zupanc, 2011).

Evolutionary ancient groups like salmon fish (Salmonidae) are characterized by high concentration of undifferentiated elements in the matrix zones of brain and parenchyma alike (Pouwels, 1978). Cerebellum is a generally accepted brain zone for the study of morphogenetic processes, since it increases the proliferative activity both under normal conditions and in case of traumatic impact (Pouwels, 1978; Zupanc and Sîrbulescu, 2013). Among poikilotherms, cerebellum retains the embryonic properties only in mature bony fish, which is also typical for other areas of their brain (Margotta et al., 2004).

Recently, it has been established that the glial fibrillary acidic protein (GFAP) is one of the markers of NSC (Kriegstein and Alvarez-Buylla, 2009; Ahmed et al., 2012). The proliferating cell nuclear antigen (PCNA) is used in the study of proliferative cell populations (Candal et al., 2005). The objectives of the chapter were to study the proliferation processes and the role of the glia and neural stem cells in the event of damage to cerebellum of juvenile masu salmon *Oncorhynchus masou*.

# **COMPARATIVE ASPECTS OF ADULT NEURAL STEM CELL ACTIVITY IN AMPHIBIANS AND FISH**

During the time of Altman's initial studies of rodents, reports on proliferation zones in brain of adult amphibians and fish were also published (Kirsche, 1967). In Amphibia,

proliferation and neurogenesis are more widespread than in amniotes and are localized in telencephalon, preoptic region, hypothalamus, thalamus, midbrain and cerebellum in urodeles and anurans (Margotta et al., 2004; Raucci et al., 2006). Unfortunately, there are no many reports on constitutive neurogenesis in amphibians, but a recent study confirms constitutive neurogenesis in the forebrain and midbrain of the adult bullfrog *Rana catesbeiana* discovered by pulse-chase experiments using co-labelling of newborn cells with a marker of early neurogenesis (Simmons et al., 2008). On the contrary, the aquatic salamander *Notophthalmus viridescens* does not show constitutive neurogenesis in the midbrain. With a specific lesion of midbrain dopaminergic neurons, however, quiescent ependymoglial cells can be activated in this species to proliferate and regenerate the lost cells (Berg et al., 2010).

In teleosts, the initial reports on proliferation zones in ventricular regions of the adult brain were subsequently extended to other teleost species and uncovered the presence of constitutive proliferation zones/neurogenic zones all along the rostro-caudal axis of the brain (Kuroyanagi et al., 2010; Tozzini et al., 2011). The widespread neurogenesis in both anamniote groups has been attributed to the protracted, perhaps lifelong, growth of the body and, notably, sensory organs. In both groups, freshly hatched animals are considerably smaller than adults. Thus, the constitutive neurogenesis observed in growing teleosts and amphibians may be attributable to a growing demand of CNS processing power in conjunction with increasing sensory input (Kaslin et al., 2008). This is nicely exemplified by the growing retina and optic tectum in amphibians and fish (Cerveny et al., 2012) and the increasing number of taste buds and growth of the chemosensory lobes in medulla in cyprinids (Komada, 1994).

It is important to note that brain proliferation zones in adult zebrafish reflect a more general proliferation pattern along the ventricular walls of teleost brain (Grandel and Brand, 2013). The teleost proliferation zones are not ill-defined but distinctly localized in all the subdivisions of brain along the rostro-caudal axis. From 12 to 16 distinct proliferation zones have been recognized as distantly related between teleost species such as stickleback *Gasterosteus aculeatus*, brown ghost *Apteronotus leptorhynchus*, and zebrafish *Danio rerio*. With the exception of minor differences, the discrepancy in number reflects the investigators' interpretation rather than an actual lack or increase of zones in these species (Zupanc and Horschke, 1995; Ekström et al., 2001; Zupanc, 2006). The partially characterized brain proliferation zones of medaka *Oryzias latipes* and *Nothobranchius furzeri* likewise correspond to the general proliferation pattern; however, observations on the posterior hindbrain in these species are missing (Kuroyanagi et al., 2010; Tozzini et al., 2011). Thus, zebrafish suits well to study adult teleost brain proliferation, especially with the opportunity to elucidate the organization of proliferation zones on a cellular level, the contribution of newborn cells to normal brain function, the fate of restriction of progenitor/stem cells and, hence, their potential to repair brain parts after an injury of brain tissue.

# **PROLIFERATION AND MIGRATION OF CELLS IN CEREBELLUM OF FISH**

The largest formation containing PCNA with cells was a dorsal matrix zone of *O. masou* cerebellum. It is located in the dorsomedial part of cerebellum's body, at the boundary

between the molecular and granular layers, and the probability density of PCNA with cells in it was higher compared to the adjoining areas of the molecular layer. According to previously conducted investigations, in the composition of this zone, we identified four types of cells in a normal state and after the damage (Stukaneva et al., 2015).

In the lateral and basal zones, proliferation processes noticeably decrease after the damage and migration processes increase (Figure 1A, B). We explain it by the fact that newly formed cells begin to radially and tangentially migrate in large amounts within two days after the damage, and this process can intensify in the following days. Within the boundaries of the lateral zone, we discovered dense clusters of intensely labeled PCNA cells separated from each other by immune- negative zones. Such clusters were identified as neurogenic niches (Figure 1C). After mechanical injury, proliferation and migration processes change their activity in different zones (Figure 1D).

Thus, results of PCNA immune labeling indicate that the proliferative activity in *O. masou* is typical mostly for the dorsal matrix area of cerebellum that agrees with the data on other fish, such as *D. rerio* (Zupanc, 2006) and *Apteronotus leptorhynchus* (Sîrbulescu et al., 2015). The results of our observations allow us to assume that the structural changes detected have a direct relation to processes of reparative neurogenesis. Thus, the obtained results are a demonstration that, after the damage, the main volume of cell proliferation is found in the cerebellar dorsal matrix zone.

Figure 1. Localization of proliferative cell nuclear antigen (PCNA) in cerebellum of *Oncorhynchus masou* 2 days after stab-wound injury of cerebellum: (A) patterns of tangential migration (red arrows) and neurogenic niche (in oval) in the molecular layer of cerebellum; (B) radial migration of PCNA+ cells; (C) neurogenic niche (in square); (D) tangential migration of PCNA+cells. Scale bar: A, 100 μm; B–D, 50 μm.

Short-term bromodeoxyuridine (BrdU) labeling experiments or PCNA staining showed widespread proliferation in the cerebellar molecular layer of zebrafish. Newborn cells migrate radially along vimentin/ GFAP/BLBP-expressing radial fibres towards the surface of the molecular layer, where they migrate tangentially and disperse laterally to finally dive in a radial direction through the cerebellar molecular layer into the granular layer, where they differentiate into granule neurons (Grandel and Brand, 2013). Migrating progenitors and differentiated cerebellar granule neurons express the transcription factors Zic1, Zic3, Pax3 and Neurod (Kaslin et al., 2009). Migration through the molecular layer occurs rapidly. Within 6 days, the molecular layer of zebrafish cerebellum becomes devoid of labeled cells as they reach the granular layer (Grandel and Brand, 2013). This behavior is also observed with most cells above the dorsal matrix zone, except for label-retaining cells that remained after up to 6 weeks of chase and still showed the initial S-phase marker plus either pH3 or PCNA immunoreactivity, indicating that they were still proliferating. Such cells are considered the presumptive stem cells in other systems (Doetsch et al., 1999). Thus, Kaslin et al. (2009) determined their molecular characterristics. Tg (nestin-GFP) animals showed transgene expression in most proliferating cells above the granular layer "cap". Tg (nestin-GFP) was also found to co-localize with label retaining cells at this position. In addition, these cells maintained expression of Sox2, Meis and Musashi 1 that were shown to localize to stem or progenitor cells in other systems (Morales and Hatten 2006). Tg (nestin-GFP)-expressing progenitors also were distinctly polarized, displaying apical adherence junctions and expressing apical markers such as ZO1, β-catenin, γ-tubulin and aPKC (Grandel and Brand, 2013). As in the case of the subpallial proliferation domain and in the periventricular margin of optic tectum, the cerebellar progenitors displayed a neuroepithelial phenotype.

To underscore this finding, Tg (nestin-GFP)-positive cells did not co-stain with the radial glia markers vimentin/GFAP/BLBP. Radial glia in the cerebellar midline consists of a nonproliferating population and may serve to guide the migrating progeny of the neuroepithelial progenitor population. How do neuroepithelial granule cell progenitors become situated within *corpus cerebelli*, apparently far off from the ventricular system? Kaslin et al. (2009) studied the development of the cerebellar stem cell niche during embryonic and larval stages which showed that cerebellar progenitors were derived from the upper rhombic lip as in rodents and birds.

Within the first 10 days, the rate of cell proliferation in the area of brain trauma in bony fish increases several times compared to other areas of cerebellar body. Experiments with labeling by BrdU have shown that cells formed 2 days before the trauma take part in the regeneration process (Zupanc and Ott, 1999). This observation presupposes a presence of a link between continuous cell proliferation in an intact brain and restoration of the area damaged due to injury. A retrograde tracing in combination with BrdU labeling of S-phase have shown that new granular neurons are projected into the molecular layer of cerebellum (Zupanc and Ott, 1999). This fact allows us to assume that these neurons integrate into the already existing neuron network of cerebellum.

In zebrafish, however, a distinct morphogenetic process during embryonic and early larval stages (24 h to 7 days) displaces medially located rhombic lip progenitors and a small portion of the fourth ventricle into cerebellar corpus to form an anterior protrusion, which has been termed as cerebellar recessus (Kaslin et al., 2009). The latter grows further anteriorly thereby carrying the progenitors from the upper rhombic lip deeper into *corpus cerebelli*. Dye labelling experiments revealed that the lumen of cerebellar recessus extends across the

cerebellar midline and remains in contact with the fourth ventricle even during adult stages. This shows that the nestin-expressing neuroepithelial-like precursors in the cerebellar stem cell niche stay in contact with the ventricular system with their apical sides, much like the precursors of subpallium and the periventricular tectal margin.

In our investigations, we verified the zones after injury with the neurogenic activity, the neurogenic niches located in the molecular layer of the dorsal, lateral, and basal areas of masu salmon's cerebellum. We linked their appearance to intensification of genetic proliferative programs in neutral stem cells and formation of local neurogenic niches as a response to damage. When damage is inflicted to neurogenic zones, active proliferation and differentiation of new cells begins, and they migrate to the damaged area, restoring the injured tissue.

According to Zupanc's data, in case of damage to *A. leptorhynchus* brain, intense neurogenesis processes start in the basal zone of cerebellum (Zupanc, 2011). Thus, this area can serve as a source of cells for reparative neurogenesis. In the basal zone of cerebellum in the area of granular eminences of juvenile masu salmon, on the contrary, the intensity of proliferation is high enough in the control and significantly decreases after a damaging effect. It is possible that the decrease of proliferation processes in this area of cerebellum is replaced by cell migration processes.

Appearance of neurogenic niches in the area of dorsal, lateral, and basal zones of the cerebellar molecular layer is the next stage of reparative neurogenesis. Neurogenic niches appear *de novo* after a traumatic impact and contain PCNA+ cells, as well as a heterogeneous population deprived of a proliferation marker. Immunolabeling of GFAP has shown that fibers of radial glia, as well as isolated small intensely and moderately labeled cells, which are phenotypically corresponding to neural stem cells described in cerebellum of other bony fish, are detected in the area of neurogenic niches (Hinsch and Zupanc, 2006; Kaslin et al., 2013; Sîrbulescu et al., 2015).

The investigations conducted allow us to conclude that, after inflicting an injury to cerebellum of juvenile masu salmon, processes of reparative neurogenesis are added to the processes of constitutive neurogenesis: active proliferation and differentiation of new cells begin, and they migrate to the damaged area, repairing the tissue. The main source of new neurons is neurogenic niches that are formed during reparation of neural tissue.

## **GFAP, DOUBLECORTINE AND OTHER MARKERS OF NSCS IN CEREBELLUM OF FISH**

In cerebellum of juvenile masu salmon in normal state, we discovered a significant level of GFAP-positivity detected in fibers of systems of the spinocerebellar tract: as a part of cerebellar peduncles located in the basal part of cerebellar body, in fibers of radial glia, and in a heterogenous population of rounded (intensely labeled) and elongated (moderately labeled) cells (Stukaneva et al., 2017).

In the lateral zone, we discovered a small amount of DC+ cells of the following two types: small cells of  $5.99 \pm 0.11/2.76 \pm 0.12$  µm in size and larger ones of  $9.07 \pm 0.26/2.76 \pm 0.12$ 0.34 μm in size. The number of intensely DC-labeled cells per visual section was no more than 15 (Figure 2A). They had a rounded or elongated shape, were deprived of process, and

located solitary or formed small clusters (Figure 2B). In the granular layer of the basal zone, the probability density of differently directed, thin, DC+ radial glia fibers was moderate (Figure 2B). In a visual field, there were, on average, 14 DC+ cells and 24 DC+ radial glia cells. In the area of white matter of the basal zone (cerebellar peduncles), there were, on average, 30 DC+ cells and 48 GFAP+ fibers per a relevant test-field of 28 000  $\mu$ m<sup>2</sup> (Stukaneva et al., 2017). In this area, fibers are prevailing GFAP+ elements, whose quantity differs significantly  $(p < 0.05)$ . After injury, on the surface of the dorsal and basal zones and deep in the molecular layer of the lateral zone, we detected small local dense accumulations of GFAP- cells, whose morphological parameters correspond to those of cells of the first type labeled with PCNA (Stukaneva et al., 2017). We consider such GFAP+/DC+ cells conglomerates as neurogenic niches emerging in masu salmon's cerebellum as a response to damaging effect (Figure 2C, D). In dorsal, basal, and lateral zones, we found niches of 3192  $\pm$  $427,6650 \pm 721$ , and  $1393 \pm 653 \text{ }\mu\text{m}^2$ , respectively (Stukaneva et al., 2017). In all the abovementioned zones, parameters of proliferative PCNA+ cells coincide with the initial morphological parameters of GFAP+/DC+ cells.

Figure 2. Expression of doublecortin (DC) in cerebellum of *Oncorhynchus masou* at 2 days post-injury: (A) general view of *corpus cerebellum*, (DC) immunopositive (ip) cells are indicated by pink arrows; (B) DC-ip cells (green arrows) and radial glia (blue arrows) in the basal part of *corpus cerebellum*; (C) DC-ip group of cells (in white oval), DC-ip single cells (white arrows) and DC- immunonegative (in) group of cells (in black oval) and DC-in single cells (orange arrows) in molecular layer of cerebellum; (D) a neurogenic niche containing DC-ip cluster of neural stem cells (in rectangle) in the molecular layer. Scale bar: A, 100 μm; B–D, 50 μm.

Comparative studies of the ratio of GFAP+ cells to fibers in the dorsal and basal zones have been conducted. At one day after inflicting a damaging effect, we observed changes of cell composition and fibers compared to the intact state. After the damage, the number of GFAP+ cells and fibers increased in the dorsal and basal zones. We suppose that the increase in number of GFAP+ cells is connected with appearance of activated astrocytes as a result of the damage (Stukaneva et al., 2017).

As a result of the damage in the dorsal matrix area, we recorded appearance of GFAP+ fibers of radial glia forming differently oriented bundles (Figure 3). Such structural formations have not been detected in intact animals. We suppose that, after the injury in the dorsal matrix area, there is a structural reconstruction, connected with appearance of additional labeled fibers in the area of the damage, that leads to twofold increase in the probability density of GFAP+ fibers in this area. We link such effects to intensification of spatial reorientation of radial glia fibers and formation of specific tracks for cells formed in this area.

Figure 3. Localization of glial fibrillar acid protein (GFAP) in the cerebellum of *Oncorhynchus masou* at 2 days post-injury. Dorsal matrix zone is outlined by black squares; GFAP-immunopositive fiber is indicated by red arrows; DMZ, dorsal matrix zone; ML, molecular layer; GrL, granular layer. Scale bar: 100 μm.

In brain of adult mammals, cells of radial glia are located in restricted neurogenic areas, such as the subgranular zone of hippocampal dentate gyrus (Morrens et al., 2012; Dimou and Goetz, 2014). In mice, GFAP-labeled glia disappears from the beginning of myelinization (Nakahara et al., 2003), whereas in fish, GFAP-labeled fibers of radial glia are identified in different segments of the brain, including cerebellum, throughout their life (Zupanc and Horschke, 1995).

We suppose that the existence of GFAP+ and DC+ radial glia in an intact brain of juvenile masu salmon reflects processes of persistent neurogenesis. The morphology of GFAP+ structures, their topography, and interactions with other structural components allow us to assume that they obviously are elements of threadlike fibers of masu salmon's cerebellum. This is, in particular, indicated by the morphology of these structures and the presence of microcytocsculpture along fibers and their terminals.

In mammal brain, GFAP is a classical marker of astrocytes with numerous radially oriented processes and terminal pedicles that are often formed on the surface of vessels (Doetsch and Scharff, 2001). It has recently been shown that GFAP is one of the markers of neural stem cells (Kriegstein and Alvarez-Buylla, 2009; Ahmed et al., 2012). However, as a rule, their phenotype is more complex and, besides GFAP, contains vimentin, nestin, S-100, Sox2 (Adolf et al., 2006; Sîrbulescu et al., 2015). In studies of several areas of brain of adult bony fish, we identified precursor cells possessing characteristics of radial glia (Chapouton et al., 2007; Rothenaigner et al., 2011). In this case, they were capable of self-renewal and creation of different cell types, which demonstrate characteristics of genuine stem cells (Rothenaigner et al., 2011). It is possible that at least some of the radial glial cells in the brain of adult *A. leptorhynchus* fish act as these precursors. Since GFAP+ astrocytes can participate in recovery of cells lost in case of injury in the subventricular zone (Doetsch et al., 1999), it is obvious that these cells have the capability of self-repair. According to the data of Ahmed et al., (2012) cortex astrocytes in mouse brain stop fission by the tenth day of postnatal development, and GFAP expression after injury becomes more pronounced compared to proliferation processes.

GFAP+ cells of masu salmon's radial glia located in the surface layer of molecular layer have small-sized somas and long unbranched processes. Thus, GFAP+ cells and fibers of radial glia are both structural and morphological components in the composition of cerebellum of juvenile masu salmon. Our data support the results obtained for *Austrolebias affinis*, *A. charrua* and *A. reicherti* (Fernandez et al., 2011), and *A. leptorhynchus* (Clint and Zupanc, 2001) concerning the presence of GFAP+ radial glia in cerebellum of bony fish. We are inclined to attribute the few identified GFAP+ cells to neural stem cells. This assumption is based on a combination of morphological and topographic properties of neural stem cells, their connection with neurogenic zones, and relationships with fibers of radial glia.

In zones of secondary neurogenesis of masu salmon's cerebellum, we identified GFAP+ fibers and cells of radial glia. Data obtained from different species of bony fish is the evidence that radial glia is the prevalent type of GFAP-immunolabeled elements remaining in brain of adult fish. In addition to these fibers, whose numbers increase after injury, cell migration also takes place (Clint and Zupanc, 2001).

Data of Ahmed et al., (2012) have shown that, after a mechanical damage to mouse brain, endogenic GFAP+ progenitor cells are activated. Approximately 50% of cells forming neurospheres in hippocampus and 75% in cortex originate from GFAP-expressing cells. According to data of Sîrbulescu et al., (2015) GFAP in cerebellum of *A. leptorhynchus* labels neural stem cells/precursor cells (Sîrbulescu et al., 2015). This agrees with a hypothesis that such cells are supposedly a source of neurospheres after the damage (Ahmed et al., 2012). However, not all neurospheres originate from GFAP+ cells: their smaller part is precursors of GFAP- cells.

#### **CONCLUSION**

Neurogenesis during adult stages is found in species of all vertebrate classes, as it serves different needs. Adult neurogenesis is considered in the context of protracted or constitutive growth or neuronal turnover. Adult neurogenesis is observed within the same class or order, even within one species, to serve these different needs. Are there fundamental differences in the generation of new neurons that show different phenotypes and serve different functions? From a morphological viewpoint, most stem cell populations retain contact to the ventricular system. Structurally, they appear as neuroepithelial cells, radial glial or astroglial cell types. The different shapes of these progenitors have been suggested to be a secondary consequence of the architecture of the developing parenchyma overlying the ventricular stem cell zone of the embryo (Kriegstein and Alvarez-Buylla, 2009). We suggest that an important step in characterizing the degree of difference between various stem cells pools is to identify the pathways that control their activity. This could be a key to our understanding of stem cell diversity and a valuable cue to the development of therapies based on yielding activation of active or dormant populations.

Certainly, in this scheme, SGZ radial astrocytes of mammalian brain are an odd element, as they are described as having no contact with the ventricle, yet they express nestin as do their cerebellar counterparts in zebrafish. This difference may be related to the late appearance of dentate gyrus in evolution which can explain the lack of a directly homologous cell type in other vertebrate groups (Kempermann, 2012). Progenitors of *eminentia granularis lateralis* have lost the ventricular contact also. It can be argued that they "only" serve the protracted cerebellar growth; however, SVZ astrocytes also serve the protracted growth of the olfactory bulb initially.

The differences between various stem cells on the level of gene expression may highlight their restriction and differences with respect to their prospective progeny. It will be interesting to find whether distinct stem cells can be forced to produce unusual progeny if needed. Such a scenario and, hence, a broader prospective potential of adult neural stem cells are confirmed by the lesion experiments in zebrafish cerebellum, which show, at least topologically, that newborn neurons will populate regions within the granular layer that are otherwise not attained. On the other hand, it still remains unclear if all the cell types that are lost after the injury are subsequently replaced indeed.

### **ABSTRACT**

Metabolism of the living organisms is associated with oxygen consumption. Microbes, plants and animals use oxygen in the major physiological and biochemical pathways. However,  $O_2$  has two unpaired electrons and the univalent reduction of the molecular oxygen produces reactive oxygen species (ROS), which lead the oxidative stress and damage biomolecules, such as lipids, proteins, DNA, cells and tissues. Living organisms have antioxidant defense to counteract the toxic effects of ROS, and it plays a key role in inactivation of ROS, and thereby controls of oxidative stress as well as redox signaling. Among antioxidant enzymes catalase (CAT) (EC 1.11.1.6.) which catalyzes the reduction of hydrogen peroxide to water and total peroxidase (PER) (the sum of SeGPx (EC 1.11.1.9) and selenium-independent GPx (EC 1.11.1.9) activities), which reduces both hydrogen peroxide and organic hydroperoxides are the main antioxidant enzymes. The study of these enzymes in different taxonomic groups of the living organisms is very important for the understanding of the mechanisms of the evolutionary process and adaptations of the species for environmental conditions. Antioxidant status of the fish depends on many biotic and abiotic factors, such as temperature, season, diet, salinity, oxygen concentration and many others, as well as on their taxonomic position and life cycle. It reflects the adaptive strategy of fish species to oxidative stress and their ability to cope with the environment. At the other side, antioxidant status is attributed with phylogenetic position and ecological peculiarities of the organism, and these parameters in primitive life are differed compared to birds and mammals. The levels of antioxidant enzymes activity are ranged in fish tissues, and they depend on the tissues specificity and physiological function. The interspecies variations of the enzymes may reflect the specific adaptations to the oxidative stress and the protective mechanisms

against ROS damage in fish, belonging to different ecological groups and inhabiting different geographical locations. Studies of antioxidant enzymes in different species are very important for the understanding the response mechanisms against pollution in fish of various taxonomic and ecological groups as well as for aquaculture purposes, and for receiving the information of repair mechanisms and adaptation to unfavorable factors. The combination of specific phylogenetic, physiological and ecological features of fish species may modify antioxidant status, and it is important for development of monitoring programs. The aim of the present work is to analyze catalase and peroxidase enzymes in different Black Sea teleosts related to their taxonomic, physiological and ecological position and for the purpose of the use of these antioxidant enzymes in fish tissues as biomarkers for the anthropogenic impact on marine environment.

### **1.INTRODUCTION**

The introduction of molecular oxygen into Earth's atmosphere billions of years ago has allowed animals to produce energy more efficiently (Falkowski et al., 2004). Metabolism of the living organisms is associated with oxygen consumption. Microbes, plants and animals use oxygen in the major physiological and biochemical pathways. Living organisms obtain and use oxygen, and evolved over hundreds or millions of years together with the evolution of oxygen-delivery systems. A steady supply of oxygen to the existence of organism was very important, because its metabolism depends on oxygen as a primary source of fuel (Fisher & Burggren, 2007). However,  $O_2$  has two unpaired electrons and the univalent reduction of the molecular oxygen produces reactive oxygen species (ROS), which lead the oxidative stress and damage biomolecules, such as lipids, proteins, DNA, cells and tissues. Living organisms have antioxidant defense to counteract the toxic effects of ROS, and it plays a key role in inactivation of ROS, and thereby controls of oxidative stress as well as redox signaling. A number of mechanisms have evolved to defend against oxygen deprivation (hypoxia and anoxia) and for the hyperoxic conditions. At the other side, ROS can play an essential role in the evolution of living organisms, because the growth of oxygen level in the atmosphere in the combination with the increased mobility and food intake, led to increase cellular level of free radicals, ROS interacted with DNA of the primitive life, enhancing mutations and providing new regulatory mechanisms and biodiversity (Yang et al., 2018).

Recent years the role of oxidative stress in the life history has been received much attention, caused the effects of the climate changes and anthropogenic pollution, and their consequences for environment and biota. However, generally the researchers focus their studies on high taxonomic groups, while the information about fish and invertebrates is less (Birnie-Gauvin et al., 2017).

Antioxidant system presents in all living organisms and it includes low molecular weight scavengers (vitamins A, E, K and C, carotenoids, SH-containing substances (glutathione) and small-molecule antioxidants namely uric acid, urea, and etc.), and special adopted enzymes (catalase, superoxide dismutase, peroxidases, especially selenium-dependent glutathione peroxidase (SeGPx) (EC 1.11.1.9), glutathione reductase (GR) (EC 1.8.1.7) and some others) (Winston, 1991). Heme peroxidases and catalases are the key enzymes of hydrogen peroxide metabolism and signaling, which present in all kingdoms of life (Zamocky et al., 2014). Among them catalase (CAT) (EC 1.11.1.6.) and total peroxidase (PER) (the sum of SeGPX

and selenium- independent glutathione peroxidase  $(GPx)$  (EC 1.11.1.9) activities), are the key antioxidant enzymes.

CAT catalyzes the reduction of hydrogen peroxide to water:

 $2H_2O_2 \rightarrow 2H_2O + O_2$ 

Heme peroxidases are the most abundant family of peroxidase catalyzing the  $H_2O_2$ dependent oxidation of a wide kinds of substrates. They involved in innate immune response, hormone and prostaglandin synthesis crosslinking of protein extracellular matrix (Øvergård et al., 2017). Additionally, they play a role in the process of the fish eggs fertilization. Total PER (SeGPx and GPx) reduces both hydrogen peroxide and organic hydroperoxides:

 $ROOH + 2GSH \rightarrow ROH + H<sub>2</sub>O + GSSG (SeGPx)$  $H_2O_2$  + 2 GSH  $\rightarrow$  2 H<sub>2</sub>O + GSSG

GPx eliminates the peroxides produced as effect of reactions of biomolecules with ROS. There are several types of GPx, which was isolated and cloned in various organisms (Liu et al., 2018).

Therefore, study of these enzymes and their activity in different taxonomic groups of the living organisms is very important for the understanding of the mechanisms of the evolutionary process and adaptations of the species to environmental conditions. Fishes are highly distributed in various water bodies with great variability of their conditions, including salinity, oxygen concentration, temperature, and etc. (Birnie-Gauvin et al., 2017). They play an important role in the aquatic ecosystems and for people, because they are the main source of seafood, which has been recognized as a high-quality, healthy and safe food type. Fish tissues are rich of the antioxidants, and some of them are present in seafood in high concentrations. Therefore, they are the main sources of these essential components for people diet and one of the most important food commodities consumed worldwide. At the other side, antioxidant enzymes namely catalase and peroxidase are good biomarkers and they are used as a tool for the evaluation of stress conditions in the wild and aquaculture fish populations (Mukherjee et al., 2017; Alti et al., 2016).

Antioxidant status of fish depends on many biotic (food consumption, reproductive strategy, aging and senescence, belonging to different ecological groups), and abiotic factors such as temperature, season, salinity, oxygen concentration in water, and many others as well as on their taxonomic position and life history. It reflects the adaptive strategy of fish species to oxidative stress and their ability to cope with the environment. At the other side, antioxidant status is associated with phylogenetic position and ecological peculiarities of the organisms, and these parameters in primitive life are differed compared to birds and mammals. The levels of the antioxidant enzymes are ranged in fish tissues, and they depend on the tissue specificity and physiological function. The interspecies variations of the enzymes may reflect the specific adaptations to the oxidative stress and protective mechanisms against ROS damage in fish, belonging to different ecological groups and inhabiting different geographical locations and biotops. Thus, the comparative studies of antioxidant defense in teleosts are very important for the understanding the main ways of evolutionary process and the mechanisms of adaptation to aerobic conditions (Filho & Boveris, 1993; Filho et al., 1993; Filho, 1996; Sole et al., 2009).

Study of the antioxidant enzymes in different species is very important for the understanding the defense mechanisms against pollution in fish of various taxonomic and ecological groups, as well as for aquaculture purposes, and for receiving the information of repair mechanisms and adaptation to unfavorable impact. Combination of specific phylogenetic, physiological and ecological features of fish species may modify antioxidant status, and it is important for the creation of monitoring programs. The aim of the present work is to analyze the key antioxidant enzymes catalase and peroxidase in different Black Sea teleosts, belonging to different taxonomic groups related to their phylogenetic position, physiological, developmental and ecological peculiarities and anthropogenic impact.

### **2. ENZYME ACTIVITIES AND FISH PHYLOGENIC POSITION**

Tested Black Sea fish species were grouped according their phylogenetic position (Table 1).

#### **Table 1. Phylogenic position of tested Black Sea teleosts (the classification is present according Boltachev and Karpova, 2017)**

The most ancient orders are recognized as *Gadiformes* and *Ophidiiformes*, the following is *Mugiliformes,* then *Perciformes,* the orders *Scorpaenoformes* and *Pleuronectiformes* are relatively recent taxonomic groups. We studied CAT and PER activity in fish red blood cells (RBC) and in the liver related to their phylogenetic position. CAT activity in the RBC of tested Black Sea teleosts tended to increase in the species, belonging to the order *Perciformes*  and *Scorpaenoformes* as compared to the species of ancient orders namely *Gadiformes* and *Ophidiiformes* (Figure 1). At the other side, CAT activity in *Platichthys luscus,* belonging to very specific order *Pleuronectiformes* was lower as compared with the species of *Perciformes.* Additionally, we could note that enzyme level varied significantly among the various species of *Perciformes,* which could depend on their biological and ecological peculiarities (see below).

Figure 1. CAT activity in RBC of tested Black Sea fish species belonging to different orders: Gadi – *Gadiformes,* Mugil – *Mugiliformes*, Perci – *Perciformes*, Scorp – S*corpaeniformes*, Pleur – *Pleuronectiformes*.

Figure 2. PER activity in RBC of tested Black Sea fish species belonging to different orders: Gadi – *Gadiformes,* Ophi – *Ophidiiformes,* Mugil – *Mugiliformes*, Perci – *Perciformes*, Scorp – S*corpaeniformes*, Pleur – *Pleuronectiformes*.

Figure 3. CAT activity in the liver of tested Black Sea fish species belonging to different orders: Gadi – *Gadiformes,* Ophi – *Ophidiiformes,* Mugil – *Mugiliformes*, Perci – *Perciformes*, Scorp – S*corpaeniformes*, Pleur – *Pleuronectiformes*.

Figure 4. PER activity in the liver of tested Black Sea fish species belonging to different orders: Gadi – *Gadiformes,* Ophi – *Ophidiiformes,* Mugil – *Mugiliformes*, Perci – *Perciformes*, Scorp – S*corpaeniformes*, Pleur – *Pleuronectiformes*.

The lowest PER activity was indicated in the RBC of examined fish species belonging to *Gadiformes* and *Ophidiiformes*, in the other tested teleosts enzyme activity varied significantly, especially in the animals of the order *Perciformes* (Figure 2).

In the liver high CAT activity was observed in the *Perciformes* species (Figure 3), and it varied widely. Enzymatic activity in the RBC of the species belonging to the other examined orders was lower, however, it was comparable with the *Perciformes* fishes. PER activity in the liver ranged widely and we could not find any phylogenetic-related trends (Figure 4).

In our previous studies we showed the lack of CAT activity in the RBC in elasmobranch *Squalus acanthias* related to several examined Black Sea teleosts. We proposed that low molecular weight antioxidants, especially SH-containing substances play an important role in the antioxidant defense in elasmobranch, which compensate the lack of CAT and low activity of superoxide dismutase (SOD) and glutathione reductase (GR). As we documented previously, enzymatic activity was less in elasmobranch tissues as compared with the teleost species, excepted PER activity in muscle, which was the greatest among the all examined fish (Rudneva, 1997a; 2012).

A comparative study of hepatic antioxidant defense enzymes in teleosts and elasmobranchs demonstrated, that their content in primitive fish species was lower than that in teleosts, and seems to follow the overall metabolic oxygen consumption or activity level from each fish major taxonomic group (Filho & Boveris, 1993; Filho et al., 1993). Decrease of antioxidant enzymes level and high content of low molecular weight antioxidants in elasmobranch tissues related to teleosts was reported by other investigators (Martinez-Alvarez et al., 2005; Sole et al., 2009). Therefore, our findings provide that more primitive species such as elasmobranch and species, belonging to ancient teleost orders have more primitive antioxidant system in which non-enzymatic compounds play an important role in defense organism against oxidative stress.

The differences between CAT and PER activities can be linked with the differences of the enzymes functions: PER is non-specific enzyme as compared with CAT, and it reduces both H2O2 and organic peroxides (see section *Introduction*), and it could compensate the lack of CAT concentration. In general, our findings demonstrated that antioxidant enzyme levels in tested Black Sea teleost species depending on their taxonomic position, however, despite this, we could suggest that biological and ecological peculiarities of fish species may play more important role in antioxidant response than phylogenetic ones.

# **3. BIOLOGICAL PECULIARITIES OF FISH**

#### **3.1. Early Development and Ageing**

Antioxidant enzyme activity was found in developing eggs of the fish. Ovoperoxidase was detected in the eggs, and it uses hydrogen peroxide as substrate, which is generated NADPH-oxidase system on the surface of egg shell (Takahashi et al., 1989; Winston, 1991). The authors demonstrated the changes in antioxidant enzyme activities in various fish species during early life. However, the trends of CAT and PER activities in various fish were not uniform and depended on species and developmental stage. Oxygen availability is one of the factor effecting hatching. Hypoxia or agents that cause hypoxia (low sea water dissolved concentration of cyanide or high concentrations of dissolved hydrogen), stimulate hatching whereas hyperoxia may suppress hatching. Therefore, antioxidant enzymes level varied during fish embryogenesis and in hatching larvae.

In our studies we found, that during embryogenesis of several Black Sea gobies *Neogobius melanostomus*, *Proterorhinus marmoratus* and blenny *Blennius sanguinolentus,*  majority of enzymes, including CAT and PER, tended to increase in developing eggs and especially in hatching larvae, while the levels of low molecular scavengers decreased (Rudneva, 1999; 2014). Our results agree with the data of other investigators, who reported the similar trends of CAT and PER levels in fish early development at the case of *Solea senegalensis* (Sole et al., 2004), *Scophthalmus maximus* (Peters & Livingstone, 1996), *Dentex dentex* (Mourente et al., 1999), *Paralichthys olivaceus* (Cao et al., 2010), *Lates calcarifer* (Kalaimani et al., 2008). Among the H2O2 -removing systems in *Salmo iridaeus* embryo development CAT seems to be the only enzyme presents at significant level and plays more important role in preventing  $H_2O_2$  damage in fish embryo as compared with GPx. During further fish development, activity of antioxidant enzymes CAT and GPx increased with the maximum at stage 33, when the formation of the swim bladder as well as pigmentation has occurred. At the end of the development the activity of glutathione-containing enzymes increased progressively and values were found to be about 85-312 fold higher than in early stages, while the variations of CAT activity was lower (Aceto et al., 1994).

Therefore, we could conclude, that the increasing rate of oxygen uptake may elevate prooxidant processes such as ROS generation, and increase in CAT and SeGPx activities with development of embryos to larvae. They would indicate a progressive need to degrade  $H_2O_2$ and peroxides from tissues (Peters & Livingstone, 1996). The increase levels of CAT and GPx may be in response to other metabolic changes occurring at this time, possibly leading to change sources of oxidative stress.

Further aging changes can be attributed to development, genetic defects, the environmental unfavorable factors and diseases. The accumulation of the negative changes and the loss of the ability to repair or detoxify them increase the risk of death (Harman, 2003). The study of aging strategy, both endogenous and exogenous factors, which it modulate in different species is very important for the understanding of the key mechanisms of aging and their early prevention. Several studies have shown that oxidative stress led the environmental factors is involved in age-related processes and modulate them. Oxygen stress relates to immune system dysfunction seems to have an important role in senescence, in agreement with the oxidation/inflammation theory of aging (De La Fuente et al., 2005).

There are many publications on the effect of age on antioxidant enzyme activities in laboratory animals including various mammalian and bird species, and perhaps for aquaculture fishes, while the information of wild species is very limited. However, the aging processes in wild fish populations are associated with many environmental factors, such as anthropogenic impact and the abilities to adapt to the changing living conditions, especially in recent decades, caused with climate changes. The life span of species might be influenced by its metabolic rate and its increase correlates with the high radical production and with oxidative damage (Zelinski & Portner, 2000). Whereas these aspects have been amply studied in mammals and especially in humans, information on fish and other aquatic animals is very limited.

Fish erythrocytes are an excellent model for the investigations of ROS and antioxidant status, especially for age-related studies, because in these cells mitochondria and nucleus were shown (Filho, 2007). In our previous studies (Rudneva et al., 2010a) we found, that the trends in antioxidant enzyme activities in blood of Black Sea teleosts were not uniform, and we showed three types of responses with aging increase, which depended on the enzyme specificity and fish species: 1. enzymatic activity increased with age; 2. enzymatic activity decreased with age and 3. enzymatic activity was not changed with age. For instance, we observed strong correlation between CAT activity and fish age in *M. merlangus euxinus* and *T. mediterraneus ponticus*, significant values was shown in *G. mediterraneus* and moderate in *M. barbatus ponticus*, and low in *S. flexuosa*. The highest negative correlation coefficients were shown between PER activity and age in *G. mediterraneus* and *T. mediterraneus ponticus*, in *S. porcus* it was significant and moderate in *M. merlangus euxinus*. CAT activity showed no age dependence in blood of *N. melanostomus*, *S. porcus* and *S. flexuosa*. Age changes in CAT level were not evident in rainbow trout *Oncorhynhus mykiss* and black bullhead *Ameiurus melas* also (Otto & Moon, 1996). *G. mediterraneus* and *T. mediterraneus ponticus* enzymatic activity decreased with the age, while in *M. merlangus euxinus* the opposite tendency was observed. In *M. barbatus ponticus* CAT activity elevated in the middle-age fish, then decreased progressively in the elder ones. The similar tendency was found in the blood cells of sturgeon *Acipenser naccarii* (Martinez-Alvarez et al., 2005). Our findings agree with the results of the other studies of age-related CAT activity in various animals. The investigators documented that CAT activity has been decreased (Semsei et al., 1989) or unchanged with the age in brain of albino rats (Yargicoglu et al., 1999). Age- and size-related changes of CAT activity was shown in mollusk *Perna viridis* (Lau & Wong, 2003).

High negative correlation was indicated between PER activity and fish age in the RBC of *G. mediterraneus* and *T. mediterraneus*, in *S. porcus* and *M. merlangus euxinus* the values were positive and moderate, while in the other examined species the correlations were not observed. In this case we could agree with the opinion of several authors who proposed, that CAT and PER activity in the brain and in the liver of freshwater murrel *Channa punctatus* were mostly maturation-related rather than senescence-related (Nayak et al., 1999, cited by Martinez-Alvares et al., 2005).

Figure 5. Age-related CAT and PER activity in RBC of Black Sea teleosts *S. porcus* and *T. mediterraneus ponticus*.

Figure 6. Age-related CAT and PER activity in the liver of Black Sea teleosts *S. porcus*, *M. barbatus ponticus, S. flexuosa*, *T. mediterraneus ponticus.*

Therefore, the age alterations of antioxidant enzyme activities in fish blood are the similar as compared with the other animals including terrestrial species. It may be the result of detrimental effect of life span that is conclude with the opinion of other researchers (Zelinski & Portner, 2000; Ahmed, 2005).

Our recent studies showed that in RBC of the several Black Sea teleosts (*S. porcus* and *T. mediterraneus ponticus*) CAT and PER level did not vary uniform related to age (Figure 5). Low correlation was detected between age and CAT activity in the blood of scorpion fish ( $r =$ 0.32), correlation between PER and fish age was greater  $(r = 0.62)$ . We noted high age-related relationships between CAT and PER level in RBC of *S. porcus* (r = -0.73). Therefore, activity progressively decreased in the RBC of scorpion fish *S. porcus,* while in horse mackerel *T. mediterraneus ponticus* the values did not change. At the other side, the ratio of CAT/PER activity ranged between 0.002-0.007 in RBC of scorpion fish and 0.009-0.008 in horse mackerel.

In the liver of tested Black Sea teleosts CAT and PER activity varied related to age, tended to decrease in the major of tested fish species (Figure 6).

Age-related correlation of CAT activity was estimated as  $r = 0.31$  in the liver of *S*. *porcus,* in red mullet *M. barbatus pointicus* the corresponding value was higher r = 0.93. No age-related correlations we found in hepatic CAT activity in high body pickerel *S. flexuosa* and horse mackerel *T. mediterraneus ponticus.* PER activity in the liver of tested teleosts demonstrated low age-related correlation  $(r = 0.17)$ , at the case of scorpion fish and high body pickerel, in the liver of red mullet *M. barbatus ponticus* it was higher  $(r = 0.50)$ . Great agerelated correlation ( $r = 0.75$  and  $r = 0.90$ ) was observed between CAT and PER activity in *S*. *porcus* and *S. flexuosa* correspondingly.

These findings agree with the data of other investigators, who described the tendency of decrease of enzymatic activity in the erythrocytes and in the liver of old fish as compared with younger ones (Otto & Moon, 1996). It was linked with accumulation of oxidative products in organism and decrease of its defense abilities. At the other side, the antioxidant system in long-lived fish species has evolved to increase its capacity with age, while the other species have constant enzyme activities, or they decline throughout their life. These differences could play important role in the regulation of the mechanisms of the lifespan of teleost fish species.

However, we could note the significant differences in antioxidant enzyme responses in examined fish species, which were attributed with the peculiarities of their ecological and physiological characteristics (see section 3.2). For instance, in our previous publication, we suggested that age alterations were much more significant in benthic and suprabenthic fish species, compared with suprabenthic/pelagic and pelagic ones. We could propose that benthic and suprabenthic forms live in more contaminant environment, because many pollutants accumulate in bottom sediments and low water layers and they impact aquatic organisms (Rudneva et al., 2010b).

#### **3.2. Reproductive Strategy and Gender Peculiarities**

Aerobic organisms, in the process of the evolution have adapted to use their living resources (e.g., energy, time, nutrients, etc.) for reproduction. They have evolved different strategy of breeding frequently, fecundity, egg hatching rate and larval survival. The costs associated with reproduction have been attributed with the increase of metabolic rate and high production in ROS (Alonso-Alvarez et al., 2004), because spawning is a highly demanding activity which elevates metabolic rate for an extended period of the time. At the case of single breeding event and further individual death, fish may not invest resources into generating antioxidant defense, and all resources have been allocated to reproduction as, for instance, of semelparous fish species namely salmonides (Wilson et al., 2014), while iIteroparous species are characterized by multiple breeding events throughout life.

Fish may reduce investments in their own antioxidant defense in favour of eggs and embryos antioxidant protection, which is essential for hatching success of embryos and survival of new hatching larvae (Fontagné et al., 2006; Taylor et al., 2015). As we described previously, high concentrations of low molecular weight antioxidants were detected in the gonads of Black Sea teleosts, while antioxidant enzyme activities, including CAT and PER were not high (Rudneva, 2012). Additionally, antioxidant enzyme activities were very low in fish gonads, while high concentrations of low molecular weight antioxidants play an important role in antioxidant defense of fish reproductive system against ROS and oxidative stress.

We could also found the differences in CAT and PER activity in the RBC and in the liver of tested fish male and female (Figure 7).

No significant differences of CAT and PER activities in RBC in the majority of tested fish species were observed, with the exception of red mullet *M. barbatus ponticus*, in which PER activity was significantly higher as compared with female value. At the other side, we could note, that in female enzyme activities tended to increase related to male.

Generally, similar trends of CAT and PER activities related to fish gender were displayed in the liver (Figure 8). However, CAT activity in *M. barbatus* and *T. mediterraneus ponticus*  was significantly greater in male ( $p < 0.05$ ).

Therefore, we could conclude, that CAT and PER level did not differ significantly in fish male and female in the majority of tested Black Sea fish species.

\* - significant difference.

Figure 8. Gender-related differences of CAT and PER activities in the liver of Black Sea teleosts. \* - significant difference.

Figure 9. CAT and PER activities in RBC of *N. melanostomus* in different stages of reproductive cycle.

Figure 10. CAT and PER activities in the liver of *S. porcus* in different stages of reproductive cycle.

Because iteroparous species are characterized by multiple breeding events throughout their life, they are less depend to the resource-based trade-off associated with reproduction and antioxidant defense changes during maturation and reproduction of fish. There are several publications of the correlation between fish reproduction cycle and antioxidant defense status. The authors reported, that reproduction in zebra finches decreases antioxidant defense, which may suggest that oxidative stress is a cost of reproduction (Alonso-Alvarez et al., 2004). In our study we found the increase of CAT and PER activity in the RBC of the female of the round goby *N. melanostomus* in the spawning time (Figure 9). However, in male of the round goby CAT activity decreased, and we could propose that paternal care was negatively correlated with oxidative stress resistance, which agrees with the data of the other investigators (Wilson et al., 2012). In the liver of scorpion fish *S. porcus* we showed the increase of CAT activity in pre-spawning and spawning period both in female and male, while hepatic PER level increased in male in spawning time and decreased significantly in female (Figure 10). Therefore, enzyme activities depend on the period of reproduction, fish gender, interspecies features and specificity of tissue. Additionally, the cumulative effect of oxidative stress across the reproductive lifespan of fish has been attributed with the ageassociated decline of antioxidant defense. At the other side, differences in oxidative stress levels during reproduction can be correlated with the specificity of diet and food deprivation, as well as to migration of the fish species.

# **3.3. Diet and Food Deprivation**

Antioxidant status of the organism depends on food composition, because many kinds of essential antioxidants are contained in the diet. For instance, antioxidants namely vitamin E, carotenoids are strictly obtained as a nutritional antioxidants in the majority of fish species, while the others (for instance, vitamins C, A) are synthesized only in few fish species. These components play an important role in their adaptation to the changing environment. Unlike mammals, fish may survive long time of starvation, however, without food they change their metabolism and evolved metabolic adaptations that involve the up- and down-regulation of the major biochemical and physiological pathways (Morales et al., 2004).

Antioxidant status of fish is linked with fish trophic level, feeding behavior and nutrition factors, which also may affected antioxidant enzymes including CAT and PER (Martinez-Alvarez et al., 2005; Sole et al., 2009). Fish with different diets may cope with oxidative stress in different ways. Several essential microelements, which play a role in many physiological functions, including antioxidant defenses (such as selenium, copper, iron, and etc.) fish obtain with their diet. Several of these micronutrients are the components of the active centers of the antioxidant enzymes, namely CAT (iron), PER (iron), GPxs (Se). The authors have documented, that antioxidant enzyme activities was generally higher in herbivorous fish (grass carp *Ctenopharyngodon idella* and silver carp *Hypophthalmichthys molitrix)* than in omnivorous species barbel *(Barbus barbus), crucian carp (Carassius carassius)* and common carp *(C. carpio)* (Radi et al., 1985). The authors suggested, that plant-based diet contains the components, which are absent in other food or the prooxidants in this type of food contains stimulated ROS production, and the change of prooxidant/ antioxidant balance, attributed with the induction of enzyme activities. CAT activity was significantly higher in the liver of Senegalese sole fed high lipid diet as comparted with fish fed low lipid diets (Rueda-Jasso et al., 2004)

In our previous studies (Rudneva, 1997b; 2012) tested Black Sea teleosts species were grouped in pelagic plankton feeders (*T. mediterraneus ponticus*), omnivorous (*S. smaris*), carnivorous (*M. barbatus ponticus*, *N. melanostomus*) and predators (*M. merlangus euxinus, S. porcus, P. lucsus*). No clear relationships between feeding groups and CAT and PER activities in the RBC and in the liver were found. However, carnivorous fish species demonstrated approximately similar enzymatic activity in the liver. It could be explained that benthic invertebrates (mollusks, crustacean and worms) and fish, which are the preferable prey for this group might accumulate pollutants from the bottom sediments and transfer them via trophic nets to fish with the effect of concentration. Hepatic antioxidant enzyme activity in pelagic plankton feeder horse mackerel and omnivorous suprabenthic/pelagic *S. smaris* was approximately similar and lower than in carnivorous forms, which was explained the similarity of their high metabolic rate and diet consumption.

Food deprivation was also attributed with oxidative stress in fish. The researchers demonstrated the changes of prooxidant/antioxidant balance in the fish at the case of lack of food or deprivation, which was correlated with the increase of lipid peroxidation and CAT and GPx activities in common dentex (*Dentex dentex)* (Morales et al., 2004). Food consumption and oxidative stress, associated with food quality and deprivation play a role in fish migration and physical activity.

#### **3.4. Swimming Activity**

Physical activity plays an important role in antioxidant defense status in fish. Our study supports the great interspecies differences in antioxidant system in tissues between various fish species, characterizing different swimming activities. Our findings agree with the results of other researchers, who reported about high variability of antioxidants level in the fish (Winston, 1991; Filho et al., 1993; Sole et al., 2009). Interspecies differences in blood, muscle and liver in Black Sea teleosts were more significantly than in gonads, which showed more homogenous response (Rudneva, 2012).

The interspecies variations of antioxidant defense may reflect the specific adaptations to the oxidative stress and protective mechanisms against ROS damage. Therefore, activity of antioxidant enzymes in fish blood correlated with their swimming capacity. In our previous study we found that CAT activity in fast swimming pelagic horse mackerel *T. meditrraneus ponticus* and high body pickerel *S. smaris* were significant higher than those in blood of slow swimming gobies, scorpion fish and flounder (Rudneva, 1997a, b). Other researchers reported also, that CAT content in blood of more active forms was higher as compared to more sluggish species (Filho et al., 1993; Filho, 1996). They suggested, that antioxidant defense in marine species in the liver and blood may be related to the oxygen consumption of the tissues and of the whole organism, while in freshwater fish it may be related to physical and chemical characteristics of the living conditions rather than to physical activity (Filho, 1996). At the same time, the changes in the sturgeon blood prooxidant-antioxidant status, as a consequence of adaptation to marine conditions, were not reflected in the liver and other tissues (Martinez-Alvarez et al., 2005).

Liver of the vertebrates exhibits a high metabolism and oxygen consumption, and it is the main organ of xenobiotic detoxification. Fish liver displayed the highest levels of the key antioxidant enzymes CAT (Filho et al., 1993; Filho & Boveris, 1993; Rocha-e-Silva et al., 2004). CAT level in the liver appears to indicate that the most active species of teleosts had greater enzyme activity compared with low mobile forms (Filho et al., 1993; Filho & Boveris, 1993). The higher activity of antioxidant enzymes in the liver of active fish correlated with higher oxygen consumption in fast swimming species and their high metabolic rate (Martinez-Alvarez et al., 2005; Filho, 2007). Animals with high metabolic rate exhibit the high rates of free radical production and show the induction of antioxidant defense mechanisms (Zelinski & Portner, 2000). Physical activity of fish is often associated with fitness, reproduction or predator avoidance. Therefore, the link between oxidative stress and physical activity may appear to be more complex.

Additionally, the majority of our tested teleosts migrate in different distances, while the others are settled (gobies, scorpion fish, flounder). Therefore, their antioxidant status depend on the specificity on abundance and complex of living conditions in biotope.

# **4. ABIOTIC CONDITIONS**

The researchers suggest, that oxidative stress in various aquatic organisms can correlate with several types of stressful conditions, such as chemical pollution, hypoxia/anoxia, microbial and viral infections and parasitic invasion, dietary influence, feed deprivation, acute temperature changes, algal blooms, UV-irradiation, and etc. (Ferreira Pereira, 2014). In this section we focus on the relationships between the ecological conditions in biotops and CAT and PER activities in tested teleosts.

# **4.1. Ecological Specificity of Abundance**

Ecological conditions of the habitats play an important role in fish antioxidant status and their adaptation to habitats. Previously we described enzyme activities in various tissues in

several Black Sea teleost and elasmobranch species (Rudneva, 2012). Here we focus on the main trends of CAT and PER activities in the RBC and in the liver of tested Black Sea teleosts, which grouped in four ecological classes namely benthic, suprabenthic, suprabenthic/pelagic and pelagic. The highest CAT activity in the RBC was indicated in benthic forms *S. porcus* and *N. melanostomus,* in the species belonging to the other ecological groups the enzyme activity was comparable with the exception of *P. luscus* and *L. aurata,*  which showed the low values (Figure 11). PER activity of examined teleosts did not vary uniform, and we can't find any trends in enzyme activities of species belonging to tested ecological groups. Similar observations we showed in the liver of checked teleosts, in which CAT and PER activity varied widely (Figure 12).

Therfore, the obtained results support the great interspecies differences in antioxidant activity in various tissues between examined species, which agrees with the opinion of many researchers studying fish antioxidants (Ciornea et al., 2009; Alti et al., 2016; Mukherjee et al., 2017). In our previous studies we showed the differences of low molecular weight scavengers in fish blood. For instance, glutathione content was relatively higher in pelagic active fish *T. mediterraneu*s *ponticus* and in sluggish benthic forms, while in other species belonging to suprabenthic and suprabenthic/pelagic groups the values were intermediate (Rudneva, 2012). We found also, that SOD activity in RBC was significantly less in sluggish forms as compared to fast moving ones, which could indicate that the oxygen transport capacity of fish blood follows the same evolutionary trend of SOD level concentration in blood (Filho et al., 1993). Similar tendency was shown in CAT activity, PER level was not uniform and varied unclearly, while GR activity demonstrated the opposite trend: it was less in pelagic fish than in animals belonging to the other groups. Therefore, the results of the present study agree with our previous data.

Wide antioxidant enzyme fluctuations in the liver within the ecological group, especially in suprabenthic/pelagic class, in which enzyme activities differed in 2-7 fold, were showed in our studies. This was explained by the specificity of fish biology and life cycle related to temperature, oxygen concentration, pressure and other abiotic conditions.

Figure 11. CAT and PER activity in RBC of Black Sea teleosts. Ecological groups: Ben – benthic, SupBen – suprabenthic, SupBen/Pel – suprabentic/pelagic, Pel – pelagic.

Figure 12. CAT and PER activity in the liver of Black Sea teleosts. Ecological groups: Ben – benthic, SupBen – suprabenthic, SupBen/Pel – suprabentic/pelagic, Pel – pelagic.

Due to the highly variable environment (absorption of solar radiation, including its UVspectra, fluctuations of salinity, depth, oxygen concentration, presence of hydrothermal vents), marine fish species impact on abiotic factors greater related to freshwater forms. These factors and their fluctuations can cause the generation of ROS.

#### **4.2. Salinity**

Due to their life history many teleost fish species were adapted to salinity fluctuations, especially in spawning period, when they migrate from freshwater rivers into marine waters (e.g., salmonids). Because salinity changes the metabolic rate of the fish associated by osmoregulatory demands and physiological stress, the ROS production changes also and fluctuations of salinity induce of oxidative stress in fish (Zeng et al., 2017). In experimental conditions the researchers indicated the increase of GPx and CAT activities in *Litopenaeus vanna*, exposed to seawater for a 48-hr period (Liu et al., 2007) and in the olive flounder *Paralichthys olivaceus* (Choi et al., 2008). Therefore, the researchers postulated, that salinity fluctuations and especially the fish transition from freshwater to marine water conditions induce oxidative stress and the changing of prooxidant/antioxidant balance. At the other side, fish respond to oxidative stress with the increase of antioxidant defense, including CAT and PER activities, and they will cope their life with changing environmental conditions.

In our studies we compared age-related trends of CAT and PER activities in the RBC of round goby *N. melanostomus* from Black Sea and Azov Sea, characterizing different salinity (Figure 13). Water salinity in the Black Sea is estimated as 18‰, while salinity in Azov Sea varies between 11.4 and 12.1‰. CAT activity in the RBC was lower in the fish from Black Sea as compared with the animals from Azov Sea. However, CAT activity decreased in the RBC of the middle-age round goby, then increased in elder ones from Black Sea, while in the animals from Azov Sea CAT activity varied lower. PER activity in the RBC of fish from Black Sea was higher related to the values of the animals from Azov Sea. It showed the

opposite trend with aging as compared with CAT level, while PER activity in the RBC of round goby from Azov Sea varied insignificantly.

Figure 13. Age-related CAT and PER activity in RBC in *N. melanostomus* from Black Sea and Azov Sea.

Therefore, we could conclude, that CAT and PER activity of fish depends on living conditions in the abundance, especially salinity, which is the result of the evolutionary process and their adaptation to the specificity of biotope.

#### **4.3. Pressure and Deep Sea Conditions**

Deep sea biotops are characterized by reduced residual light, decreasing temperature, available nutrients, the low-oxygen environment or increased pressure. The researchers proposed, that physical and chemical conditions of this dark, poorly oxygenated environment, the meso- and bathypelagic waters of the oceans might be considered as refuges against oxidative dangers in the fish (Janssens et al., 2000). The study of antioxidants in the tissues of 16 species belonging to meso- and bathypelagic groups, which abundance was estimated between the surface and a depth of 1300 m indicated the differences of their antioxidant system status. The levels of SOD and GPx decreased in parallel with the exponential reduction in the metabolic activity in fish tissues, while CAT activity was affected neither by the metabolic activity nor by the depth of occurrence of the fishes. High levels of metabolic and antioxidant enzymes were observed in the light organs of bioluminescent species. The authors suggested that the adjustment of the activity of SOD and GPx to the decreased metabolic activity in deep-sea fish are used primarily against metabolically produced ROS, whereas the maintenance of CAT, remained unchanged while metabolic rates declined with increasing depth of occurrence (Janssens et al., 2000). The researchers postulate, that CAT and GPx activities in fish tissues were linked with the depth of their abundance (Ribata et al., 2015). Additionally, the lower metabolic rates of deep-sea animals are functionally adaptive for life in the high depth and the oxygen minimum layer and are not specifically evolved adaptations to the low food availability or low  $O_2$  levels in these habitats (Section 4.4.). The declines of metabolic rate of the deep-sea aquatic organisms reduced metabolic requirements and this is attributed with the decrease of SOD and GPx activities. However, higher level of pollution of sediments and deep water layers is associated with the prooxidants and ROS generators (Porte et al., 2000).

In experimental conditions the researchers investigated the effects of exposure to 10.1 MPa (equivalent to 1000 m in depth) hydrostatic pressure on silver European eel (*Anguialla anguilla*, Anguillidae) oxidative stress and ROS production, no harmful oxidative damage was observed in the fish. Among our tested Black Sea teleosts we have not deep-sea forms and we *can't* discuss the influence of pressure on the CAT and PER enzymes of Black Sea fish.

# **4.4. Oxygen Availability**

Marine environments are characterized by high oxygen concentrations in the euphotic zone and by a decrease to lower oxygen levels in the deep sea. Since oxygen is essential for aquatic organisms, they developed adaptations to oxygen concentrations and able to survive extreme oxygen level in deep sea regions (Janssens et al., 2000; Welker et al., 2013). In experimental conditions the researchers found an increase in fish antioxidant defense under hypoxia/anoxia, as "preparation for oxidative stress" to enhance their ability to degrade ROS production upon return to usual oxygen concentration (Hermes-Lima et al., 1998; Lushchak & Bagnyukova, 2007).

In deep-sea fish species SOD and GPx activity increased with depth, while CAT activity was not changed (Janssens et al., 2000), and the authors proposed that deep sea fish species demonstrated less oxidative stress with the decrease of their metabolic rate and low ROS production. Therefore, fish have evolved special mechanisms of regulation of prooxidant/antioxidant balance in changing oxygen conditions. Both hyperoxic and hypoxic conditions can induce oxidative stress in fish and increase antioxidant enzyme level, including CAT and GPx in tissues (Lushchak, 2011). However, oxygen availability is species-dependent, because fishes have evolved to different living conditions and they inhabit different biotops, where the oxygen level varies widely. For instance, pelagic fish species (*T. mediterraneus ponticus*) abundance is characterized high oxygen level, while benthic forms (*N. melanostomus, S. porcus*) live in the water, where oxygen concentration is lower. In addition, metabolic rate of horse mackerel is higher related to benthic forms, and we can propose, that antioxidant activity in pelagic forms is greater, than in bottom ones. In this context hepatic CAT activity in pelagic horse mackerel is significant higher, than in benthic and suprabenthic fishes, however, PER activity was very low (Figure 11). We could conclude, that characteristics of antioxidant defense in fish depended on the complex of living conditions in biotope and relationships among them and fish species, which was demonstrated at the case of temperature.

#### **4.5. Temperature**

Global climate change may cause stress to aquatic ecosystems and organisms, damage their health, growth and reproduction. Climate changes are accompanied with the temperature increasing caused the emission of greenhouse gases  $(CO<sub>2</sub>, CH<sub>4</sub>, SO<sub>2</sub>,$  nitrogen oxides, and etc.). Seawater temperature of 2-3º*С* above long-term average summer temperature results stress in aquatic organisms, led oxidative damage. High temperature elicits a series of physiological responses, such as increasing of standard body metabolism. Temperature has

been known to alter metabolic rate, enzyme activities, oxygen consumption and oxidative stress, attributed with the changes of prooxidant/antioxidant ratio of the organism (Dubey, 2013). It is predicted that global climate change will increase water temperature by  $2^{\circ}C$  by the end of the  $21<sup>st</sup>$  century (IPCC Report, 2013) and biochemical alterations including oxidative stress in aquatic organisms will also elevate.

An increase in temperature is associated with an increased metabolic rate and oxygen consumption, attributed with an enhancing of ROS production (Almroth et al., 2015). The authors suggested, that although stenothermal fish can modulate their antioxidant capacity, they can only do so in a transient manner, the latter which remains insufficient in degradation of increased ROS production accompanying the enhance in metabolic rate with increased water temperature. Further accumulation of oxidative products in the cells and tissues can lead to a decrease in fitness and damage physiological functions in the organisms, which is important at the case of prediction of global warming consequences.

In experimental conditions the researchers indicated, that the activity of both SOD and CAT displayed only small changes across treatments and tissues during long-term acclimation of three notothenioid fish species to decreased seawater pH and increased temperature (Enzor & Place, 2014). The oxidative stress and antioxidant defense changes attributed with the water temperature fluctuations, were highly depended on tissues, and the researchers postulated, that basal antioxidant protection is kept high in those tissues that may have a stronger impact on health and fitness (Luschak, 2011).

We study the season changes of CAT and PER activity in the RBC and in the liver of several Black Sea teleosts. Our findings indicated, that in warm season the activity of tested enzymes increased in the majority of Black Sea teleosts, which could explain both water temperature increasing and the enhancing of fish metabolic rate (Figures 14, 15, 16).

Figure 14. Seasonal changes in RBC CAT and PER activity of Black *S. porcus*. \* - significantly difference related to spring and winter values ( $p < 0.05$ ).

In summer at high water temperature CAT activity was significantly greater in the RBC and in the liver of scorpion fish related to the values of the other seasons, while the highest PER level was indicated in autumn, when the water temperature was decreased insignificantly. In cold seasons, at the beginning of spring and winter, the enzyme activities in the RBC and in the liver of *S. porcus* was significantly lower (Figures 14, 15). However, in the RBC of round goby *N. melanostomus* high CAT activity was observed in spring and summer time, then it significantly decreased in autumn and in winter (Figure 16), while the highest PER level was indicated in winter. Our results agree with the opinion of the other investigators, who documented, that temperature-related differences of the antioxidant enzymes demonstrate tissue- and species-dependent peculiarities and evolved in the complex of fish physiological and metabolic adaptations to the living conditions (Alti et al., 2016; Mukherjee et al., 2017).

Figure 15. Seasonal changes in hepatic CAT and PER activity of Black Sea *S. porcus*. \* - significantly difference related to spring and winter values ( $p < 0.05$ ).

Figure 16. Seasonal changes in RBC CAT and PER activity of Black Sea *N. melanostomus*. \* - significantly difference related to spring and winter values ( $p < 0.05$ ).

Finally, present data demonstrated that CAT and PER levels showed variations depending on the physical environment, but the changes are exclusively site as well as tissue and species specific. These findings also suggest that the effects of environmental factors on oxidative stress mechanisms may be tissue-and species-dependent and that species may have evolved different mechanisms to deal with the oxidative challenges induced by environmental stress of selection underlying adaptive divergence in these fish species. Because CAT and PER enzymes play a role in the adaptation of the fish to changing environmental conditions, they may modify their activities as a function of water temperature, pressure, salinity, oxygen concentration and the presence of various pollutants, they may use in ecotoxicological studies as biomarkers of fish response on unfavorable living conditions and anthropogenic impact.

# **5. ANTHROPOGENIC IMPACT**

ROS production can be induced by external factors. Environmental pollution may be one of the strong cause of the ROS generation in the organisms. Chemicals represent in the environment (transition metals Cu and Fe, which catalyze the production of hydroxyl radicals through Fenton reaction, toxic elements Cd, Hg, Ni, biphenyls, quinones, nitroaromatics and drugs) can also induce production of superoxide by redox cycling and via biotransformation reactions (Winston, 1991; Livingstone, 2001; Lesser, 2006). The response on oxidative stress in fish is tissue-dependent and species-dependent. Fish in polluted habitats showed changes of CAT and PER activity, however, the trends were not uniform in the tissues and examined species. Finally, the results obtained provide evidence, that exposure to heavy metals in fish can unsettle the redox balance and alter antioxidant defenses. Aquatic environments are affected by various anthropogenic contaminants like pesticides, oil, polychlorinated biphenyls (PCBs), nanoparticles, microplastic, human pharmaceuticals, which can induce oxidative stress in fish. Coastal marine ecosystems are the main recipients of waste waters and effluents, containing high concentrations of various pollutants, which modify water hydrological properties, biodiversity and community structures. The indicators of oxidative stress in fish are very sensitive to this impact and can reflect the ecological status of habitats, as we described previously (Rudneva et al., 2012; Rudneva et al., 2016a, b; 2017). The present study also demonstrates the fluctuations of CAT and PER activities as markers of antioxidant defense in fish caught in polluted and non-polluted marine areas (Figure 17). We studied CAT and PER activities in the RBC of scorpion fish collected in the Sevastopol bays with different pollution levels as following (from the most polluted to reference area): Streletskaya→Alexandrovskaya→Karantinnaya→ Kazach'ya. High CAT activity was indicated in the fish from polluted waters of Streletskaya Bay and Alexandrovskaya Bay, while in reference area Kazach'ya Bay and less polluted Karantinnaya Bay the values were lower. However, at the case of PER activity in scorpion fish RBC we found the highest level in the fish caught in Alexandrovskaya Bay, while the enzyme activity in fish RBC from the other tested bays were lower or the similar.

Furthermore, the study of CAT and PER activity in the blood of round goby from three Sevastopol bays, characterizing different levels of pollution in two periods (2003 and 2012), also demonstrated significant differences of enzyme activities (Figure 18). CAT activity was higher in the RBC of round goby in 2012 as compared with 2003 in three tested bays, similar trend was shown in PER activity with the exception of the fish from Karantinnay Bay. We could conclude, that in recent years, when anthropogenic impact on marine water was increased, the fish responded the increase of antioxidant defense, including the induction of CAT and PER level in the RBC.

At the other side, the response of antioxidant system and antioxidant enzymes can be different in the tissues and depend on fish species (Figure 19). Hepatic CAT and PER activity was higher in the majority of fish from Alexandrovskaya Bay, with the exception of horse mackerel *T. mediterraneus ponticus,* while enzyme activities in the examined fish species collected in Karantinnaya Bay were lower. Therefore, the response of CAT and PER activity in the fish on pollution impact in the tested areas was not uniform and depended both on the contamination level, specificity of the enzyme, tissues and fish species. It is very important for the understanding the main mechanisms of teleosts adaptations to changing environmental conditions, including the anthropogenic impact which is one of the main factor of the evolution at recent decades.

Figure 17. CAT and PER activity in RBC of *S. porcus* from different bays. \* - significantly difference related to other bays ( $p < 0.05$ ), \*\* - significantly difference related to Alexandrovskaya and Streletskaya bays ( $p < 0.05$ ).

Figure 18. CAT and PER activity in RBC of *N. melanostomus* from different bays at the period of 2003 and 2012.  $*$  - significantly difference related to other bays ( $p < 0.05$ ),  $**$  - significantly difference related to periods ( $p < 0.05$ ).

These findings suggest that in general, pollution of aquatic environments reflected physiologically in fish by perturbing normal free radical processes, leading to increase in oxidative damage and disturbance of antioxidant defenses. It would therefore be advisable to consider oxidative ecology in fisheries science and monitoring, given the extent of pollution in many waterbodies and the fish species that live within them (Birnie-Gauvin et al., 2017).

Recent decades, the new pollutants, namely microplastic, nanoparticules and human pharmaceuticals are highly distributed in the aquatic environments, and they are accumulated in the animals tissues. The information of their biological effects is very limited and there is an increasing need to assess wild populations subtle alterations that may indicate the presence of environmental stressors (Amerand et al., 2010; Oliveira et al., 2017a, b). Antioxidants and key antioxidant enzymes CAT and PER may be used for these purposes as a good biomarkers.

Figure 19. CAT and PER activity in the liver of Black Sea teleosts from different bays. \* - significantly difference between tested bays ( $p < 0.05$ ).

# **CONCLUSION**

On the basis of the data described above, we can conclude, that key antioxidant enzymes catalase and peroxidase in tested Black Sea teleosts may provide information about interspecies differences and the mechanisms of their adaptation to environmental conditions, including the complex of biotic, abiotic and anthropogenic factors. Moreover, the global climate changes in recent decades can directly and indirectly influence on fish antioxidant status and together with the local factors may be suitable for the understanding of the mechanisms of fish evolution and adaptation to variety of ecological conditions in marine ecosystems. At recent decades, anthropogenic impact on marine environment has become one of the important factor of ecosystem transformation and could use in the evolutionary process of fish. Therefore, fish are good monitors for the understanding of this process and their biomarkers may successfully use in monitoring programs.

# **ABSTRACT**

The retina of teleosts has become a powerful model system in which to study different aspects of development and regeneration. While retinal development is completed during embryogenesis in most classes of vertebrates, it continues in teleosts throughout much of the animal´s life. The mature retina grows from two specialized niches that sustain retinal stem cells (RSC): (i) the ciliary marginal zone (CMZ), a narrow ring of tissue located in the most-peripheral region of the retina that is composed of stem cells and progenitor cells that generate new neurons added to the periphery of the growing neural tissue, and (ii) the Müller glial cells, the radial glia of the neural retina, which generate neuronal progenitor cells that continue to proliferate and migrate to the photoreceptor layer, where they become precursor cells that are committed to differentiating into rod photoreceptors. Additionally, in the teleost retina, Müller glia have neurogenic capacity and mediates regeneration when stimulated by acute damage, by re-entering the cell cycle and re-establishing retinal cell types.

It has been suggested that the regenerative response of retinal tissue to injuries diminishes through the course of evolution from fish to mammals. Thus, the addition of new neurons from RSC is diminished in chickens compared to that observed in fish and amphibians. In contrast, the neuro-regenerative capacity of RSC in mammals is minimal

or non-existent and therefore, degenerative retinal diseases in humans are irreversible. There are many genes, including structural proteins, signaling pathways and transcription factors that are expressed by normal RSC in teleosts that may be related to maintaining progenitor-like properties. Understanding the combinatorial expression of genes involved in the stimulation of the formation of neurogenic RSC in teleostean experimental models might lead to new genetic treatments for retinal degenerative diseases in humans.

# **ADAPTATIONS OF THE FISH EYE**

The fish eye has morphological, structural, and physiological adaptations to the aquatic medium (Bejarano-Escobar et al., 2014) (Figure 1). Fish normally present lateral eyes (Figure 1A) and they usually have a flattened cornea, usually thinner than that of terrestrial vertebrates. Most of the fishes cannot control the amount of light entering the eye due to the absence of eyelids and a fixed pupil aperture. They also have a highly developed reflecting surface in the choroid that is called the *tapetum lucidum,* and a high refractive spherical lens (Figure 1B,C). The lens in teleosts is pulled back towards the retina by muscles called retractors, whereas in some chondrychthyes it is pulled away from the retina by muscles called protractors. Fish vision also shows adaptation to particular photoenvironments. Thus, deep sea fishes have an all-rod retina or a rod-dominated retina with a few cones sustaining a monochromatic vision. On the contrary, cones are generally found in diurnal active species. However, most of the fish species have color vision and generally have rod cells and cone cells.

Figure 1. Structures and adaptations of the fish eye.A) Scanning electron microscopy of a *Solea senegalensis*  symmetrical premetamorphic larvae. B) Section of the eye of *S. senegalensis* that shows the typical multilayered structure of the retina. C) Scheme of the structures of the fish eye. One of the most notorious adaptations in the fish eye is the shape of the lens. As it can be observed in picture B, the lens has a spherical shape. *IPL, inner plexiform layer; OPL, outer plexiform layer.* Scale bars: 200  $\mu$ m (A), 100  $\mu$ m (B).

### **The Fish Retina**

The fish retina is an excellent model in which to study developmental and physiological events. The neural retina is a thin layered structure whose main function consists on transducing light into nerve signals. It is located at the back of the eye upon which the visual image is focused by the cornea and lens. The retina is part of the central nervous system (CNS), originated as an outgrowth of the embryonic prosencephalon (see below). The neural retina is organized into different layers (Figure 2) which are, from the outermost to the innermost region: the outer nuclear layer (ONL), that is located next to the retinal pigment epithelium (RPE); the outer plexiform layer (OPL); the inner nuclear layer (INL); the inner plexiform layer (INL), the ganglion cell layer (GCL) and the optic fiber layer (OFL) (Figure 2). Nuclear layers are those containing cell bodies whereas plexiform layers are those ones where synaptic contacts between cells occur. The retina is constituted by six different types of neuronal cells that are: photoreceptors (cones and rods), bipolar cells, horizontal cells, amacrine cells and ganglion cells. Moreover, one type of radial glial cell can be found, the Müller glia (MG) (Figure 2B). Accessory glial cell types, such as microglial cells, can also be found in the teleost retina (Bejarano-Escobar et al., 2012b).

#### **Fish Eye Development and Retinogenesis**

Eye development follows a common pattern in all vertebrate animals (Figure 3). Eye morphogenesis occurs early in the developing fish embryo. It starts with a bilateral evagination of the diencephalon on the early neurula that leads to the formation of the optic vesicles (Figure 3A). These extend towards the surface ectoderm through the adjacent mesenchyme. Then, the vesicles come into contact with the ectoderm, displacing the

mesenchyme. Concomitantly, the surface ectoderm thickens forming the lens placode (Figure 3B). Both lens placode and optic vesicle invaginate, becoming the lens vesicle and a doubledlayered structure called the optic cup, respectively (Figure 3C). The inner layer of the optic cup forms the neural retina, while the outer layer becomes the RPE (Figure 3D).

Concerning the process of cell differentiation, RPE cells synthetize melanin. On the other hand, proliferating neuroepithelial cells are found in the presumptive neural retina (Figure 4A,E). The nuclei of these retinal stem cells migrate in an apical-to-basal manner and in phase with the cell cycle (Figure 4E). Thus, abundant apical mitoses are always found at the ventricular surface of the retina by these initial stages of eye development. As development proceeds, asymmetrical cell divisions produce migratory neuroblasts that lose contact with the ventricular surface of the retina and migrate radially to their final location, in which they differentiate (Figure 4D). During stages previous to the beginning of cell differentiation, retinal rudiment is composed of a neuroblastic layer (NbL) (Figure 4B). As cell differentiation occurs, the emergence of the retinal layers can also be observed (Figure 4C), increasing in thickness with the progression of retinal maturity (Figure 4D).

Figure 3. Development of the fish eye. Morphogenesis of the optic vesicle (A, B), the optic cup (C), the lens vesicle (C) and the mature lens and the differentiated retina (D). *C, cornea; Ec, ectoderm; L, lens; LP, lens placode; LV, lens vesicle; Mes, mesenchyme; OC, optic cup; ON, optic nerve; OT, optic tract; OV, optic vesicle; PE, pigmented epithelium; R, retina.*

This change in the potential of retinal cells is likely to be due to a combination of intrinsic and extrinsic factors, such as transcription factors and signaling molecules, respectively (Xiang, 2013). The onset of cell differentiation can be determined by using retinal markers to show the cessation of proliferative activity in the retinal tissue, or by employing cell-type-specific markers (for a review, see Bejarano-Escobar et al., 2014). This process will result in the formation of all neural retinal cell types described above (Figure 4E).

Fish species differ in their mode of development. Whereas in precocial species the specimens skip the larval period and exit the egg in a juvenile state, altricial prolarvae exit the egg in an undeveloped state. Concerning to visual system, retinogenesis is completed during

the embryological period in precocial species, such as goldfish (Sharma and Ungar, 1980), brown trout (Candal et al., 2005), medaka (Kitambi and Malicki, 2008), and several species of chondrichthyes (Harahush et al., 2009; Ferreiro-Galve et al., 2010; Bejarano-Escobar et al., 2012a; 2013) (Figure 5A,B). However, altricial species are born blind, and the acquisition of the full adult complement of cells does not occur until several days, weeks or even months after hatching, as occurs in the tench (Bejarano-Escobar et al., 2009), Senegalese sole (Bejarano-Escobar et al., 2010), or the gilthead seabream (Pavón-Muñoz et al., 2016) (Figure 5C, D).

Figure 4. Fish retinogenesis. A-D) Toluidine-blue stained sections show the different phases of development of the retina. A) The retina is composed of a pseudostratified epithelium of multipotent progenitor cells. B) The retina is constituted of a neuroblastic layer. At this stage, neuroblastic cells migrate along the tissue to be located on its final position. C) Emergence of the nuclear and plexiform layers (asterisks). D) Mature retina shows a typical multi-layered structure. E) Cell differentiation. Migratory neuroblasts move from the vitreous (S phase) to the ventricular (M phase) region. When these cell types leave the cell cycle, the process of differentiation begins. *AC, amacrine cells; BC, bipolar cells; C, cones; GC, ganglion cells; GCL, ganglion cell layer; HC, horizontal cells; INL, inner nuclear layer; IPL, inner plexiform layer; L, lens; MC, Müller cells; NbL, neuroblastic layer; NE, neuroepithelium; ONL, outer nuclear layer; OPL, outer plexiform layer; PE, pigmented epithelium; R, rodes.* Scale bars: 100 µm.

Figure 5. Retinal maturity at hatching in precocial (A, B) and altricial (C, D) fish species. At the hatching day, the retina of altricial species is still undifferentiated and is composed of a neuroblastic layer (A, B) while the retina of precocial species shows a completely differentiated tissue (C, D). Scale bars: 10 mm (A), 500 µm (C), 100 µm (B, D).

In any case, the retina of both precocial and altricial teleost species presents a very intense postnatal neurogenesis. Thus, as the fish grows, the retina continues to grow throughout its life and new neurons are constantly added to the mature retinal tissue. It is now widely recognized that retinal stem cells persist in specialized "niches" in the adult teleost retina where they generate a large number of different types of neurons (Raymond et al., 2006, Stenkamp, 2011; Lenkowski and Raymond, 2014).

# **Stem Cell Niches in the Teleost Retina**

#### *Healthy Retina*

The proliferating cells in the mature fish retina are shown to accumulate  ${}^{3}H$  thymidine (Raymond and Rivlin, 1987) or BrdU (Julian et al., 1998; Otteson et al., 2001). They can also be identified immunohistochemically with antibodies against the proliferating cell nuclear antigen (PCNA) (Bejarano-Escobar et al., 2009; 2010; 2014; Pavón-Muñoz et al., 2016) (Figure 6B,D,F,H) and against phospho-histone H3 (pHisH3) (Pavón-Muñoz et al., 2016) (Figure 6C,D,G,H). Proliferative activity is mainly detected in the ciliary marginal zone (CMZ), a circumferential ring of cells located at the periphery of the neural retina (Figure 6). Furthermore, proliferative Müller cells are also detected in the INL. These cells continue to divide and likely give rise to the precursor cells that migrate to the ONL and, after several cycles of cell divisions, differentiate into new rod photoreceptors (Figure 6). These stem cell niches are detailed below.

Figure 6. Niches of stem cells in mature retina.pHisH3 and PCNA-immunoreactivities of *Sparus aurata* retina. Magnifications of A-D are shown in E-H. Sections were counterstained with DAPI. The presence of the CMZ can be observed at the periphery of the retina (asterisks in B,D,F,H). At this region, CMZ is composed of retinal stem cells and retinal progenitor cells that generate retinal neurons. Anti-PCNA antibody shows the presence proliferative photoreceptors (arrows in B,D,F,H) that originate from proliferative Müller cells (B,D,F,H). Anti-pHisH3 antibody shows the presence of mitotic activity in the CMZ and in the photoreceptor layer (arrowheads in C,D,G,H). Scale bars: 200 µm in A (A-D), 100 µm in E (E-H).

#### *Ciliary Marginal Zone (CMZ)*

The CMZ is also known in other vertebrates as *ora serrata*, *ora terminalis*, or circumferential germinative zone (CGZ) (Amato et al., 2004; Fischer et al., 2014). The CMZ is a remnant of the embryonic neuroepithelium preserved at the retinal margin following cell differentiation and lamination centrally (Raymond et al., 2006). It has been shown that new

rings of cells are constantly added from the teleost CMZ to the mature tissue. Therefore, cells situated more peripherally are younger than central ones. The teleost CMZ is able to generate an enormous number of progeny, since the total number of retinal cells generated far exceeds the number of CMZ cells present at the end of embryogenesis (Figure 7). However, reptilian and avian retinal histogenesis takes place almost exclusively during embryonic stages (Figure 7). Proliferative activity is detected in the CMZ of younger chicks (<30 days) and few retinal tissue is generated in the peripheral region in hatchlings (Fischer and Reh, 2000). The proliferation of these undifferentiated cells located in the CMZ can be greatly enhanced postnatally by intraocular injections of EGF, IGF-I, or insulin (Fischer and Reh, 2000). On the contrary, mammals do not show evidence of proliferative activity at the peripheral edge of the normal retina at birth, suggesting that mammals do not have CMZ (Figure 7).

Figure 7. Schematic representation of the presence and absence of the CMZ among the vertebrates and its contribution to retinal growth. Neurogenesis continues after embryonic stages. In fish and amphibians, most of the retina derives from the CMZ, which contributes to the regeneration of this tissue. The presence of the CMZ is conserved in turtles and birds but its contribution to the generation of the retina is minimal. Most of this tissue is embryonic. In mammals, the CMZ is absent and the whole retina originates from embryonic ectoderm. (*Adapted from Moshiri et al., 2004)*.

In order to determine the histological organization of the CMZ, Raymond et al., (2006) systematically examined the expression patterns of selected genes involved in retinogenesis by using *in situ* hybridization. They subdivided the zebrafish CMZ into four anatomical regions: peripheral, middle, central-outer, and central-inner. Retinal stem cells are located in the peripheral sub-region and more restricted retinal progenitors lay closer to the differentiated retina. Thus, the definitive GCL derives from the middle sub-region of the CMZ. Progenitors at the central-inner CMZ give rise to cells located in the INL, and the central-outer sub-region generates cone photoreceptors in the ONL (Raymond et al., 2006). More recently, the clonal analysis and imaging studies showed that, as the retina develops, retinal stem cells located in the extreme peripheral edge of the CMZ divide asymmetrically to

generate a new retinal stem cell that remains in the stem cell niche, and a second daughter cell that is pushed centrally, where it becomes a more restricted retinal progenitor cell (Wan et al., 2016). Therefore, the CMZ is able to generate all the retinal cell types with the exception of rods (Figure 8) that are generated by the Müller glia (see below).

#### *Müller Glia*

In the normal developing and mature healthy retina, Müller cells have been characterized as the "radial glia" of the retina. Based on functional similarities, many of those authors considered MG as astrocyte-like cells. These cells are clearly defined by structure, function, and gene expression patterns (Reichenbach and Bringmann, 2013; Gallina et al., 2014; Lenkowski and Raymond, 2014). MG are involved in homeostasis, retinal innate immunity, retinal diseases and regeneration of the visual system, and phagocytosis of cell debris and diverse foreign bodies under physiological, pathological, and experimental conditions (Reichenbach and Bringmann, 2013; Gallina et al., 2014; Goldman, 2014; Gorsuch and Hyde, 2014; Lenkowski and Raymond, 2014; Hamon et al., 2016; Vecino et al., 2016; Bejarano-Escobar et al., 2017). However, within the past years, MG have been identified as a source of retinal cells in the healthy (Bernardos et al., 2007) and injured teleost retina (Fausset and Goldman, 2006). Thus, it has been shown that MG of teleosts continue to divide slowly and give rise to rod progenitors which form clusters in the INL that align in radial columns. These rod progenitors migrate away from the INL and into the ONL, where they continue to divide and differentiate into new rod photoreceptors (Julian et al., 1998; Bernardos et al., 2007) (Figure 8).

Figure 8. Neurogenesis of the fish retina during growth and regeneration. The CMZ is composed of retinal stem cells and retinal progenitor cells. RPCs are located in the peripheral retina and they will differentiate into retinal neurons. Müller cells are retinal progenitor cells that give rise to rodes. When the retina is damaged, microglial cells are activated and remove cellular debris. Nuclei of Müller cells move to the apical surface and divide asymmetrically. This process results in the formation of RPCs that migrate to the right position to generate the typical retinal neurons. (*Adapted from Lenkowski and Raymond, 2014*).

#### *Injured Retina: Regeneration*

It has been shown that adult teleosts can regenerate their retinas after different methods of injury such as cytotoxic lesion by injection of neurotoxins (Fimbel et al., 2007; Sherpa et al., 2008), surgical approach (Hitchcock et al., 1992; Fausset and Goldman, 2006), localized heat (Raymond et al., 2006), laser or light damage (Vihtelic and Hyde, 2000; Bernardos et al., 2007; Thummel et al., 2008; Bejarano-Escobar et al., 2012b). In the case of constant intenselight exposure, cone-diurnal retina of albino fish (Allen et al., 1999; Vihtelic and Hyde, 2000; Allison et al., 2006), or rod-dominated retina of larval epibenthonic teleosts (Bejarano-Escobar et al., 2012b), are suitable models because of their relatively high susceptibility to light damage. In any case, after cell degeneration in the teleost retina, regeneration is conducted by the stem cells present at the niches described above. Thus, it has been demonstrated that retinal damage in teleosts causes increased cell proliferation at the peripheral edge, suggesting that the CMZ contributes to retinal regeneration (Raymond et al., 1988; Hitchcock et al., 1992). There is also evidence that after neurotoxic treatment, cones regenerate with a different pattern and density at the periphery than in the central goldfish retina (Stenkamp et al., 2001). This suggests that two cone populations arise via two spatially and cellularly distinct mechanisms. These authors suggest that the CMZ is the major source of the regenerated peripheral retina, but not of the central one. It was recently demonstrated that after rod cell ablation, CMZ stem cells generate all retinal cell types with the exception of rod photoreceptors (Wilson et al., 2016). It remains unclear why the proliferative response of the CMZ increases in rod degenerative fish models since they do not contribute to rod neurogenesis.

Although under normal physiological conditions, MG generate only rod photoreceptors, it is well established that a subset of Müller cells are the source of central retinal regeneration in teleosts (Fausset and Goldman, 2006; Bernardos et al., 2007; Thummel et al., 2008). Thus, after retinal damage, MG reenter the cell cycle and act similar to retinal progenitor cells during embryonic development, exhibiting inter kinetic nuclear migration apically to undergo a single asymmetric mitosis to self-renew and to produce a proliferating retinal progenitor (Nagashima et al., 2013). Nuclear migration is facilitated by the actin cytoskeleton and Rhoassociated coiled-coil kinases (Rocks) and it is necessary for photoreceptor regeneration in the adult zebrafish retina (Lahne et al., 2015). The newly generated cell divides rapidly and repeatedly and a cluster of progenitor cells is raised. The vitreal or scleral migration of dividing progenitors and post-mitotic neural precursors is a necessary step to replace the population of cells that has been lost and restore the functional vision (Figure 8). Thus, the selective ablation of photoreceptors recruits progenitors to the ONL (Vihtelic and Hyde, 2000). In contrast, the ablation of cells located in the inner half of the retina retains the retinal progenitors in the INL to replace amacrine or ganglion cells (Fimbel et al., 2007) (Figure 8).

Different cytokines secreted after retinal damage in teleosts promote MG dedifferentiation and proliferation by the expression of several proneural transcription factors. Thus, the pro-inflammatory cytokine  $TNF\alpha$  produced by apoptotic neurons initiates MG proliferation (Nelson et al., 2013). Stat3, as well as members of the MAPK and Akt signaling pathways, increase their expression in MG prior to their de-differentiation and proliferative response (Kassen et al., 2007). Stat3-dependant signaling pathway is stimulated by ciliary neurotrophic factor (CNTF) (Kassen et al., 2009). The expression of the proneural basichelix-loop-helix transcription factor Achaete-scute homolog 1a (Ascl1a) and the subsequent induction of lin-28, a pluripotency mRNA binding protein, is necessary for teleost MG and retinal regeneration (Ramachandran et al., 2010). These authors also showed that Müller glial cells respond by re-expressing pluripotency genes such as *c-myc, nanog, nox2, and oct4.*  Other studies have shown that Ascl1a-Dkk-Wnt signaling pathway, in conjunction with Pax6, Stat3, and Hspd1, regulates MG de-differentiation and progenitor proliferation (Kassen et al.,
2009; Qin et al., 2009; Thummel et al., 2010; Ramachandran et al., 2011). A recent transcriptomic analysis has revealed that several other categories of genes/signaling, such as nuclear factor-κB (NF-κB), clock genes, and prostaglandin metabolism, rapidly up-regulate in reactive MG (Sifuentes et al., 2016). More recently, it has been shown that sex determining region Y-box 2 (Sox2) (Gorsuch et al., 2017), and atonal homolog 7 (Atoh7) (Lust et al., 2016) are re-expressed in Müller cells after injury and lead them to proliferate and generate new retinal neurons. Additionally, Sox2 has the capacity to induce Ascl1a and Atoh7 expression, which are able to activate lin-28 expression themselves. It has also been shown that Notch signaling-inhibition collaborates with Ascl1a and Lin28a to stimulate widespread MG proliferation in the uninjured retina (Elsaeidi et al., 2018). Recently, microRNAs (miR) have also been identified to control the generation of new neurons derived from teleosts MG (Madelaine and Mourrain, 2017). Thus, the depletion of miR-9 increases the number of undifferentiated progenitors in the teleost retina. One of the transcription factors mentioned above, *lin-28,* which is involved in inducing proliferation of neural retinal stem cells after damage, is a target of miR-9 (La Torre et al., 2013). Other authors have shown that microglial cells and macrophages are critical for proper rod cell regeneration, stimulating the activation of retinal MG to a stem cell-like state (White et al., 2017).

#### **Therapeutic Applications**

As we have previously shown, the retina of the teleost fish has a remarkable potential to regenerate new neurons after various types of injury. Our understanding of the molecular mechanisms that regulate retinal regeneration from MG in fish has advanced rapidly during the last decade. Currently, the MG is recognized as the primary source of new neurons after retinal damage also in birds (Gallina et al., 2014).

Mammals do not generally show evidence of proliferation at the peripheral edge of the neural retina, suggesting that this group of vertebrates do not have CMZ. Therefore, the attempts to stimulate retinal regeneration in the mammalian retina have focused on the MG. Retinal injury results in reactive gliosis and glial scaring in mammals (Bringmann et al., 2009) and traditional studies have failed to identify any regenerative potential in the mammalian retina. Thus, degenerative retinal diseases in mammals can lead to vision loss. However, retinal injury in either fish or mammals induces the up-regulation of many mitogenic factors (Kassen et al., 2009; Wan et al., 2012; 2014). Therefore, the initial steps in the response to injury that lead to regeneration in teleosts are also conserved in the retina of mammals. Thus, *in vitro* studies have demonstrated that mammalian Müller cells could act as progenitors of bipolar (Pollak et al., 2013) and photoreceptor cells (Giannelli et al., 2011). More recently, it has been shown that forced expression of Ascl1 promotes MG proliferation and differentiation into amacrine, bipolar, and photoreceptor neurons following retinal injury in young mice (Ueki et al., 2015). The combination of Ascl1 expression with a histone deacetylase inhibitor increases the differentiation of MG into new neurons in the mouse adult retina (Jorstad et al., 2017).

Therefore, our understanding of the molecular mechanisms that regulate retinal regeneration from stem cells in teleosts could bring insights into the molecular mechanisms that either sustain or prevent neural cell replacement and therefore help to design therapies to stimulate retinal regeneration in mammals.

## **ABSTRACT**

The Gulf of California comprises a great diversity of benthic ecosystems. The western coast in particular is dominated by rocky and coral reefs that shelter a wide diversity and abundance of species. Despite the importance of benthic ecosystems for the structure and organization of associated communities, few studies have focused on the importance of benthos in the trophic organization of the fish community. In this chapter the fish communities of four areas of the Los Frailes rocky reef differing in benthic structural complexity (BSC) were evaluated through visual censuses. According to the BSC two low benthic structural complexity (LBSC) areas and two high complexity (HBSC) areas were identified. The HBSC areas had a higher number of cavities, greater depth and greater substrate heterogeneity. However, despite differences in structural complexity, the trophic organization of the ichthyofauna did not show significant changes in terms of formation of functional trophic groups (FTG) between the HBSC (21 FTG) and LBSC (19 FTG) locations. The biomass flow diagram of the different prey species of carnivorous, omnivorous and herbivorous fish present in the reef showed variable connections and biomass flow, with dominance of benthic prey species, which highlights the importance of benthic invertebrates as a source of energy for the reef ichthyofauna.

## **INTRODUCTION**

Reef systems represent the interdependence between the physical environment and organic activity. Physical factors are decisive in reef formation and in the specific composition of the benthic community that lives there (Jones & Endean, 1977). It has been shown that the factors that determine the benthic community structure of reef systems are caused by physical parameters that dictate the structure in shallow areas, and by biological parameters that are decisive in deeper areas, where competition for food and space is an important factor in this type of community (Glynn et al., 1972; Liddell & Ohlhorst, 1987; Borges-Souza, 2003).

The composition of the fish species assemblage associated to rocky and coral reef systems is the result of the interaction of several processes, including biotic factors associated with recruitment, predation and competition, and abiotic factors such as habitat structure (Ebeling & Hixon, 1991). Reef fish can respond to several aspects of habitat structure (substrate type, size and shape of cavities, crevices, rocks, algal growth, coral growth, etc.) that influence their distribution, abundance, specific richness and diversity (Álvarez-Philip, 2004). Several studies have examined the effect of different habitat characteristics and different attributes of the community (Luckhurst & Luckhurst, 1978; Roberts & Ormond, 1987; Öhman & Rajasuriya, 1998). Some of these studies reported a positive relationship between structural habitat complexity and ecological community indices such as fish diversity and rugosity (Risk, 1972; Roberts & Ormond, 1987). However, other studies report no such relationship (Sale & Dybdahl, 1975; Luckhurst & Luckhurst, 1978).

These differing results could be due to not all structural characteristics of the habitat having the same influence on each attribute of the fish community and influencing differently each of the species that comprise it (Roberts & Ormond, 1987; Grigg, 1994; McClanahan, 1994; Gratwicke & Speight, 2005). Depending on the structural complexity of the habitat, a greater or smaller number of microhabitats can be established that impact the degree of competition among species and individuals, as well as the persistence of the predators and their prey, which in turn impacts directly the different attributes of the community (abundance, species richness and diversity) (Crowder & Cooper, 1982; Wooton, 1990; Gerking, 1994).

To analyze jointly the functioning and feeding organization of the ichthyofauna within a community context it is necessary to investigate the effect of the habitat structural complexity and existing trophic relationships (functional groups) (Elliott et al., 2007). In this chapter we analyzed the effect of the habitat complexity on the structure and trophic organization of the conspicuous ichthyofauna of the Los Frailes reef, B.C.S., in order to determine the ecological role of the habitat structural complexity (as one of the main factors) in the variability of benthic fish associations in this area of the mouth of the Gulf of California (GC).

The Los Frailes reef is located at 23º25´N and 109º30´W (Figure 1). It is part of Cabo Pulmo National Park, at the entrance to the GC (Robinson & Thomson, 1992; Reyes Bonilla, 1997). The Los Frailes Bay is located in a transition zone between the Eastern Tropical Pacific and the Temperate Eastern Pacific, where three water masses converge: (1) cold lowsalinity water (34.6 PSU; practical salinity units) of the California Current; (2) warmer medium-salinity water (34.65-34.85 PSU) from the southeast, carried by the Costa Rica coastal current; and (3) warm high-salinity water (>34.9 PSU) from the GC (Álvarez-Borrego & Lara-Lara, 1991).

Figure 1. Los Frailes reef. Locations Z1 and Z2 have low benthic structural complexity (LBSC) and locations Z3 and Z4 have high benthic structural complexity (HBSC).

There are no studies to date on oceanographic variables at Los Frailes reef, only isolated measurements of some variables taken in Cabo Pulmo reef (Trasviña-Castro et al., 2013). The mean temperature on the reef is 24.9ºC, but there are temperature records of 17ºC in February 1988 and of 32ºC in August 1997 (Anaya-Reyna, 1993). Salinity remains relatively constant at 35 PSU year-round. Water in the area has low turbidity and precipitation is low at 200 mm year-1 , although two creeks flow into the Los Frailes area and provide an important volume of fresh water and terrestrial sediment. The rainy season ranges from July to September (Anaya-Reyna, 1993). Large structures and rocks can be observed in this area from the intertidal zone to 15 m depth, with presence of sandy patches (Moreno-Sánchez, 2009). Four sampling areas were chosen at locations Z1 and Z2, found at a shallow depth of between 1 and 3 m. These two locations are characterized by high energy waves, by rocky material that ranges in size from pebbles (20 to 30 cm) to blocks over 3 m in diameter, and by a not very steep beach slope. Both locations had 80 percent rock cover and presence of coral heads.

The Z3 and Z4 locations were situated at an intermediate depth of 7 to 10 m. At these locations there were fewer pebbles, the slope was steeper, there was 70% percent cover of rocky material, with up to 20% sand cover. These two locations were at the transition between the rocky part of the reef and the sandy ocean bottom (Figure 1). The submarine Los Frailes canyon, with a depth of over 1000 m, is located near the reef. This bathymetric feature enables the presence of pelagic species and of local events such as upwelling (Fiedler, 1992; Reyes Bonilla, 2001). To characterize the benthic structural complexity (BSC) the following characteristics were taken into account at each location:

Sampling trips were carried out monthly from November 2004 to October 2006 at four locations (Z1 and Z2 at shallow depths, Z3 and Z4 at intermediate depths), within the Los Frailes reef, B.C.S. The method of visual censuses by scuba and free diving was used, which is a method commonly used in fish ecology studies of this type of community (Bortone et al., 1991). Censuses were carried out along transects. This technique is recommended when a quantitative estimate of abundance is needed.

In this chapter transects 50 m long by 5 m wide were used (Elorduy-Garay & Jiménez-Gutiérrez, 2000). Censuses were carried out during daylight hours between 10:00 and 16:00, which is when illumination is best. Transects started from a fixed point along the shore where coordinates were taken using a global positioning system (GPS). All fish species and abundances were recorded on acrylic sheets using graphite pencils. Photographs and videos were also taken for later reference, comparing with specialized bibliography (e.g., Fischer et al., 1995; Thomson et al., 2000; Gotshall, 2001; Robertson & Allen, 2008).

With the recorded information a systematic list of conspicuous fish at the Los Frailes reef was assembled. The composition was evaluated counting the number of species present in each sample at each location (Brower & Zar, 1977).

In order to obtain a hierarchical location of species within the community, species were grouped into four categories according to their frequency and relative abundance at each location in the following manner (Villegas-Sánchez et al., 2009):

- Rare species: relative abundance under 0.1%
- Common species: relative abundance under 1% and over 0.1%
- Frequent species: relative abundance over 1% and under 10%
- Abundant species: relative abundance over 10%

To evaluate the diversity of functional trophic groups defined as a set of permanent or temporal polyphyletic species sharing morphological characteristics and carrying out equivalent functions in the ecosystem (Naeem & Li, 1997; Blondel, 2003), a search of ecological attributes and morphological characteristics was carried out. The ecological attributes taken into account were diet, trophic level, species residency (frequency and abundance), and position in the water column, whereas the morphological characteristics taken into account were length (cm), average weight, form of the caudal fin, position and type of mouth. These attributes and characteristics were selected based on studies by several authors who selected them as key characteristics associated to the function of a species within an ecosystem (Sánchez-Gil & Yáñez-Arancibia, 1997; Mathieson et al*.*, 2000; Dumay et al., 2004; Álvarez-Filip & Reyes-Bonilla, 2006). The information was obtained from books, scientific articles and the FISHBASE data base (Froese & Pauly, 2006; http://www.fishbase. org).

Excepting diets, all data were standardized using the square root transformation. Diet was recorded as the percent weight of each prey species. A cluster analysis was carried out starting from a similarity matrix (calculated using the Bray-Curtis similarity index with complete linkage). The samples were successively joined in groups according to the highest similarity value. This process ended when one unit containing all samples was obtained (Clarke & Warwick, 2001). Results were represented in a dendrogram, where the "y" axis represented all groups and the "x" axis defined the similarity level at which all groups or samples were deemed to be joined. The trophic categories (TC) were obtained using the program PRIMER 6.1.6. The selection of the cut-off point in the dendrogram was arbitrary, selecting a similarity level that would produce a manageable number of groups and would at the same time maximize the biological coherence among the members of each TC (Simberloff & Dayan, 1991; Petchey & Gaston, 2002).

To determine the importance of benthos in the trophic organization of the fish community the differences between the number of species and the functional trophic groups (FTG) were evaluated. The biological consistency of the functional groups was analyzed using the species that integrated a FTG in particular and presented similar characteristics in habitat use. We also determined whether several species carried out the same ecological role within the community (ecological redundancy). To estimate the importance of the benthos in the trophic organization of the fish community of the Los Frailes reef the FTG were integrated into three feeding categories: herbivores (diet composed of over 70% algae), omnivores (diet composed of 30% algae and 70% animals), and carnivores. On this basis a biomass flow diagram was designed. This type of analysis allows the visualization of how the different prey and predator species are connected, as well as the number of connections within the reef.

Figure 2. Habitat characteristics at each location. Z1 northwest, Z2 northeast, Z3 southwest, Z4 southeast. (a) average depth (□) and standard deviation (Τ); substrate cover, (b) white: rock cover, grey: coral cover, black: area cover, (c) number of cavities; (d) rugosity – average  $(\square)$  and standard deviation (T); (e) rock size, average  $(\square)$  and standard deviation (T).

The Z3 and Z4 locations were deeper (mean = 8 meters; Figure 2a). There was a high percentage of rock substrate at all locations; the Z3 location had more sand cover, and the Z1 location had more coral cover (Figure 2b). The Z3 and Z4 locations had more cavities and higher rugosity (Figure 2c and d). The Z3 location had small-sized rocks, while the Z1 and Z4 locations had larger rocks (Figure 2e). The descriptors of BSC allowed the separation of locations in two groups with different levels of complexity: the shallow Z1 and Z2 stations made up the low BSC group (LBSC), while the Z3 and Z4 stations made up the high BSC group (HBSC) (Figure 2f).

#### **Composition of the Fish Community**

A total of 88 monthly sampling trips were conducted in 2005 and 2006. A total of 34,887 fish were counted, belonging to 31 families, 61 genera and 89 species (Table 1). The total richness was 89 species. In the HBSC locations species richness was 89 species with an average of 25 species, while at LBSC locations species richness was 77 species, with average values of 17.36 species at Z1 and 16.36 species at Z2 (Figure 3a).

Figure 3. Species richness and total abundance, average and standard deviation (T) at low benthic structural complexity (LBSC) and high benthic structural complexity (HBSC) locations.

#### **Abundance**

A total of 34,887 individuals were counted. The highest abundances occurred at the HBSC locations, where 18,284 individuals were recorded, with an average of 415.54 individuals. At LBSC locations 16,603 individuals were counted, with an average of 377.34 individuals (Figure 3b).

## **Table 1. Systematic list of reef fish species in Los Frailes, including scientific name, abundance, frequency, classification according to abundance and frequency, presence in HBSC or LBSC, warm or cool season. O = species present, X = species absent**

## **Table 1. (Continued)**

#### **Table 1. (Continued)**

## **Classification of Species According to Their Relative Abundance**

Of the 89 recorded species two (*Thalassoma lucasanum* and *Chromis atrilobata)* were categorized as abundant. A total of 16 species were categorized as frequent, including *Prionurus punctatus*, *Abudefduf troschelii, Stegastes rectifraenum*, *Arothron meleagris*, and *Plagiotremus azaleus*. A total of 42 species were categorized as common, among which were

included *Acanthurus triostegus*, *Halichoeres semicinta*, *Scarus ghobban* and *Apogon retrosella*. There were a total of 29 rare species, present at one or two locations with a low number of individuals; among these were: *H. chierchiae, H. nicholsi, Scorpaena plumieri, Crocodilichtthys gracilis* and *Synodus lacertinus* (Figure 4). The HBSC locations had a higher number of abundant (4.9%) and rare species (76.5%), as well as higher species richness, while LBSC locations had higher values of frequent (43.7%) and common (76.5%) species (Figure 4).

Figure 4. Classification of species according to their frequency and abundance in low benthic structural complexity (black bars) and high benthic structural complexity (grey bars) habitats.

## **Trophic Organization**

Of the 89 species making up the fish fauna of the Los Frailes reef, 32% were at a trophic level between 3 and 3.5; only 21% were level 4 predators, while 12% belonged to low trophic levels  $(2 – 2.5)$ . A total of 58% of fish species were associated to the bottom, 3% were species associated to the surface, and of the total of recorded species only five were territorial. There was a dominance of small-sized fish (67%), while there were few medium and large fish (25% and 8%, respectively). The type of fin of most species was emarginate (43%), followed by the lunate type (25%) and forked (10%).

#### **Functional Trophic Groups**

In HBSC areas a total of 89 species were recorded and a total of 21 functional trophic groups (FTG) were integrated (Figure 5). In the LBSC areas a total of 78 species were recorded, which were grouped into 19 FTG (Figure 6).

Figure 5. Functional groups in HBSC locations. Numbers represent each functional group and the species that comprise it.

Figure 6. Functional groups in LBSC locations. Numbers represent each functional group and the species that comprise it.

There were differences in the number of species contained in the functional trophic groups between the areas. The FTG in the HSBC locations are denoted as 1, 2, 3, 4…, and FTG in the LSBC locations are denoted as  $1^a$ ,  $2^a$ ,  $3^a$ ,  $4^a$ ...

1. This group was made up by mainly piscivorous species, most of which were pelagic and some demerso-pelagic. They were catalogued as common and rare.

1 a . This group comprised the same species as group 1, excepting *E. lineatus* and *N. pectoralis* which did not occur in LBSC areas.

2. This group comprised carnivorous species, which were not abundant and inhabited the reef bottom among rocks and cavities.

2 a . This was a mono-specific group (*Gymnothorax castaneus*).

3. This group was made up by piscivorous species, although some invertebrates were also included (crab, shrimp, polychaetes) in their diet. All these species had a high trophic level (>3.95); they inhabited the bottom and mid-water over the reef, and were common and rare species.

3 a . This group comprised nine species that had the same trophic function in LSBC as in HSBC locations.

4. This group was made up by herbivorous species (70-90% of the diet) and corallivorous species (20-10% of diet). The trophic level of this group was less than 2.5. Species occurred on the reef bottom and in mid-water.

4 a . This group comprised the same nine herbivorous species and had the same trophic relationships in HBSC as in LBSC locations.

5. This group was made up by three herbivorous species (40–60% of diet), although echinoderms, fish remains, sponges and bivalves were also included in their diet. Their trophic level was between 2.75 and 2.85. These were frequent and common species, associated to the bottom and territorial.

5 a . This group included the same species in LBSC locations.

6. In HBSC locations the group was comprised of species that fed on sponges (80 to 85% of diet), algae (5 to 10%), and invertebrates (less than 5% of diet). These were common species associated to the substrate and mid-water, with slow swimming speeds.

6 a . This group of species remained the same in LBSC locations.

7. This group included two species that fed mainly on shrimp and on a lower proportion of crab and other fish. These species were considered common and were associated with the bottom and mid-water.

7 a . This group did not change with the benthic structural complexity; the same members and trophic functions were maintained.

8. This group included species that fed on shrimp, sea urchins, crab, brown algae and sponges. The species were considered common and were found on the bottom and mid-water.

8 a . This group remained the same in LBSC locations.

9. Nine species comprised this group. They fed on echinoderms, pellecipods and gastropods. They were considered common and rare species related to the bottom.

9 a . This group comprised 10 species, also including *Pseudobalistes naufragium*.

10. This group was made up of three species that fed on echinoderms, sipunculids and tunicates. They had low abundance and frequency on the reef and were associated to the bottom.

10<sup>a</sup>. This group was made up only by *Arothron hispidus*, since *D. hystrix* was not recorded in LBSC locations and *P. naufragium* was included in group 9 due to its trophic characteristics.

11. This group included only one species that fed mainly on ophiurids (sea stars). It had low frequency and abundance and was associated to the bottom.

11<sup>a</sup>. The species that conformed this group in HBSC locations was not recorded in LBSC locations, so that this group did not occur there.

12. This group was made up of three species that fed on crab and complemented their diet with echinoderms and gastropods. They had a trophic level of 3.5 and were considered rare species on the reef.

12<sup>a</sup> . This group was made up of only two species: *Alphestes multiguttatus* and *Labrisomus multixanti*, since *Malacoctenus margaritae* was not recorded in LBSC locations.

13. This group was made up of four species that fed on a high percentage of algae (over 90%) and a lower proportion of detritus (10%). In general these organisms had low presence on the reef and were found in mid-water.

13<sup>a</sup>. This group did not show changes in the number of members and trophic functions in LBSC locations.

14. The only species in this group was *Chaetodon humeralis*. It fed on copepods, green algae, polychaetes, amphipods and shrimp. It was considered frequent on the reef.

14<sup>a</sup> . This group did not occur in LBSC locations.

15. Two species made up this group. They fed on the same organisms (copepods, polychaetes, amphipods, bivalves and gastropods) mainly on the benthos. They had a high trophic level (>3.5) and were considered rare.

15<sup>a</sup> . This group did not occur in LBSC locations.

16. The only species in this group was *Abudefduf troschelii*. It fed on anthozoans, copepods, tunicates, polychaetes and fish eggs. Its position was on the reef surface.

16<sup>a</sup>. This mono-specific group did not show changes in LBSC locations.

17. This group was made up by two species of the Pomacentridae family, which fed on copepods, fish eggs and shrimp. They were found in the water column and only associated with the substrate to lay eggs.

17<sup>a</sup>. This group remained constant in LBSC locations.

18. This group was made up of two species that fed on bivalves and gastropods, and that were considered rare.

18<sup>a</sup>. This group was made up by *Trachinotus rhodopus* and *Paranthis colonus*, which consumed bivalves and gastropods. *Rhinoptera steindachneri* was not recorded in LBSC locations.

19. This group was made up by three species (*Diodon holocanthus, Novaculichthys taeniourus* and *Chilomycterus reticulatus*) that fed on gastropods and bivalves. Their trophic level was similar. These species were considered common to rare and were associated to the bottom and mid-water.

19<sup>a</sup> . This group was made up by three of the four species, since *Chilomycterus reticulatus* was not recorded in LBSC locations.

20. This group was made up by four species that fed on polychaetes, shrimp, crab, gastropods and other benthic components. They were rare species associated to the benthos and demerso-pelagic.

20<sup>a</sup> . This group did not change as to the number of species or trophic organization in the two types of location.

21. This group was heterogeneous, and included 10 species that fed on ostracods, copepods, polychaetes, chaetognaths, crabs, echinoderms, gastropods, bivalves, sipunculids, algae (brown and green), isopods, fish eggs (associated to the benthos), and sponges. They were considered abundant and common.

21<sup>a</sup>. This group remained constant, excepting *Paranthis colonus*, which was included in group 18. The nine remaining species maintained their trophic functionality in LBSC locations.

#### **Diagram of Biomass Flow in the Reef**

In order to estimate the importance of the benthos in the trophic organization of the fish community of the Los Frailes rocky reef, a diagram of biomass flow was created of the different prey species and the fish community, categorizing it according to feeding components as herbivorous, omnivorous or carnivorous.

Figure 7. Diagram of biomass flow in Los Frailes reef. Feeding categories (large black rectangles), food components (small black rectangles), connections (arrows), and biomass percentage of each food component.

In the diagram of biomass flow the herbivore category comprised 13 species, which were assigned to trophic guilds 4 and 13. The omnivorous category comprised 17 species assigned to trophic guilds 5, 6, 14 and 21, while carnivores comprised 59 species assigned to the remaining 15 guilds.

Omnivores and carnivores shared 20 food components belonging to the benthos and 2 components from the pelagic zone. The chaetognaths were the only components that were exclusive to omnivores, while cephalopods from the pelagic zone, and prosobranchs, asteroids and opistobranchs from the benthic zone were exclusive to carnivores.

In general, the connections and biomass flow within the reef were varied, but there was great dominance of benthic species, which confirms the importance of invertebrates as a food source for reef fish (Figure 7).

## **DISCUSSION**

#### **Habitat Structural Complexity**

The objective of the present chapter was to analyze the effect of benthic structural complexity (BSC) on the trophic organization of the conspicuous ichthyofauna of the Los Frailes reef. The first step was to evaluate some habitat characteristics such as number of cavities, substrate heterogeneity, rugosity, number of rocks, and depth. These attributes were considered ideal to measure the degree of BSC because they are conceptually descriptive, easily measured and allow comparisons at different spatial scales (McCormick, 1994).

According to results of the grouping analysis, zones one  $(Z1)$  and two  $(Z2)$  were categorized as low benthic structural complexity (LBSC) areas, while zones three (Z3) and four (Z4) were categorized as high benthic structural complexity areas (HBSC). McCormick (1994) and Bartholomew et al. (2000) reported that locations with high values of these attributes are not only more complex from the architectural point of view, but also from the biological point of view, so that it can be inferred that benthic complexity has an effect and is reflected on the trophic organization of the reef (Ángel & Ojeda, 2001).

LBSC locations were found in the shallow zone (between one and three meters depth), while HBSC locations were found at intermediate depths (between eight and nine meters depth). It should be mentioned that the grouping analysis did not take into account depth values because they affect grouping *per se*, and given the shallow depth of the Los Frailes reef (10m) it was considered that the effect of depth on community structure was limited, due to the variability of other factors such as temperature, hydrodynamic processes, water pressure, light intensity, and space available in the water column (Bayle-Sempere et al., 1994; Chabanet & Letourneur, 1995; García-Charton & Pérez-Ruzafa, 2001).

Substrate heterogeneity is an important part of HSC and has a differential effect on the ichthyofauna (Roberts & Ormond, 1987) because depending on its characteristics specific election preferences are created that influence directly the distribution and abundance of fish, and therefore, the community structure (Ruitton et al., 2000).

HBSC locations were characterized by a higher number of cavities than LBSC locations. Hixon & Beets (1989) reported that habitats with these characteristics offer a higher number of potential refuges, which promotes recruitment by juveniles and increases the number of species (predators and prey) and their density (Shulman, 1984; Kellison & Sedberry, 1998).

HBSC locations were located between the rocky reef and sandy areas of the ocean bottom. This "edge effect" promoted higher abundance and diversity due to the convergence of different species that inhabit both habitat types. In other parts of the world this same pattern has been observed, and the presence of rare species associated only to these transition zones has been detected (Acosta & Robertson, 2002; Friedlander & Parrish, 2002).

Rugosity is defined as the ratio of substrate contour to linear distance (Luckhurst & Luckhurst, 1978), that is, how sinuous the bottom contour is. This characteristic provides refuge and space for new recruits, and settlement areas for algae and invertebrates, in an indirect manner. Martin-Smith (1993) reported that epifaunal settlement is dictated by high substrate rugosity, because substrate is proportional to the contact area of organisms. Rugosity was also different among locations, being lower for LBSC areas.

Each HSC has an effect on the structure of the fish community to a greater or lesser degree and therefore on trophic organization, so that it is important to determine the relationship between the habitat (benthos) and the species, since each modification to HSC will have an effect on the fish community structure.

#### **Fish Community Composition**

The list of fish species in the Los Frailes reef during the two year study period comprised 89 species (Table 1). The reef contained approximately  $0.8$  species  $m<sup>2</sup>$ , which makes it more diverse than other nearby areas within the Gulf of California. The Los Frailes reef shelters the equivalent of 31% of reef fish species recorded for the entire Gulf of California (281 species; Thomson et al*.*, 2000), and 38% of species reported for the Cabo Pulmo reef (236 species recorded over a 12 year period; Villareal-Cavazos et al., 2000).

It should be mentioned that this chapter focused mainly on conspicuous species, underestimating cryptic and nocturnal species (Sale, 1997; Villareal-Cavazos et al., 2000; Romero-Ponce, 2002). Other contributions of this chapter lay in the systematic sampling and methods used, which, although they did not take into account cryptic species, were relevant for comparative analyses of seasons and habitats with different degrees of structural complexity.

Studies carried out in several areas within the Gulf of California are not easily comparable among each other due to differences in structure, depth, number of refuges and latitude of the reefs, and in some cases, due to the existing variation in the census method used. In other Gulf of California locations fish studies have been carried out using visual censuses. Pérez-España et al. (1996) recorded 75 species in four areas within the Bahía de La Paz; Sánchez-Ortíz et al*.* (1997) recorded 101 species in 11 locations ranging from north to south from Isla San Dieguito to Isla Cerralvo; Arreola-Robles & Elorduy-Garay (2002) recorded 80 species during censuses carried out in five islets and one wreck in the Espíritu Santo archipelago; Aburto-Oropeza (1999) counted 102 species, of which only 72 were identified using visual censuses (Aburto-Oropeza & Balart, 2001); and Villegas-Sánchez et al. (2009) recorded 84 species at five locations of Isla San José. Species richness in Los Frailes reef (with a lower number of sampling areas) was similar or even higher than the species richness reported in those studies.

#### **Trophic Organization of the Fish Community**

The highest abundance of recorded species (89) in the Los Frailes reef corresponded to carnivorous fish, followed by omnivores and a low percentage of herbivores. This type of trophic structure is commonly found in tropical and subtropical areas of the eastern Pacific (Roberson et al., 2004), including Cabo Pulmo (Álvarez-Filip & Reyes-Bonilla, 2006), Bahía de La Paz, Loreto, Bahía de Los Ángeles (Viesca-Lobaton et al., 2007), Bahía de Acapulco (Palacios-Salgado, 2005) and the Clipperton Atoll (Allen & Robertson, 1997).

It should be mentioned that despite there being fewer herbivorous than carnivorous species in these systems, their relative abundance in tropical areas is much higher than in temperate areas, with a gradual decrease from the equator towards the poles. This could be due to fish having more efficient digestive processes in warm waters (Floeter et al., 2004).

Among the most abundant carnivorous species in the Los Frailes reef are *Lutjanus viridis, Mycteroperca rosacea, Serranus psittacinus* and *Cephalopholis panamensis*. All these species feed mainly on fish, and according to their size and swimming capabilities, can complement their diet with invertebrates from the reef itself or from nearby sandy areas (Hobson, 1968; Thomson et al., 2000). Among low abundance carnivorous species are *Muraena lentiginosa, Synodus lacertinus* and *Alphestes multiguttatus*, which are associated to edge areas of the reef; they are ichthyofagous and have a stalking tactic to hunt their prey (personal observation). Carangids such as *Caranx caninus* and *Caranx melampygus* are visual, active predators that spend a great part of their time on the reef searching for prey (Hobson, 1968; Cervigón, 1972).

One of the main herbivorous species on the reef was *Prionorus punctatus*, which is one of the most characteristic fish species in Baja California Sur reefs (Montgomery et al., 1980). It feeds on filamentous and crustose algae, and forms schools that move about the reef stopping briefly to feed (Moreno-Sánchez et al., 2014). Species that feed on coral include the scarids *Scarus ghobban, S. compressus, S. perrico,* and *S. rubroviolaceus*. These species were abundant probably because of the great quantity of coral present (Álvarez-Filip, 2004).

*Plagiotremus azaleas* was categorized as a parasitic species, since if fed on the mucus and skin of other fish (Hobson, 1968; Fischer et al., 1995). Omnivores were the second representative group on the reef, of which the species *T. lucasanum*, *S. rectifraenum, M. dorsalis, H. passer* and *A. meleagris* were most abundant. These species fed on invertebrates and algae, and are considered key in the trophic webs of reef systems (Acero & Rivera, 1992), because detritus enters the food chain of fish mainly through benthic invertebrates that are preyed on by these species (Lieske & Myers, 1996).

## **Effect of Benthic Structural Complexity on the Trophic Organization of the Ichthyofauna of the Los Frailes Reef**

It was determined that the benthic structural complexity had little effect on the trophic organization of the fish community at Los Frailes reef. A total of 21 functional trophic groups (FTG) were defined at LBSC locations, and 19 FTG were identified at LBSC locations. These results contrast with what was reported by Ángel & Ojeda (2001), who compared two macroalgal areas with different HSC levels in the northern Chile coast. These authors found that complex habitats (benthos with different algae species, variation in density, size and

shape of fronds) provided higher spatial heterogeneity for the settlement of a greater quantity and variety of invertebrates and fish. The FTG were more interconnected due to the manner in which prey were shared.

This pattern has also been reported for fish communities in rivers. Pouilly et al. (2006) documented a change in the trophic structure of rivers in Bolivia due to the habitat structural complexity, and recorded changes in conductivity, pH, temperature, slope, speed and width of the river. These factors had a favorable effect on primary productivity.

Willis et al. (2005) detected a positive correlation between benthic structural complexity and functional diversity in the fish associations present in the Cinaruco River in Venezuela. The relationship was based on leaf litter mounds, logs and other substrate providing more area for higher benthic production and resulting in greater density of fish that used these sites for feeding and protection.

The abundance and diversity of resources in this type of habitat allow fish to exploit resources in different ways. For example, fish enter into cavities and crevices of logs to feed and seek protection. Larger omnivores with protractile mandibles can also feed on the organisms found in crevices (Angermeier & Karr, 1984), promoting in this way an increase in the presence of different species and therefore of fish diversity.

Friedlander & Parrish (1998) reported that in several locations in Hawaii the spatial relief of the reef bottom, equivalent to the number and size of cavities, depth, bottom configuration and location of reef patches, was the main promoter of biomass and abundance of the fish community.

The discrepancy between the results presented in this chapter with what was found by the previously-mentioned authors is probably related to the fact that we did not analyze the diets of all species at each location, and that diet was assigned independently of the sampling area. This was decisive in not finding significant differences in the number of FTG. Ángel & Ojeda (2001) stated that richness and abundance of species were not critical in the conformation of the number of FTG. A clear example of this is *Isacia conceptionis*, a species recorded at both location types. In high complexity locations, this species functions as an omnivore feeding on the benthos (on 5 main food components), while in low complexity areas it functions as a pelagic carnivore (with 3 main food components).

It was determined that *Arothron meleagris* was an omnivorous species, since it fed on a great variety of benthic species (sponges, sea urchins *Echinometra vanbrunti*, corals *Pocillopora* spp., *Porites* spp., bryozonas and *Crepidula arenata*). Reyes-Bonilla & Calderón-Aguilera (1999) reported that this same species in a nearby zone of Cabo Pulmo fed on coral, which could be indicative of its trophic plasticity.

The diagram of the fish community biomass flow showed high flow among the different categories. This same pattern was documented in Cape Hatteras, North Carolina, by Garrison & Link (2000), who did not find differences in the trophic structure of 40 species that integrated 14 trophic guilds. In that study a wide spatial scale was covered with 400 sampling stations, a depth range of 8 to 400 m, and diets that were sampled over 25 years. The authors reported that ontogenetic diet changes were the main factors that determined the differences found between trophic guilds, and that these changes were produced by morphological and habitat changes. Although that study was not focused on determining the effect of habitat complexity, the authors mentioned that a more detailed analysis could have found differences related to those factors.

Aburto-Oropeza & Balart (2001) reported that in Bahía de La Paz the structural complexity of the benthos (rugosity, size of cavities, cover of the different substrate types) could have a different effect on the behavior of individuals that chose sites for protection, feeding, reproduction and recruitment. The authors determined that several species were generalists with a wide distribution over different habitats. They also reported that empty spaces can be important for larvae and juveniles, and that survival depends in great part on the characteristics of the location.

Viesca-Lobaton et al. (2007) compared the functional groups formed in Bahía de La Paz, Loreto and Bahía de Los Ángeles. They reported that although the presence of functional groups was maintained in the entire area, there was an ecological substitution of species among regions due to the latitudinal change. This was possibly associated to the different physiological adaptation of species to cold water conditions, and secondarily, to a change in the feeding habits of the species due to resource availability.

It should be pointed out that this same effect occurred in the functional trophic groups (FTG) formed in Los Frailes reef. Although almost the same FTG were maintained, within each FTG some species and their abundance varied slightly depending on the structural characteristics of the habitat. For example, FTG number one was comprised of coastal pelagic species with ichthyofagous habits (*Euthynnus lineatus, Nematistius pectoralis, Fistularia commersoni, Elops affinis, Gnathanodon speciosus, Caranx caninus, C. caballus* and *C. melampygus*) (Hobson, 1968; Sierra et al., 1990; Fischer et al., 1995; Thomson et al., 2000). The first two species did not occur in the LBSC locations because they are mainly oceanic. The presence of FTG one in the reef is related to feeding, because during sampling this FTG was observed feeding on *Harengula thrissina*, an abundant prey species during the summer months, when the presence and frequency of predators was also higher. This same behavior has been reported in several locations of the Gulf of California and Bahía Magdalena (Thomson et al., 2000; Moreno-Sánchez, 2004).

*Fistularia commersoni* shares few morphological characteristics with the remaining species, but was integrated into FTG one due to its trophic level. It occupies the same space in the water column as the other members of this group, feeding on recently settled fish (mostly in LBSC locations), using a stalking tactic. Hobson (1968) reported that this species feeds on reef fish smaller than 5 cm at any time of day.

The species from the Carangidae family (*Gnathanodon speciosus, Caranx caninus, C. caballus* and *C. melampygus*) feed on fish but also consume components of the benthos to complement their diets. They are active and visual predators that feed mainly during the day (Daneman, 1993; Cruz-Escalona & Abitia-Cárdenas, 2004).

The second trophic functional group included *Gymnothorax castaneus, Muraena lentiginosa* and *Cephalopholis panamensis* at HBSC locations, while *Gymnothorax castaneus* only occurred at LBSC locations. These three species have similar feeding habits, consuming a high percentage of fish and a lower proportion of shrimp and crab (Randall, 1967; Raymundo-Huizar, 2000; Thomson et al., 2000). They are ambush predators associated to rocky bottoms that can be found among cavities and crevices from where they attack their prey; they have no specific feeding time (Hobson, 1968). The HSC could have an important effect on their presence and feeding.

In HBSC areas species usually employ stalking or ambush tactics because there are more places to hide (Coen et al., 1981). In fact, the coexistence of ecologically similar species could be possible due to resource sharing along one or more niche edges (Gladfelter  $\&$ 

Johnson, 1983), which in this case would be the number and size diversity of cavities as well as consumption of prey species, since despite feeding on the same items, the proportion of each species was different. In this scenario *Gymnothorax castaneus* could occur over the whole reef, independently of benthic complexity. This species´ morphology, aggressiveness, voracity and trophic plasticity give it a competitive advantage over the other two species (Werner & Hall, 1988).

The third FTG included species catalogued as roaming species that are distributed near the bottom without depending on it (demersal). They have a wide trophic spectrum comprised of fish, crab, shrimp, and polychaetes (Randall, 1967; Hobson, 1968; Fischer et al., 1995; Raymundo-Huizar, 2000; Thomson et al., 2000).

This FTG included the same members at both locations, except for *Synodus lacertinus*, which was not recorded at LBSC locations because its main prey occur at the edges of rocky reefs and sandy areas. It is a stalking predator, a voracious carnivore that propels itself from the bottom upwards to capture prey, usually small fish (Fischer et al., 1995; Raymundo-Huizar, 2000), and tends therefore to be located in deep areas. The characteristics that could favor this behavior can be observed mainly in HBSC locations. The occurrence of this FTG at both locations suggests efficiency in sharing of feeding resources.

FTG number four was made up by herbivorous species that occurred in both types of benthic complexity, although the abundance and frequency at each location was different. In general these species feed on three types of algae (Chlorophyta, Phaeophyta and Rhodophyta) and coral (Randall, 1967; Montgomery et al, 1980., Thomson et al., 2000). Anaya-Reyna & Riosmena-Rodríguez (1996) reported that 61 species made up the systematic list of macroalgae present in the coral reef of Cabo Pulmo-Los Frailes, highlighting the algal diversity in both areas.

The analysis of the feeding habits of the herbivores *Acanthurus nigricans* and *Prionorus punctatus* indicated that they have different diets (Abitia-Cárdenas et al., 2011; Moreno-Sánchez et al., 2014). *A. nigricans* feeds mainly on *Ulva linza* (50% relative importance) and *P. punctatus* feeds on *Gracilaria* spp., *Jania Mexicana* and *Hypnea musciformis*. Montgomery et al. (1980a, b) compared the diet of two herbivorous species (*Stegastes rectifraenum* and *Microspathodon dorsalis*) that differed considerably in their feeding behavior in this same reef: the first is selective and the second is not. In both cases the sharing of resources among herbivores was manifest.

The presence of species from the Scaridae family (*Scarus ghobban, Nicholsina denticulata, S. rubroviolaceus, S. compressus, S. perrico* and *Calatomus* spp.) could be explained by the nearness of Los Frailes reef to Cabo Pulmo, where they are common, implying that they could move from one reef to the other. These species feed on live coral, which in Los Frailes reef comprises up to 10% of cover. Their presence could also be due to the need to find refuge at night, as these organisms rest among cavities and crevices of rocky areas and segregate a mucus that presumably prevents predators from smelling them (Thomson et al., 2000; Viesca-Lobatón, 2003).

There was temporal segregation between *Acanthurus nigricans* and *Prionurus punctatus* in FTG four. *A. nigricans* occurs in higher abundance during the cold season and in lower abundance during the warm season. *P. punctatus* is common all year long. This FTG was not affected by the HSC, because these species feed on algae with a high turnover rate (Abitia-Cárdenas et al., 2011; Moreno-Sánchez et al., 2014).

FTG five was made up of species that feed mainly on algae and also consume invertebrates (Randall, 1967; Hobson, 1974; Montgomery, 1980; Thomson et al., 2000). These species are morphologically similar; they feed on the same prey and occur in the same position on the reef. Although this functional group was integrated in the two HSC types, the abundances of *O. steindachneri* and *C. punctatissima* were higher at HBSC locations, probably because these species need refuges to get protection from predators (Thomson et al., 2000). However, their dependence on the substrate was markedly higher than that of *M. dorsalis*, which is an herbivorous species that moves near the substrate but only depends on it to lay eggs (Hernández-Olalde, 2008). In general this FTG is little affected by the HSC and occupies both areas.

The sixth FTG occurred at both locations. The species that made up this group fed on algae, invertebrates and a high percentage of sponges (Hobson, 1974). These species had moderate abundance and frequency (common species). The presence of the group at both HSC locations could be related to spacing within the reef because none of these species depends strictly on the substrate (Thomson et al., 2000).

The seventh FTG group was made up by *Apogon retrosella* and *Haemulon maculicauda*, which were present at both HSC locations. Their diet was composed of shrimp, crab and fish. They are considered common species that occupy the space from the bottom to mid-water; they are nocturnal species.

The eighth FTG was one of the most diverse in trophic spectra, feeding behavior and morphology, and could be found at all locations. The diet of the species included this group was made up of algae and invertebrates (Randall, 1967; Hobson, 1968; Hobson, 1974; Pérez-España & Abitia-Cárdenas, 1996; Thomson et al., 2000). The abundances of each species varied among locations. For example, at HBSC locations, *C. oxycephalus, H. dispilus* and *P. azaleus* were numerous. These are small-sized species that measure between 5 and 15 cm and need to be close to their refugia to feed and hide (Hobson, 1976). *B. diplotaenia* and *H. passer* were considered roaming species in the reef: *B. diplotaenia* feeds on organisms on the substrate, and *H. passer* is coprofagous, living in the water column, usually under schools of *C. atrilobata* (Reynolds & Reynolds, 1977; Pérez- España & Abitia-Cárdenas, 1996; Aburto-Oropeza et al., 2000; Thomson et al., 2000). *Arothron meleagris* and *Sufflamen verres* were more abundant at LBSC locations. These are generalist species, with great trophic plasticity (Reyes-Bonilla & Calderón-Aguilera 1999; Thomson et al., 2000; Moreno-Sánchez et al., 2009).

The ninth FTG included species that fed on echinoderms, pellecipods and gastropods (Hobson, 1968; Hobson, 1974). These species were not very abundant or frequent, and were affected by the HSC. These labrids are small and live among crevices to avoid being preyed on; they were abundant at HBSC locations (Thomson et al., 2000). Of the four recorded species, two were the most abundant (*H. notospilus* at LBSC locations and *H. semicinctus* at HBSC locations) so that despite this group occurring at both locations, there was spatial segregation.

*Hoplopagrus guntheri* and *L. multiporosus* are relatively small species that also occupy cavities and crevices for refuge. These are icthyofagous reef-roaming species (Thomson et al, 2000).

Despite this functional group occurring in both areas, the abundance of its members changed according to the HSC. Most members use cavities and crevices to find refuge; therefore the species most dependent on the substrate were most abundant in HBSC areas. In

a similar way to previous cases, there was sharing of resources that facilitates coexistence among species.

The tenth FTG included *Pseudobalistes naufragium, Diodon hystrix* and *Arothron hispidus* in HBSC locations. *A. hispidus* was recorded only in LBSC locations. The three species depend on substrate characteristics to feed and are catalogued as reef-roaming species. The most important food components were sea urchins, which can be consumed due to the characteristics of the mouth apparatus of these species. *Diodon hystrix* and *A. hispidus* have plate-shaped teeth and *P. naufragium* has eight prominent teeth (Fischer et al., 1995; Thomson et al., 2000). These species complement their diet with sipunculids and tunicates (Randall, 1967). This FTG was more abundant at HBSC locations where a greater quantity of echinoderms was recorded.

The eleventh FTG was monospecific, with only *Malacoctenus hubbsi* being recorded. This species requires specific habitat characteristics and is therefore sensitive to benthic complexity. Thomson et al., (2000) reported that this is an aggressive and abundant species that inhabits preferentially depths over 8 m and feeds mainly on sea stars. In the Los Frailes reef it was recorded at HBSC locations, where this type of habitat is commonly found.

The twelfth FTG group included *Alphestes multiguttatus, Labrisomus xanti* and *Malacoctenus margaritae*. These species were recorded at both locations, except *M. margaritae* which was not found at LBSC locations. This is probably related to this being a comparatively small species that also needs small cavities, which are more abundant and frequent at HBSC locations. *A. multiguttatus* and *L. xanti* are larger species that depend on the substrate for feeding but are not territorial. Although the abundances of the members of this group differed depending on the HSC, they could carry out their activities in both areas.

The thirteenth FTG group, which included the herbivorous species *Kyphosus analogus, K. elegans, Acanthurus nigricans* and *Microspathodon bairdii*, was sensitive to the HSC. These species feed on algae, diatoms and detritus (Hobson, 1974; Montgomery, 1980 a and b; Thomson et al., 2000). No effect of benthic characteristics could be identified, since algal production is sufficient for all herbivorous species present in the area, although competition with more territorial or aggressive species could influence the presence of some of the members of this group, such as *S. rectifraenum* (Hobson, 1968, Moreno-Sánchez et al., 2011).

The fourteenth functional group included only *Chaetodon humeralis* at HBSC locations. This fish fed on copepods, green algae, polychaetes, amphipods, and shrimp, among other components (Randall, 1967; Hobson; 1974; Thomson et al., 2000). Due to its morphological characteristics this species could compete with FTG 15. There seems to be spatial segregation since this FTG did not occur at LBSC areas.

Despite *Halichoeres nicholsi* and *Sphoeroides lobatus* being different morphologically (Fischer et al., 1995), they made up the fifteenth functional group because they share food resources (copepods, polychaetes, amphipods, bivalves, gastropods). *H. nicholsi* needs cavities to find refuge from its predators and moves from the bottom to mid-water. *S. lobatus* inhabits preferentially the reef edges (rock-sand interface; Randall, 1967; Thomson et al., 2000). In this system this species was classified as rare. Due to its habitat requirements it was not recorded in LBSC locations. For this FTG the HSC did have an effect on *S. lobatus* due to its habitat requirements.

The sixteenth FTG was monospecific, it only included *Abudefduf troschelii*. This species has characteristics that give it a competitive advantage over other species such as *C. atrilobata*. For example, it has a wide feeding spectrum (including anthozoans, copepods,

tunicates, polychaets and fish eggs) and diverse feeding areas (water column and benthos). The dependence of this species on the substrate occurs during the reproductive period. When it nests its eggs need cavities with specific size and shape, with presence of algae (Hernández-Olalde, 2008). In general the species was well represented in both locations. There are reports of this species interacting with *C. atrilobata* in the pelagic zone and with *S. rectifraenum* on the benthos. *A. troschelli* occurs all year long and practically in all reef environments. It was classified as a frequent species.

The seventeenth FTG included two Pomacentrids, *Chromis atrilobata* and *C. limbaughi*. Both species were recorded in LBSC and HBSC locations, although the highest abundances and frequencies occurred in HBSC locations. At these locations depth is considerable, and in this type of habitat cavities are heterogeneous and are used as refuge areas during the night (Hobson, 1968; Hobson, 1974; Thomson et al., 2000). Strong interspecific competition could be detected in this functional group because both species use benthic resources in a similar way and feed practically on the same prey.

The eighteenth FTG included *Trachinotus rhodopus* and *Rhinoptera stendanchneri* in HBSC locations, while in LBSC locations *R. stendanchneri* was substituted by *Paranthias colonus*. The HSC had an important effect on this FTG, due to the habitat requirements of *R. steindanchneri*. This species needs sandy substrate near the reef edge, where it searches for food (bivalves and gastropods) at depths over 7 meters (Thomson et al., 2000).

*Trachinotus rhodopus* is a carangid with all the characteristics of a pelagic organism, but it feeds on a high percentage of benthic organisms (bivalves and gastropods; Randall, 1967; Moreno-Sánchez, 2004). *P. colonus* is a mainly planktofagous species, although it also consumes a lower proportion of organisms from the benthos (Thomson et al. 2000). In general this group shares space and food resources, which probably allows them to coexist.

The nineteenth FTG included *Chilomycterus reticulatus, Diodon holocanthus, Novaculichthys taeniourus* and *Xyrichtys pavo*, of which only *C. reticulatus* did not occur in LBSC locations. These species feed on gastropods and bivalves (Randall, 1967; Hobson, 1974; Thomson et al., 2000) and are associated to the bottom and mid-water. Their abundances changed according to the HSC, being higher in HBSC areas, probably due to the greater quantity of invertebrates present at these locations.

The twentieth FTG was made up by *Haemulon flaviguttatum*, *Sargocentron suborbitales*, *Gerres cinereus* and *Myripristis leiognathus,* and occurred in both HSC locations. It should be mentioned that all these species are considered rare. They feed on a great variety of benthic organisms such as polychaetes, shrimp, crab and gastropods (Randall, 1967; Hobson, 1968; Thomson et al., 2000), which could explain their presence in both areas.

The twenty-first FTG was one of the most diverse in its feeding habits and was made up by three pomacentrids (*Stegastes rectifraenum, S. acapulcoensis* and *S. flavilatus*), two labrids (*Thalassoma lucasanum* and *T. gramaticum*), two haemulids (*Haemulon sexfasciatum*  and *Microlepidotus inornatus*), an acanthurid (*Acanthurus xanthopterus*), a mullid (*Mulloidichthys dentatus*), and a serranid (*Paranthias colonus*).

The feeding requirements of *S. rectifraenum, S. acapulcoensis* and *S. flavilatus* are similar. They occupy a territory of approximately one meter in radius, which they defend constantly to reduce predation pressure (Wellington, 1982; Wellington & Víctor, 1988, Moreno-Sánchez et al., 2011). Pomacentrids occurred at both location types but their abundances were higher in HBSC areas, possibly because there is a greater number of cavities and refuges there. During the two years of sampling it was observed that despite these species

sharing the same areas, there was a succession, with *S. flavilatus* being found first, then *S. rectifraenum,* and lastly *S. acapulcoensis*. It is possible that *S. rectifraenum*, being the dominant species, occupies the best sites.

The labrids *T. lucasanum* and *T. gramaticum* use the benthos in a similar way, with *T. lucasanum* being dominant because its abundance is ten times higher than that of *T. gramaticum*. Its trophic diversity, enormous fecundity, capacity to reproduce twice a year and to tolerate wide variations in temperature confer it a good competitive advantage (Fischer et al., 1995; Thomson et al., 2000; Robertson & Allen, 2002, Hernández-Olalde, 2008).

The serranid *Paranthis colonus* was included in this FTG due to the quantity of copepods that it consumes. This species does not compete with the other group members because it is distributed over the entire water column (Thomson et al., 2000; Robertson & Allen, 2002). *Acanthurus xanthopterus* feeds on benthic invertebrates (Hobson, 1968; Fischer et al., 1995; Thomson

et al., 2000).

The haemulid *Haemulon sexfasciatum* fed on brachiurans, but contrary to other members of this FTG, it fed during the night, roaming around the edges of the reef during the day. It is possible that competition with this species is lower because of the wide heterogeneity of its diet (number and diversity of components). There was no change in this species´ abundance with HSC (Hobson, 1968; Fischer et al., 1995; Thomson et al., 2000).

*Microlepidotus inornatus* fed mainly on sipunculids and other benthic invertebrates. The highest abundances of this species were recorded at HBSC locations. It is a nocturnal predator and during the day it forms schools that roam the reef (Hobson, 1968; Fischer et al., 1995; Thomson et al., 2000).

*Mulloidichthys dentatus* feeds on small bivalves and crabs in rocky and sandy areas. It is a nocturnal predator but the smaller individuals feed during the day. This could explain the higher abundances recorded at HBSC locations, where observed individuals were small (10 to 15 cm). Competition for food with the other members of the FTG was low because the total population size is small (Hobson, 1968; Fischer et al., 1995; Thomson et al., 2000).

The benthic structural characteristics did not have a significant effect on the trophic organization of the fish community, because although there were small changes in the number of FTGs and in the species that integrated them, these variations were not significant. This could be indicative of food not being a limiting factor in Los Frailes reef. It is known that upwelling occurs at the mouth of the Gulf of California all year, enriching superficial waters, favoring algal blooms and increasing the general system productivity (Álvarez-Borrego & Lara-Lara. 1991). Results could also be explained by the high redundancy of the functional groups present in the reef (Álvarez-Filip & Reyes-Bonilla, 2006).

## **CONCLUSION**

Benthic heterogeneity, the number and size of cavities, the size of rocks, rugosity, and depth are robust variables that characterize adequately the benthic structural complexity (BSC) of the Los Frailes reef. Ecological indices of the fish community structure (species richness and abundance) were higher at HBSC locations than at LBSC locations. It is possible that this is due to an increase in BSC being related to a higher availability of benthic microhabitats. The BSC did not have a measurable effect on the trophic organization of the fish

community in Los Frailes reef. It was observed that at both locations there was almost the same number and composition of trophic functional groups (high functional redundancy). Few species differed from this pattern. This is possibly due to the restricted effect that the benthic structural characteristics have on fish feeding habits.

#### **ACKNOWLEDGMENTS**

The authors are grateful for economic support provided by the projects SIP-IPN (20050315; 20061088; 20070856; 20080985). XGMS thanks the Instituto Politécnico Nacional (IPN) for economic support through the Contratación por Excelencia Program. XGMS and LAAC are grateful for support received through COFAA and EDI. OES thanks CONACyT for economic support received through the program Cátedras CONACyT. OES thanks to CONACyT for the economic support through the program "Cátedra CONACyT project 2137, FACIMAR-UAS. JSRP received a scholarship from EDA-UAS and appreciates the support given by the project CONACyT 231525. This project was made possible by agreements made through the Red interinstitucional para la evaluación, manejo & aprovechamiento de los recursos acuáticos (RIEMARA).

### **ABSTRACT**

The Mexican Caribbean and the Atlantic coast of Mexico have 3,294 km of coastline with diverse habitats and rich biota. Coastal ecosystems, unfortunately, are experiencing wide range of pressures due to siltation, eutrophication, coastal development and climate change. Those species that adapt to these pressures will expand their living boundaries while others may fade away. Accordingly, the study of coastal biodiversity is of great concern globally and constitutes an important element of global change research. Peninsula of Yucatan has 1,940 km of coastline, reportedly with rich diversity of seaweeds. Previously published accounts on seaweed biodiversity were mainly in the form of checklists. The present study is a timely publication based wholly on primary data. Data were collected through extensive and systematic field studies conducted by the authors during different seasons over an eleven years period since 2004 to 2014, also we checked herbarium's specimens that are housed in the herbarium ENCB. Analysis of the information showed that Rhodophyta has the greatest diversity with 317 species; Chlorophyta has 180; Phaeophyceae 70 and finally Cyanobacteria with 38 species. One of the groups best represented in the study area is the Order Corallinales with two families and 43 species, these organisms are of major ecological importance in the reefs of the Peninsula. Three species are new records from Mexican Caribbean, *Centroceras* 

 $\overline{a}$ 

Corresponding Author's Email: am7124@gmail.com.

*hyalacanthum, Metapeyssonnelia tangerina* and *Sarcodiotheca divaricate*, and sixteen species are new records for the study area The importance of epiphytic algae in the study area is discussed as well as the use of molecular markers in order to solve taxonomic problems of selected genera of algae. The floristic list includes data on distribution, tidal level and habitat. On the other hand Quintana Roo is the state that has the greatest diversity of marine algae in the Gulf of Mexico and Mexican Caribbean's shores with 551 species. Topics on economic importance and extraction of bioactive substances are discussed, as well as suggestions on conservation of seaweeds from Yucatan Peninsula. Finally, several coastal towns in the Yucatan Peninsula are being impacted by natural events such as hurricanes as well as urban; tourism and industrial development, so it is important continue studies that allow us to characterize the changes that populations of seaweeds are undergoing.

#### **INTRODUCTION**

Floristic studies on the marine algae growing in Yucatan Peninsula area were made by several workers [1, 2]. Huerta et al. [1] reported on a preliminary survey of shallow water marine algae of coastal and islands area of Yucatan Peninsula, although much pertinent new information has accumulated since its publication. Aguilar-Rosas et al. [3] and Collado-Vides et al. [4] studied the Chlorophyta of the Mexican Caribbean. Callejas-Jiménez et al. [5] reported the seaweeds of several localities of Campeche; Mateo-Cid et al. [6], publishes lists on subtidal Rhodophyta of Cozumel Island, Mendoza-González et al. [7] listed offshore seaweeds of Mujeres Island. Cetz-Navarro et al. [8] reported new records of seaweeds for the Mexican Atlantic coast as well as update data on the floristic richness of the Mexican Caribbean. Mateo-Cid et al. [9] presented the results of the study on benthic marine algae in eight localities from the coast of Campeche; these authors reported 30 new records of seaweeds for Campeche. Until now have been recorded 635 species of seaweed for the Yucatan Peninsula, in this sense, it is noted that the algal flora of this region is still not well known. On the other hand is obvious the lack of knowledge on ecology and conservation of marine algae in this region, in addition oil spills and pollution are a persistent danger for the significant risk involved for human lives and the health of shallow and deep marine habitats. Furthermore, it is remarkable the numbers of hurricanes that have affected the Yucatan Peninsula in the last ten years, the risks associated with hurricanes are: storm surge, high winds, heavy rains, landslides and flooding. It is expected that under these arguments is important to know the changes in the short and medium terms of marine algae in this region, which possible to assess the risks to which these organisms as well as their management and sustainable use.

The present chapter was undertaken with a view to know the composition of seaweed and its distribution in the study area, as well some effects of pollution and human. The data achieved for a period of ten years from July 2004 to June 2014 are presented in this chapter and would be very much useful to the seaweed industries about the occurrence of economically important agar and algin yielding seaweeds for commercial exploitation and for conservation.

#### **Study Area**

The Yucatan Peninsula is a biogeographical area comprising the entire territory of the Mexican states Campeche, Yucatan and Quintana Roo, adjacent small portions of Tabasco and Chiapas, The El Petén department in Guatemala, and the northern half of Belize (Figure 1). The coastal environment of the Yucatan Peninsula includes a wide variety of ecosystems ranging from mangroves to coral reefs, resulting in a heterogeneous landscape. Specifically, the marine system is characterized by environmental differences which respond to regional and local forcing functions such as marine currents and groundwater discharges. Yucatan Peninsula has 1,940 km of coastline, its coast has been characterized as low lying coastal area, where 57% is represented by coastal lagoons with barrier islands and 43% is ocean front, 85% of this ocean front is sandy coast. The tidal regime is mixed with a diurnal dominance, with a tidal variety of 0.1 m for neap tides and 0.8 m for spring tides. Reported grain size values are only available for the Progreso beach area ranging between 0.2 mm (at 0.5 m depth) to 0.5 mm (swash zone) with poorly sorted grains. Coastal ecosystems of the Yucatan Peninsula experience three well-defined seasons: dry (March to May), rainy (June to October), and "nortes" (November to February), which is dominated by cold fronts. Additionally, the hurricane season (from August to September) has a strong influence on coastal lagoon stability and disturbance regime. The Yucatan Peninsula has unique hydrogeological characteristics, including low relief, lack of rivers, highly permeable karstderived soils, and substantial submarine groundwater discharge [10].

The Yucatan Peninsula is affected by extreme wind waves generated by two meteorological systems: (i) mid latitude anticyclonic meteorological systems which generate northerly cold fronts known as "nortes"; and (ii) cyclonic systems known as Tropical Cyclones including tropical depressions and hurricanes [11]. Along the Caribbean coast of the Yucatan Peninsula; brackish ground water (mixed fresh water and sea water) is channeled through upper Pleistocene limestone via fracture-controlled caverns. In caves, cenotes, and caletas at Xcaret, Yalku, and Tancah, this open-flow coastal mixing zone comprises three major layers: (1) an upper dilute zone of gradually increasing salinity with depth (slow mixing), (2) a thin intermediate zone of rapidly increasing salinity with depth (rapid mixing), and (3) a lower saline zone of gradually increasing salinity with depth. The intermediate layer occurs at different absolute salinities at different localities, and it generally corresponds to the level of a notch in the wall rock of the caverns [12].

Collections were made using SCUBA for subtidal; while, seaweeds in the intertidal zone were collected during low tide periods by hand picking in different habits such rocky and sandy. Collections at 40 locations were made during twenty five visits since 2004 to 2014. Algae were preserved in formalin/sea water at a 1:19 ratio. Semi-permanent slides were prepared using corn syrup/water 1:1 with a trace of phenol added to prevent fungal growth. Identification was made with specialized literature [13, 14, 15, 16, 17]. Voucher slides and specimens are deposited at the herbarium of the Escuela Nacional de Ciencias Biológicas (ENCB) at the Instituto Politécnico Nacional in Mexico City, D.F. Mexico. The taxa were identified with from the collections are listed following the order proposed by Wynne [18] and Guiry and Guiry [19]. Each species is presented with data regarding distribution in the study area, tidal level, habitat and observations (Table 1).

### **RESULTS**

A total of 605 species of benthic marine algae were found in Yucatan Peninsula (Table l), of the total of marine algae identified, 38 species correspond to Cyanobacteria, 317 to Rhodophyta, 70 to Phaeophyceae and 180 to Chlorophyta (Figure 2). The percentage of species for each group is: Cyanobacteria 6.2%; Rhodophyta, 52.3%; Phaeophyceae, 11.6%; Chlorophyta, 29.9%, of them three species are new records from Mexican Caribbean, *Centroceras hyalacanthum, Metapeyssonnelia tangerina* and *Sarcodiotheca divaricata.* In addition sixteen species are new records for the study area; seven corresponds to Cyanobacteria, three to Rhodophyta and six to Chlorophyta (Table 1, column of observations). The family with highest species richness of the division Rhodophyta was Rhodomelaceae with 64 species, eleven of the genus Chondria and eight of *Laurencia, Neosiphonia* and *Polysiphonia.* It is followed in importance by the family *Corallinaceae*, with 39 taxa of which twelve belong to the genus *Neogoniolithon* and seven to the genus *Amphiroa.* Ceramiaceae has 26 species, of which 13 are of the genus *Ceramium.* 

Figure 2. Total number of species for divisions in Yucatan Peninsula.

Regarding the class Phaeophyceae, the family Dictyotaceae was represented by twenty seven species, eleven of the genus *Dictyota* and five of the genus *Padina.* Concerning Chlorophyta the families Caulerpaceae and Cladophoraceae were the best represented with 31

taxa each one, 30 of genus *Caulerpa* and 19 of *Cladophora.* Udoteaceae was represented by 24 species of which twelve belong to the genus *Udotea*. The group with the lowest number of species was the division Cyanobacteria; the families Oscillatoriaceae, Phormidiaceae, Schizotrichaceae and Entophysalidaceae were represented by four species each one (Figure 3). The number of species found each state is: Campeche 271; Yucatan 214 and finally Quintana Roo with 551 (Figure 4), these data shows that the last state has the greatest diversity of marine algae in the Gulf of Mexico and Mexican Caribbean's shores [1, 2, 5, 8].

Figure 3. Number of species of best represented families in Yucatan Peninsula.

Most marine algae are indifferent to the chemical nature of their substrate; epiphytic algae can develop on other algae. Epiphytes that occur on a certain species of alga are closely related to the texture of the host, whose life span should be long enough to allow the epiphyte to complete its life cycle on it. In some cases, the occurrence of an epiphyte on a host is fortuitous, whereas in others, there is a high degree of specificity. The presence of epiphytic marine algae on other larger algae is a well-known phenomenon. Most epiphytes use the host as a support structure [20]. A significant number of epiphytes were found in this chapter, in total 257; of which 240 occurred on different algae, seagrasses and mangrove roots, with no preference for any one of them (Figure 5). The other 17 did show specificity, such as *Catenella impudica, Bostrychia scorpioides, B. montagnei* and *Laurencia laurahuertana,*  among others. In fact, it is known that a large number of species of algae are obligate epiphytes and in many cases form permanent associations with some species of algae, marine phanerogams and mangroves.

Figure 4. Number of species for states in Yucatan Peninsula.

On the other hand, there are genera as *Amphiroa, Hydrolithon, Palisada, Neogoniolithon, Ceramium, Chondria, Udotea* and *Caulerpa* which represent a taxonomic defiance, because of their high morphological plasticity and that there are probably cryptic species. The use of DNA sequence data has profoundly altered our understanding of the phylogenetic relationships among seaweeds and new Order, families, genera and species have been stablished into Rhodophyta, Chlorophyta and Phaeophyceae, among others, based on DNA sequence data and supported by morpho-anatomical characters [21, 22, 23]. In this sense, it is necessary to use molecular methods to resolve the taxonomic problems that arise in the above-mentioned genera.

Species of *Padina, Acetabularia, Liagora* and *Halimeda* were observed in Yucatan and Quintana Roo but they are not well distributed. In Quintana Roo *Sargassum* and *Turbinaria*  species dominated in rocky shore environment. *Neogoniolithon, Udotea, Caulerpa* and *Halimeda* showed dominance in rocky with sandy areas. Coralline algae like *Amphiroa, Jania, Hydrolithon* and *Neogoniolithon* dominated in the reef areas of Peninsula, these organisms are of major ecological importance in the coral reefs of Campeche, Yucatan and Quintana Roo. Commercially important seaweeds like *Gracilaria cervicornis, G. damaecornis, G. debilis, Gracilariopsis andersonii, Hydropuntia crassissima* and *Eucheuma isiforme* were found on rocky coast of several localities of Campeche and Quintana Roo. *Sargassum cymosum, S. vulgare* and *Turbinaria turbinata* were found in large quantities in Quintana Roo coast.

Figure 5. Number of species epiphytes, endophytes and parasites in Yucatan Peninsula.

Seaweeds are potential renewable resource in the marine environment. Most of the compounds of marine algae show anti-bacterial activities. Many metabolites isolated from marine algae possess bioactive principles. Compounds with cytostatic, antiviral, anthelmintic, antifungal and antibacterial activities have been detected in green, brown and red algae. For example, *Ulva fasciata* have showed antimicrobial activities against *Staphylococcus aureus*. Several extractable compounds such as cyclic polysulfides and halogenated compounds are toxic to microorganisms and they are responsible for the antibiotic activity of seaweeds [24]. Seasonal and geographical variation also contributes in the antimicrobial activity levels of marine algae. Species found in Yucatan Peninsula as *Ulva compressa*, *U. lactuca*, *Caulerpa lamourouxii*, *C. mexicana, C. sertularioides* and *C. paspaloides* are potential species for use as a source of bioactive substances.

### **CONSERVATION**

The biological diversity, high productivity, and ecosystem services provided by tropical coastal systems are well recognized; indeed, these same characteristics may promote human settlement and urban development. Approximately 60% of the total human population lives in coastal areas and human impacts on coastal systems are increasing [10]. While losses of coral reefs and mangrove habitats are probably the most significant in terms of losses of biodiversity it should not be forgotten that other critical coastal habitats are also disappearing. Wetland areas, estuaries and seagrass beds are known to be key nursery areas for coastal fisheries and yet are being destroyed rapidly without there being full ecological and economical appraisal of the consequences even in developed countries, also the eutrophication caused by excess of nutrients and sewage discharged into coastal waters is an expanding problem and incidents are known from almost for every coastal countries. The initial effects are of altered species composition both in the water columns and in benthic communities [25]. Furthermore, examples of infrastructure damage and coastal use alteration produced by coastal storms are numerous; for instance, one of the most recent events of this kind was hurricane Sandy which impacted the mid-Atlantic region on Oct. 29 and 30, 2012 with economic damages estimated in 30 - 50 billion US dollars. These hazards are becoming more common, as can be stated by the increasing trend found in the number and intensity of storms in the last decade [11]. Yucatan Peninsula has been affected by several hurricanes in the last decade. In 2005, "Emily" made landfall in Playa del Carmen as a category IV, affecting the zones of Xel-Ha at Riviera Maya, about 145 miles south of Cancun. In the same year "Wilma" struck the Yucatan and Quintana Roo, as a category IV, with sustained winds of 250 km/h. In 2007, Hurricane "Dean" hit southern Quintana Roo, hurting mainly 2 types of vegetation: mangrove and evergreen tropical forest. Hitting the coast in category V, just north of the Majahual, with maximum winds of 280 km/h. In 2009, the most intense hurricane was "Bill" category IV, with maximum sustained winds of 215 km/h, with gusts of 260 km/h. In 2010, three hurricanes hit the area: the most intense was "Igor" with category IV, and maximum winds of 240 km/h and gusts of 295 km/h. The hurricane Alex made landfall on the southwestern tip of the state of Quintana Roo, as a tropical storm, 90 miles southwest of Chetumal, Quintana Roo, with maximum sustained winds of 95 km/h and gusts of 110 km/h. "Karl," was another cyclone which affected Mexican territory, impacting as a tropical storm, 15 miles south-southwest of Puerto Bravo, Quintana Roo, with maximum sustained winds of 100 km/h and gusts of 120 km/h. In early August 2011, "Ernesto" made landfall as a Category I in southern Quintana Roo. Under these arguments it is evident that the Yucatan Peninsula is exposed to natural disasters and the ever-increasing human influence. In addition, the total diversity of the Yucatan peninsula flora, including previous records and the results of this investigation are 739 species; however, of these total species 134 of them were not located in the present study (Table 2) probably due to the effects of hurricanes, anthropogenic influence, especially for the modification on the coast for both of these influences which brings diverse habitats disappear with its species, the climatic conditions present and the negative effect of the expansion of the national oil industry in offshore waters, because the unfortunately accidental blowout of the Ixtoc-I in June 1979 caused the first- world massive oil spill in tropical environment. More than 3.4 million of barrels of crude oil were liberated in an ecosystem, which produced two effects one for the oil and other for the long-term environmental consequences derived from the residual hydrocarbon compounds accumulated in coastal of the Southern Gulf of Mexico [26]. In this chapter, is found a great marine algae biodiversity in Coral Reefs rather than the coast of Yucatan and Campeche. The best way to conserve marine diversity is to protect habitat and landscape diversity in the coastal area. Marine protected areas are only a part of the conservation strategy needed. It is suggested that a framework for coastal conservation is integrated coastal area management where one of the primary objectives is sustainable use of insular and coastal biodiversity.

# **ABSTRACT**

Rocky shores are areas of high diversity and productivity providing goods and services. Since humans are altering nature at an unprecedented rate, producing shifts in important parameters for life such as temperature, habitat availability, water quality, among others, it is expected that species will respond by changing their natural distributions and/or abundances. To understand how species will respond to such changes, it is necessary to learn the processes that determine these patterns. The South American Research Group on Coastal Ecosystems was established to assess marine diversity and biomass along both coasts of South America through an international collaboration. The main goals of SARCE are to: (1) Test hypotheses about latitudinal gradients and patterns of local and regional biodiversity, (2) Identify the relationship between biodiversity and ecosystem functioning, (3) Assess the effect of environmental gradients and anthropogenic stressors, (4) Carry out capacity building and training activities aimed to solve environmental problems for the benefit of society. The SARCE network has sampled the coasts of nine countries around South America with a standardized protocol in more than 150 sites (2010-2014), ranging from 11º North to 55º South. This chapter provides a description of the biodiversity of the sites sampled by SARCE, along with a review of the uses and services that these ecosystems provide to human populations and the main threats and impacts these uses have caused.

### **INTRODUCTION**

Biodiversity has been a subject of interest for many decades by scientists and conservationists. More recently, other groups such as managers, government agencies and industries have also been involved in establishing its ecological and economical value, as well as the consequences of its loss. Up to date, an important number of papers have attempted to identify the importance of biodiversity for ecosystem functioning (Loreau et al. 2001, Pachepsky et al. 2001, Cardinale et al. 2002, Pfisterer & Schmidt 2002, Gessner et al. 2004) and the processes by which any diversity loss will be negatively reflected in the number and quality of services that a particular system might provide (Balvanera et al, 2006; Cardinal et al, 2006, O´Connor et al., 2006).

Figure 1. Map of South America showing the localities sampled by the SARCE network (South American Research Group in Coastal Ecosystems) in the Caribbean Sea, and in the Atlantic and Pacific oceans.

Coastal marine ecosystems have a very high biodiversity (Ray 1996). Within these, the macroalgal habitats rank among the highest along with coral reefs and seagrass communities, due to the fact that they are dominated by bio-engineering organisms that build threedimensional structures, providing substrate, food and habitat complexity, which ultimately increases species richness (van Oppen et al. 1996, Phillips 1997, Walker & Kendrick 1998, Wysor et al. 2000, Duarte 2000, Engelhardt & Ritchie 2001, Duffy et al. 2001, Sommerfield et al. 2002, Bulleri et al. 2002). On the other hand, due to their particular location (i.e. landsea interface) these coastal areas are also severely impacted by human activities such as fisheries overexploitation, alteration of the physical environment, pollution, introduction of alien or invasive species and recreational activities, all of which have inevitably impoverished marine biodiversity (Beatley 1991, Norse 1993, Gray et al., 1997, Walker & Kendrick 1998, Cury 1999, Bax et al. 2001, Tilman & Lehman 2001, Piazzi et al. 2001, Barnes 2002).

In this sense, the study of biodiversity is crucial for the sustainable use of coastal resources (Gray 1997), especially in Marine Protected Areas (Ray 1985, Olsen 1999, Ward et al. 1999). Biodiversity has been measured at many different levels and scales and by different methods (France & Rigg 1998). This has made comparisons difficult, so a unified approach to study biodiversity at a global scale was much needed (Rabb & Sullivan 1995, Valero et al. 1998, Mikkelsen & Cracraft 2001). As a response to this need, the NaGISA project (Natural Geography in Shore Areas: www.nagisa.coml.org) of the Census of Marine Life program (CoML: www.coml.org) provided the necessary framework to study biodiversity in rocky shores at a global scale. The NaGISA project was a collaborative effort aimed at inventorying and monitoring habitat specific biodiversity with a standard protocol in coastal marine areas at a global scale (Konar et al. 2010). Thanks to NaGISA (2003-2010), the first global baseline of nearshore biodiversity was initiated [see: Diversity in the Nearshore: The NaGISA Collection (2010) PLoS Collections: http://dx.doi.org/10.1371/issue.pcol.v01.i06], and in South America, it has continued through the South American Research Group on Coastal Ecosystems network (SARCE). This network was established to assess marine diversity and biomass along the Pacific and Atlantic (including the Caribbean) coasts of South America through an international collaboration. The main goals of SARCE are to: (1) Test hypotheses about latitudinal gradients and patterns of local and regional biodiversity, (2) Identify the relationship between biodiversity and ecosystem functioning, (3) Assess the effect of environmental gradients and anthropogenic stressors, (4) Carry out capacity building and training activities aimed to solve environmental problems for societal benefit. The SARCE network includes more than 30 researchers from 9 South American coastal countries and has sampled with a standardized protocol in more than 150 sites around the continent (Figure 1). In this chapter we provide a description of the biodiversity of the sites sampled with the SARCE protocol (http://sarce.cbm.usb.ve/for-scientists/), along with a review of the uses and services that these ecosystems provide to human populations and the main threats and impacts these uses have caused.

# **THE INTERTIDAL ROCKY SHORES IN SOUTH AMERICA: MAIN FEATURES AND ASSOCIATED BIODIVERSITY**

# **The Caribbean**

#### *Colombia*

The Caribbean coastline of Colombia has an extension of 1760 km, of which 25% are rocky shores (Posada & Henao 2008), mainly composed by unstable shores highly affected by wave action and coastal erosion. Most of these shores have steep slopes and in the areas where the platform occurs can harbor rich and abundant macro-algal communities (Garcia & Diaz-Pulido 2006). The tide range is 0.5 m due to this is common to find in small areas a mixture of organisms that belongs to different intertidal levels (high, mid and low tide), factors as wave action, substrate type and slope, determine the community composition (Lopez-Victoria et al. 2004). Due to the small tidal range only high and low tide levels can be easily differentiated. According to Lopez-Victoria et al. (2004) the rocky shore can be divided into two types of rocks, cohesive or non-cohesive, each having a particular associated community (algae and macroinvertebrates). The first type of rocks is stable, hard and with low erosion rates, with a high rate of colonization and a well developed community with advanced succession stages. The second type of rocks is unstable, the shores are highly affected by wave action, and therefore, species diversity and richness is lower, and the community cannot reach advanced succession stages. The climate presents two main periods: dry and rainy seasons with a transition season in between. The sea surface temperature and salinity during the dry and rainy seasons vary between 25.5-27.5ºC / 35.6-37 ppt and 27-  $29.5\textdegree$  / 34.5-36.5 ppt respectively. The waves are higher during the dry season (1.5 to 2.5 m) in relation to the rainy season (0.5 to 1.4 m) (Posada & Henao 2008). An upwelling system is present from December to March in the north coast and the sea surface temperature can drop below 20ºC.

In the Colombian Caribbean, the SARCE project sampled in 15 sites within two localities: Santa Marta and Darien. In Santa Marta (Figure 2A), the rocky shore is dominated by cliffs (metamorphic schist rocks), with different size boulders at the base that gives complexity to the shore and offers a variety of habitats that can be exploited by intertidal organisms. The cliffs are part of the Sierra Nevada de Santa Marta system that branches down to the sea. Due to the upwelling, there is a major change in algae composition, species of *Sargassum* can reach a meter in length and other algae species grow and cover most of the rocky substrate. Along the different sites of the Santa Marta bay, the geology varies from cliffs that continue as rocky shores with boulders in the north (Punta Verde) which are highly exposed to wave action, to rocky platforms between 5 to 10 m wide in the south (Playaca). The most abundant invertebrate species in the high intertidal in the north are *Nerita versicolor* and *Littorina* sp, while the low intertidal is dominated by coralline algae, by *Palisada perforata*, *Zoanthus pulchellus* and *Hypnea musciformis*, and the invertebrates *Echinometra lucunter* and *Isognomon bicolor*. In the south, the high intertidal is mostly rock; with some areas with filamentous algae. The most abundant macroinvertebrate species are *Plicopurpura patula*, *I. bicolor* and *Dendropoma* sp. In the low intertidal, dominant species are coralline and filamentous algae along with *Laurencia obtuse, E. lucunter*, *I. bicolor*, *Spirobranchus giganteus* and *Balanus* sp. The low intertidal is also covered by the canopy of large *Sargassum.* The east side of the bay (Playa Grande) is characterized by a rocky platform covered by a thin layer of vermetids. Here, the high intertidal is mostly rock with some areas covered by filamentous algae, the dominant macroinvertebrate species being *N. tesellata* and *Brachidontes domingensis*. In the low intertidal, dominant species are the macroalgae *Acanthophora spicifera*, *Dictyopteris deliculata* and *Neoralfsia expansa* and the invertebrates *Dendropoma* sp. and *I. bicolor*. Other localities sampled in the Santa Marta region were Inka Inka, Puerto Luz, and Aeropuerto. The first two were rocky platforms, while the third was an exposed sandy beach with flat rocks that may be periodically covered by sand due to wave action. In these, the high intertidal was dominated by *N. tesellata*, *P. patula*, *Echinolittorina* 

*ziczac* (Inka Inka); *E. ziczac*, *E. angustior* and *P. patula* (Puerto Luz); and *E. interrupta*, *E. angustior* and *Chthamalus sp*. (Aeropuerto). The low intertidal was dominated by coralline algae, vermetids, filamentous algae, *E. lucunter*, *I. bicolor*, *Mitrella ocellata*, *Sargassum* (Inka Inka), *A. spicifera*, *L. obtuse*, filamentous algae, *Dendropoma* sp., *E. lucunter*, *I. bicolor* (Puerto Luz), and *A. spicifera*, *Lyngbya* sp., coralline algae, *Centroceras* sp., *B. domingensis*, *Fissurella nimbosa*, *Stramonita haemastoma* (Aeropuerto).

The locality of Darien is located west of the Uraba Gulf, where mangroves and soft bottoms dominate the landscape; the sediments and nutrients are brought by the Atrato River, one of the largest rivers in the Atlantic basin of Colombia. Tropical rainy forest is the most common type of vegetation; however, grasses for cattle growth have replaced large extensions of this forest. In this region, the volcanic rock shore is located north of the delta of River Atrato, followed by large sandy beaches and abrasion platforms of coralline origin towards the Panama border. This area has little urban development and human settlements are small, there are no roads and the main way of transportation is by boats and most of the settlements are located on the coast. The Darien was sampled in the Trigana area which is located north to the Atrato River delta, with a rocky shore of volcanic origin, interrupted by sandy beaches, and with several small islands in front of the coast. The intertidal in this area is affected by freshwater runoff. The sites ampled were Isla Napú, an islet with a narrow rocky platform that falls to the sea reaching a maximum of 2 m depth in the surrounding areas; Trigana, a platform 10 m wide; Titumate, an islet with a soft slope and shallow sandy bottom  $(< 1 \text{ m})$  and sea grasses; Capurgana, located in the northwest part of the Uraba Gulf with a rocky shore composed by abrasion platforms of coralline origin; Sapzurro, a bay close to the Panama border, with a soft slope shore and an abrasion platform of coralline origin; and Isla Narza, an islet of volcanic origin in front of Capurgana village, the shore consisting of a cliff in the exposed side and boulders in the sheltered side. In these sites, the high intertidal was dominated by E. angustior, *E. ziczac* and *E. interrupta* (Napu), *E. angustior* and *S. rustica* (Trigana), *E. angustior*, *B. domingensis* and *N. tesellata* (Titumate), and *E. angustior* (Sapzurro and Isla Narza). The low intertidal is dominated by *L. obtusa*, *Pterocladiella capillacea*, *Lyngbia* sp., *Gracilaria domingensis*, *Centroceras* sp., the barnacles *Chthamalus*  sp. and *Balanus* sp. which form a complex with vermetids (Napu); filamentous and coralline algae, *S. serratum*, *Centroceras* sp., *L. obtuse*, *G. domingensis*, *Chthamalus sp*., *S. rustica* (Trigana); *S. serratum*, *L. obtuse*, *Centroceras* sp., *Chthamalus* sp., *S. rustica* (Titumate); *L. obtuse*, coralline algae, *E. lucunter*, *Cittarium pica* (Sapzurro), and coralline and filamentous algae, *E. lucunter*, *Ceratozona squalida,* and *Chiton squamosus* (Isla Narza).

#### *Venezuela*

Rocky shores along the 3964 km of the Venezuelan coastline are very heterogeneous in terms of their geological composition and structure (Miloslavich et al., 2005). Due to small tidal ranges in the southern Caribbean (20-30 centimeters) (Torres and Tsimplis, 2012) Venezuelan rocky shores have been described considering only two levels or strata: high intertidal and low intertidal. The low intertidal is constantly under wave action whereas, the high intertidal is washed rarely by waves, only receiving sea's spray. Consequently, in some Venezuelan rocky shores, gaps openings and/or depressions in the substrate of only few centimeters of depth can generate zones that remain submerged most of the year. These habitats, henceforth called substrates depressions, are located between the high and the low intertidal on platform rocky shores and their species composition is completely different to

that found in the high and low intertidal. Given their large extensions, "substrates depressions" are different to rock pools or tide pools.

Characteristics of rocky shores are very heterogeneous and respond to the geomorphology of the different regions of the Venezuelan coast. In the Western coast, from the Paraguana Peninsula to Patanemo, rocky shores are emerging platforms and are composed of limestone rocks (Figure 2B). The Central coast, from Ocumare to Chirimena (Figure 2C), is characterized by narrow rocky stripes formed by sandstones and conglomerates. Sites sampled on the mainland of the Eastern coast, from Santa Fe to La Pared (Figure 2D), had a very steep slope, whereas those sampled in the insular region were emerging horizontal rocky platforms. Nevertheless, all rocky shores in the East are formed by limestone's rocks. Most of the platforms are narrow (3-10 meters), except for San Juan de los Cayos platforms that are between 60 to 120 meters wide. The length of platforms is highly variable. In the western region, they can reach few kilometers, whereas in the central coasts they do not surpass hundreds or tens of meters (Kennedy et al., 2014; Ellenberg, 2010).

Figure 2. Sampling sites in the Caribbean. A. Colombia – Taganaga, Santa Marta. B. Venezuela - Cabo San Román, West Coast. C. Venezuela – Chuspa, Central Coast. D. Venezuela – Mochima, East Coast.

Estimates of rugosity were moderately high for both strata:  $0.809 \pm 0.002$  and  $0.745 \pm 0.002$ 0.003 for low and high intertidal, respectively. The rock's irregularities form microhabitats that are used by some organisms like whelks, crabs, limpets and snails that protect them from desiccation and high temperatures during low tides, which in turns contribute to the high diversity reported for the Southern Caribbean. Crevices, scars and holes over the rocky substrate are due to erosion of wind and wave, as well as to the activity of some organism such as the sea urchin *Echinometra* sp. (Bak, 1994).

Despite a small tidal amplitude (Torres and Tsimplis, 2012), desiccation levels can vary significantly due to the effect of wind. Northern Trade winds blow on Venezuelan coasts intensively between December and June, increasing intensity and height wave, and consequently decreasing exposition levels. Besides, trade winds are responsible of annual upwelling, between January and May, in different zones of Venezuelan coast (Castellanos et al., 2002; Muller-Karger, 2004); which has been reported to enhance algae growth and increase the production of herbivores in rocky shores (Wieters, 2005; Bosman et al., 1987). This has not been tested for the Venezuelan Coast, however, the only study done (western region, Peninsula de Paraguna) found no correlation between Sea Surface temperature Changes generated by upwelling and changes in the structure of assemblages associated with rocky shores (Herrera unpublished data).

Like many rocky shores in the continent and the world, assemblages living in Venezuelan rocky shores are mainly composed of seaweeds and small mollusks. The most common seaweeds belong to phylum Rhodophyta, being genera such as *Laurencia* and *Polysiphonia* the most abundant. Also, algae of phylum Chlorophyta (mainly *Ulva* spp.) and Ochrophyta (mainly *Sargassum* spp.) can be widely found. The species complex made of crustose coralline algae (commonly named CCA) was present in almost all sampled sites. It is very likely that the species composition of these complexes change among zones, sites, regions and strata; but identification of species of crustose coralline algae in the field is not possible. This complex was present as primary cover usually below corticated, articulated and foliose algae, as well as secondary cover on top of sessile and mobile animals. The most common mollusks living in Venezuelan rocky shores were snails, limpets, whelks, key-hole limpets and chitons.

The dominant functional groups in Venezuela were primary producers (macroalgae), small herbivores (gastropods and chitons), large herbivores (sea urchins and crabs), filter feeders (bivalves and barnacles) and predators (mainly the gastropods *Plicopurpura patula*, *Stramonita* and *Vasula* species; and octopuses). In the southern Caribbean, unlike other rocky shores, the dominant echinoderm was not a sea star but the sea urchin *Echinometra lucunter*. It has been proposed (but not tested) that *E. lucunter* plays a key role in structuring these assemblages due to its high densities, high herbivory rates and bio-erosive activity. Another peculiarity of Venezuelan rocky shores is the low density of barnacles in the intertidal. In Venezuela, they are only present in the central and western coast, usually associated to rockwalls, cliffs and artificial structures.

Continuous monitoring of assemblages associated with rocky shores in Venezuela has shown that they vary importantly at different temporal and spatial scales, and between strata. For example, during the rainy season, conspicuous changes occur due to massive algae cover decrease, and the composition is dominated by opportunistic species such as *Ulva*, *Dictyota*, *Padina* and *Chaetomorpha*. Also, from a spatial point of view and despite large variation at small spatial scales (10s to 100s meters), important differences can be detected among regions (e.g. presence of barnacles only in central and western coast).

Intertidal rocky shores of Venezuela are part of the highly diverse coastal ecosystems of the Southern Caribbean. Using SARCE's protocol, 31 sites across the Venezuelan coast were sampled, detecting a total of 217 species in total: 85 marine algae (40 Rodophyta, 20 Chlorophyta, 18 Ochrophyta, 5 Cyanobacteria, 2 seaweeds not identified), 89 molluscs (66 Gastropoda, 17 Bivalvia, 6 Polyplacophora), 21 cnidarians (17 Anthozoa, 4 Hydrozoa), 8 arthropods (5 Malacostraca, 3 Maxillopoda), 5 echinoderms (2 Echinoidea, 2 Ophiuroidea, 1

Holothuroidea), 5 marine sponges (Demospongie), 3 ascidia (Ascidiacea) and 1 seagrass (Tracheophyta).

In the high intertidal of Venezuelan rocky shores, algae presence was uncommon; and when they were, these usually were crustose calcified algae CCA and *Pseudolithoderma extensum*, or filamentous algae such as *Lyngbya* spp. and *Bostrychia tenella*. Mobile species were represented mostly by small herbivores mollusks such as *Nerita versicolor*, *Nerita*  peloronta, *Nerita tessellata*, *Echinolittorina ziczac*, *Echinolittorina interrupta, Acanthopleura granulata*, *Echinolittorina angustior*, *Cechritis muricatus*, *Tectarius antonii* and *Acmaea* and *Siphonaria* species. Carnivorous mollusks (i.e. *Plicopurpura patula*) were also present but were not as abundant as herbivores species. Assemblages in the high intertidal were highly dominated by few species, especially by Littorinids that commonly had abundances between thousands and tens of thousands of individuals per square meter. Neritidae species were not as abundant, but densities could reach hundreds per square meter. In crevices and gaps, bivalves belonging to genus *Brachidontes* and *Isognomon*, were found in low densities. Sessile mollusks of the family Vermetidae were also occasionally found in very dense patches with abundances ranging between the tens and hundreds of individuals per square meter.

Assemblages in depressions or mid platforms shallow lagoons were dominated by corticated foliose algae such as *Dictyota* and *Padina*, articulated calcareous algae such as *Halimeda opuntia*, foliose calcareous algae such as *Udotea sp* and *Penicillus sp*, and the foliose algae *Ulva* spp. Because these environments are constantly covered by water, cnidarians belonging to genus *Zoanthus* and *Palythoa* were commonly found. Principal mobile organisms in these microhabitats were small fishes belonging to Gobiidae family and hermits crabs. These two groups, however, were not considered in this study. These habitats are constantly submerged by water that is constantly being replaced, but due to their shallow characteristics, temperature is usually few degrees above normal Sea Surface temperature. Consequently, substrate tends to be dominated by one or two of the species mentioned above.

The low intertidal of Venezuelan rocky shores was dominated by macroalgae, mollusks and sea urchins; whereas some cnidarians and other echinoderms (sea cucumbers and brittle stars) were found occasionally. The most abundant and commonly found algae in all sampled sites, were the crustose calcified algae comples CCA and *P. extensum*, the corticated corticated algae *Laurencia obtusa*, *Laurencia papillosa* and *Gelidiella acerosa*, the filamentous algae *Polysiphonia atlantica*, the leathery macrophyte *Sargassum* spp, and filamentous microalgae *Lyngbya* spp. Few species, as the opportunistic green foliose algae *Ulva* spp, the green filamentous algae *Chaetomorpha* spp, and cnidarians *Palythoa* and *Zoanthus* were not commonly seen in all sites; but when they were present, they occupied an important proportion of the primary and secondary substrata. The most abundant mobile species in the low intertidal were herbivores *E. lucunter*, *Chiton squamosus* and *Fissurella*  spp, as well as carnivores *Stramonita rustica*, *P. patula* and *Vasula deltoidea*. The carnivore gastropod *P. patula* has its highest densities in the high intertidal (very close to the transition between the high and the mid), however it is present in the low intertidal as well. The sea urchin *E. lucunter* was commonly found in almost all the sites sampled, reaching densities of up to 72 ind/m<sup>2</sup> . It is likely that *E. lucunter* plays a key role as the principal herbivorous on Venzuelan rocky shores, but this conceptual model has not yet been tested. Other large herbivores such as the gastropods *Cittarium pica* and *Astraea* spp, are found in low densities and small sizes, very likely due to the pressure of artisanal fishermen.

#### *Trinidad and Tobago*

Trinidad and Tobago is a twin-island state located on the continental shelf of north eastern South America. Trinidad is approximately 12 kilometers from the mainland while Tobago is 30 kilometers North East of Trinidad. Trinidad is the most southerly of the Caribbean islands. The continental origin of the islands is reflected in the similarity of terrestrial fauna and flora. The coastal areas of Trinidad and Tobago are largely comprised of sedimentary rocks. The north coast however is comprised of non-sedimentary rock with low grade metamorphic and small areas of volcanic rock (Georges, 1983). The geomorphology is generally of gently sloping beaches and cliffs. Current flow around Trinidad and Tobago is driven by the South Equatorial current coming north from South America. The current splits with movement to the west entering the Gulf of Paria and to the east moving and merging with the Atlantic Ocean.

Prior to the NAGISA project (2005), the intertidal rocky shores of Trinidad and Tobago had not been studied in any detail. The sites sampled with the SARCE project are on the north-east coast (Saybia, Toco) and the north coast (Maracas Bay). In the north-east coast location (Saybia, Toco there is a fringing reef which offers some protection although there is a strong westerly longshore current. In the north coast (Maracas Bay) area there are generally strong offshore winds and a strong longshore current, although some protection is offered by the headlands. The mean tidal range in Trinidad and Tobago is around 1.2m and is semidiurnal with a high and low every 12hrs.

The biodiversity associated with the intertidal sites typically included the common groups: macroalgae (green, red, and brown), bivalves (*Isognomon* sp. the most common but only found at Salybia and Toco Bay), gastropods (*Littorina* sp. the most common), polyplacophorans, crustaceans (barnacles found at all sites except Las Cuevas), and tunicates. The red algae, mostly *Heterosiphonia* were the most dominant species, while brown algae were least dominant, and *Chaetomorpha* sp. was the most common green algae (found at Maracas and Blanchisseuse). Coralline algae were well represented at all sites except for Salybia. There were greater numbers of species of soft corals (22) as opposed to soft corals (2), all of which were found in Salybia and Toco Bay, sites nearby to coral reef systems.

# **The Atlantic**

*Brazil*

# **The Northeast: Ceara**

The Ceará state coastline is dominated by long sand beaches, interrupted occasionally by beachrock reefs (Aquasis, 2003). The beachrocks have a more recent origin, and are composed by sand, shell fragments and pebbles cemented by calcium carbonate and iron oxide (Smith and Morais, 1984). These reefs are generally tabular, of variable extension and sloping gently towards the sea. The coastline is more E-W oriented, along typically equatorial latitudes. The climate is typically semi-arid, ruled by the intertropical convergence zone, with 2 seasons characterized by the pluviometry: a rainy season from January to June, and a dry season from July to December (IPECE, 2013). The coast is washed by the North Brazil current, running from E to W, following the strong trade winds that are characteristic for the region (Aquasis, 2003). The North Brazil current water mass is considered oligotrophic, with

temperatures varying little around 26ºC and salinity around 36 (NOAA, 2014). The constant trade wind regime blowing from E-SE with 6.4 m.s-1 on average, reaching more than 10 m.s-1 during the dry season (Jimenez et al., 1999). Wind waves are permanently splashing over the reefs, sometimes combined with swell waves, ranging from 1.8 to 3.6 m in height (Aquasis, 2003). The tidal regime is typically semidiurnal, with a mean spring tidal range of 3.3 m, and mean neap tidal range of 1.2 m.

The beachrock reefs of Ceara host a very diverse community which is still poorly studied. The rocky intertidal shows a typical biodiversity zonation from the supralittoral to the subtidal zones. The supralittoral fringe is barely colonized, and the dominant species is *Echinolittorina lineolata*, a small mobile gastropod that fits into minute crevices avoiding extreme desiccation. The same species is also abundant in the high intertidal, but the space is occupied now by barnacles, especially *Chthamalus proteus* and patches of the green algae *Ulva fasciata*. The association of these two species characterizes the whole upper littoral zone, which is considerably poor in terms of species richness. The mid littoral zone is more diverse and the dominant species may vary at different locations. In Caucaia (Figure 3A), near urban capital Fortaleza, there is a belt of the bivalve *Brachidontes exustus* at the higher portion of the upper littoral zone, and a continuum of large colonies of the polychaete *Phragmatopoma caudate* is also present. The dominant algae species are *Chondracanthus acicularis*, *Gelidiella acerosa*, and *Hypnea musciformis*. Other dominant species are *C. proteus* and *U. fasciata*, which are still abundant in the lower littoral zone. In Trairi, there is not a conspicuous band of *B. exustus*, and the mid littoral zone is then dominated by *U. fasciata*, *Pterocladiella caerulescens* and *Laurencia papillosa*. Large colonies of *P. caudata* are present, and the zoanthid *Palythoa grandiflora* also covers large areas of this zone. The mobile fauna present in the mid littoral zone is mainly composed of crabs, especially *Pachygrapsus transversus*, hermit crabs, such as *Clibanarius antillensis* and *Calcinus tibicen* (Herbst, 1791). The lower littoral zone is the most diverse, and fully dominated by algae. The most abundant species vary by location and site. In Caucaia, the most common species are *Centroceras clavulatum*, *C. acicularis*, and *U. fasciata*, while in Trairi the dominant species are *P. caerulescens*, *Gracillaria* spp., *Amansia multifida*, and crustose coralline algae. The mobile fauna at the lower littoral zone is also more diverse and includes the species mentioned for the mid littoral zone plus the gastropods *Stramonita haemastoma* and *Tegula viridula* (Gmelin, 1791). Recent surveys of the whole littoral zone detected a total of 110 species for Caucaia and 103 for Trairi. Most species are shared by the two locations, but Trairi is considerably more diverse in terms of sessile organisms (both animals and algae), while Caucaia has more motile animals. In terms of composition, the most specious taxa, in decreasing order, were: Rodophyta (45 spp.), Chlorophyta (18 spp.), Mollusca (18 spp.), Ochrophyta (11 spp.), Crustacea (8 spp.), Porifera (7 spp.), Ascidiacea (7 spp.), Cnidaria (5 spp.), Polychaeta (3 spp.) and Echinodermata (2 spp.).

The data collected using the SARCE protocol for large and conspicuous organisms in the intertidal shows that there is a considerable biodiversity along the beachrock reefs in Ceará. There are about 130 species in total, the vast majority of them of algae, especially red and green algae. There is also a tenable difference among locations and sites along this stretch of coast, which highlights also a degree of beta diversity. It is worth mentioning that the protocol favored the algae component of the intertidal community by accounting only for organisms "over" the substrate. Previous surveys aimed at producing inventories had come out with different numbers. For instance, results form the PROBIO initiative in Ceará indicated for the

same area 109 species of algae, 53 species of Crustacea, 44 species of Mollusca, 28 species of Ascidiacea, 24 species of Polychaeta, 22 species of Cnidaria, and 9 species of Echinodermata (Matthews-Cascon and Lotufo, 2006). Even these numbers are underestimating the total diversity, because the effort was still punctual.

#### **The Northeast: Sergipe**

Sergipe is the smallest Brazilian State, and the third shortest coast in extension (160 km). Located in the northeastern, it limits with the State of Alagoas in the north, and the State of Bahia in the south. Aracaju, the main city, comprises 25% of the state's population and has two harbor complexes. Sergipe has no real rocky shores, but rather beaches with boulders and rocky outcrops, and few areas with biolithic substrates (*Pragmatopoma caudata*). Beaches are composed by fine sand, and the linear coast is fringed by esturies and mangroves, associated with the rivers Real, Vaza-Barris, Sergipe and São Francisco.

The State has 47.3% of its territory inside of the "Drought Polygon" polígono das secas (FAO). The climate is tropical, with the highest humidity by the coast and in semi-arid backlands. The highest rainfall occurs between January and March.

In Sergipe, the SARCE project sampled, from south to north in three beaches: Praia do Saco, Coroa do Meio, and Praia do Jatobá. A total of 106 taxa were found represented by 34 species of invertebrates, 66 of macroalgae, and 6 species of filamentous cyanobacteria. The supralittoral zone is characterized mostly by bare bolders, which may be colonized by periwinkle gastropods of the complex *Echinolittorina ziczac*, and filamentous cyanobacterias. The high/medium intertidal, not always well zonated, contains a belt of the barnacle *Chthamalus bisinuatus* and the mussel *Brachidontes solisianus*, usually fouled by the red algae *Bostrychia* spp. and other filamentous red and green macroalgae. The low intertidal was the most diverse characterized mainly by barnacles (*Tetraclita stelifera*), oysters (*Crassostrea rhizophorae*), crab (*Aratus pisonii*), *Lottia* (*Collisela*) *subrugosa*, and mussels (*Perna perna*). Regarding macroalgal assemblages, the biomass was dominated in general by filamentous, leathery and terete functional groups. A total of 66 taxa were found: 41 *Rhodophyta*, 16 *Chlorophyta* and 9 *Phaeophyceae*, dominated by *Rhodomelaceae* (9 species), *Ceramiaceae* (5 species.), *Corallinaceae*, *Cystocloniaceae*, *Cladophoraceae* and *Ulvaceae* (4 species). The most conspicuous species were *Gayralia brasiliensis*, *Rhizoclonium riparium*, *Ulva flexuosa*, *Sargassum platycarpum*, *Centroceras clavulatum*, *Gracilaria cervicornis*, *Jania adhaerens*, *Hypnea valentiae*, *Solieria filiformis* and *Pterocladiella capillacea*.

#### **The Northeast: Bahia**

In Bahia, rocky substrates are mainly biogenic and sandstone, but some granitic substrate is also found. The SARCE project sampled five locations: Itacaré (Arruda, Corais, Figure 3B, 3C, 3D), Ilhéus (Backdoor, Praia do Sul), Itaparica (Penha, Mar Grande), Salvador (Stella Maris), and Litoral Norte (Guarajuba, Itacimirim), Litoral Norte and Itacaré located within a State marine protected area. Among these, Corais, Penha and Stella Maris are the only sampling sites that are characterized by granitic substrate.

The total number of species found at these sites varied between 29 (Mar Grande) and 58 (Arruda). Macroalgal diversity at all sites was very high and dominated the assemblage. The total number of macroalgal species varied between 18 (Mar Grande) to 46 (Arruda), with red algae being the most speciose group, followed by green and brown algae. In the high intertidal, the most abundant species were *Brachidontes*, *Chthamalus*, *Lyngbya* and *Ulva* 

*flexuosa*. The mid intertidal was dominated by *Ulva lactuca, Palisada perforata* and *Gelidiela acerosa*, but in general, *P. perforata* and *G. acerosa* were also abundant species in this zone. The low intertidal was dominated by *Sargassum,* but *Bryothamnion triquetrum* and *Amphiroa anastomosans* were also dominant species at Penha and Praia do Sul respectively.

#### **The Southeast: Espírito Santo**

Espirito Santo State is bordered by Minas Gerais, Bahia and Rio de Janeiro. Climate is coastal humid tropical. Rainfall is highest during summer (1.000 mm and 1.500 mm/year), and mean air temperatures are around  $22^{\circ}$ C and  $24^{\circ}$ C. The south coast is rocky, with sandstone cliffs, and in the central coast, biolithic and granite formations can be found. The south-central coast is very indented with coves and bays sheltered by rocky outcrops. The coast is more indented in the center-south, and open sea to the north. The State comprises the higher seaweed diversity and biomass in Brazil, been influenced by the South Atlantic Central Water upwelling. The SARCE project sampled sites at the localities of Paraty, Ubu (Figure 3E), and Manguinhos.

A total of 183 taxa were found comprised by 48 invertebrate species and 131 macroalgae conspicuos taxa. The supralittoral zone is mostly bare but periwinkle gastropods of the complex *Echinolittorina ziczac*, and the green filamentous algae *Rhizoclonium* may be found. The high/mid intertidal, not always well zonated, contains a belt of the barnacle *Chthamalus* sp., oysters (*Crassostrea rhizophorae*), the mussel *Brachidontes solisianus*, and a complex of the red algae *Bostrychietum*. The low intertidal was more diverse and characterized by the barnacles *Tetraclita stelifera*, and *Lottia (Collisela) subrugosa*, muricid gastropods, and *Palithoa caribeorum*. Regarding macroalgal assemblages, the biomass was dominated in general by foliose, terete and calcareous (crustose and articulated) functional groups. A total of 131 taxa were found: 69 Rhodophyta, 37 Chlorophyta and 25 Phaeophyceae. The most conspicuous species were *Anadyomene stellata*, *Caulerpa* spp. (maily *C. racemosa* and *C. cupressoides*), *Codium* (mainly *C. intertextum* and *C. isthmocladum*), *Valonia aegragopila*, *Canistrocarpus cervicornis*, *Colpomenia sinuosa*, *Dictyopteris delicatula*, *Dictyota menstrualis*, *Neoralfsia expansa*, *Padina gymnospora*, *Sargassum cymosum*, *Arthrocardia flabellata*, *Dichotomaria marginata*, *Gelidium* spp., *Hypnea spinella*, *H. valentiae*, *Jania adhaerens*, *Lithotamnium/Lithophylum* complex, *Ochtodes secundiramea*, and *Palisada flagellifera*.

#### **The Southeast: São Paulo**

Nine rocky shores were sampled along 150 km of the coast of São Paulo State, Brazil, within three localities: Baixada Santista (Guaiúba/Guarujá, Ilha Porchat/São Vicente, Itaquitanduva/Praia Grande), São Sebastião (Baleeiro/São Sebastião, Feiticeira/São Sebastião, Itassucê/São Sebastião), and Ubatuba (Enseada/Ubatuba, Itaguá/Ubatuba, Praia Grande/Ubatuba). This coastline faces south - southeast, with variable complexity, from long linear stretches in Bertioga (Figure 3F) and southern São Sebastião, where long sandy beaches prevail, to very intricate coasts in Ubatuba, where small sandy beaches (tens to a few hundred meters) and mangrove forests are interspersed along a general rocky shoreline, forming several small bays and coves (Tessler et al. 2006). This general feature is an outcome of major tectonic dynamics leading to a gradual emergence towards the southwest, leading to the formation of coastal plains and long sandy shorelines, and to submersion towards the northeast, where a sinking mountain range, part of the Serra do Mar system, makes up most of a remarkably convoluted shoreline and coastal islands (Martin & Suguio 1975, Almeida 1976). The rocky intertidal is usually steep, never forming large platforms, and often broken into very large boulders. As in most of the Serra do Mar, rocks are mostly constituted by gneiss and granite (Almeida & Carneiro 1998). The climate regime varies from tropical do humid subtropical (Sant'Anna Neto 1990) within this area. In Ubatuba, where historical climate data are available and have been extensively modeled (e.g. Valentim et al. 2013), temperature is maximum during February  $[27.8$ <sup>o</sup>C air temperature (AT), 28.6<sup>o</sup>C sea surface temperature (SST)] and minimum during July (21.1°C AT, 21.9 °C SST). Continuous measurements during the austral summer of 2011, taken at Baleeiro, São Sebastião, showed that temperature at the rock surface in the mid intertidal averaged 28.8  $\degree$ C and occasionally exceeded 40°C (Kasten & Flores 2013).

The sampled shores varied from sheltered (Enseada, Itaguá), moderately exposed (Guaiuba, Ilha Porchat, Itaquitanduva, Baleeiro, Feiticeira, Itassucê) and exposed (Praia Grande), within an area where wave height frequencies from 0.5 to 2.0 m sum up 90%, with a wave height interval between 1.0 to 1.5 m making up half the observations (Bomtempo 1991). Wave exposure is apparently related to the midshore height (MH), from the upper limit of the coralline algal turf to the upper limit of the chthamalid barnacle cover. Roughly, the MH is lower than 0.5 m at sheltered shores, betwen 0.5 and 1.0 m at moderately exposed shores, and higher than 1.0 m at exposed shores. In this area, coastal primary production is comparatively low when compared to temperate areas prone to intensive seasonal upwelling (Gianesella et al. 2008). Estimates of nitrate concentration based on SST time series taken in the São Sebastião Channel indicated variation from only 0.2 to 0.7 μM (Flores unpublished data). Local upwelling of South-Atlantic Central Waters (SACW) may take place sporadically, during summer months, but more frequent inputs to the coastal zone take place via remote forcing, mostly during the passage of cold fronts during winter (Ciotti et al. 2010). The tidal regime at this coastline is a semidiurnal one, with the tidal range at spring tides ranging from 1.1 to 1.5 m. There is often a clear intertidal zonation, with the barnacle *Chthamalus bisinuatus* dominating the upper midlittoral (level 1), the mussel *Brachidontes solisianus,* and the volcano barnacle *Tetraclita stalactifera* prevailing in the lower midlittoral zone (level 2), and a coralline algal turf, associated to a very diverse assemblage of other macroalgae, making the most of the infralittoral fringe (level 3). These three levels were the targets of sampling protocols attempting a complete report of species presence and abundance.

Intertidal biological assemblages at the study sites - The upper levels sampled in this survey (levels 1 and 2) showed little variation among localities, but species turnover was very high in the lowest level (level 3), rendering almost shore-specific assemblages. At this lowest level, diversity was very high due to the presence of a large number of small macroalgal species. The most common species at all sites in level 1 in terms of cover were *Chthamalus bisinuatus* and *Brachidontes solisianus*, while *Collisella subrugosa* was one of the most abundant reaching densities of more than  $70$  ind/m<sup>2</sup>. Level 2 was dominated by *Phragmatopoma caudate, Brachidontes solisianus, Tetraclita stalactifera,* and *Chthamalus bisinuatus*. Level 3 showed differences in among the different sites, with *Collisella subrugosa, Fissurella clenchi, Phragmatopoma caudate, Ulva lactuca, Stramonita haemastoma,* and *Caulerpa fastigiata* as some of the most abundant and conspicuous species.

#### **The South: Paraná and Santa Catarina**

The rocky coasts along south Brazil are formed by granitic or basaltic rock, resulting from the erosion of the border of the Serra do Mar mountain chain, which lies parallel to the coastline. Biolithic formations are also observed as an important coastal substrate, mainly at Paraná and Santa Catarina States. It is not a continuous ecosystem, but forms more or less extended outcroppings between sandy beaches and around numerous coastal islands. In some beaches there is a large rocky wall with different inclinations, where the intertidal zone is 5 – 6 m wide, but in most cases boulders of different sizes accumulate in front of these walls and the intertidal community covers a band of just  $1.5 - 2$  m high in each boulder. Usually the tide ranges from -0.2 to 1.8 m and water temperatures range from  $17 - 23$  °C but surface water temperatures can reach peaks of  $26 - 28$ °C. The Paraná comprises the shortest coast in extension in the South and the second shortest in Brazil (98 Km). The area is between two Estuarine Complexes (Paranaguá and Guaratuba Bays), resulting in low transparency and high concentration of dissolved organic matter.

The monitoring of rocky coasts in the Brazilian southern region covered the following beaches from north to south: Morro do Farol (Figure 3G) and Praia Grande (Mel Island), Farol Island (Matinhos), Ferry Boat and Morro do Cristo (Guaratuba), in state of Paraná; First outcrop and Third outcrop (Itapema do Norte, Itapoá), Papagaio Point and Praia de Cima (Palhoça), in state of Santa Catarina; and Praia da Cal and Guarita Park (Torres) in state of Rio Grande do Sul. The northern seven sites listed are close to large estuarine systems (Paranaguá Bay, Guaratuba Bay, Babitonga Bay) and consequently exposed to low salinities (33-34) and high loads of sediment (turbid waters) and high concentration of dissolved organic matter.

A total of 160 species were found, around 60 invertebrates and 100 conspicuous macroalgae distributed along the three states, but known species richness in the southern Brazilian coast can reach 220 taxa at Santa Catarina (ca.), 131 taxa in Paraná (Pellizzari et al. 2014) and 85 taxa in Rio Grande do Sul (ca.). Rhodophytes dominated over Chlorophytes and Phaeophycean. The supralittoral zone mostly comprises bare space used by the periwinkle gastropods *Echinolittorina lineolata* (d'Orbigny, 1840), which are the most common and characteristic organisms at the lower part of this zone. Abundances can be as high as 150 individuals per 100 cm2. The high intertidal contains a dense belt of the barnacle *Chthamalus bisinuatus* Pilsbry, 1916, where many *Echilittorina* are still present. The mid intertidal is dominated by the mussel *Brachidontes solisianus*, usually fouled by the algae *Pyropia* (formerly known as *Porphyra*) *suborbiculata*, *Bostrychia* spp., and *Gelidium pusillum* during the winter time. In this zone sand accumulates among the bivalves, sometimes almost covering all the shells, in which a community of vagile invertebrates such as polychaetes and nematodes is found. The community of the low intertidal is more variable among sites. In some beaches, barnacles (*Tetraclita stalactifera*) are very common (Morro do Farol, Morro do Cristo, Ponta do Papagaio), while in others, the mussel *Perna perna* is the dominating species (Ferryboat, Praia de Cima, Praia da Cal, Guarita Park). Below the barnacle and mussels zone, high densities of the sabelariid polychaete *Phragmatopoma caudata* are found forming sand reefs that can extend 50-70 cm away from the substrate. Not all rocks are covered by the sand reefs and macroalgae are also very abundant in this zone. Regarding seaweed assemblages, filamentous, foliose and terete functional groups dominated the biomass. Species with higher coverage in the low intertidal were *Acantophora spicifera, Centroceras clavulatum, Gelidium spp., Gymnogongrus griffthsiae, Hydropuntia caudata,* 

*Hypnea musciformis, Pyropia acantophora, Laurencia* spp*., Bryopsis pennata, Cladophora*  spp*., Codium taylorii, Gayralia brasiliensis, Ulva lactuca, U. flexuosa, Bachelotia antillarum, Colpomenia sinuosa, Dictyota* sp*., Padina gymnospora and Sargassum* spp. The most important herbivores in the area are sea-urchins and turtles. In some beaches, hydroids are also common in the low intertidal such as *Obelia dichotoma*, *Orthopyxis sargassicola,* and *Acharadria crocea*. The sea anemone *Bunodosoma caissarum* as well as the sponge *Hymeniacidon heliophila* were also frequent. When the tide is very low and the sublittoral fringe gets exposed, a few ascidian species can be found (*Polysyncraton aff. amethysteum*, *Didemnum galacteum*, *Botryllus planus,* and the introduced *Eudistoma carolinense*). Among the grazers, there were five mollusk species and one sea-urchin, while among the predators, *Stramonita braziliensis* was the only ubiquitous and abundant invertebrate species. No seastars were found, however, 20 years ago, *Asterina stellifera* was common in the intertidal zone of this region.

Along the Brazilian coast in general, macrofauna does not show significant differences in composition, however seaweed assemblages are strongly marked by latitudinal differences on their composition and biomass. The highest diversity of macroalgae is found between the coasts of Espírito Santo and Bahia States, while the highest biomass is found in the Brazilian Northeastern and also Santa Catarina, in the South, associated probably to the influence of the South Atlantic Central Water (ACAS), distance to large estuaries (affect water transparency), and finally to the availability of hard substrates.

#### *Uruguay*

The Uruguayan marine and estuarine coastlines (ca. 500 km, between 34º and 35ºS) include sandy beaches interrupted by streams and coastal lagoons and rocky (mainly metamorphic and igneous) outcrops forming capes or peninsulae. Since the Uruguayan coast is under the influence of the the Río de la Plata estuary, one of the largest estuaries of South America, a salinity gradient roughly oriented east–west can be identified. Based on salinity, three main regions can be identified: a west region influenced by freshwater  $\left\langle \langle 1 \text{ppt} \rangle \right\rangle$ , a central region that is influenced by water of variable salinity (1–30 ppt) and an east region open to ocean waters (>30 ppt) (Brazeiro, Borthagaray, and Giménez, 2006; Defeo et al., 2009; Giménez et al., 2010). Diluted waters (i. e. salinity <33.2) dominate shallow coastal area (i.e. depths <50m) and can reach the offshore producing a buoyant fresh water layer during extreme continental discharge that determine variations in coastal water input (Ortega and Martínez, 2007). Upper waters temperature could exceed 20ºC (e.g. Tropical Water) (Thomsen, 1962) at surface. In the boundary between the estuarine and oceanic zone (Punta del Este), water temperature can fluctuate between 10.7ºC in winter and 24.6ºC in summer, (Burone and Bayseé, 1985; Milstein and Juanicó, 1985). The coast experiences a semidiurnal tide (range < 0.5 m) with the water level influenced mainly by wind conditions (direction and speed). Winds blow south-west during winter and north-east during summer. The rocky platforms have variable slopes and are exposed to different degrees of wave action according to their orientation. SARCE sampling sites are located in the east region (Figure 3H).

Across the Uruguayan coast, intertidal species richness of both macroalgae and invertebrates, increased from west to east; this was most notable for sessile fauna and macroalgae (Giménez et al., 2010). In the east region, two to three zones can be identified,

Figure 3. Sampling sites in the Brazilian and Uruguayan Atlantic. A. Northeast Brazil – Caucaia. B. Northeast Brazil – Bahia/Itacaré. C. Northeast Brazil – Bahia/Arruda, octopus fishing. D. Northeast Brazil – Bahia/Itacaré. E. Southeast Brazil – Costao de Ubu/Espirito Santo. F. Southeast Brazil – Sao Lourenco. G. South Brazil – Morro de Farol/Parana. H. Uruguay – Punta del Este.

following classical zonation schemes: a high intertidal zone dominated by a cyanobacterial film, a middle intertidal zone dominated by barnacles and a low intertidal and shallow subtidal zone characterized by a dense cover of mussels and/or macroalgae. Intertidal mussel beds are thus a conspicuous feature of Uruguayan rocky shores, providing important economic and ecological services (Borthagaray and Carranza, 2007; Riestra and Defeo, 1994; Riestra and Defeo, 2000). Along this gradient, the intertidal mussel beds changes in species composition and structure. Currently, the western region is characterized by the invasive mussel *Limnoperna fortunei*. *Brachidontes darwinianus* and *Mytella charruana* occupy consolidated substrata along the central region (Maytía (Maytia and Scarabino, 1979; Neirotti, 1981; Scarabino et al., 2006), overlapping with *Brachidontes rodriguezii* from the

eastern half of the central region and being replaced by this species in the eastern region (e. g. Amaro (Amaro, 1965; Maytia and Scarabino, 1979; Scarabino et al., 2006). *Mytilus edulis*, in turn, is distributed from the eastern half of the central region, being the dominant mussel species in this zone. *Brachidontes rodriguezii* and *Mytilus edulis* originate dense banks in the more saline part of the Río de la Plata, the first being characteristic of the intertidal (also occurring in the Atlantic shores), the second mostly subtidally although some intertidal exposed zones have been observed to be dominated by this species (Borthagaray and Carranza, 2007). The brown mussel *Perna perna* originates large banks in the subtidal of the eastern coast (Rocha) but its presence (in very low abundances) reaches Punta del Este. The Uruguayan coast was massively colonized by this species in the late ´50ths. Since this first colonization, *P. perna* almost disappeared in the late 70s to 1997, when a new process of colonization occurred in the area (Carranza and Borthagaray, 2008; Orensanz et al., 2002). The annotated list of macroalgal species of the Uruguayan coast given by Coll and Oliveira (1999) reported the presence of 69 species sampled from 27 sites located along the central and east sectors of the Uruguayan coast. Conversely, a single site (Cerro Verde) can yield more than 40 invertebrate taxa, including the small mobile (e.g. amphipods, polychaetes), and encrusting (e.g., briozoa, hydrozoa) fauna. Under the SARCE sampling protocol, two sites located in the eastern region showed a combined richness of 20 species, including 9 metazoans (4 Gastropoda, 2 Bivalvia, 2 Cnidaria Anthozoa and 1 Cirripedia), 4 Chlorophyta and 7 Rhodophyta bortha (Borthagaray and Carranza, 2007).

#### *Argentina*

The Argentinean marine coast extends along more than 4700 km and twenty degrees of latitude. It comprises the Argentinean and Magellanic biogeographical provinces, which are delimited by the Valdés Peninsula. The Argentinean Biogeographic Province extends from 36 to 43º S, including the provinces of Buenos Aires and Río Negro, and the north of Chubut province. The Magellanic Biogeographic Province, extends from 43ºS to 56ºS along southern Chubut province as well as Santa Cruz and Tierra del Fuego provinces (the latter includes the Malvinas/Falklands and South Atlantic Islands) (López Gappa et al., 2006, Balech and Ehrlich, 2008). Intertidal rocky platforms in Argentina increase in frequency and extend from North to South. In the northernmost coastal province (Buenos Aires), rocky coastal stretches are markedly discontinuous. They rarely exceed 1 km length and are frequently associated to urban areas. Most intertidal platforms in this province are formed by consolidated sediments (e.g., limestones, sandstones, calcretes) that support both epilithic and endolitic biota (Bagur et al. 2013, 2014). The only exceptions are a handful of metamorphic rock (ortoquartzite) platforms adjoining the city of Mar del Plata (38° S).

SARCE sampled two sites were sampled in the province of Buenos Aires: Playa Chica, an orthoquartzite platform located in the urban zone of Mar del Plata (Figure 4A) and at a calcrete platform located immediately north of the port of Quequén. Both localities are exposed to waves and face the open sea. The tidal regime at these sites is semidiurnal and microtidal (mean and maximum amplitude are 0.83 and 1.65 m respectively). Water temperature varies from a media of 5º C in winter to a media of 18 º C in summer (Servicio Meteorologico Nacional-Argentina, http://www.smn.gov.ar). The next province to the south, Rio Negro, presents intertidal platforms of varying substrate, including sedimentary (e.g., sandstones, limestones) and igneous rock types (e.g., granite, ignimbrites) (Kokot et al. 2004). Tidal regimes are semidiurnal and macrotidal through the whole coastal range. The sampling

sites in this province were: El Espigón, La Lobería (Figure 4B), Playa Los Suecos, and Punta Colorada. El Espigón and La Lobería face the open ocean and are characterized by sedimentary rock substrates and maximal tidal amplitude of 4.32 m. Playa Los Suecos and Punta Colorada are located within the San Matías Gulf and show igneous rock substrates and maximal tidal amplitude of 8.72 m (Kokot et al. 2004). Southwards, the rocky shores of Chubut province are exposed to unusually harsh physical conditions, particularly with regard to desiccation (see Bertness et al. 2006). The region is characterized by persistent and intense winds (up to 90 km/h, annual average 16.6 km/h) and low precipitation (mean 235.9 mm/yr (Paruelo et al., 1998, Labraga & De Davies, updated 2013). The tidal regime is semidiurnal and macrotidal. Consolidated sediments are the dominant substrate type across these rocky shores. Sampling sites in Chubut were Puerto Lobos, Punta Este (Figure 4C), and Camarones. Puerto Lobos is located by the Southern end of the San Matías Gulf and its maximal tidal amplitude is about 6 m. Punta Este is located within the Nuevo Gulf, 8 km south from the city of Puerto Madryn. Mean tidal amplitude at this site is 3.8 m (Maximal: 5.7 m). The town of Camarones is located within the homonymous bay. This site is characterized by monthlyaveraged wind speeds ranging from 13 to 31 km/h and an average tidal amplitude of 4 m, platforms are characterized by sedimentary rocks although some igneous rock are present. The southernmost continental sampling site was Puerto Deseado (Figure 4D) in Santa Cruz Province. This site is located in the Deseado Massif geological province, and characterized by igneous rock substrates (rhyolites; see Pankhurst and Rapela, 1995; Pankhurst et al., 1998). Climate is also dry and windy with a mean annual precipitation around 200 mm and an average annual air temperature of 8.2 °C (Servicio Meteorologico Nacional-Argentina, http://www.smn.gov.ar). The tidal regime is mesomacrotidal (Isla and Bujalesky, 2008), with amplitudes ranging between 2.5 and 5.5 m. Two additional sites were sampled in Tierra del Fuego Island: Estancia Viamonte (Figure 4E) and Playa Larga (Figure 4F). Estancia Viamonte is located 40 km south of the city of Río Grande and characterized by an extensive limestone abrasion platform (the low tide level is ca. 2 km distant from the high tide line) that faces the open ocean. The tidal regime is macrotidal, with amplitudes ranging between 2.2 and 8.4 m (Bujalevsky 1997, 2007). The area shows a dry and windy climate (340 mm/yr precipitation) with the mean annual temperatures of  $5\n-6$  °C and low between-month variations (Bujalevsky 1997, 2007). Playa Larga is located 3.5 km east of the city of Ushuaia in the Beagle Channel. The rocky shore at this site is characterized by methamorphic rocks and a sharp slope. The tidal regime is microtidal (1.1 m mean amplitude). Mean annual temperature and precipitation are 6°C and 500 mm, respectively. This shore faces the dominant SW-W winds and, thus, is exposed to considerable wave splash. The subtidal all along the Beagle channel is characterized by dense forests of *Macrocystis pyrifera* (Figure 4G) down to the channel's mouth to the Atlantic at Estancia Moat, a planned sampling site (Figure 4H).

The main feature of this extensive coast is the low biodiversity of its rocky intertidal shores, which at the same time involve low biomass (Wieters et al. 2012). From North to South, the two localities in Buenos Aires Province have different geological substrates, and are 120 km apart. Even if both assemblages have the same species composition; the structure and relative abundance of species between localities were different. In Mar del Plata, the locality with quarzitic substrate, the bivalve *Brachidontes rodriguezii*, the limpet *Siphonaria lessoni* and the introduced barnacle *Balanus glandula* are the more abundant species of the high intertidal. In the mid intertidal level, several algae species were added to the

assemblages, being *Hildenbrandtia* sp. *Polysiphonia fucoides*, *Ulva* sp. and two nonindigenous red algae *Anfeltiopsis devoniensis* and *Schyzimenia dubyi* the most abundant. In the low intertidal level, the most representative species are *Polysiphonia fucoides* and *Siphonaria lessoni* in Mar del Plata and *Corallina officinalis* and *Balanus glandula* in Quequén. The presence of non-indigenous algae species is limited to Schyzimenia *dubyi*, and in very low coverage.

Figure 4. Sampling sites in Argentina. A. Mar del Plata. B. La Lobería. C. Punta Este. D. Puerto Deseado. E. Río Grande. F. Playa Grande. G. Estancia Moat – *Macrocystis pyrifera*. H. Estancia Moat.

The Rio Negro Province comprises two localities and also an area of ecotone among two biogeographic regions, the Argentinean and Magellanian provinces. The differences among localities involve not only changes in the species composition but abundance of the ones that are present in both regions. In El Espigón and Loberia, a great variability was found between sites, the high intertidal is inhabited mainly by *Mytilus platensis* in one site and by *Ralfsia expansa* and *Enteromorpha linza* in the other. The mid intertidal level could have up to 98 % coverage of *Brachidontes rodriguezii* in one site and 0 % in the other. *Siphonaria lessoni* is the second more abundant species in this level. In the low intertidal the areas are patchly covered by *E. linza* and *Corallina officinalis* in one site or almost exclusively covered by *C. officinalis* in the other. In Playas Doradas, the most abundant species that inhabits the high intertidal are *Siphonaria lessoni* and *Brachidontes rodriguezii*, but in a very low percentage cover (approximately 12 %). In the mid intertidal, *Brachidontes pupuratus* replaces *B. rodriguezii* and it is the most abundant species followed by *Ralfsia expansa* and *S. lessoni*. For the low intertidal, *C. officinalis* is the most abundant followed by a complex of *Aulacomya actra* and *Mytilus platensis* forming mussel beds. The Chubut Province is characterized by sites with no human settlements. In the north of the province, the biodiversity pattern is similar to the localities in the province of Rio Negro, with *B. purpuratus* being the most abundant species in the high and mid intertidal and *C. officinalis* in the low intertidal. In Puerto Madryn, a site with a local population of 80,000 residents, the pattern is similar but with a greater proportion of the green algae *Ulva* sp. in the mid intertidal, depending on the season. High and mid intertidal are dominated by the mytilid complex of *Brachidontes rodriguezii* and *Brachidontes purpuratus* that produce an heteregenous habitat that facilitates settlement for several species. Also the non-indigenous barnacle *Balanus glandula* is present in high and mid intertidal levels, while the gastropod *Trophon geversianus* is a carnivore specialized on mytilid bivalves. The low intertidal is dominated by the alga *Corallina officinalis* and the herbivore gastropod *Tegula patagonica*. In Camarones, the zonation is similar to Puerto Madryn, presenting zones with 100% of coverage of *Brachidontes purpuratus* dominating the mid intertidal, and the invasive species *Balanus glandula* in the mid and high intertidals. The low interidal is dominated by the calcareous algae *Corallina officinalis*, while *Aulacomya atra* and *Siphonaria lessoni* are abundant in some localities. The gastopod *Trophon geversianus* is less common in this zone, probably due to the harsh physical stress.

Santa Cruz is the last province of the continent and the one with less population, with nearly 10,000 residents on the coast, but with an important port in the sampling locality Puerto Deseado. Here, even if biodiversity increased slightly, patterns of the most abundant species were kept. The high and mid intertidal were dominated by *Brachidontes purpuratus* and the algae *Bostrichia*, while the in the low tide *Corallina officinalis* and *Chondria* were the most abundant. In the low intertidal level the presence of the non-indigenous red algae *Anotrichium furcellatum* was detected as one of the most abundant. In Tierra del Fuego Island, assemblages are different according to their degree of exposure (open ocean vs Beagle channel). In the open ocean locality, Estancia Viamonte, near Ushuaia (56,000 residents), mussel beds are composed mainly by *Mytilus edulis platensis* and covered from 50 to 87% of the mid and high intertidal. In the low intertidal, the incrusting algae *Corallina* sp. is the more abundant sessile species. The biodiversity of mollusks increased in this site, being *Nacella magellanica*, *Kerguelenella lateralis* and *Trophon geversianus* the most abundant. In the locality in the Beagle Channel, Playa Larga, macroalgal biodiversity increased, being the most conspicuous group in the low and mid intertidal along with *M. edulis platensis*. The limpet *Notochthamalus scabrosus* is the more abundant species in the high intertidal. As observed in the open ocean site, the biodiversity of mobile mollusks increased with *S. lessoni*, *K. lateralis*, *N. magellanica* and *T. gerversianus* the most abundant species in the three intertidal levels.

# **The Pacific**

#### *Colombia*

In general terms, two main regions/features can be recognized on the littoral of the Pacific coast of Colombia: mangrove swamps and muddy flats to the south and rocky shores to the north; with a hybrid zone almost in the middle of the coast: Málaga and Buenaventura Bays. The shoreline is very broken, interrupted by numerous small rivers and creeks characteristic of one of the rainiest and most bio-diverse areas in the World: The Tumbes-Chocó-Magdalena region. Despite this condition or perhaps due to it, most of the coast is unpopulated, with only two relatively large cities: Buenaventura (the most important commercial port in Colombia), located almost in the middle of the coast and Tumaco, a smaller city located at the south, near the border with Ecuador. Although these two are the main cities, there are numerous small towns, such as Guapi and Bahía Solano, among others. The transportation system in the region is precarious. The underdeveloped roads infrastructure is limited to Buenaventura and Tumaco, and all other settlements can only be reached by boat or in few cases by plane, a fact that makes it difficult and expensive to undertake research projects in the Pacific coast of Colombia.

The Pacific coastline has an extension of nearly 1544 km, of which 636 km are exposed rocky shores (Londoño-Cruz et al., 2008, Londoño-Cruz et al., 2014). Despite this exposure, wave action is moderate most of the year round, reaching, on average, wave heights of up to 1 m in most locations (INVEMAR, 2003). Tidal range is relatively large (ca.  $4.5 - 5.0$ ) and has a semidiurnal frequency (ca. 6:15 hrs. between high and low tide). Currents, on the other hand, respond to prevalent winds and to the movement of the Intertropical Convergence Zone (ITZC). The most important surface currents are the North Equatorial Current, the North Equatorial Counter-current, the Panama Gulf Current, and the Colombia Current. Although there are hypothesis regarding the existence of upwellings in the Pacific coast of Colombia, these have not been unambiguously confirmed; if they do occur, they happen during the first months of the year and at the northernmost of the Colombian Pacific (Vides and Sierra-Correa 2003). Rocks forming the large extension of rocky shores on the Colombian Pacific are composed by volcanic rocks from the Secondary or Tertiary periods and by sedimentary rocks from the Quaternary. The volcanic rock characterizes the rocky shores of the northern regions and the Gorgona and Malpelo Islands, while the sedimentary rocks characterize the rocky shores of central (Málaga Bay, Pichidó Isthmus, and Tortuga Gulf) and southern (Gallo Island) regions (INVEMAR, 2004). Due to the relatively large tidal range, the rocky intertidal can be easily divided into three levels, which vary in dimension depending on the slope of the shore. It is very common to find cliffs along the coast, with scattered abrasion platforms and rocky/boulder beaches. Zonation in the intertidal zone is very typical, with periwinkles and *Nerita* spp. occupying the upper intertidal; barnacles, limpets, other snails and bivalves in the middle and a richer arrange of species in the lower. In these rocky shores, the algal coverage

is very low as compared to shores in higher latitudes or the Colombian Caribbean; so although species richness in general is high, species abundances are relatively low. It is also important to note that space seems not to be a limiting factor, since there is plenty of free space in almost every rocky shore along the coast. One might hypothesize that the reason for this low abundance is low algal coverage and long exposure periods during low tide, which may bring very high temperatures or very low salinities (during high rainfall).

The localities sampled by SARCE (from North to South) include El Choco (Punta Ardita, Cabo Marzo) (Figure 5A), Málaga Bay (Los Negritos, Isla Palma), and Gorgona Island (La Ventana, La Camaronera, Piedra Redonda) (Figure 5B). Punta Ardita at El Choco is the northernmost locality, near to the border with Panamá, practically undisturbed by human presence. The volcanic rocky shores in this locality are edged by large sandy beaches. The high intertidal is mostly bare rock with *Cladophoropsis* sp., *Nerita scabricosta*, *Echinolittorina conspera*, *Chthamalus panamensis, Lottia mesoleuca*, and *Acanthina brevidentata*. The mid intertidal is dominated by *Cladophoropsis* sp., *Acanthina brevidentata*, *Fissurella microtrema*, *Phragmatopoma* sp., *Fissurella microtrema*, and *Lottia mesoleuca*. The most common species in the low intertidal are *Cladophoropsis* sp., *Echinometra vanbrunti*, *Telmatactis* sp., bryozoa, and *Balanus* sp. Cabo Marzo is an isolated locality with no human settlements nearby and practically undisturbed. Rocks, as in the previous locality, are volcanic. There is some coralline formation in this place, waters are very transparent. Wave conditions are relatively rough. Dominant species of Cabo Marzo are *Chthamalus panamensis*, *Echinolittorina conspera*, and *Nerita scabricosta* in the high intertidal, Corallinales, *Fissurella virescens*, and *Siphonaria maura* in the mid intertidal, and Corallinales, *Chiton stokesii*, *Siphonaria maura*, *Nucella melones*, and *Chama frondosa* in the low intertidal.

At Málaga Bay the rocks are sedimentary. This bay is part of a National Natural Park and there is a relatively large human settlement (Juanchaco) at the mouth of the bay, as well as a Navy Base along with several other scattered minor settlements. Seasonal tourism is, perhaps, the main economic income for the inhabitants. The first site, Isla Palma, is an island (uninhabited), while the second site, Los Negritos, is an intertidal rocky reef with both volcanic and sedimentary rocks. Dominant species at Isla Palma were *Chthamalus panamensis*, *Balanus* sp., *Lottia mesoleuca*, *Echinolittorina paytensis*, *Echinolittorina dubiosa*, and *Echinolittorina apicina* in the high intertidal; *Verrucaria* sp., *Lithophyllum* sp., *Nerita funiculata*, *Lottia mesoleuca*, and *Balanus* sp. in the mid intertidal; and *Cladophoropsis* sp., *Bostrychia* sp., *Lithophyllum* sp., *Echinometra vanbrunti*, *Nucella melones*, and *Brachidontes* sp. in the low intertidal.

Gorgona Island is also a National Natural Park. Most of the island's shores are rocky and cliffy. Rocks are volcanic with few exceptions. Basically all sort of rocky shore types can be found in the island. This locality is perhaps, the most sampled area in the entire Pacific coast of Colombia. The main rocky ecosystems sampled (La Ventana, La Camaronera, and Piedra Redonda) are located at the south and western sides of the Island. At La Ventana, the dominant species were *Nerita scabricosta*, *Cladophoropsis* sp., *Echinolittorina conspera*, and *Siphonaria gigas* in the high intertidal, *Nerita funiculate* and *Cladophoropsis* sp. in the mid intertidal, and *Nucella melones* and *Nerita funiculata* in the low intertidal. At La Camaronera, high intertidal is dominated by *Echinolittorina conspera* and *Nerita scabricosta*, the mid intertidal by *Nerita funiculata*, and the low intertidal by *Cladophoropsis* sp., *Nerita funiculata*, and *Tegula pellisserpentis.* At Piedra Redonda, the high intertidal is dominated by

*Nerita scabricosta*, the mid intertidal by *Cladophoropsis* sp., *Nerita funiculata*, and *Fissurella virescens*, and the low intertidal by *Cladophoropsis* sp. and *Nucella melons*.

#### *Ecuador*

The coast of Ecuador extends for 4,403 km from north to south and includes several isles, islets and estuaries. The continental platform exceeds 100 km in amplitude mainly at the Gulf of Guayaquil (Sonnenholzner et al, 2013) and a depth of 200 m from the coastline (Mora et al, 2010). About a third of the coast is covered by mangroves, mostly in the north and in the south. The central and part of the north coasts are characterized by large sandy beaches interrupted by a few rocky areas, cliffs, lagoons and rocky reefs (Sonnenholzner et al, 2013; Miloslavich et al, 2011). The rocky shore intertidal has mid to steep slopes formed by stratified rocks within cliffs entering the sea and forming platforms within the sandy beaches. At the base of some of the cliffs, an eroded narrow terrace can be observed, or the beach may be narrow with boulders. Despite the importance of rocky shores, they have been poorly studied in Ecuador, and knowledge on its biodiversity is limited to some taxonomic studies on specific groups such as molluscs (Bonilla 1967; Cruz 1977, 1983, 1992a, b, 1996, 2007 y 2009; Mora and Reinoso 1981; Mora 1989, 1990; Arias 2012), poliychaetes (Villamar 1983, 1986, 1989), echinoderms (Avilés 1984, Sonnenholzner et al. 2013), and macroinvertebrates (Massay et al. 1993; Arroyo and Calderón 2000; Mair et al. 2002; Cruz et al. 2003; Ayala 2010; Mora et al. 2010).

SARCE sampled at two localities at the central and south-west of the coast of Ecuador: Caráquez Bay (Punta Bellaca and Punta Gorda) and at the Santa Elena Peninsula, the localities of Puntilla de Santa Elena (Base Naval and La Lobería) (Figure 5C) and Ballenita (El Barco and El Faro) (Figure 5D) which are located at the provinces of Santa Elena and Manabí. The sites with more human impact were Punta Bellaca and Ballenita, while Punta Gorda and Puntilla de Santa Elena were less impacted.

Punta Bellaca and Punta Gorda are characterized by almost vertical, high cliffs of up to 100 m interrupted by deep valleys with steep slopes (Ochoa et al, 1987). These cliffs are unstable and landslides are common. The beach is narrow and in some places, eroded rock terraces can be found inserted within sandy beaches (Boothroyd et al, 1994). Weather in this area is tropical dry with an average temperature of 25°C. Rainfall is not uniform due to the complexity of the Oceanic Front, and varies between 200-800 mm (Ochoa et al, 1987). A total of 16 species were found (10 at Punta Bellaca and 4 at Punta Gorda), mostly represented by molluscs (50%), macroalgae (25%), and crustaceans (25%). The most diverse group was the mollusks represented by 7 species of gastropod and one bivalve species. The most abundant species were the gastropods *Nodilittorina aspera*, *Nodilittorina paytensis* and the macroalgae *Enteromorpha* sp. and *Bachelotia* sp..

The high intertidal was mostly represented by bare rock and patches of sand, but some rocks were colonized by the *Brachidontes semilaevis*/*Balanus amphitrite* complex. The most common species in the mid intertidal were *Balanus amphitrite* and *Enteromorpha* sp. and *Bachelotia* sp. in the low intertidal.

At the Santa Elena Peninsula, Ballenita is a public watering place with hotels all along the border of the coast. The weather is tropical with a mean average temperature of 24°C. The intertidal is characterized by short, vertical, and unstable cliffs. The rocky platforms are inserted within the sandy beaches, and have a soft slope (Ochoa et al, 1987). Boothroyd et al. (1994) proposed that the low cliff originated from a system of barrier/littoral plain formed by

sand poorly cemented to the carbonates and clay. Wave energy is highest during the rainy season (Brito, 2014). The rainy season occurs in January-April followed by the dry season which extends to November-December (Ochoa et al, 1987). Precipitation varies from 62.5 to 125 mm (Ochoa et al, 1987).

Figure 5. Sampling sites in the Colombian and Ecuadorian Pacific. A. Colombia – Ñuqui/Choco. B. Colombia – La Ventana/Gorgona. C. Ecuador – Puntilla de Santa Elena. D. Ecuador – Ballenita.

The Puntilla de Santa Elena is within a marine protected area known as "Reserva de Producción de Fauna Marina Costera Puntilla de Santa Elena" or REMACOPSE. The intertidal here is irregular, with low vertical, unstable cliffs that continue at sea, emerged, for a few hundred meters. Between these formations, sandy beaches with coarse sand and steep slopes are found. The base of the cliffs are continuously eroded by wave action (Boothroyd et al, 1994; Soledispa, 2008). From the geological point of view, the most outstanding feature at La Lobería is the Cayo Formation, represented by sandstone, chert and silicified clays (Soledispa, 2008). Wave action is stronger than in the previous site and also highest during the rainy season (Brito, 2014). At the Navy Base, the Beach is characterized by medium size rocks covering a great extension that goes into the sea. According to Soledispa (2008), these lay directly on top of the Cayo Formation where deposits from the quaternary are found and composed by calcarean sandstone and conglomerates with abundant fossils. When the tide is low, numerous intertidal pools can be observed among the sand. Weather in this area is arid, with a mean annual temperature of 24°C, and precipitation, determined by the Humboldt Current, varies between 62.5 and 125 mm (Ochoa et al, 1987).

At these localities, a total of 66 species were found. These were mostly represented by molluscs (39%), macroalgae (24%), crustaceans (14%), cnidarians (9%), bryozoans (5%), echinoderms (5%), sponges (3%), and tunicates (1%). Ballenita had a higher number of species (30 species) in comparison to Puntilla de Santa Elena (19 species). The most diverse group were the mollusks (29 gastropod species plus 2 bivalve species) followed by macroalgae (9 species of rodophytes, 3 of chlorophytes, 3 of phaeophytes plus an unidentified species), and barnacles. The most abundant species were *Balanus amphitrite*, *Brachidontes semilaevis*, *Nodilittorina aspera*, *Nodilittorina paytensis* and one bryozoan. The dominant species in the high intertidal were *Nodilittorina aspera*, *Nodilittorina paytensis*, and the complex *Balanus amphitrite/Brachidontes semilaevis*, while the mid intertidal was dominated by *Pachygrapsus transversus*, *Echninometra vanbrunt,* and *Nerita funiculate;* and the low intertidal by *Nodilittorina aspera*, *Thais brevidentata*, *Padina* sp., and a bryozoan species. The vertical zonation was more evident in the high and mid intertidal which are dominated by littorrinid gastropods, barnacles and mussels (*Nodilittorina aspera*, *Nodilittorina paytensis* and the complex *Balanus Amphitrite*/*Brachidontes semilaevis*) as observed by Cruz (2009) and Brito (2014) at the Santa Elena peninsula. This pattern is dependant on the tide and time of exposure to air (Sibaja-Cordero and Vargas-Zamora, 2006).

#### *Peru*

The coastline of Peru extends for 2414 km along the Peruvian Biogeographic Province and is greatly under the influence of the Humboldt Current System, one of the major upwelling systems of the world (Miloslavich et al., 2011). SARCE sampled at seven localities, from north to south: Paita, Huarmey (Figure 6A), Ancón, Paracas (Figure 6B, 6C), Marcona, La Meca, and Punta Colorada (Figure 6D). The geological and physical conditions of these localities are very variable according to their origin and latitude, which ranges from a tropical warm province in the north, to a cold, sub-Antarctic province in the south. These changes are reflected in the composition of the intertidal flora and fauna.

In the north, Paita, located near the border with Ecuador, at the Panamic Province of the Tropical West Pacific is one of the most intense upwelling zones in the coast of Peru and characterized by high productivity (Fahrbach 1981, Huyer 1987, Grados 2002, Graco 2007). It is considered suptropical with very dry weather. Coastal diversity is high at these warm conditions (Ramírez et al., 2003), however, it is temporally affected by ENSO events (Paredes et al. 1998, Paredes et al. 2004), that produce the migration of some vertebrate species and the arrival of larvae or propagules of more tropical species. Sampled areas are relatively small beaches  $(\sim 100 \text{ m}$  in extension), exposed to wave action and located south of the bay of Paita. In this bay, 5 to 9 km from the sampling sites, functions the second largest port of Peru, dedicated mainly to fishing activities and transportation of agriculture products. The coast is characterized by black metamorphic rocks, over which Cretacic rocks can be found, mainly from the quaternary forming sandstones and cliffs of up to 50 m (Palacios Moncayo 1994). Tides are semidiurnal that may reach 1.73 m (HIDRONAV, 2012), and SST varies between 15-29°C (INEI, 2014), with the highest values in summer (February-March) and the lowest in spring (September-October). Paita is also under the influence of of the Peruvian Coastal Current which is characterized by cold Waters but also of tropical ecuatorial surface warm waters (Zuta & Guillen 1970, Cabrera et al. 2005). Very little is known about the biodiversity of these coasts. An abundant species is the barnacle *Pollicipes elegans* which is commercially exploited for exportation (Villena 1995, Oliva 1995, Pinilla 1996). Population density of this barnacle is very high during ENSO events, but after the event, population decreases significantly and is replaced by other invertebrates such as *Semimytilus algosus*, *Austromegabalanus psittacus* and *Balanus* spp (Kameya and Zeballos 1998). As for macroalgae, a total of 35 species were identified in the intertidal zone, of which 22% are considered to be endemic. This diversity is seasonal, decreasing during the winter or during other cold events such as La Niña (Benavente 1994).

In central Peru, the sites sampled at the Bay of Huarmey are exposed to wave action and located at 6.5-11.7 km north of the Port of Huarmey, important for mineral transportation and fishing activities. The rocky shores are part of the Casma Formation, from the late Cretacic, mainly volcanic spills of weathered andesite and inserted sediments. The weather is considered dry, subtropical desert, and tidal amplitude reaches 1.16 m (HIDRONAV, 2012). SST varies between 18-22 °C (Puerto de Chimbote, INEI 2014). Upwelling events are not frequent, but when they occur, SST may decrease to 15 °C (Berru Paz et al 2007). The most common species found in the rocky shores are *Fissurella* spp, *Polyplacophora*, *Pyropia* spp., *Chondrocanthus chamissoi*, which are also commercial species and monitored by IMARPE as artisanal fishing resources (Tam et al. 2007). The sites sampled at Ancón are within the area known as Volcánico de Ancón, which is characterized by pyroclastic rocks and volcanic andesites, typically metamorphic with plagioclases. Also a desert area, it was declared a natural protected area in 2011 along with the islands in front of the coast. The main port of Peru, El Callao, is located 33 km south of Ancón. Sampled sites are protected from wave exposure, tides reach 1.16 m, and SST varies between 14-22°C (Tarazona, unpublished). Upwelling events are frequent and generate hypoxia and even anoxia by the effect of bubbling from the bottom of sulphur compounds and other gases (Tarazona 1984, Tarazona et al. 1988, Tarazona et al. 1996). Biodiversity studies have been carried out since the 1970s (Paredes, 1974), and report 127 invertebrate species. The high intertidal is characterized by barnacles (*Jehlius cirratus* and *Notochthamalus scabrosus*) and littorinid gastropods (*Nodilitorina peruviana* and *Austrolittorina araucana*), the mid intertidal by a zone of mytilids in two bands, the upper band of *Perumytilus purpuratus* and the lower band of *Semimytilus algosus*, among macroalgae, and the low intertidal is characterized by *Austromegabalus psittacus* (Paredes & Tarazona 1980). Other spcies found in the intertidal are *Fissurella* spp., Polyplacophora, *Chondracanthus chamisoii*, and *Patallus mollis.* The locality of Paracas is located within the protected area known as Reserva Nacional de Paracas, the first marine reserve in Peru. The landscape is a coastal cordillera that reaches the sea forming cliffs of 50 to 400 m in height (Palacios et al. 1995). One of the sampling sites is located in the Ambo Formation from the Carboniferous, and the rocks are characterized by carbon sheets, which were formerly exploited. The other site is located on the Paracas Formation from the early Tertiary, characterized by phosphate sandstone and bentonites (Fernandez Dávila 1993). Both sampling sites are protected from wave exposure, tidal range is 1.12 m (HIDRONAV, 2012), and SST varies between 13 a 17 °C, however, at spatial scales of 1 to 2 kilometros, increases of up to 7°C may be observed due to water circulation and wave exposure in the bay (Romero 2000; Quispe et al. 2010, Moron et al. 1998). Intertidal fauna is represented by *Concholepas concholepas*, *Fissurella* spp., *Pyropia* spp., Polyplacophora, *Lessonia nigrecens*, among other species.

In the south of Peru, Marcona is an important area of mineral extraction, but also an area for the conservation of sea lions and pinguins (Punta Marcona). Rocky shores of the sampling sites are characterized by granitic formations from the Coastal Basal Complex, on which sedimentary rocks of the San Juan and Pisco formations have deposited sandstone of calcareous origin (Caldas Vidal 1978). These shores are exposed to wave action, however this is mitigated by a surrounding rocky reef. Tidal amplitude reaches 1.23 m (HIDRONAV, 2012) and SST varies between 12-24°C, with a marked seasonal pattern (Apaza & Figari

1999), and predominance of cold coastal waters. Upwelling events are common in this area (Rojas de Mendiola 1981). The most common species in these shores are the macroalgae *Lessonia* spp., *Macrocystis pyrifera* and *Pyropia* spp., and the invertebrates *Loxoechinus albus* and *Concholepas concholepas* (Galindo et al 1999). La Meca is located near the Wetlands of Ite, which were once heavily polluted by heavy metals from mining. Sampled sites are continuos rocky shores of sedimentary origin with sandstone and some volcanic outcrops from the Chocolate Formation of the coastal cordillera (Acosta Pereira et al. 2012). The sites are exposed to wave action but this is mitigated by rocky reefstidal range reaches 1.38 m (HIDRONAV, 2012) and SST is around 14 °C. This area is visited by artisanal fiherman extracting crabs (*Leptograpsus variegatus*), *Concholepas concholepas*, and macroalgae. The most southern locality is Punta Colorada, also characterized by outcrops of the coastal cordillera and some volcanic Rocks. The shore is exponed but some rocky reefs are also present. Between thes two localities, there are several artisanal fishing ports (Estrella Arellano et al. 1998).

#### *Chile*

The coastline of continental Chile extends over  $4200 \text{ km}$  (from ca.  $18^{\circ}\text{S}$  to  $56^{\circ}\text{S}$ ) encompassing from subtropical to sub-Antarctic waters (Santelices, 2001). The regular and relatively straight coast changes south of Chiloé Island (41°29'S) which is replaced by many gulfs, islands, channels and fjords. The rocky shores in northern and central Chile are mostly exposed to strong wave action (Thiel et al., 2007). Substratum is composed of rock of volcanic, granitic or sedimentary origin. Most of the coastal range consists of Jurassic and Cretaceous volcanic rocks (Fariña et al., 2008). Most of the coastline is influenced by the flowing Humboldt Current System, coastal upwelling and periodic occurrence of El Niño-Southern Oscillation (ENSO) (Thiel et al., 2007).

#### **Northern Chile: Iquique, Antofagasta and Copiapó**

This area represents one of the driest regions of the world, annual precipitation is extreme low (1 mm to 80 mm) with occasional rainfall episodes during austral summer, but no large differences between winter and summer exist (Schulz et al. 2011) (Figure 6E, 6F).

Species richness at Iquique, Antofagasta and Copiapó intertidal rocky sites was 41, 37 and 52 respectively. The high intertidal communities are dominated by the chthamalid barnacle *Jehlius cirratus* and the periwinkle *Echinolittorina peruviana*, occasionally small limpets *Siphonaria lessoni* and *Scurria variabilis* can be also found. Few macroalgae are present, mostly *Porphyra* sp. and *Pyropia* sp. The middle intertidal is dominated by the anemones *Phymactis papillosa* and *Anemonia alicemartinae,* the purple mussel *Perumytilus purpuratus* and macroalgae such as the ephemeral green alga *Ulva* spp. and the fleshy crustose brown *Ralfsia* sp., particularly in Antofagasta sites the middle and low intertidal are dominated by a dense turf of the red alga *Caulacanthus ustulatus* but in Antofagasta Bay extensive aggregations of the barrel-shaped tunicate *Pyura preaputialis* dominated the middle and low intertidal fringe, this is a non-indigenous species that affect the presence of native organisms (Caro et al. 2011). The low intertidal is dominated by a conspicuous belt of the kelp *Lessonia berteroana*, this brown alga is an ecosystem bioengineers and its holdfast provides habitat for high variety of small invertebrates (Vásquez & Santelices 1984), patches of the red algae *C. ustulatus* and *Corallina officinalis* var. *chilensis* are also present. At several sites the calcareous crusts of *Mesophyllum* sp. and *Lithophyllum* sp. dominates the

substrata, over the crusts several individuals of the snail *Tegula atra*, the black sea urchin *Tetrapygus niger*, the edible barnacle *Austromegabalanus psittacus* and the large mollusc *Enoplochiton niger* can be found. At shadow protected places, the sea cucumber *Patallus mollis* and the anemone *Phymactis papillosa* (mostly the blue morph) are quite abundant. Several filamentous algae can be also found at middle and low intertidal, such as *Centroceras clavulatum*, *Polysiphonia* sp. and *Ceramium* spp. In some places the brown algae *Colpomenia sinuosa*, *C. tuberculosa* forms patches of several individuals.

#### **Central-Northern Chile: Coquimbo, Los Vilos and San Antonio**

In central Chile, Mediterranean climate is predominant characterized by a winter rainy season and a dry period in summer. The ocean proximity moderates temperatures, averages between 10°C in winter and 17°C in summer can be found. Presence of snow and frost are rare, day-night oscillation is also lower. Species richness at Coquimbo, Los Vilos and San Antonio intertidal rocky sites was 58, 69 and 70, respectively. The chthamaloid barnacle *Jehlius cirratus* dominates the sessile communities at high intertidal. The mobile communities are dominated for *Echinolittorina peruviana* and the small limpet *Siphonaria lessoni*. Mostly fleshy crustose macroalgae are present, such as *Hildenbrandia lecanellieri*, *Ralfsia* spp. and patches of the lichen *Thelidium chilensis*. The middle intertidal is dominated mostly by beds of the purple mussel *Perumytilus purpuratus*, and red algae *Mazzaella laminarioides*, *Hildenbrandia lecanellieri* and the turf-forming alga *Gelidium chilensis*. The mobile organisms in the middle zone are dominated by small limpets such as *Scurria araucana*, *Scurria variabilis* and the pulmonate gastropod *Siphonaria lessoni*. The low intertidal zone is dominated in rocky exposed shores mainly by crustose algae such as *Lithothamnium* spp., *Hildenbrandia lecanellieri* and the articulate calcareous coralline *Corallina officinalis* var. *chilensis*. In lower proportion the mussel *Semimytilus algosus* can be found and a conspicuous belt of the *Lessonia spicata.* The most common mobile organisms in the low intertidal zone were *Scurria araucana, S. scurria* and the key holelimpets *Fissurella crassa* and *F. costata*. Several species such as *Perumytilus purpuratus*, *Gelidium chilense* and *Corallina officinallis* var. *chilensis* are considered ecosystem bioengineers and it loss can have significant changes in the community structure (Kelaher et al. 2007). On the other hand, is important to mention that in Central Chile a meso-scale eddy activity has been described (around 30ºS) (Hormazábal et al. 2004). Therefore expected differences in the structure of populations across this region can be found (Narváez et al. 2006).

# **Central-Southern Chile: Concepción and Valdivia**

This area represents one of the rainiest regions in Chile, where the annual precipitation is very high, reaching up to 1250 mm (average last 10 years = 847 mm) at Concepción and 2400 mm (average last 10 years = 1800 mm) at Valdivia, with constant rainfall episodes during austral winter (June-September), and also occasionally rainfall during spring, and even during austral summer (December-February) (Figure 6G).

Species richness at Concepción and Valdivia intertidal rocky sites was 48 and 52 respectively, the communities at the high intertidal are dominated principally by the chthamalid barnacle *Jehlius cirratus* and the littorinid snails *Austrolittorina araucana*, occasionally the small limpets *Siphonaria lessoni*, *Scurria scurra* can be also found.

Figure 6. Sampling sites in the Peruvian and Chilean Pacific. A. Peru – Huarmey. B. Peru – Paracas. C. Peru – Paracas. D. Peru – Tacna/Punta Colorada. E. Northern Chile - Huayquique. F. Northern Chile - Copiapo. G. Central-southern Chile – Cocholgue. H. Southern Chile – Fuerte Bulnes.

The middle intertidal is dominated by dense beds of mussels *Perumytilus purpuratus* and *Semimytilus algosus* covered by the red macroalgae *Mazzaella laminarioides*, and in some sites, the red macroalgae *Mastocarpus latissimus* and *Gelidium pseudointrincatum*. Among mobile species, the limpets *Scurria scurra* and *S. variabilis*, and the snail *Tegula atra* are common inhabitant in the middle zone. The low intertidal is dominated by the red macroalgae *Ahnfeltiopsis furcellata* and patches of *Corallina officinallis* var. *chilensis*. At several sites, the foliose green macroalgae *Ulva* sp. is also found. Over and into primary substrate

individuals of the snails *Tegula atra* (in some places assorted with *Prisogaster niger*) and *Acanthina monodon* are very abundant. At shadow protected places, the anemone *Phymactis papillosa* is quite abundant. Others species as the polychaete *Phragmatopoma moerchi*, the solitary ascidian *Pyura chilensis*, and the kelp *Lessonia spicata*, although less important in density, are considered important component on these latitudes because are considered ecosystem bioengineers, which may change significantly the surrounding community structure (Cancino & Santelices 1984, Sepúlveda et al. 2003a, 2003b).

#### **Southern Chile: Punta Arenas**

This area represents one of the most austral regions of the world, where annual precipitation is high, reaching up to 640 mm at Punta Arenas, with constant rainfall, snow and hail episodes during all year (Figure 6H). Winds are frequent and often exceed 100 km/h. The minimum temperature during winter can drop up to -2°C approximately (Butorovic 2013). Species richness at Punta Arenas intertidal rocky sites was 48. The communities at high intertidal are dominated by the barnacle *Jehlius cirratus* and the red macroalgae *Porphyra*  spp. and *Pyropia* spp., and over the primary substrate the small limpets *Siphonaria lessoni*  can be found in medium densities. In the middle intertidal patches of several macroalgae can be found, such as the coarsely branched *Nothogenia fastigiata, Mazzaella laminariodes*, the brown alga *Adenocystis utricularis*, *Ulva* sp. and filamentous of several Ceramiales species (e.g. the introduced species *Polysiphonia morrowii*), in this zone *S. lessoni*, and patches of *Perumytilus purpuratus* are also found. The low intertidal is dominated by the brown algae *Caepidium antarcticum* and *Lithophyllum rugosum*, however, the most conspicuous component are the gastropods *Nacella magellanica* and *N. deaurata*, which are found in high densities.

# **USES AND THREATS TO THE INTERTIDAL ROCKY SHORES IN SOUTH AMERICA**

The intertidal rocky shores around South America represent a valuable resource for local populations in many aspects. The main uses given to these shores along with the threats that such uses produce is summarized in Table 1. In general, localities with dense human settlements face the problems associated to urbanization and sewage discharges along with unregulated tourism, while in less densely populated areas, the uses are basically associated to the extraction of invertebrates and macroalgae for food. Industrialization (e.g. oil and gas extraction, mining) is another issue affecting the services that these ecosystems may provide.

# **The Caribbean**

In the Colombian Caribbean, besides populated human settlements, the main economic activity is tourism, so the marine environment is under pressure constantly due to these related activities and waste disposal. Exploitation of some resources also occurs, for example the snail locally known as Burgao or Cigua (*Cittarium pica*), lobsters (*Panulirus* spp.), the Caribbean king crab (*Damithrax spinosissimus*), various fishes (snappers, groupers),

octopuses and chitons (Lopez-Victoria et al. 2003). Due to the exploitation, sometimes exceeding sustainable population limits, several of these species have been allocated in different risk categories of red lists (Ardila et al. 2002, Mejia et al. 2002). In less densely populated areas such as Taganaga, next to the Tayrona Natural National Park, small fishermen villages (ca. 4000 people) have precarious sanitary services polluting the coast with untreated sewage.

In Venezuela, some of the threats to Venezuelan rocky shore's biodiversity are related to freshwater runoff, sedimentation, pollution, tourist pressure, oil spills and urbanization (Miloslavich et al., 2003; Paz-Villaraga et al., 2015). In particular, two of the most important sources of freshwater on the Venezuelan coast are the Tocuyo River, and the Tuy-Carenero Rivers system. The Tocuyo River discharges near Morrocoy National Park (Bastidas et al.,
1999), and the sediment plume of Tuy-Carenero system can be large enough to affect the rocky shores of Cabo Codera and Chirimena (Cedeño, 2009). Both rivers are highly polluted, they receive untreated water from a wide array of agricultural and industrial sources, and the discharge from drain sewage from urbanization and rural areas; including untreated waters from Caracas, the capital city of Venezuela. However, no correlations were found between the structure of assemblages associated with rocky shore and their relative distances to these rivers. It is very likely that other factors such as the selective collection, for human consumption, of gastropods, bivalves, and urchins could be affecting these communities. Some populations of invertebrates have shown an alarming decrease of their densities, which might be related to fishermen activities. Some of the gastropods in this situation are *Cittarium pica* and *Astraea tecta,* whose juveniles can be found on the low intertidal (Díaz-Ferguson et al., 2010). *C. pica* is the second gastropod most heavily fished in the Caribbean (Gómez-Gaspar, 1999; Miloslavich and Huck, 2009; Schmidt et al., 2002); however, there are no statistics available for this fishery (Robertson 2003) in the Venezuelan coast. When *C. pica* was present (7 of 31 sites), the diameter sizes ranged between 25mm and 40mm, which represented a clear diminution when compared to values reported in the Archipelago Los Roques National Park on 1987, where maximum size was 115 mm (Castell, 1987; Osorno et al., 2009). Also, this size is classified as small for *C. pica* in the Colombian Caribbean coast, Virgin Island and Puerto Rico (Schmidt et al., 2002; Robertson, 2003; Osorno et al., 2009). Minimum and maximum densities of *C. pica* were 0.4 ind/ $m^2$  and 1.2 ind/ $m^2$ , respectively; which is lower than densities reported by Castell in 1987  $(5.6 \text{ ind/m}^2)$ . Finally, despite intertidal rocky shores in Venezuela are not the principal touristic attraction on the coast, some of them (e.g. Peninsula of Paraguaná, Morrocoy and Mochima Nationals Parks, Patanemo, La Sabana and Chirimena) are visited by an important number of tourists, where random collection of shells and invertebrates is a common practice.

In Trinidad & Tobago, the rocky shore areas are very important for shoreline protection and they provide habitats for various species of fish, crustaceans, molluscs and macroalgae. Some rocky areas are very popular for recreational fishing and ecotourism. The main threats to biodiversity and the marine ecosystem in T&T is from land-based activities. These include expanding industrialization and urbanization (e.g., land clearing for housing etc.), and accompanying pollution and contamination (solid, liquid and gaseous wastes). As with the rest of the region, overfishing and unmanaged coastal development and agricultural practices also exacerbate these problems. More recently, extreme weather conditions reflected in increased rainfall during the wet season and extremely dry seasons (attributed to climate change) continue to result in increased flooding, freshwater runoff and sedimentation. Trinidad and Tobago is a highly industrialized country with 2 very large industrial estates involved in a range of activities dominated by the petrochemical sector. As the largest oil and natural gas producer in the Caribbean, Trinidad and Tobago's also houses one of the largest natural gas processing facilities in the Western Hemisphere. With 11 ammonia plants and seven methanol plants, Trinidad and Tobago is the world's largest exporter of ammonia and the second largest exporter of methanol, according to IHS Global Insight (2013). Trinidad and Tobago's coastal areas contain rich biodiversity reserves including productive and critical habitats- coral reefs, sea grass beds, estuaries, mangrove forests and coastal swamps, beaches and bays. These coastal areas account for approximately 90% of annual fish production. Fishing occurs throughout the marine environment around both islands, in estuaries, nearshore coastal waters and deep oceans. Today, the local fishing industry is largely

artisanal, based on resources occurring in the coastal and territorial waters, and is characterized by multi-species, multi-gear and multi-fleet operations (Fisheries Division, 2002). In 2005, the marine fisheries sector contributed \$63 million to the Gross Domestic Product (GDP). Other coastal and marine resources include crustaceans (shrimps, lobsters, crabs), cephalopods (squid), cetaceans (marine mammals including whales, dolphins, and porpoises) and sea turtles. Historically, T&T has not been a recognized tourist destination and as recent as 2010 T&T's contribution to the overall Caribbean was only 10.9%. It was estimated that on an annual basis approximately 33% of visitors to Trinidad and Tobago use the coastal resources (Tourism Development Company, 2010). Several beaches in Trinidad and Tobago (Pigeon Point, Maracas, Mayaro etc.) are very popular for recreation and tourism but it is the Buccoo Reef in Tobago which generates the greater tourism income (both local and foreign). The reefs provide livelihoods for a large portion of the local population through both fisheries and tourism (Burke, 2008). In 2006, the value of the reefs to recreation and tourism was estimated to be between US\$100 and \$130 million, or approximately 45% of Tobago's GDP for that year. At the same time, the value of the reef fisheries was approximately 0.8 to 1 million USD. The coral reef shoreline protection value was calculated at between US\$18 and US\$33 million in 2006 (WRI 2008). These ecosystem services (coral reef and rocky shores) are important to the island, at the same time they are most vulnerable to erosion and storm damage.

#### **The Atlantic**

In the region of Ceará in Brazil, the intertidal reefs are vital for many human populations established along the shore. Most of the small villages depend on the artisanal fisheries and tourism for subsistence, but the aquaculture has also gained importance in the last decades. The reefs play an essential role as nursery habitat for many fish species and also for the spiny lobster, the most important economic resource of the region (Igarashi 2010; Godinho and Lotufo 2010; Cunha et al. 2008). Tourism is a relevant source of income for the state's economy and is present in more or less intensity along the whole coast. In the last three decades, the development of tourism has followed what happened throughout the world, with an increasing number of tourists visiting especially the coastal zone, attracted by the warm water and constantly sunny days of the region (SETUR 2009; Aquasis 2003). The beachrock reefs in Ceará have been strongly impacted by human activities along the shore. The reefs closer to large urban areas, such as Caucaia, receive a large amount of pollutants carried by the rivers that run through farmlands, industrial districts and densely populated cities (Nilin et al. 2007). Locations outside the influence of urban areas are also under stress, because of the exploitation of algae for industrial use, mainly *Gracillaria birdiae* (Plastino and Oliveira 2002). Although not properly evaluated, the impact of algae exploitation is easily noticed when the areas are visited. As an alternative, the cultivation of the algae has been stimulated in different coastal communities, with variable degrees of success. Also, fishermen looking for young lobsters, crabs and especially octopuses, constantly visit these reefs. The strategy used by fishermen for capturing octopus is dislodging the animal with the use of chlorine or large amounts of salt thrown directly on the burrows or tide pools. Aquasis (2003) has presented and discussed extensively the importance of the state's coastal zone, pointing out the conflicts and problems with the management (or absence of management) at both local

and regional scales. The main problem is that rocky shores are one of the least studied areas of the Brazilian coast, and the northeast region as a whole is going through an accelerated process of development and increasing pressure over these coastal ecosystems.

At Sergipe, the coastal zone is a contrasting area, in which there are many activities, interests and conflicts, in a scenario that consists of urbanized areas, agricultural (sugar cane, orange and coconut), extractive, industrial and port activities, besides tourism and sale of properties. Moreover, this area is permeated by low density of occupation and occurrence of ecosystems of high environmental significance, but which have been subject of accelerated occupation, a tourism subproduct. This issue generates environmental degradation that hinder the practice of many activities, including tourism. Regarding the disorderly occupation, it noteworthy that 25% of the territory is coastal zone. Sergipe's coastal zone has extensive areas of mangroves associated with estuaries. However, mangroves have been the target of multiple human impacts, mainly shrimp farming and crab catching. In addition, mangroves and dunes are turning into garbage dumps, without any legal or environmental criteria in the area. Petroleum, natural gas, limestone and potassium (largest mine in the Southern Hemisphere) are the main products from mineral extraction, Sergipe is the 6th Brazilian state in oil production, following Rio de Janeiro, Rio Grande do Norte, Amazonas, Bahia and Espirito Santo. Pirambu is a new port area in the State comprising a large off-shore terminal operating primarily with petro and chlorochemical, besides being a vector to expand the economy and the tourism, it is also a potential environmental problem. The most important stressing factors on Sergipe rocky shores are the harbor presence, the trampling effects of tourists and shrimp and crab catching. Other stressing factors are the influence of the petro and chlorochemical industries, sewage pollution, and coastal erosion.

In Bahia, the main use observed at the rocky shores is trampling, especially for fisheries of octopus, sea urchin and fish. However, there is no sign of overfishing in these areas, as there were low numbers of fishermen and most was subsistence fishing by local communities. Even though all sampling sites are considered important touristic areas, there is no evidence of strong pressure in most sampling sites. Itaparica and Litoral Norte are the closest locations to Bahia state capital, Salvador, and thus a popular touristic destination. Tourism in Litoral Norte increased during the past 15 years with the construction of luxurious hotel complexes and the improvement of a state highway. During the holiday season it is common to see people walking on the rock shores. However, considering the number of visitors in that area, it is likely that the rocky shores are affected by trampling and fishing, but this needs further experimental tests. This is especially important in Litoral Norte as it provides feeding and resting habitats for adult and sub-adult green turtles (Jardim et al., 2014). Natural sedimentation is also common in Litoral Norte. Mar Grande (Itaparica location) and Praia do Sul (Ilhéus) are the most threatened sampling sites regarding pollution. Both are located close to urban areas and are subjected to urban runoff, solid waste and domestic sewage discharge. Even though Stella Maris is located in Salvador, it is not a high populated area when compared to the other parts of Salvador and not highly exposed to urban runoff and pollution. Ilhéus is the second largest city, among all sampling sites, with around 220 thousand inhabitants. Itacaré sites are inside an ecological touristic area with a relative low number of visitors. Thus, touristic pressure and water pollution and solid wastes, here, are not a threat.

Espirito Santo, in contrast to the Paraná State where ca. 68% of the territory is preserved by specially protected areas (APA), has only 2% of APA. Furthermore the coastal area of Espirito santo is out of the Conservation Units (UC). The most important stressing factors on Espírito Santo rocky shores, directly or indirectly, are tourism, sewage pollution, industrial complex presence (trading coffee, chocolate, edible oils, citric juices and cellulose), and a harbour complex that handles petrochemical (mainly oil and natural gas, being the second petroleum province in the country). Espirito Santo also encompasses the second largest ore mining dock in the world managed by Vale do Rio Doce Company.

In Sao Paulo, coastal land use and human impacts - The Baixada Santista, at the Southern end of the sampled coastline, is a major economic zone within São Paulo State and heavily urbanized area, which includes the cities of Praia Grande, São Vicente, Santos and Guarujá. Together, these cities sum up 1.6 million habitants, imposing severe impacts on the coastal environment. Particularly problematic is the Santos Harbour, the largest in South-America. Apart from a very intense traffic, the channel needs to be frequently dredged to allow the passage of large cargo vessels, further impacting the seafloor and the water column due to excessive siltation and suspended materials, including heavy metals and other major pollutants. Further north, socio-economical activities are leaded by tourism, although there is increasing pressure for the expansion of the São Sebastião Harbour. At the northernmost locality, Ubatuba, the coastal impact is relatively small, although the population has been gradually increasing. Today, the population in Ubatuba is around 85.000 habitants, and domestic sewage is already a major pollution source.

In Parana, the most important stresses on rocky shores communities are the trampling effects of tourists and fisherman, the selective collecting for food, oyster and crabs catching, and mussel seeds for cultures, sewage pollution and bio-invasions. All the sites studied receive a large amount of tourists every summer (from the end of December to the beginning of February) and weekends. Coastal environmental problems in the South also include unplanned occupation nearby the shoreline. Besides the destruction of the frontal dunes, the occupation invades the beach altering the balance of the whole coastal system. Trampling effects on the community have been studied only in one rocky coast at the southeastern region and a negative effect on *Chthamalus bisinuatus* was observed suggesting that the cumulative effect over years is significant (Ferreira & Rosso, 2009). Furthermore, the small towns at the coast double or triple their population during summer months and domestic sewage pollution and consequent eutrophication of coastal areas is certainly occurring, but the consequences to rocky shore communities are not known. The brown mussel (*Perna perna*) is the main item harvested both to be used directly for food, for commercialization or as seeds for cultures. The Brazilian government started a regulation since 2006 forbidding the extraction of this species from natural stocks from September to December each year and also regulating its extraction during the rest of the year. Although the brown mussel was supposedly introduced in Brazil from Africa (Sousa et al. 2004), it is well established in the intertidal community along the southeast and south Brazilian coasts. More recently the brown mussel belt has been invaded by another mussel, *Isognomon bicolor* (Adams, 1845), which forms dense aggregations in some sites in southeastern Brazil displacing *P. perna*, but that have not been so abundant in the Paraná and Santa Catarina coasts. We only found *I. bicolor* in one beach (Praia de Cima) during 2010 surveys and none in 2013 surveys. Also in the south of Brazil, the Paranaguá Harbor is the largest cereal port in Latin America, exporting mainly soybean, and the 3rd largest port of containers from Brazil, following Itajaí, a strategic zone to monitor alien or invasive species. The port area also presents serious problems of waste disposal. The presence of large ports along the south coast (Paranaguá, São Francisco, Itajaí and Imbituba) in addition to the extensive area of bivalve culture in Santa Catarina poses a constant threat of

species invasion in this region. During the surveys we found introduced barnacles at most sites visited, being *Megabalanus coccopoma* (Darwin, 1854) the most frequent, but also *Amphibalanus amphitrite* (Darwin, 1854) and *A. reticulatus* (Utinomi, 1967) (Kloh et al. 2013). In the Paranaguá Bay, *Ulva australis* (formerly known as *U. pertusa*) was detected as a free floating thallus. Monitoring is being carried out to confirm the alien species in the area.

In Uruguay, human uses of rocky shores are mainly recreational, although some species e.g. mussels) may be harvested by tourists or by a subsistence, small scale hand-gathering fishery and/or to be sold in local markets (Carranza et al., 2009; Scarabino, 2004). Extraction of the algae *Ulva* spp. may also occur associated to uses in local gastronomy, especially during the summer. Sport fishing (generally unregulated) are frequently observed in these sites, although some rocky shores are included in the National Protected Area System (SNAP). Commercial fisheries are restricted to subtidal mussel beds located at Isla Gorriti (34º57'S 54º58'W) and Isla de Lobos (35º0'S 54º53'W), targeting the blue mussel *Mytilus edulis* (Defeo, 1991; Niggenmayer and Masello, 1992; Riestra and Defeo, 1994). To date, threats to rocky shores biodiversity have not been evaluated at a national level. However, although not occurring in the intertidal, the invasive rapa whelk *Rapana venosa* is a matter of concern since this species preys mainly over mussels in the estuarine-oceanic interphase (Carranza et al., 2010; Carranza, Delgado, and Martinez, 2013). Other exotic species such as *Isognomon bicolor* (Breves et al., 2014) has been detected, but does not seem to have established so far.

In Argentina, the Buenos Aires province coastline is highly urbanized and harbors important ports. Playa Chica is located ca. 1.2 km of Mar del Plata Harbour (the most important fishing port in Argentina) and Quequén is located ca. 2 km m from Quequén Harbour. Both sites are subject to intense recreational use by summer visitors and pollutants associated to maritime traffic and urban runoff, such as policyclic aromatic hydrocarbons (PAHs), trace metals, and Tributyltin (TBT), all of which have been detected in their nearby ports (Marcovecchio et al. 1998, Bigatti et al. 2009, Albano et al. 2013). The Quequén site may also be impacted by a nearby (ca. 5 km) sewage effluent (López-Gappa et al. 1990). Río Negro is not very populated (El Espigón, Punta Colorada) and human settlements are mostly limited to small summer vacationing villages (La Lobería, Playa Los Suecos). Yet, the shipping of iron pellets from a loading dock in Punta Colorada might have contributed with pollutants to this area in spite that the dock in question was intermittently operational over the past two decades. In Chubut Province, Puerto Lobos is an artisanal fishermen place, with no evident contamination, and no ports are present. In Puerto Madryn, the local population is about 80,000 residents but in the summer season this number may duplicate due to the tourism. In this city, the 2nd port in importance regarding fisheries landings in Argentina is settled, as well as different industries in nearby the port. Pollutants such as (PAHs), organochlorinated compounds, trace metals and TBT are present in areas with intense maritime activity in Golfo Nuevo coasts (Commendatore et al., 2000; Esteves et al., 2006; Gil et al., 2006; Commendatore and Esteves, 2007; Massara Paletto et al., 2008; Bigatti et al., 2009; Commendatore et al., 2012). Imposex (masculinization of female gastropods) has been detected in the port zone but at a low frequency in the sampling sites. These are used mainly for tourism at Punta Este during the summer season. In Camarones, the population is around 1300 habitants and the port is used by fishing boats. Near the port, imposex and TBT contamination were detected (Bigatti et al., 2009), while the sampling sites far from this place are imposex free. The sampling site "Algueros" is a place of algae collection for industrial purposes, and the other places are used by tourist for recreation and sport fishing. At Puerto Deseado, near the port, where the maritime traffic is high, TBT contamination has been detected (Bigatti et al., 2009), however, TBT was not detected in the sampling sites. Recollection of the limpet *Nacella magellanica* is common within the local people. At Tierra del Fuego Island, Playa Larga is likely the most impacted by human activities due to its proximity to Ushuaia. This city is situated in the coast of the Beagle Channel and hosts the southern port of South America, characterized by intense maritime traffic. Contamination by TBT (Bigatti et al., 2009), PAHs (Esteves et al., 2006), metals (Giarratano et al., 2010) and sewage were detected at this area, and up to 100% incidence of imposex was observed in female gastropods.

#### **The Pacific**

In the rocky shores of the Colombian Pacific, the main resources exploited are lobsters (*Panulirus gracilis*) and fishes (snappers, groupers), however, some other species such as oysters (families Ostreidae and Pteriidae), and snails (families Littorinidae and Muricidae) are locally exploited. Another source of perturbation is the removal of rocks in the search for shrimps (*Upogebia* spp.) that are used as bait in fishing activities (Lopez-Victoria et al. 2003). The population density on the Pacific coast is very low in comparison to the Caribbean, with most of the shore basically uninhabited. In this way, human disturbance is localized and/or of low impact.

The rocky shores of Ecuador are used for urbanization, fishing, tourism, recreation, and marinas. Punta Gorda is relatively far away from human settlements and therefore, less impacted, but Punta Bellaca, more accessible was once a fishing ground for the lobster *Panulirus gracilis* and it is used sporadically at present by tourism. The main threats detected in the coast of Ecuador are sedimentation, pollution with sewage waters, diesel spills at the marinas, development of vacational complexes and unplanned human settlements.

In Peru, fisheries are a key component of the countries economy. Such fisheries are mostly pelagic resources, however, several species of the coastal zone are also fishing targets. At Paita, the barnacle *Pollicipes elegans* is commercially exploited and exported (Villena 1995, Oliva 1995, Pinilla 1996). Along the coast, there are several benthic species subject to artisanal fisheries in the intertidal including invertebrates and macroalgae: *Fissurella* spp, Polyplacophora, *Pyropia* spp., *Chondrocanthus chamissoi*, *Patallus mollis*, *Concholepas concholepas*, *Lessonia nigrecens*, *Lessonia* spp., *Macrocystis pyrifera*, *Pyropia* spp., and *Loxoechinus albus* among others (INRENA, 2002). At Paracas, subtidal artisanal fisheries also occurs (Mendo & Wolff 2003). Mining has been very intensive in Peru and some areas show pollution associated to mineral exploitation including heavy metals (Jacinto et al. 2001, Jacinto et al. 2003, Jacinto et al. 2008).

In Chile, the impact of human activities on the rocky intertidal has been studied extensively (see Fernández et al. 2000 and references therein). Several types of human impacts clearly affecting nearshore ecosystems can be identified along the coast of Chile, although the intensity, extent, and persistence of these sources vary geographically (Fernández et al. 2000). One of the most important human impacts along the Chilean coast, in terms geographical extent and persistence, are sewage discharges and the harvesting of invertebrates and algae in rocky shores (Gross & Hayek 1998). The removal of several

important ecologically species during low tides have a dramatic effect on the structure of the intertidal communities. Historically, intertidal populations were exploited as a food resource but in modern times, flora and fauna are also collected for fish bait, for research, as souvenirs, and for home aquaria uses. A keystone muricid gastropod *Concholepas concholepas*, locally known as "loco" is intensively targeted by food gatherers affecting the functioning of food webs at intertidal rocky shores (Castilla, 1999). The increasing international demand for brown large macroalgae and local requirement as food for abalone aquaculture has caused deterioration of natural kelp populations along the rocky shore in Chile, especially between 18° and 42°S (Vega et al. 2014). Impact of non-indigenous species have been poorly documented, some species have displayed an expansion of their geographical range and increasing of their abundance, such as the anemone *Anemonia alicemartinae* (Hausermann & Forsterra 2001) and the red alga *Mastocarpus* sp. (Macaya et al. 2013). Together with exploitation of marine species, sewage discharges are important in geographical extension and persistence having an impact along the Chilean coast (Fernández et al. 2000).

## **GAPS IN OUR KNOWLEDGE AND FUTURE PROSPECTS**

Knowledge of the intertidal rocky shore ecosystem is very variable among the different South American countries, and also between different areas within each of the countries. While some countries seem to have a long tradition of research in these ecosystems (e.g. Chile), other are just beginning to study them (e.g. Venezuela). In the Southern Caribbean, rocky shores remain virtually unexplored, despite the high diversity that these ecosystems support (Miloslavich et al., 2010). For example, in Venezuela, most of the research articles on these ecosystems are non-published descriptions or informal inventories about the fauna and algae that inhabit them. Few studies have considered quantitative description of patterns of temporal and across different scales, which would allow proposing underlying mechanisms that drive assemblages associated with intertidal rocky shores (Cruz-Motta, 2007). Furthermore, the total number of scientific publications for this ecosystem is the lowest for coastal and marine ecosystems of Venezuela (Miloslavich et al., 2003). Consequently, describing patterns and determining processes affecting assemblages associated with Caribbean intertidal rocky shores is still a prevailing necessity. Caribbean rocky shores harbor an important biodiversity, however their economic benefits and ecosystem services are still poorly studied and understood. Threats to biodiversity in this ecosystem, and other coastal ecosystems, are imminent; therein lies the importance not only of knowing their biodiversity, but also of monitoring the ecosystem to be able to understand their patterns and processes, their connectivity to other coastal ecosystems, the population dynamics of key species, and finally to have the necessary knowledge to transfer to policy makers so they can take scientifically based informed decisions.

There are several limitations to achieve these goals. The first of them is the funding required to go to the field on a yearly basis, and the commitment to do so, especially at such large geographical scale like the one presented in this chapter. Initiating a long term time series is not an easy task. The second is related to human capacity. The team required to produce quality information is quite complex, with background in marine ecology, biology, taxonomy, genetics, fisheries, and oceanography to mention a few. This expertise is rarely

found altogether within a same country, therefore, the importance of establishing and collaborating within the umbrella of an international network. Initiatives like SARCE, and previously NaGISA of the Census of Marine Life, have contributed significantly in the region to increase our understanding of these important but traditionally neglected ecosystems.

Finally, for all the South American region, the use and abuse of the rocky intertidal resources has been intensive during the last years, needing a full re-evaluation of the human impacts along the South American coastline, in order to demonstrate the need for conservation of these ecosystems. The implementation of marine reserves and laws aimed to halt the collection of organisms has proved to be successful in some areas but ultimately depends on the enforcement of the laws and compliance by the public (e.g. Chile). Even, if collecting is stopped through enforcement, other impacts of human use, ranging from local and specific activities such as trampling or overturning of rocks to large scale impact such as pollution and climate change, still persists. Therefore, effective protection of rocky intertidal communities will require an approach that may need to go beyond the singular focus on collecting to reduce the full suite of impacts (Smith et al. 2008).

## **ACKNOWLEDGMENTS**

SARCE was sponsored by TOTAL Foundation through the project Marine diversity and biomass assessments on coastal ecosystems in South America: Ecosystem function, monitoring, and human impacts. We thank the editor, Rafael Riosmena-Rodríguez, for inviting this chapter to the book.

## **ABSTRACT**

*Acanthophora spicifera* is a red alga, native to the Caribbean, was introduced to the Hawaiian Islands in the early 1950's, where he Invasive catalog. His success as an invader is attributed to having the ability to reproduce both sexually and vegetatively by fragmentation or by spores. Their growth is accelerated and invades Pacific coral reefs. Prevents nutrients and sunlight to penetrate these ecosystems producing that reduce populations of resident seaweeds and corals. In Punta Roca Caimancito, BCS, a blanket of *A. spicifera*, which formerly dominated the brown algae of the genus Sargassum found. The temperature at which develops in Punta Roca Caimancito was 20-29. It can be found growing on a variety of substrates epilithic hard rock, dead coral or shells, even as an epiphyte on other species of macroalgae or epizoica invertebrates. They have a simpodial and apical growth, presents secondary branches, has a rough or rough texture, has a disk-shaped, in its main axis no thorns. It is characterized by a highly branched and bushy, leafy thallus. Apical meristem, spines of 3 mm, which may vary morphologically.

 $\overline{a}$ 

<sup>\*</sup>Corresponding Author's Email: sissivalerie@hotmail.com.

In cross-section was observed that pericentral cells are dense. Commonly axial cells in the center. In the study area this invasive alga reproduces asexually (fragmentation). The extension of the mantle in Punta Roca Caimancito of has continued to increase since 2006 in which you registered for the first time. The current extension (2009) is  $31536.93m<sup>2</sup>$  or 3.16 Hectares. The maximum average biomass dry weight was 8.12 t/ha and 3.16 minimum 1.18 Ton/3.16 h. The color varies from brown to red. The average length of the thalli was 163 mm and 108 mm maximum minimum in the period October 2008 to October 2009. The annual average was 154 mm. The ANOVA showed differences between different months being October others to present longer that season. The maximum number of branches value was 7 and at least 5 branches per thallus. ANOVA performed for the numbers of branches not show significant differences. The average monthly number of spines has a maximum value of 5.4 mm² and a minimum of 3.9 mm². The ANOVA shows differences per month, October being the one with the highest number of spines. The biomass is higher in the autumn season. And in winter drastically reduces the population. The average of the highest biomass is  $0.26 \text{ kg/m}^2$  and was presented in November; the minimum dry weight biomass was presented in February  $0.0375 \text{ kg/m}^2$ . The average annual biomass dry weight is  $0.29 \text{ kg/m}^2$ . The flora and fauna that was associated with A. spicifera goes from epiphytic algae molluscs, echinoderms, sponges to fish. The maximum monthly average was  $0.20 \text{ kg} / \text{m}^2$  and a minimum of  $0.031 \text{ kg/m}^2$ . The result of the correlation indicates no relationship between biomass and plant-fauna (r = -0.1892.). We conclude that *A. spicifera* its development at temperatures ranging from 20-29°C. Morphological characters posing *A. spicifera* of Punta Roca Caimancito are similar to those reported by other authors. The main mode of reproduction of *A. spicifera* is asexually by fragmentation and occurs all year round (perennial). Sexual reproduction was limited in spring-summer, only empty conceptáculos were observed. Presents greater lengths during autumn and lower in winter. The number of spines is not related to the length of the branch. The maximum number of branches was  $\overline{7}$  in autumn and winter and minimum of 4 branches per talo in summer. The maximum number of thorns thorns was 5.4 mm-2 and the minimum was 3.9 mm-2 spines. The percentage of wet weight biomass of A. spicifera is greater in autumn with 3.50 kg/m2 and the lowest was in winter with  $0.59 \text{ kg/m}^2$ . The percentage of biomass dry weight of *A. spicifera* is greater in autumn with 0.86 kg/m<sup>2</sup> and the lowest was in winter with 0.0375 kg/m<sup>2</sup>. The impact of *A. spicifera* in Punta Roca Caimancito is negative for coral reefs because high densities of this alga can affect the uptake of light and nutrients and thus affect their growth.

## **INTRODUCTION**

Invasive species play an important role in marine and terrestrial ecosystems, and damaging to native species and move. Within this theme different definitions that must be understood are handled, the first is naturalized, it relates to non-native species that were established in the region. The second definition is the invasion that has been used for the species has become naturalized and has spread widely in the region. And last and most important invasive species refers to any species that occupy a region in which it was not historically present (Sax et al. 2005).

Invasive species have always been a controversy around the world, because as the name says, invading regions and affect native organisms. This occurs both on land and in the marine environment. Within the marine environment have been studied invasive species in much of the world's oceans (Carlton et al. 1990; Shiganova 1998; Godwin 2003; Work et al. 2003).

#### **Ecological and Economic Impact of Marine Invasive Species**

Alterations of ecosystems caused by global climate change with introduced species are the result of biotic homogenization; this is a process by which ecosystems dominated dominant species and opportunists. This pattern has always been observed in localities affected by environmental degradation and invasive species (FAO 2010).

The ecological impact of non-residential marine groups has been observed in some ecosystems in the Bay of San Francisco on the Asian clam *Potamocorbula amurensis*, Schrenck 1861, which was discovered in 1980 in North America, is characterized by be an invasive species that has colonized freshwater bodies in many countries in Europe and America. This produces major environmental and economic problems as it has a great ability to reproduce. Studies have been done in Portugal where they say this clam sequesters carbon and alters the channel and ecosystem functioning, also presents risks of mass mortality from sudden changes in temperature (Carlton et al. 1990; Godwin 2003).

Another invasive species such as jellyfish *Mnemiopsis leidyl*, A. Agassiz 1865 in the Black Sea, feeding on eggs and larvae of fish and has been a fall in stocks of economic importance (Shiganova 1998).

Among vertebrates, the fish Lutjanus Kasmira, Forsskål 1775, is an invasive fish from the 1950 in the Marquesas Islands belonging to the French Polynesian. Its introduction was intentional and harmed native reef fish (Work et al. 2003; Godwin 2003).

Finally the starfish Asterias amurensi, Djakonov 1950, was discovered in the year 1980 in Tasmania, Victoria and South Australia. A. amurensis has the potential to create large populations in new areas. It is a threat and is considered a pest because it caused the decline of fish belonging to Hand Brachionichthyidae Family. Also in mariculture has mainly played havoc in cultured mussels, oysters and salmon (Godwin 2003; Dommisse et al. 2004).

#### **Impact on Coral Reef**

Coral reefs are an important ecosystem as it forms part of the habitat of many organisms and is one of the most productive in the world. These ecosystems can be composed of reef zones, barriers, patches or atolls. Coral reefs are a potential attraction for tourists and are important because they form a natural protection and prevent the erosion of the waves on the coast.

The economic value of reefs is considerable. For example, in Indonesia the annual contribution of these ecosystems for tourism is 191 million dollars, 221 million dollars fishing health and \$ 4.8 million dollars, making an annual total of 327 million dollars. Also in Hawaii fisheries in these ecosystems generates 2.5 million annually, tourism \$ 304 million, and the value of biodiversity is around \$ 17 million. Therefore, coral ecosystems in this region generate an annual total of 363.5 million dollars (Cesar et al. 2004).

Currently, coral reefs are being depleted rapidly in many parts of the world due to factors such as illegal fishing, coral mining, marine pollution and sedimentation. Another important aspect that affects the reefs are invasive species such as the red alga *Acanthophora spicifera* (M.Vahl) Børgesen 1910, this like the others mentioned aspects contribute to the decline of coral reef ecosystems where it has invaded.

One effect of A. spicifera on coral reefs is competing for light and nutrients associated with corals and algae. On the other hand, industrial pollution (chemicals and industrial wastes) is an anthropogenic factor that contributes to the deterioration of coral reefs (Cesar 2002).

#### **Economic Importance**

It has now been recognized that biodiversity and marine resources of the world are threatened by human activities influence. In particular, overfishing and climate change have produced an alteration and destruction of habitat. Invasive algae are increasingly popular because they often have dramatic effects on ecosystem structure and function (Schaffelke et al. 2007).

Globally about 221 species of algae of commercial importance, of which 145 are used for food, for production of phycocolloids 110 (agar, carrageenan, acids, alginic) are known. Some algae are only used for direct food source and you are *Ulva* Linnaeus, 1753, *Caulerpa*, J.V Lamouroux, 1809, *Codium* Stackhouse, 1797, *Pyropia* J.Agardh, 1899 *Laminaria* Lamouroux, 1813 and *Undaria* Suringar, 1873 (Khan et al. 2003).

In countries like Japan, China, Chile, Indonesia, USA have also been used for pharmaceutical or nutritional studies. In this case, the chemical substances extracted from seaweed are used to treat diseases. While nutrition, are used as a food supplement and as part of the diet of many organisms.

Food additives are also extracted as carrageenan, agar and alginates (phycocolloids) these are the most traditional uses of algae. The red seaweed *Digenea* C. Agardh, 1822, produces an acid derived from glutamic acid, which is used as a central nervous system stimulant, the prototype of amino neuroexcitation used in experimental animals. Other red algae as *Ptilota* C. Agardh, 1817 produce a protein called lecithin. Asparagopsis Montagne in Barrer-Webb and Berthelot, 1840 *Sarconema* Zanardini, 1858, are used to control goiter is iodine deficiency (Khan et al. 2003).

The seaweed production has increased in the past twenty years and has reflected an overall increase in trade and economic activities. This production is currently given in 35 countries among which we can find North Korea, South Korea, Japan, China, Chile, Indonesia, United States and India. These countries account for 95% of world production of algae and 90% of production comes from crops. Annual earnings for algae production globally is estimated between \$ 5.5 and \$ 6 billion. The total of the products consumed by humans is \$ 5 trillion. 7.5 An annual production of 8 million tons of wet weight, either algae extracted from wild and cultivated is obtained (Pickering, et al. 2007; Schaffelke et al. 2007). The brown algae are the most widely grown with over 5 million tons, while red algae approximately 1 million tons are produced annually and finally green algae with approximately 33,700 tons per year. The algae is cultivated kelp *Laminaria japonica* J.E Areschoug, 1851, production of this alga constitutes 60% of the total, the rest is for *Pyropia*  and *Kappaphycus* Doty, 1988, *Undaria* Suringar, 1873, *Eucheuma* J. Agardh, 1847 and *Gracilaria,* Greville 1830. *Pyropia* is one of the most grown in China and its production

generates \$ 1.8 billion annually (Mumford et al. 1988). Philippines contribute about 80% of the production of *Eucheuma* Weber-van Bosse cottoniicon, 1913 which equates to 130,000 tons per year (Khan et al. 2003). Khan et al., 2003 mentions that between 1981 and 2000 the production of aquatic plants increased from 3.2 million tons to 10.1 million tons of wet weight. By 2000 world trade in seaweed left an economic impact of \$ 6 billion, while in 1990 it was only \$ 250 million (Khan et al. 2003; Valentine et al. 2003).

## **Algae Introduced**

The assessment of the ecological impacts of invasive species has been recognized as a research priority in recent years (Johnson et al., 2007). The impact of invasive algae has been identified as one of the major stressors in coastal ecosystems. A recent study in Hawaii confirmed that the economic impact of invasive species is higher than \$ 30 million dollars per year (Schaffelke 2007). However, relatively few studies on the impact of invasive algae in relation to marine animals (Johnson et al. 2007).

Currently there have been over 260 species of introduced algae. Current key impacts of invasive algae have spread to other taxa. It is believed that invasive algae are potentially destructive and can cause a potentially serious impact, which can alter ecosystem structure monopolize space. Particularly worrying is its rapid spread is the effective spread, along with significant environmental and economic consequences (Schaffelke 2007).

Documented impacts of invasive algae are really few. As is the case of *Caulerpa taxifolia* (M. Vahl) C. Agardh, 1817, this alga was documented as invasive in the Mediterranean since 1980. *C. taxifolia* was introduced into the Mediterranean through the wastewater from the Oceanographic Museum in Monaco where he was planted aquarium purposes. Currently covers more than 13,000 hectares of seabed in this region and directly affects all the other vegetation and algae, especially Posidonia. But go slowly eliminating native vegetation indirectly so does the wildlife that feed or live in that environment (fish, sponges, sea urchins, and other less mobile) (Anderson 2005)

*Codium fragile* Suringar, 1867 is kind is known worldwide and has had an easy reproduction (asexual) and may displace other native algae and crustaceans, polychaetes and tunicates (Trowbridge 1999).

*Sargassum muticum* (Yendo) Fensholt 1955, is an invasive species native to the coasts of China-Japan and the Pacific Northwest. Its primary means of dispersal have been boat and floating pieces of sticks, has a rate of growth and high fertility. It also produces the displacement of other native species (Harries et al. 2007).

*Undaria pinnatifida* (Harvey) Suringa1873 r is native to Asia and now invades the coastal zone in many countries around the world. In 1971 he was found in the Mediterranean later in the Atlantic Ocean in Britain and subsequently settled in UK, Spain, New Zealand, Australia, Argentina, and the North Pacific Ocean (Martin et al. 2008; Russell et al. 2008). The shipping traffic is perhaps the most important vector of accidental dispersal of the species, which can be introduced into new geographic areas. This can be carried attached to the hulls of ships as well as spores in ballast water. In summary, invasive algae have been great and dramatic changes in marine ecosystems, as you move through geographical or ecological barriers and displace residents algae (Kilar et al. 1986; Martin et al. 2008 ; Valentine et al. 2003).

#### *Acanthophora spicifera* **an Invasive Seaweed**

*Acanthophora spicifera* was introduced to the Hawaiian Islands in the early 1950's, and was classified as invasive. Today it is one of the most common in this archipelago. Successful Invasive Acanthophora is attributed to having the ability to reproduce both sexually and vegetatively by fragmentation.

The advantages that may have reproductive capacity are: (1) the extent of distribution of the species, (2) increase in the abundance of organisms and individual biomass and (3) colonization of areas where the sexual propagules have a high mortality rate. Plus it plays throughout the year. Pacific reef is in constant competition with the resident marine algae such as Laurencia spp. and Hypnea cervicornis. It is characterized by epifitar different taxa including invertebrates and other algae such as *Laurencia* (J.V Lamouroux 1813) *Gracilaria* (C. Agardh) Greville 1830), *Padina* ((Linnaeus) Thivy in WR Taylor 1960), *Caulerpa* ((Forsskål) JV Lamouroux 1809), *Halimenia*, and seagrasses, *Halodule* Den Hartog. Has a wide adaptability to environmental conditions.

In the last three decades have presented two important negative alterations are invading seaweed 1) threat in the coral reef habitat by preventing the growth of corals and other photosynthetic organisms in the absence of light and given its high abundance also affects recruitment, biodiversity and sustainability of the structure of reef ecosystems, 2) at the periphery of mangroves creates a barrier that directly affects water quality and flows, ie, decreases the wave propagation and this affects the entire biota (Smith et al. 2002; Walters et al. 2002; O'Doherty et al. 2007; Schaffelke et al. 2007; Tsuda et al. 2008; Weijerman 2008).

Another important aspect is that *A. spicifera* not only cause negative effects where it has been introduced, as has also been found to be a source of food for the green turtle, *Chelonia mydas* (Linnaeus 1758), herbivorous fish and sea urchins crustaceans (Kilar et al. 1986; Russell 2003).

In an experimental study in Kaloko Honokohau, Hawaii in 2005, he tried to control *Acanthophora* using herbivorous fish. The obtained results showed that the introduction of herbivorous fish can reduce the biomass itself *Acanthophora* but for better control, biological suggested combining this method with a regular manual removal (Weijerman 2008).

The main objective of this work was to identify and investigate the phenology, biomass and reproductive aspects of *A. spicifera* Punta Roca beach Caimancito Bay of La Paz, BCS providing critical information to their taxonomy, ecology and reproduction in a new ecosystem is invasive algae.

#### **Description of Genus**

Genus of Acanthophora (J.V. Lamouroux 1813) is within the Phylum Rhodophyta in *Chondrieae* tribe. This is one of the oldest groups of eukaryotic plants.

Within this class we find about 4000 species (Guiry et al. 2010; Lee 2008). Genre *Acanthopho*ra described 27 species of which only 6 have been taxonomically recognized as: *Acanthophora aokii* Okamura 1934 *Acanthophora dendroides* Harvey1855, *Acanthophora nayadiformis* (Delile) Papenfuss 1968 formerly *Fucus navadiformis* (Delile 1813), *Acanthophora pacific* (Setchell) Kraft 1979 *Acanthophora ramulosa* Lindenberg ex Kützing 1843, and *Acanthophora spicifera* (M.Vahl) Børgesen 1910 (Cecere 2002).

#### **Description of the Species**

One of the unique features of *Acanthophora spicifera* is that the main shaft has no thorns. They are upright plants that grow up to 250 mm, with solid cylindrical branches 2-3 mm wide. (Oliveira et al. 2005) Some branches are short and have irregular shapes with numerous spines that are arranged radially. The apical growth is present, grows attached to a hard substrate with a long and irregular bra which arise many erect spines. In deep water, where there is less water movement, they are smaller and can measure 40-100 mm long, are rather compact and very dense thallus. Compared with specimens from shallow water, where the petals are 100 to 250 mm and more open branches. The coloration of this alga can vary, it is usually red but can see in the following colors: purple, the Yellow, orange and brown. The greater the depth the algae will be darker. In shallow areas the color is lighter or sandy color. *A. spicifera* is abundant in shallow calm waters, reefs, intermediate and low intertidal rocky areas. Usually lives embedded in hard substrates such as rocks, mollusks and corals. Can also be found fragments of alga are floating freely in the water column. As for structural characteristics, must be the apices are pyramidal with trichoblasts. Pericentral cells are dense and Corticadas, axial cells are commonly in the middle. *A. spicifera* commonly associated with other algae that are more tolerant to exposure of the tide and are able to retain water when exposed to air (Kilar et al. 1986; Perrone et al. 2006).

#### **Geographical Distribution**

*Acanthophora* members of the genus are found in all latitudes from Ecuador to the coldest seas. The mean sizes of algae are varied depending on the geography of the region. The more fleshy species usually occur in temperate areas, while in tropical areas can find smaller and filamentous (De Reviers 2003; Lee 2008).

#### **Floristic Records of Algae**

Since the last century there have been collections of marine algae in the Gulf of California (Dawson 1944). Although no taxonomic studies of macroalgae made almost over 260 years in the Gulf of California, in any of them referring to the presence of *Acanthophora spicifera* in the Gulf of California is made. (Howe 1911; Setchell and Gardner 1924; Dawson 1953; Dawson 1966; Norris 1972; Norris 1975; Mendoza-Gonzalez and Mateo-Cid 1986; Martinez-Lozano et al. 1991; Mateo-Cid et al. 1993; Serviere-Zaragoza et al. 1993; Mateo Cid et al. 1994; Casas-Valdez et al. 1997; Serviere-Zaragoza et al. 1998; Rodriguez-Morales and Siqueiros-Beltrones 1999; Aguilar-Rosas et al. 2000; Paul Chavez and Riosmena-Rodríguez 2000 and Aguilar-Rosas et al. 2002). For this reason, it is necessary to perform extensive sampling of this species in the Gulf of California, in order to have further evidence of its distribution in the Gulf of California. In 2006 *A. spicifera* it began observing in the Gulf of California and has been dispersed in shallow areas. *A. spicifera* could harm local flora decreasing coverage and biomass of these.

In the Bay of La Paz *A. spicifera* associated with rocky reefs where we can observe that the forests of *Sargassum* area residents, which exhibit rapid growth, may be observed

displaced. *Acanthophora* has been established at points where could financially affect residents because fishermen associated commercial fish are extracted *sargassum* forests. So it could also be endangered coral reefs because they can take to prevent sunlight necessary for their development. This event directly affect the fish that live there, also disturbs the attraction also directly harm the regional economy (Riosmena et al. 2009).

*Acanthophora spicifera* alga is a native of the Caribbean and now has spread throughout many tropical and subtropical marine ecosystems. In the Hawaiian archipelago this alga was introduced by ships since the 50`sy is considered an invasive species that has caused severe impacts on the ecosystem.

Figure 1. a) Image of the Baja Peninsula where the Bay of La Paz, Baja California Sur, Mexico b) Caimancito Punta Roca beach that lies between the Coromuel (1) and Costa Baja beach (2), c) location is located study area, Beach Punta Roca Caimancito (TP1) transect parallel to the coast line (TP2) transect perpendicular to the shore line.

However, recent studies indicate that this alga has the Mexican Pacific coast come (Riosmena-Rodriguez et al. 2009) no research has been about their adaptive capacities and the effects it has on the ecosystem. This alga is found in parts of the Bay of La Paz (southwestern Gulf of California). Therefore it is essential to study some aspects of its life cycle as their type of reproduction (sexual and asexual), biomass, distribution and behavior of the same in the marine environment as it can be harmful to many organisms. An example is the coral reef as was mentioned harms the ecosystem along with all the associated species.

The aim ofthe work was establish the phenology reproductive, estimate the variation in the biomass an annual cycle, and other aspects of *A. spicifera* in the Bay of La Paz, BCS, Mexico.

## **Study Area**

The Bay of La Paz (Figure 1a) is a semi-protected body of water that is located on the south eastern side of the peninsula of Baja California. It covers approximately  $2635 \text{ km}^2$ , has an oval shape with a width of 35 km and 80 km long and is separated from the Gulf by a narrow peninsula. Its depth can vary from 10 m to 450 m.

It also presents a system of mixed type semidiurnal tide with a higher level at 1 m during spring tides (Obeso-Fog et al. 2008). Caimancito Beach Punta Roca (Figure 1b) is in the extreme southwest of the Bay (24º12'07.36 "N and 110º18'03.10" W), between the beach and the Coromuel Costa Baja (figure 1c). It is characterized by a shallow area of sandy bottom with patches of rock. On this beach you pass a deep channel through which water enters and leaves the Ensenada de La Paz. This beach has waves of very low intensity and algal community is located at shallow depths (<2 m) (Figure 2) (Ceseña-Arce 2003).

## **MATERIALS AND METHODS**

In the study area where Caimancito Punta Roca A. spicifera distributed randomly placed two quadrants PVC 25x25 cm (0.0625  $m<sup>2</sup>$ ) at a distance of 20 m from each other at a depth of 1.5 m. Within each quadrant all thalli of *A. spicifer*a present, and associated organisms (flora and fauna) were collected. The material was placed in plastic bags previously labeled.

Then, in the laboratory of Marine Botany UABCS partner agencies separated this invasive macroalgae and weight (g) of each taxonomic group with an analytical balance (Chyo JL180) was obtained. Subsequently, *A. spicifera* samples were dried in an oven (VWR-1350F) at  $60^{\circ}$ C to obtain the dry weight (g). With these data, the biomass (g. dry weight m-<sup>2</sup>) *Acanthophora* and partner agencies estimated. Furthermore, in the study area were collected randomly from 20 thalli *A. spicifera* with which the average maximum length (mm) was determined as the average number of branches (number of branches per thallus) and the number of spines per branch, the average of each side branch with thorns (number of spines per linear mm of secondary branches) was taken. The average number of spines in three heights of the plant (apical, middle and bottom) was also compared. These measurements were made in order to determine whether the structural complexity of the plant varies over thallus and also temporarily.

Figure 2. Mantle *Acanthophora spicifera* at Beach Punta Roca Caimancito, BCS.

Figure 3. Seasonal variation of temperature (ºC) and salinity at Punta Roca Caimancito.

This allows us to pursue a relationship with the diversity and abundance of associated organisms. It was also noted if the thalli containing reproductive structures, for this three transects along the talus was performed and a sample of each side ie top, middle and base took part. The cuts were applied aniline blue staining in order to have a better resolution of the reproductive structures. Observations were made under a light microscope (Olympus CX31, CX40) with a resolution of 10, 20 and 40 X, and pictures of the different structures were taken with a (Olympus, Model C-4040ZOOM) digital camera.

The frequency of these samples was monthly within the study area, October 2008 to October 2009. Only in December 2008 did not sample.

## **RESULTS**

#### **Environmental Conditions**

A maximum temperature of 29°C in the months of October 2008 and July and August 2009 and a low of 20°C in the month of January 2009 (Figure 3) was recorded. While the higher salinity (37) was recorded in April and July 2009 and the lowest (34) in February (Figure 3).

## **General Features and Morphological of Punta Roca** *Acanthophora spicifera* **in Punta Roca Caimancito**

In Punta Roca Caimancito, an extension of the mantle (Figure 4) of Acanthophora has continued to increase since 2006, when it was first recorded in this area. The current extension (2009) is  $31536.93$  m<sup>2</sup> or 3.16 hectares.

Figure 4. a) Mantle *A. spicifera* Punta Roca Caimancito over time. In b) shows the area before the onset of *A. spicifera* in 2004 and 2005, one can observe a lower density of various algae. c) In 2006, first observed at Punta Roca *A. spicifera* Caimancito d) shows how the mantle has increased in the last year (2009) sampling Caimancito Punta Roca.

## **Table 1. Flora and fauna associated with** *A. spicifera* **in Punta Roca Caimancito**

The estimated maximum biomass entire mantle was 8.12 ton DW in November, and the lowest was 1.18 ton in February DW (Figure 5). The Wet weight was 110.71-ton maximum, and the minimum was 18.71 ton WW (Table 6 and 7).

*A. spicifera* in this area can be found growing on a variety of hard substrates, including epifitando other species of seaweeds or invertebrates (Table. 1) (cnidarians, corals, sponges, mollusks) (Figure 6). However, a major substrate adheres is rock, coral and shells died (Figure 6), this is referred to as epizoic and epilithic, that is, which are subject to animals and rocks respectively. The coloration of *A. spicifera* going from brown to red (Figure 7a and b). In mature thalli coloration goes from light to dark (Figure 7a) brown.

Present an apical sympodial growth and presents secondary branches, has a roughened or rough texture, has a discoidal holder irregularly, in the main axis no spines. It is characterized by a highly branched and bushy, leafy (Figure 7a) talo. Thalli that were found were usually mature and very few were juveniles. We can also see runners with rhizoidal form at the bottom of the algae, they also serve to hold onto the substrate and give rise to a new thallus (Figure 7c).

*A. spicifera* presents an apical growth meristemal (Figure 8a). It has thorns with an average length of 4.5 mm, which can vary morphologically. These are pointy and there is a space between them, that is, are not on each other (Figure 8b). In cross-section was observed that the pericentral cells are dense Figure 9b). Axial cells are in the center of the talus and give support (Figure 9c).

Figure 5. Total biomass mantle *A. spicifera* in Punta Roca Caimancito wet weight (blue) and dry weight (Red).

Figure 6. *A. spicifera* specimens growing on different substrate types (coral, algae and spong).

Figure 7. Anatomical characteristics of the thallus of *A. spicifera* Punta Roca Caimancito BCS, Different shades of color are distinguished; **a)** red specimen, **b)** brown specimen. **c)** proliferation of youth fronds in the bottom of the runners (black arrow).

Figure 8. **a)** Morphology of spines. **b)** Meristemal cells in the apical growth zone *A. spicifera*.

Figure 9. a**)** Cross section where marrow cells that support the thallus of A. spicifera, **b)** pericentral cells (red arrow) **c)** axial support or cells are observed.

Figure 10. *A. spicifera* pericentral cell in the apical part of the thallus.

In this cross-section (Figure 10) we can see that the pericentral cells are less dense by being in the apical region where they do not act as supporting cells. Marrow cells alone have these characteristics, as they are found in the basal part of the stalk (Figure 10).

In the study area this invasive alga reproduces mainly asexually (fragmentation). However, indications were observed also reproduced sexually. Female gametophytes were observed in the apical part (Figure 11a) where the bones are, and only cystocarp spina found. It was observed that was ripe cystocarps (Figure 11b). Male gametophyte, called spermatangia (Figure 11c) have long, thin filaments called compact trichoblasts found in the apical part of the male gametophyte (Figure 11d).

The average maximum length of the thallus of A. spicifera was 163 mm in the fall of 2008 (October) and the minimum length was 108 mm in summer (August) (Figure 12).

Figure 11. a) The arrows show the area sympodial growth of the female gametophyte. b) Mature cystocarp. c) Structure of the male gametophyte. d) Approach espermatangio where trichoblasts, the thallus of *A. spicifera* (black arrows).

Figure 12. Average monthly length thalli *A. spicifera* in Punta Roca Caimancito.

The annual average was 154 mm. Before analyzing ANOVA data was obtained that are normal and are not homogeneous ( $p < 0.05$ ). The result of ANOVA by ranks (Kruskal-Wallis) (Appendix, Table 3) shows that the length of the thallus varied significantly over time  $(p < 0.001)$ . Thallus length was significantly higher in the month of October 2008. Branch number per talli did not change significantly during the study period. The monthly average was 7 branches maximum and a minimum of 4 branches per thallus (Figure 13).

The annual average was 5 branches. An analysis of variance of a channel, where a priori tests indicated that the data are normal ( $p = 0.579$ ) and varianzias are homogeneous ( $P =$ 0.670) was performed. The resulting ANOVA (Table 4) showed no statistical difference in the number of branches between months ( $p > 0.05$ ).

**Number of Spines.** The number of spines by 4.5 mm long linear branchessecondary in the thallus of A. spicifera not vary significantly between areas (apical, medium, low) of the plant (ANOVA,  $p > 0.05$ ). The maximum monthly average was 5.4 linear 4.5 mm thorns and spines minimum 3.9 mm by 4.5 (Figure 14). The annual average was 4.5 spines 4.5 mm length of the side branch. However there were significant differences (ANOVA,  $p < 0.05$ ) were recorded throughout the year (Table 5). Tukey's test indicated that the density of spines in November (2008) was significantly higher than in the other months.

#### **Percentage of Wet and Dry Weight**

The average wet weight biomass (WW) was higher in November (2008) WW 3.5 kg/m<sup>2</sup> and lowest in February with WW  $0.59 \text{ kg/m}^2$  (Table 6).

Figure 13. Seasonal variability in the average number of branches per thallus *A. spicifera* in Punta Roca Caimancito.

Figure 14. Number of thorn in 4.5 mm linear length of the secondary branches of the thalli of *A. spicifera* in Punta Roca Caimancito.

The annual mean biomass was  $1.63 \text{ kg } WW/m^2$  (Figure 15). The variation of biomass dry weight (DW) showed a similar trend, the highest monthly average was recorded in October 2009 and was 0.86 kg DW/m<sup>2</sup> and the minimum in February (2009) is 0.0375 kg DW/m<sup>2</sup> (Table 7) (Figure 16). The annual average biomass dry weight was 0.29 kg DW /  $m^2$  (Table 7). Priori testing resulted not exhibit normal ( $p < 0.050$ ) nor homogeneity of variance ( $p <$ 0.050). So the ANOVA (Table 8) rank (Kruskal-Wallis) showed us that there are significant differences in biomass throughout the year  $(P < 0.001)$ .

#### **Flora and Fauna of** *Acanthophora spicifera*

The flora and fauna associated with *A. spicifera* was represented by several groups, of which the most common were molluscs, echinoderms, epiphytic algae from different divisions, seagrasses, sponges and fish (Figure17). The maximum of these organisms monthly biomass was  $0.20 \text{ kg/m}^2$  (6.27 ton for the entire mantle) in September and the minimum of  $0.03 \text{ kg/m}^2$  (1.01 ton) in November. The annual average biomass associated with this cloak of *A. spicifera* organisms was 0.071 kg/m<sup>2</sup> (Table 9).

The result of the correlation indicated no relationship between dry weight biomass and biomass *Acanthophora* flora-fauna in dry weight (r = -0.1892).

#### **DISCUSSION**

*Acanthophora spicifera* is native Caribbean but now has been documented in many tropical and subtropical coastal zones around the world, which has been considered as an invasive species (Collado-Vides, et al. 1995; O'Doherty et al. 2007; Quiros-Rodríguez et al. 2010;. Tsuda et al. 2008 Serviere-Zaragoza et al. 1992).

Figure 15. Seasonal variability in the wet biomass *Acanthophora spicifera* per square meter per hectare in Punta Roca Caimancito.

Figure 16. Seasonal variation of biomass dry weight and *Acanthophora spicifera* per square meter per hectare Total in Punta Roca Caimancito.

Figure 17. Monthly Average biomass of all the flora and fauna associated with the mantle of *A. spicifera* Caimancito Punta Roca.

Caribbean of Panama for example, it has been reported that the optimum temperature for this species is 25°C. Also on Pearl Harbor, O'ahu, Hawaii, we can find it adapted to a temperature range of 23-29°C (Coles 2006). In our study area (Punta Roca Caimancito) temperature conditions ranged from 20-29ºC. And considering that tolerates a wide temperature range, this species could in turn spread through all the bays and shallow waters of the Gulf of California, and that within this system water temperature varies between 16-29ºC (White-Betancourt et al. 2004) similar to those in our study area (Naim 1993) values. In the Caribbean, this species can be found from the intertidal zone to a depth of 8-22 m (Kilar et al. 1986; Littler et al. 2000). In Pearl Harbor, O'ahu, Hawaii dwells at an average depth of 9.2 m (Coles 2006). At sites where it is distributed within the bay of La Paz (Mexico), this algae can be found from 50 cm to 5 m depth in the subtidal zone in Punta Roca Caimancito this depth distribution could be associated with the availability hard substrate (rock, coral, shell, etc.).

The length of the thalli of *A. spicifera* in Punta Roca Caimancito ranged from 99-171 mm and maximum sizes were recorded in October (autumn 2008) and the minimum in August (summer 2009). In Tanzania length posing A. spicifera is 200 mm (Olivera et al*.* 2005). In the Caribbean there have been *A. spicifera* lengths over 250 mm (Littler et al. 2000). Making a comparison with the thalli Bay Peace these are much smaller than those in the Caribbean and the Indian Ocean.

In Punta Roca Caimancito a clear seasonal variation was detected in the length of this species in other regions. This macroalgae showed larger sizes in autumn and minimum in summer. Hawaii for example, a peak in summer is recorded and subsequently a decrease in the length in the winter. In fact, it has been observed that during the winter the thallus showing signs of necrosis with minimal possibility of adhering to a substrate and persist (Tsuda et al. 2008). In the eastern Arabian Sea A. spicifera reaches greater lengths during spring (March) (Desai et al. 2003). *A. spicifera* is one of the most dominant algae in the subtidal zone of Punta Roca Caimancito. The biomass of this alga was higher in October 2008 with 15.70 kg/m<sup>-2</sup> and the lowest was in February 2009 with 1.33 kg/m<sup>-2</sup>. The decrease in biomass detected in winter possibly because the availability of nutrients in the summer is higher than in winter (Reyes-Salinas et al. 2003). Other species of the same genus as *A. nayadiformis* reaches higher biomass values in summer and autumn with a strong decrease in winter. Therefore in the Mediterranean in those stations *A. nayadiformis* is the most dominant species among the community of subtidal algae with a rate approximately 40% (Cecere et al. 2000).

In this study we observed that *A. spicifera* had pericentral and central cells. The spines are dense and are oval in major axis extremities separated from each other. The length of the spines is 0.5 to 6 mm. For records of the species in the Caribbean measuring up to 0.55 mm in length (Littler et al. 2000). In this sense, some authors who have studied species of this genus show that if the spine is very swollen means there may be spores within it (Cecere et al. 2002). In our study this phase was observed, this might be because he had expelled the gametes. In the cross sections was observed that the spines containing an empty cavity may also be that under these environmental conditions sexual reproduction is not very common.

*A. nayadiformis* in the number of thorns varies depending on the length of the branch, that is, the longer the greater the number of spines (Cecere et al. 2002). The same author also mentions that the spines are made up of cells that build tissues and present of 3-5 spines on the apical side. *A. nayadiformis* plants develop from primordium spines are more robust and abundant monopodial growth (Cecere et al. 2002). The most common is that the thalli can

become vegetative propagules. Branches can be regenerated from anywhere in the talo and form new thalli without sexual reproduction (Cecere et al. 2002).

*A. spicifera* is an abundant algae in the subtidal zone of Punta Roca Caimancito where it forms part of a small reef where various organisms (flora and fauna) benefit to get shelter and available substrate (Table 1 and 2). Within associated algae we can find species phyllum Chlorophyta (green), Rhodophyta (red) and Heterokontophyta (brown). A lot of animals living among *A. spicifera* such as fish, sponges, cnidarians, molluscs, arthropods were also found.

*A. spicifera* not only found in coral reefs but it also can be found associated complexes mangrove ecosystems (Barrios et al. 2003). However, in some Hawaiian coral ecosystems invaded by *A. spicifera*, has detected a negative impact because it prevents nutrients and sunlight reaching the coral community, which may attract some problems for communities of animals and plants who live there (Martinez-Danaras 2006).

In Punta Roca Caimancito thalli *A. spicifera* easily fragmented (even without waves or strong currents) generating clones that are dispersed by currents as in other regions (Kilar et al. 1986). This feature has favored the spread of this invasive alga by different sites within the Bay of La Paz. O'Doherty *et al*., 2007 mention *A. spicifera* that is a species capable of even flourish under range of environmental conditions for this species and do not need a special environment to reproduce asexually. Unlike sexual reproduction that does require specific environmental conditions that stimulate the production of Tetrasporangia (structures within which tetraspores occur) and also involves a lot of energy expenditure. In populations of A. *spicifera* present in the Hawaiian Islands has been suggested that this truncated life story and that have not been observed gametofitos O'Doherty *et al*., (2007). In Punta Roca Caimancito the tetrasporophytes were observed. Ie carposporangia but empty or perhaps initiating development were observed but not viable.

This alga has spread rapidly through the Bay of La Paz and is present throughout the year (perennial species). It is currently distributed to over 20 km in different parts of the east coast of the Bay of La Paz. Contrary to what happens with native algae like Sargassum is annual, we only see their fronds (higher density and size) during summer and winter only survive fasteners and lots of stipes (Riosmena-Rodríguez et al. 2009) or Porphyra that only occurs during the autumn-winter period (Smith 2002).

#### **CONCLUSION**

*Acanthophora spicifera* is a perennial species that is present throughout the year in Punta Roca Caimancito and tolerates a wide temperature range of 20-29°C. Morphological characters posing *A. spicifera* Punta Roca Caimancito are similar to those reported by other authors for other regions of the world.

The main mode of reproduction of *A. spicifera* is asexually through fragmentation and occurs throughout the year. Sexual reproduction was evidenced by the presence of carposporangia between spring and summer, however, these were never observed containing carpospores. Presents *Acanthophora spicifera* presents larger during fall and lowest during the summer. The number of branches in the thallus of *A. spicifera* was significantly higher in the period of autumn-winter than in the summer.

Ecofriend, 2011; Schrope, 2008.

The maximum number of spines was 5.4 4.5 mm linear spines on secondary branch and the minimum was 3.9mm for linear secondary branch. The percentage of biomass by wet weight of *A. spicifera* is higher in autumn and winter less. The percent dry weight of biomass is greater *A. spicifera* fall and lower in winter. *A. spicifera* impact in the study area can be positive for some species of wildlife that benefit from this alga to obtain shelter and food, but for the case of coral communities, the impact appears to be negative as the high density of the algae can affect light and nutrient uptake and thereby affect its growth.

#### **RECOMMENDATION**

As already mentioned *A. spicifera* is an invasive algae that has invaded marine ecosystems in the Pacific, and has been shown to be a highly competitive body (light and nutrients) with native corals and algae. It has also been noted that competes for space with a great diversity of sessile organisms. Here, in Hawaii has developed a technology to remove the algae from the invaded area. It is a vacuum machine called "Super Sucker", which has been successful in controlling the algae as it can draw up to 800 kg per hour. Subsequently, these invasive algae are packed in bags and delivered to farmers for use as fertilizer. Therefore, it could recommend the use of these machines to control the high biomass of A. spicifera in places where it is distributed in the Bay of La Paz. Although it is also recommended to first assess the impact of the cleaner for other native organisms associated (National Geographyc 1996-2011; Ocean Power Magazine 2011).

# **ENVIRONMENTAL IMPACTS ON MARINE BENTHIC COMMUNITIES IN AN INDUSTRIALIZED CARIBBEAN ISLAND-TRINIDAD AND TOBAGO**

## *Judith F. Gobin*

Department of Life Sciences, University of the West Indies, St. Augustine, Trinidad and Tobago

#### **ABSTRACT**

The twin island state of Trinidad and Tobago is the Caribbean's southern-most island state located between  $10^0$  to  $11^0$  North latitude and  $60^0$  to  $61^0$  West longitude. Like most of the Caribbean small-island states, Trinidad and Tobago's coastal waters are an economically important natural resource and at the same time, a vulnerable one. Trinidad and Tobago is a producer of oil and natural gas with the energy sector being by far, the most important contributor to the country's GDP, Government revenues and foreign exchange. Crude oil production averaged 122,902 barrels per day (bbl/d) in 2004, while natural gas production averaged 2,938 million standard cubic feet per day (Ministry of Planning and Development Central Statistical Office, 2007). The petrochemical sector (at Point Lisas Industrial Estate, west coast of Trinidad ) has continued to expand in line with natural gas production producing methanol, ammonia, urea, and natural gas liquids. In this respect, Trinidad and Tobago is the 5<sup>th</sup> largest exporter of liquid nitrogen gas (LNG) in the world, and the single largest supplier of LNG to the U.S.A. (between 70-75% of all LNG imported into the U.S.A, Ministry of Planning and Development Central Statistical Office, 2007). Coupled with this, La Brea on the south-west coast of Trinidad is home to the world famous Asphalt or Pitch Lake. This coastal area in Trinidad has one of the highest known natural seepage rates on earth - an estimated 100 barrels per dy per 2560  $km<sup>2</sup>$ .

#### **INTRODUCTION**

Macrobenthic research and marine species diversity give a good indication of the nature of the environment at that location. Benthic organisms are effectively sessile living in the bottom sediment and they tend to act as integrators of the effects of various kinds and levels of disturbances including pollutants etc. Other marine organisms (e.g., fish and larger macrofauna) feed on the benthos, hence the status of the benthic community needs to be maintained if the quality of the environment (including our rich marine resources) is to be preserved. Against existing baseline information, knowledge of changes in abundances, species compositions and diversities of benthic organisms may be attributable to environmental impacts. In this respect, benthic research is very important towards assessments of environmental impacts on overall marine communities. This research is especially valuable to nations such as Trinidad and Tobago which has a history of maritime oil exploration and production.

#### **BRIEF REVIEW OF LOCAL BENTHIC ECOLOGICAL ASSESSMENTS**

For Trinidad and Tobago and the Gulf of Paria (west coast area, Figure 1), one of the earliest published descriptions of macrobenthic data was as a result of an extensive survey carried out in 1952 to 1953 (Van Andel and Postma 1954). This information provides significant baseline data since it was acquired prior to the drilling of the very first offshore wells (by Trinidad Northern Areas Ltd.) at Soldado. Later, the Institute of Marine Affairs (IMA) carried out several macrofaunal surveys in the coastal areas of the Gulf of Paria. The first of these was in the area of the Point Lisas Industrial Estate (PLIPDECO/IMA 1982, Vol. 5) (Figure 1, Inset Map, No.2). That macrobenthic survey (including chemical and geological data) was not strictly pre-construction since there were already a few existing (and operational) sites at that time e.g., the Brechin Castle sugar factory and Federation Chemicals –FEDCHEM (now Trinidad Notrogen (TRINGEN). Such information is still important baseline data however, since the present day operations now include approximately 94 industries - petro-chemical related sites and factories as well as a number of light industries. Results (at that time) indicated that while the inshore coastal areas at Point Lisas were typical of coastal estuarine conditions, there was already evidence of a certain amount of environmental stress. A "hot spot" area close to FEDCHEM, was identified where a number of stations were already abiotic for macrobenthic organisms.

In a baseline survey of the Scotland Bay area (Figure 1, Inset Map, No. 1), Chaguaramas (Alkins and Kenny 1980), the marine biological communities studied included benthic fauna and flora. Scotland bay at that time supported a wide range of fairly small communities of corals, a sea grass bed, a mixed coral/sponge/algal community, an algal community, an intertidal and sublittoral mud community and a sand and rock community. The authors described interesting community features and suggested that they should be protected from overuse or pollution. The coral communities in particular, had already been described earlier as "under physiological stress as they are growing on the edge of their salinity tolerance range" (Kenny 1975).

Figure 1. Map showing macrobenthic stations sampled (circled = re-sampled) in the Point Lisas coastal area.

Another detailed macrobenthic survey (including chemical and sediment geological data) was carried out in the coastal area extending from Diego Martin to Port of Spain (Figure 1, No. 1) during 1982 (Agard 1984). Over both a wet and dry season, forty seven (47) stations were sampled for macrofaunal content. The most abundant species was *Streblospio benedicti*  (a polychaete*)* a good indicator of organic pollution (Pearson and Rosenberg 1978). Its' distribution was restricted to the Sea Lots/Laventille area where there were overloaded sewage treatment ponds with overflow pipes (Agard 1984). The amphipod *Ampelisca parapanamensis* which is very sensitive to low level pollution was the second most abundant species. Its' distribution was ubiquitous except for the areas dominated by *S. benedicti* and where there were elevated levels of petroleum hydrocarbon.

In general, Agard (1982) found that the spatial effects of pollution (high sediment organic content and low dissolved oxygen) on the benthic macrofauna at the Sea Lots/Laventille area, were far more pronounced than the temporal variation due to seasonal climatic change. The author described the presence of 5 ecological zones (ranging from very polluted, polluted, semi-healthy 1, semi-healthy 11 and healthy) each of which had its own characteristic faunal assemblage. This study provides good baseline information with which further monitoring results can be compared especially with respect to the presence or absence of the tentative indicator species identified: *S. benedicti* and *A. parapanamensis*.

Another comprehensive macrobenthic survey was carried out by the IMA in the area extending from Pointe-a-Pierre to La Brea (Figure 1, Inset Map, No. 3). This area is subject to chronic natural oil seepage and oil spillage from oil production activities (Agard and Gobin 1992; Agard, Gobin and Warwick 1992). Three (3) major station groups (based on

hierarchical classification and multidimensional scaling ordination) showed concordance with differences in water depth and sediment type. Abundance/Biomass comparison plots indicated that macrobenthic communities near the oil refinery were grossly to moderately stressed while those close to the Trinidad Pitch Lake (one of the largest natural oil seeps in the world were not). Contamination occurs here at La Brea on what is probably an evolutionary time scale from one of the world's largest hydrocarbon seeps (Wilson et al., 1974; Geyer and Giammona, 1980). This is in contrast with contamination over ecological time from an oil refinery at Pointe-a-Pierre, a few kilometers away (Agard et al., 1988). Results near the La Brea oil seep suggest a diverse benthic macrofauna (Government of Trinidad and Tobago, 1984 and Agard and Gobin 1992, Gobin et al., 2012). It is thought that these organisms may rely on hydrocarbon degrading bacteria as a food source (Zobell and Feltham, 1938, Gobin et al., 2012).

There have been 2 other studies carried out by Nansingh (1993) and Price (*in prep*). Nansingh (1993) sampled quantitatively for macrofauna in the intertidal zones of 4 different areas of the Gulf of Paria – Caroni and Carli Bay (mudflat) areas, Granville and Williams Bay (sandy beach areas).Stations were sampled using cores at the 4 stations with additional mangrove root samples at Caroni Swamp. The mud flat stations reflected the greater diversity of species compared to the inner swamp area. Based on his results Nansingh and Jurawan (1999) described vulnerability of coastal areas and suggested that a potential oil spill could impact on these habitats with severe consequences. The authors applied a coastal environmental rating (an index of 1 implied "least" sensitive while 10 was "most" sensitive) and rated the studied areas as follows: Caroni swamp -9, Williams Bay-7, Granville Bay-7 and Carli Bay-7. Price (MPhil Thesis *in prep*) sampled the benthic macrofauna associated with seagrass beds at Williams Bay (Chaguaramas, Trinidad) William's Bay and St. Peter's Bay in Trinidad and compared them with La Guira Bay and Bon Accord Lagoon in Tobago.

#### **Environmental Impacts on Macrobenthos in the Point Lisas Industrial Estate (PLIE) Coastal Area**

Trinidad and Tobago is a highly industrialised country with 2 very large industrial estates: Point Lisas Industrial Estate (PLIE) and La Brea Industrial Estate. The Point Lisas Industrial Estate (PLIE) is today, the heart of Trinidad and Tobago's petrochemical sector. The Estate is a world-class facility, covering 860 hectares and represents an investment of over US \$2 billion ( http://www.plipdeco.com/main/index.php?page=estate-managementoverview). The PLIE is home to 94 companies involved in a range of activities dominated by the petrochemical sector.

As the largest oil and natural gas producer in the Caribbean, Trinidad and Tobago's hydrocarbon sector moved from an oil dominant to a mostly natural gas based sector in the early 1990s.Trinidad and Tobago now houses one of the largest natural gas processing facilities in the Western Hemisphere- the Phoenix Park Gas Processors Limited (PPGPL). With 11 ammonia plants and 7 methanol plants, Trinidad and Tobago is the world's largest exporter of ammonia and the second largest exporter of methanol (IHS Global Insight 2013).

Following the original Point Lisas Industrial Estate survey (PLIPDECO/IMA 1982, Vol. 5), a detailed benthic survey was carried out during 1984 to 1986 in a similar coastal area of Point Lisas (Gobin 1988). This quantitative study of polychaetes (Annelida- which contribute

approx. 70% of total macrofauna here) was carried out to determine the distribution and abundance of these communities in the coastal area of the Estate. These distributions were evaluated with respect to proximity and effects of potential "polluting effluents" or disturbances. The polychaetes were well distributed over the study area except for the well known indicators of "organic pollution" *Capitella capitata* and *Streblospio benedicti* which were confined to some inshore stations. Additionally at some inshore stations there were elevated levels of zinc, petroleum hydrocarbons, ammonia and temperature (max.  $41^{\circ}$ C). There was also a marked seasonal shifting of sediment at some stations (e.g., at Couva River mouth) accompanied by some patchy species distribution. A general conclusion of that study (Gobin 1988) was that there appeared to be no marked deterioration in the Point Lisas coastal area since the original study (PLIPDECO/IMA 1982). This was based on the fact that the "stressed stations" appeared to be at the same locations for both studies (although 8 years apart) with elevated levels of "pollutants" being confined still mainly to inshore areas.

With the continued expansion of developments and increased activities at the Point Lisas Industrial Estate, increasing volumes and variety of effluents continue to enter the Gulf of Paria. These continue to potentially pose serious threats to the quality of this environment which is a major fishing ground. These effluents have already been suggested as responsible for "contaminating" and "polluting" environmental status (Agard, Gobin and Warwick 1993). A more recent project approximately 25 years later (by the author J. Gobin 2010) attempted to evaluate changes in the benthic communities in the area. This is the first study of its kind in the history of benthic community analyses for Trinidad and Tobago.

#### **MATERIALS AND METHODS**

A subset (comprising of 13) of the original 25 stations which had been previously sampled in May 1985 (Gobin 1988) were re-sampled during May 2010 (Figure 1). The same methodology was used for both macrofaunal surveys (1985 and 2010). Benthic sediment grab samples were taken using a 0.025 m<sup>2</sup> van Veen grab at each of the thirteen (13) stations (2008). At each station, 3 replicate grab samples were collected and each sediment sample was sieved and washed (using sea water) through a .05 mm<sup>2</sup> sieve mesh. The fauna retained was stained using Rose-bengal (a proteinaceous dye) to facilitate sorting and preserved in a 10% formalin solution. All 39 samples were transported back to the laboratory where they were re-sieved and gross sorted, separating the polychaetes from all other taxa. All polychaetes were identified as far as possible to species level using the relevant taxonomic keys. All other taxonomic groups were identified to Family or Genus or species, as far as possible also using relevant keys. All identifications were carried out by the author (J. Gobin) for both surveys (1985 and 2010).

Species abundances, richness and SWI (Shannon-Wiener Index) diversities were calculated (Shannon and Weaver 1963) towards an overall understanding of the distribution of the benthic organisms at the stations (for 1995 and 2010 data). The macrobenthic data were analysed using the PRIMER (Plymouth, UK) multivariate analyses programmes (after Field, Clarke and Warwick 1982; and Agard, Warwick and Gobin 1993). Similarity matrices were used to produce plots (MDS- multidimensional space) in which similarity between stations is represented as physical distances (Field, Clarke and Warwick 1982) - for both 1995 and 2010 data.

#### **GENERAL RESULTS**

In keeping with the macrobenthic review focus of this paper- only some results of this study are presented here. In the 1985 samples, a total of 3140 polychaete individuals belonging to 70 species were identified. Overall in 1985, the dominant polychaete was *Capitella capitata* (an indicator of high organic content- at station D) with *Armandia maculata* (Ophelidae) being the next. In the absence of any major changes one would expect about half the number of individuals and species for approx. half the number of samples (13). In the 2010 samples the number of individual polychaetes was severely reduced to 412 belonging to 43 species. The dominant polychaete was *Paraprionospio pinnata* (of the Spionidae). Species diversity (for polychaetes) values recorded at each station for the 1985 and 2010 survey are presented in the following figure (Figure 2). Stations 1.3 to C 1.5 (13 in total) have been re-labelled incrementally as: A to M on these plots.

Figure 2. Species Diversity (H') at stations (A to M) sampled (with replicates combined) for 1985 (0 yrs =  $^0$ ) and for 2010 (25 yrs later =  $^{25}$ ).

Overall the benthic polychaete species have clearly decreased markedly in terms of species diversity at 7 of the 13 re-sampled stations, twenty-five years later. At least 3 stations (B, E and K) however reflected similar diversity for both sampling times. At the same time, three (3) stations C, D and I have increased species diversity after 25yrs. Station F had the greatest species diversity in 1985 with stations E and I having the highest in 2010. After 25yrs of continued industrial activity the macrobenthos in the Point Lisas area is still reasonably diverse.

#### **DISCUSSION**

Trinidad and Tobago's west coast has been reasonably very well surveyed in terms of its macrobenthic faunal species and their diversities (PLIPDECO/IMA 1982, Gobin 1988, IMA 1994 etc.). In addition to the number of studies reviewed (above), there have been a large number of surveys which contribute to the "grey literature." For example, there have been a number of macrobenthic assessments as components of Environmental Impact Assessments (EIAs)- a requirement by the local Environmental Management Authority (EMA) for proposed development activities. A large number of these have been done as pre-drilling surveys for oil and gas exploration activities and were concentrated on the East and Northeast offshore areas of Trinidad. The author (J. Gobin) has also contributed (as the only specialist Benthic Ecologist) in Trinidad and Tobago) to the majority  $(> 40)$  of these assessments between 1995 and 2007 (e.g., (i) 2005 Gobin, J. *Benthic Ecology Section of Document prepared for British Gas, TT: the North Coast Marine Area (NCMA) Report*; (ii) 1998 Gobin, J. *An Environmental Impact Statement on the effects of Siltation in the area of Atlantic LNG, Point Fortin. Benthic Ecology Section of a report prepared for Atlantic LNG, Point Fortin, by CANE and Associates Ltd*. etc.) There have been very few postdevelopment (e.g., post exploration drilling) surveys carried out in these areas although these have been proposed within the various EIAs' terms of reference (TORS). This is of course quite unfortunate, since continued monitoring surveys should follow baseline studies in order to provide key information on "real" changes (as a result of the activities) in macrobenthic species compositions and distributions compared to "predicted" changes (as is typical of EIAs).

This re-survey (25 years later) provides some significant benthic macrofaunal data (and the first of its kind) for Trinidad and Tobago and the Point Lisas Industrial coastal area.

Although only a small component of a more complex environment, these results confirm that macrobenthic species (polychaetes in this instance) are reasonably hardy organisms and are therefore good indicators of the state of the environment. The use of the type of data (polychaete species level) is supported by Warwick et al., (1990) and Somerfield and Clarke (1995) who confirm that aggregation patterns at different taxonomic levels are very useful for determining patterns of impact. Results suggest that in general, species diversities have markedly decreased at some of the stations over the years in those areas of the Gulf of Paria which were re-surveyed (25 years later). This was not surprising given the major expansions that have occurred at the PLIE and the increased volumes and contaminants being released in this coastal area. According to UNDP/EMA (1998) some pollutants in liquid effluent that are of greatest concern in Trinidad and Tobago are: "Total Dissolved Solids (TDS), mainly from the ammonia production sector in the Point Lisas Industrial Estate; Nitrogen (N) from the urea plant at PLIE (72%); Oil and Grease mainly from the ammonia production sector in the PLIE and Metals in effluent from the steel mill (at PLIE)."

The recent Global Environmental Outlook Report (GEO 5 2012) describes those damaged ecosystems globally as "great damage to the very ecosystems that support human livelihoods". The report further predicts that ecosystems will take centuries to recover from damages if they recover at all (http://www.un-ngls.org/spip.php?article3907). Global and large scale disturbances over time (e.g., pollution, logging/farming, climate shifts etc.) have already altered "original baselines" of marine benthic ecosystems. In studies such as this,

recovery of the variables are therefore only being measured on a contemporary timescale. Jones and Schmitz (2009) tested the prediction of "irreparable harm" using a synthesis of recovery times compiled from 240 independent studies reported in the scientific literature. They provided startling evidence that most ecosystems globally can (given human will) recover from very major perturbations on timescales of decades to half-centuries.

Results of a similar (to this study) comparative tropical study (Webber and Webber 1998) also described increases in nitrate concentrations and increases and changes in the plankton community associated with excessive eutrophication of Kingston Harbour waters (Jamaica) over a 20 year period (1970s to 1990s). Much earlier predictions for Kingston Harbour, Jamaica (Wade 1976) was a- much deteriorated and possibly abiotic coastal area. This prediction was also made for this Point Lisas coastal area (IMA archival data, PLIPDECO/ IMA 1980). Results of this study confirm a reasonable diverse benthic community.

In consideration of disturbance and effluent contaminants in the PLIE area the benthic communities may be considered in terms of benthic macrofaunal resistance and/or resilience. Resistance implies that the macrofauna are able to to some extent to tolerate these disturbances, while resilience defines the speed at which an ecosystem can return to its former state following a disturbance. Coastal ecosystems tend to be naturally resilient and Jones and Schmitz (2009) suggest that "recovery may be independent of the magnitude of perturbation and instead, idiosyncratic to the ecosystem type". Community composition and ecosystem function may change very little where environmental impacts are such that organisms can acclimate to the change or at least tolerate it, for some time. Results of this study confirm macrofaunal resistance and/or resilience.

This high recovery potential for benthic communities was described for the Baltic sea as being due to very strong seasonality of the ocean, strong physical disturbance and short generation times of most coastal animal species (Hällfors et al., 1981). The author (J. Gobin) has confirmed that approximately 7 to 9 months is the average time needed for coastal species in Trinidad and Tobago to regenerate following dredging activities (Gobin, archival data). However, all organisms have limits to what they can temporarily or permanently tolerate, and when change exceeds some of these limits, the ecosystem functioning and in turn community compositions are likely to change. Monitoring surveys to determine or chart further changes to benthic communities are therefore a key recommendation for the PLIE and the oil and gas East coast area of Trinidad and Tobago.

It is well documented that small island developing states (SIDs) face special environmental hazards and problems not which of the least are impacts due to climate change. At the same time, most SIDs lack human resources in critical fields such as science and technology, governance and economics which are all required for a holistic and systems approach to sustainable development (http://www.unep.org/pdf/Emerging\_issues\_for\_small\_ island\_developing\_states.pdf 2014). For example, virtually all Pacific island countries lack adequate skilled and trained workforce (http://www.ilo.org/wcmsp5/groups/public/@asia/ @ro-bangkok/documents/projectdocumentation/wcms\_120577.pdf).

This is interestingly not the case in Trinidad and Tobago which has a number of very well trained scientists, technologists, governance and economics professionals. Additionally there are 2 Universities (University of the West Indies and University of Trinidad and Tobago) as well as an Institute of Marine Affairs – institutions which can provide guidance and advice as well as a number of key Environmental and Maritime divisions and research departments (within Ministries). Trinidad and Tobago is however typical of a SIDS economy which relies

on a relatively narrow base of commodity; in this case oil and gas resources. This economic dependency has created a scenario where *scientific findings and data do not mix with oil and gas exploration*! In other words, Trinidad and Tobago's economic driver takes precedence over scientific findings and the "paper" requirements for surveys and studies detailing "impacts on the benthic communities" within the EIA requirement (as submitted by the various multinational and local companies) is exactly that! The author is not aware of any company being refused permission to carry out exploration activities in the waters of Trinidad and Tobago based on marine environmental concerns! Other scholars (Burdge and Vanclay 2010) were similarly not optimistic about the ability of EIAs and SIAs (Socio economic Impact Assessments) to make substantial changes in the politics of development decisions

Given the recent fluctuations in oil prices and the growing unsustainability of supplies, renewable energy is an alternate area with great potential for consideration by Trinidad and Tobago. At the same time, this much needed economic diversification will result in less degradation to the overall marine environment and the associated macrobenthic biodiversity. This even if the some components of the marine environment appear to be resilient or tolerant.

#### **ACKNOWLEDGMENTS**

The author wishes to thank Coastal Dynamics Ltd. for assistance with the field sampling as well as for the preparation of the map and Ms. Alana Jute for her assistance with the analyses.

### **ABSTRACT**

We examined the possibility of using the length of the outermost sheath (OSL) to predict values of different variables of *Zostera marina* (eelgrass), as our previous observations indicated a strong correspondence between eelgrass length structures (leaves and sheaths) and its biological and morphometric variables, i.e., growth, production, and leaf area. We first determined leaf growth and production by means of the Ibarra-Obando and Boudouresque (1994) technique, and then used correlation matrixes to explore the relationship between length of shoot leaves and sheaths, and the following variables: shoot growth (SG), leaf production (LP), shoot weight (SW  $=$  sum of weights of all leaves and sheaths in a shoot), and shoot leaf area (SLA) in order to predict them, based on a single shoot structure easy to measure in the field. Our results indicate that the OSL

is a reliable and easy technique to measure a variable that can be used to predict the variables mentioned above on two-week and monthly periods. Then we must emphasize the importance to developing predictive equations for each study region as the only way to prevent over or underestimation of the variables of interest.

#### **INTRODUCTION**

Assessment of plant growth and production has been the object of much research, both in terrestrial and aquatic environments (reference). The trend through time has been toward a simplification of the methods used (reference). Examples of a simple and useful technique comes from agronomy, where the growth patterns or plant density indicates the seed production in some cultivars; or from forestry, where engineers use tree length and trunk circumference (diameter at breast height) to calculate tree growth, basal area, biomass or wood production (Husch et al., 1982; Brokaw, and Thompson, 2000). Snedaker and Snedaker (1984) extended these techniques to mangroves and other plants. Relatively simple techniques have been developed for aquatic plant biomass assessment (Maceina et al., 1984; Downing and Anderson, 1985), some of which are based on morphometric relationships (Daoust and Childers, 1998). For seagrasses, rather complicated mathematical models have been used to understand seasonal variations in *Z. marina*'s distribution, biomass, and production (Verhagen and Nienhuis, 1983; Bach, 1993; Bocci et al., 1997, Echavarria-Heras et al., 2012, 2013). Recently has been development some techniques to measure seagrass growth and others biological variables using statistical and allometric tools (Short and Duarte 2001; Gaeckle et al., 2006, Echavarría-Heras et al., 2013).

Seagrasses' vegetative morphology is rather simple (den Hartog, 1970). Vegetative shoots are produced through lateral shoot production. Each shoot has a series of leaves bound to their sheath, which correspond to rhizome node in a 1:1:1 (Leaf: sheath: rhizome node) relationship. This means that there is more than one sheath in each shoot. As a consequence, a strong relationship exists between these structures and growth and production dynamics (Bak, 1980; Short, 1983; Duarte, 1991; Ibarra-Obando and Boudouresque, 1994; Meling-López and Ibarra-Obando, 1997; Short and Short, 2000; Gaeckle et al., 2006).

Allometric models have been developed to assess eelgrass leaf production under natural (Solana-Arellano et al., 1991; Echavarria-Heras et al., 2013) or laboratory conditions (Hamburg and Hoffmann, 1986), and shoot length has also been estimated using biometric relationships (Bak, 1980). Ibarra-Obando and Boudouresque (1994) proposed using the length of the outermost sheath as a morphological index of leaf growth and production. The main differences between this and traditional techniques (i.e., Kentula and McIntire, 1986), is the use of the first node instead of the ligule, as the reference point to assess leaf growth. The possibility of using the length of the outermost sheath as a morphological index of shoot growth and production was tested by Meling-López and Ibarra-Obando (1997), who during an annual cycle marked eelgrass shoots simultaneously with a traditional technique (Kentula and McIntire, 1986) and with the Ibarra-Obando and Boudouresque (1994) technique. During summer, a high and significant correlation between techniques was found, for shoot growth and production, which was not observed during winter because Kentula and McIntire's technique is more sensitive to high values and/or variance among measurements (Meling-López and Ibarra-Obando, 1997).

The observation that strong relationships exist between eelgrass morphological structures, that these relationships can be expressed in statistical terms, and that they reflect not only leaf growth and production but shoot growth and production as well (Ibarra-Obando and Boudouresque, 1994), allowed us to use regression equations to predict these and other variables, like leaf area, and shoot weight (we refer shoot weight as the sum of weights of all leaves and sheaths in a shoot) by measuring a single structure. Here we consider whether the sheath might be this structure. The sheath has two advantages: 1) It is less fragile than the leaves, and remains intact for longer periods of time, and 2) its measurement in the field is easy.

With this background, we formulated the hypothesis that shoot growth, leaf production, shoot weight, and leaf area of *Z. marina* can be assessed using regression equations that only incorporate the length of the outermost sheath. These equations would have the advantage that just the measurement of a single shoot structure would be required. Therefore, the objective of this study was to develop and validate these equations. We proceed in three different stages. The first one corresponded to the calculation of the regression equations. The second one was the validation of the equations for two-week periods, and the third one, the development of monthly predictive equations.

#### **MATERIALS AND METHODS**

*Z. marina* vegetative shoots were collected at San Quintín Bay, Baja California (30 24' N; 115 56' W) during August-December 1992, and February-August 1993. At every low spring tide (every two weeks), at a depth of -0.1m MLLW (Mean Low Water), 21 shoots at random were marked following Ibarra-Obando and Boudouresque (1994) technique. Marking new shoots and harvesting marked shoots were simultaneous processes in every field visit. A total of 459 vegetative shoots were marked during the two-week study period.

Shoots were marked with a hypodermic needle at the level of the ligule, and the length of the outermost sheath (OSL) recorded. We refer to the outermost sheath as the oldest one attached to the shoot (Figure 1). Once in the laboratory, shoots were dissected, and only the above ground parts were considered. Notice that in the laboratory leaves and sheaths were numbered from next to oldest (1) to youngest (5), acknowledging that fully developed sheaths are only present in the oldest leaves. As a consequence, the 1:1 proportion (Leaf: sheath) is not always present (Figure 1). The following variables assessed:

*Sheath length*. It is the distance (cm) from the first node to ligule. The OSL was recorded again in the lab to determine if there had been any increase in length during the incubation time. Results indicated there were no changes in length during this period (results not shown). The length of the other sheaths present in the shoot was also recorded.

Leaf growth. For marked leaves the distance (cm time<sup>-1</sup>) from the ligule to the needle mark was measured, and to it, the OSL subtracted. This means that the remaining lower portion of the marked leaves represented new growth. In the case of new leaves, their whole length was considered new growth. Whole leaf lengths were also measured to estimate the proportion represented by growth in each instance.

Figure 1. Description of field and laboratory work for the Ibarra-Obando and Boudouresque (1994) technique with *Zostera marina* vegetative shoots. At the marking time  $(T_0)$  shoots are marked at the level of the ligula with a hypodermic needle, and the length of the outermost sheath (OSL), indicated in black, is measured Two weeks later  $(T_1)$  marked shoots are harvested. Dots in the leaves correspond to the needle mark. Once in the laboratory, shoots are dissected, and individual leaves and sheaths are separated. The oldest leaf has already been lost. Leaves and sheaths are numbered from next to oldest (1) to youngest (5), acknowledging that fully developed sheaths are only present in the oldest leaves.

Leaf production (LP). Leaf growth expressed in weight (g DW time<sup>-1</sup>).

*Sheath growth.* This variable was considered proportional to LP. The percentage of leaf length represented by its growth was assigned to its sheath (cm time<sup>-1</sup>). The portion of the sheath representing new growth during the incubation period was also identified in its lower portion.

*Shoot Growth (SG).* The sum of growth for all leaves and sheaths in a single shoot during the incubation period expressed in length units (cm time-1 ).

*Shoot Weight (SW).* The sum of both leaf and sheath growth in a single shoot during the incubation period expressed in weight units (g DW time-1 ).

*Shoot Leaf Area (SLA).* The sum of individual leaf lengths multiplied by their widths (cm<sup>2</sup> time-1 ). The sheaths were not included.

For all the variables mentioned above two-week averages were obtained and used to explore different combinations of correlation matrices to select the most appropriate shot structure to be used. Results not only showed significantly and high correlations between the different variables, but also in combination with some of the selected length structures (results not shown). It was decided to use only those length structures that showed high and significant correlations with SG, LP, SW, and SLA, and which were easy and fast to measure

both in the field and in the laboratory. These structures were leaves and sheaths of the outermost sheath (OSL), and those in positions 1 and 2. Resultant regressions were later used as predictive equations.

To validate the above-obtained regression equations, a series of two-week samplings took place from October 1993 to March 1995, following the same procedure described above for field and laboratory. Results from the field and laboratory (observed values) were then compared with those estimated from the previously developed equations (calculated values).

Using the two-week data from August-December 1992, and February-August 1993, we calculated monthly average values for all the variables described in the first stage, and the two kinds of data sets (observed and calculated) were compared and analyzed statistically with the same procedure as above. High and significant correlations were found, allowing the calculation of monthly predictive equations, which were validated through monthly sampling from June 1996 to November 1997. SW values were calculated using the biomass  $(gDWm^2)$ and density (shoots  $m<sup>-2</sup>$ ) relationship. It was found that the observed data were not statistically different from the calculated values, allowing the development of monthly regression equations for SG, LP, SW, and SLA.

As samples were independent and random, and data sets followed the normal distribution and presented variance homogeneity, parametric statistics were applied (Hays and Winkler, 1970; Zar, 1984) using the STATISTICA 6.0 (StatSoft) program. To test whether the whole set of homologue series (observed and calculated) were significantly different or not, an ANOVA test was used. Total averages of the two sets of data (observed and calculated) were compared with a t-student test. We considered the general assumptions for regression and correlation analysis. We used the  $r^2$  value instead the r value to find out whether the observed values were significantly different from the calculated ones, considering them different if the  $r^2$  value was not significant and/or smaller than 0.5, and no different if the  $r^2$  value was significant and bigger than 0.5. In all cases, the confidence level was set at 95%.

#### **RESULTS**

Leaves length showed high correlation with their corresponding sheaths ( $r^2 = 0.92$ ; p < 0.01), that was also valid for contiguous leaves and sheaths (Table 1). The dataset for twoweek periods indicated that the sheath represented, in average, 17% of leaf length (0.69  $\pm$  1 SE), varying between 15% during winter and 25% during summer (Figure 2). Individually, the sheath can represent up to 33% of its corresponding leaf length, with this high percentage corresponding to summer. For intermediate leaves the relationship is lower, as the sheath is not yet fully developed while internal leaves do not present a sheath; this indicates that leaves develop and mature earlier than sheaths. In this last analysis described above, we did not consider the outermost leaf and sheath, as the oldest leaf falls apart during the incubation period.

Leaves and sheaths presented their maximum length during summer-autumn and their minimum values during winter-spring (Figure 3). These seasonal trends can also be observed in shoot growth, leaf production, shoot weight, and shoot leaf area (data not shown). SG, LF, SW, and SLA were highly correlated with leaves and sheaths. Shoot growth and leaf area showed their highest correlation with sheath number 1 ( $r^2$  = 0.9390, and 0.9326 respectively;

p< 0.051), while leaf production and shoot weight were highly correlated with sheath number 2 ( $r^2$  = 0.9047, and 0.8691 respectively; p< 0.05). Correlation values with the outermost sheath were lower (Table 2), despite this fact, we selected the length of the outermost sheath (OSL) as the structure that could reflect SG, LP, SW, and SLA, as its length remains constant through time (growth has ceased). As already mentioned the sheath also has the advantage that measurement of its length, both in the field and in the lab, is easy.

#### **Table 1. Correlation matrix for** *Zostera marina* **leaves and sheaths length. Only values for the most external or oldest structures (leaves and sheaths)**  are presented, as  $r^2$  values were the highest ( $p < 0.05$ )

Figure 2. *Zostera marina* leaf length: sheath length throughout the two-week study period. Bars represent  $\pm$  1SE.

Figure 3. Averages for the two-week periods for leaf #1 and sheath #1 length (cm).

Figure 4. The regression line for Shoot Growth SG (cm two-week<sup>-1</sup>), and Outermost Sheath Length OSL (cm). Standard error of estimate (S. E. E.) =  $1.7$ ;  $p < 0.05$ .

**Table 3. Correlation matrix (r<sup>2</sup> values) among the measures of** *Zostera marina* **biological variables (p < 0.01)**

Variables	<b>Shoot Growth</b>	Leaf Production	Shoot Weight	Shoot Leaf Area
Shoot Growth				
Leaf Production	0.8796			
Shoot Weight	0.8818	0.9387		
<b>Shoot Leaf Area</b>	0.9554	0.8392	0.8814	

Figure 5. The regression line for Leaf Production SP (g DW shoot<sup>-1</sup> two week<sup>-1</sup>) and Outermost Sheath Length (OSL) (cm). Standard error of estimate (S.E.E.) =  $1.1$ ; p < 0.05.

Figure 6. The regression line for Shoot Weight SW (g DW two week<sup>-1</sup>) and Outermost Sheath Length (OSL) (cm). The standard error of estimate (S. E. E.) =  $1.1$ ;  $p < 0.01$ .

The predictive equations obtained were all significant  $(p < 0.01)$  and showed high correlation values (Figures 4, 5, 6, and 7). We also noticed that a high correlation existed between these variables (Table 3). These last correlations represent Thus, an alternative way to predict these variables.

**Table 4. Equations developed to predict monthly values (mo-1 ) of the assessed variables: Shoot Growth (SG), Leaf Production (LP), Shoot Weight (SW), and Shoot Leaf Area (SLA), with respect to the Outermost Sheath Length (OSL). Correlations (r<sup>2</sup> ) and Standard Error of the Estimate (SEE) are given (p < 0.01)**

Figure 7. The regression line for Shoot Leaf Area (SLA)  $(cm^2 \text{ shoot}^{-1}$  two week<sup>-1</sup>) and Outermost Sheath Length (OSL) (cm). The standard error of estimate (S. E. E.) = 1.4,  $p < 0.01$ .

When the observed values for the two-week period were compared with the calculated ones, no significant differences were observed ( $p > 0.05$ ). In a similar way, the t-student test indicated no significant difference  $(p > 0.05)$  between the total averages of the two series of data. This result was confirmed by the correlation values among the series of data ( $r^2 = 0.8$ ; p < 0.01), indicating that there existed indeed a strong correspondence between observed and calculated data (Figures 8, 9, 10, and 11).

Equations to predict monthly values for each variable are presented in Table 4, all being significant ( $p < 0.01$ ). It can be noticed that the fit was improved due to the reduction of variance. SW values obtained during the monthly samplings from August 1996 to November 1997, were compared with the calculated values for SW from the predictive equation (Figure 12). Neither the ANOVA nor the t-student test indicated significant differences between the two sets of data or their averages ( $p < 0.05$ ).

Figure 8. Comparison of observed and calculated Shoot Growth (SG) values (cm shoot<sup>-1</sup> two week<sup>-1</sup>) from October 1993 to March 1994. Average (142 and 154), highest (258 and 242), lowest (62 and 74), and SE (19.5 and 18.7), respectively from each data series. Bars represent  $\pm$  1SE.

Figure 9. Comparison of observed and calculated values for Leaf Production (LP) (g DW shoot<sup>-1</sup> two week-1 ) from October 1993 to March 1994. Average (0.054 and 0.57), highest (0.090 and 0.094), lowest (0.013 and 0.013), and SE (0.0085 and 0.0085), respectively from each data series. Bars represent  $\pm$  1SE.

Figure 10. Comparison of observed and calculated values for Shoot Weight (SW) (g DW shoot<sup>1</sup>) from October 1993 to March 1994. Average (0.13 and 0.189), highest (0.19 and 0.18), lowest (0.019 and 0.013), and SE (0.019 and 0.020), respectively from each data series. Bars represent  $\pm$  1 SE.

Figure 11. Comparison of observed and calculated values for shoot leaf area (cm<sup>2</sup>) from October 1993 to March 1994. Average (67.7 and 71.9), highest (131.6 and 126.3), lowest (13.9 and 22.0), and SE (12.3 and 11.6), respectively from each data series. Bars represent  $\pm$  1 SE.

Figure 12. Comparison of observed and calculated values for Shoot Weight (SW) (g DW) from June 1996 to November 1997. Average (0.302 and 0.321), highest (0.464 and 0.491), lowest (0.102 and 0.129), and SE (0.25 and 0.26), respectively from each data series. Bars represent  $\pm$  1 SE.

## **DISCUSSION**

In this study, we have explored whether the length of the outermost sheath could be used to predict *Z. marina* shoot growth and leaf production. Our results indicate that, although higher correlation values corresponded to leaves or sheaths in position 1 and 2 (Figure 1 and Table 1), and these structures could have been used as well, the use of the OSL is more convenient as it prevents shoot destruction. We validated our statistical models for two-week and monthly time intervals, finding no significant difference between observed and estimated values.

Using statistical techniques, not only we have confirmed Ibarra-Obando and Boudouresque (1994), and Meling-López and Ibarra-Obando (1997) results for SG and LP estimation but have also been able to predict two more variables: shoot weight and shoot leaf area. To transform SW estimates to biomass values we just need to incorporate shoot density values (Meling-López and Ibarra-Obando, 1999). Rapid assessment of biomass, growth and production are necessary, as these variables are considered basic in understanding seagrass beds structure (den Hartog, 1970), and to monitoring *Z. marina* beds (Gaeckle et al., 2006).

The fact that a strong correlation exists between all the selected variables (Table 3) represents another alternative to predict one variable from the other. Indeed, Poumian-Tapia and Ibarra-Obando (1999) have mentioned that eelgrass biomass in San Quintín Bay could be estimated from LAI (Leaf Area Index) values but this procedure is more time consuming, as all the leaves in a shoot need to be measured. Instead, the sheath method requires that only the OSL be measured.

The use of regression equations as a technique to estimate values for the previously mentioned *Z. marina* variables have the advantage of presenting a fast, reliable and nondestructive technique; however, these equations could be site specific and may need to be developed for every location. If it is true, this will require fieldwork to obtain values for those variables to be predicted. Although initial field work is required to establish the relationship between sheath length and leaf growth, Gaeckle et al., (2006) showed that a set of four periodic measurements is adequate. Once the regression equations have been developed, they would need to be validated with extra fieldwork, but once the relationship is established between sheath length and leaf growth, measurement of sheath length alone yields an accurate assessment of current leaf growth any time during the year (Gaeckle et al., 2006). Although the proposed sheath technique might seem tedious, complicated and time-consuming, once the regression equations have been developed**,** field work will be considerably reduced, and the lab work could be not necessary, and sampling can be extended to new locations, areas and depths, allowing comparisons,

The result indicates that two-week and monthly equations can be used to predict SG and LP, SW and SLA in an easy and reliable way, and that the OSL is a good indicator of eelgrass dynamics, instead most of the techniques used to asses both leaf growth and shoot production in Z. Marina, Lake leaf marking or plastochron are expensive, destructive, more lab time consuming (Kentula and McIntire, 1986, Ibarra-Obando and Boudouresque 1994, Short and Duarte, 2001), and the data are difficult to explore or needs an expensive statistical program as Echavarría-Heras et al., (2012, 2013) and Solana-Arellano et al., (1991, 2008).

Long-term monitoring of eelgrass growth and biomass is important to capture seasonal and yearly trends (Gaeckle et al., 2006), but both of them are hard to measure accurately (Short and Duarte, 2001), the technique we are proposed is a reliable form to save time and explore data in an easy way.

As seagrasses in general present a similar simple morphology (den Hartog, 1970; Duarte, 1991), equations like the ones we have developed for Z. marina on the Pacific coast of Baja California should be feasible to develop for other seagrass species, and locations. If we consider the possibility of a different growth dynamics in each geographic location, then the probability exists that the sheath length represents a different proportion of the total leaf length and as a consequence of SG, LP, SW, and SLA as well. Then we must emphasize the importance to developing predictive equations for each study region as the only way to prevent over or underestimation of the variables of interest.

# **ABSTRACT**

The geographic and bathymetric patterns of distribution of *Nephropsis occidentalis*, the only marine decapod crustacean of the infraorden Astacidea known from the eastern Pacific Ocean, were studied on the continental slope off the Mexican Pacific, and environmental drivers of those patterns were investigated. Samplings were performed using an Agassiz dredge and a benthic sledge in three main areas: the Gulf of California, the west coast of the Baja California Peninsula and the southern Mexican Pacific. Twelve sampling cruises were performed from 1991 to 2014, by which 171 hauls were obtained between 522 and 2309 m. Temperature, oxygen, salinity and total organic matter from sediments were sampled simultaneously, and data of surface production were recorded. The relationship between the patterns in abundance of *N. occidentalis* and potential environmental drivers was explored through generalised linear models. In addition, all previously published and unpublished records of the species were compiled and bathymetric patterns of distribution along latitude were explored. Within Mexico, 85 specimens of *N. occidentalis* were captured over a narrow bathymetric range, mainly between 1000 and 1300 m, at oxygen concentrations above hypoxia. Because of its high level of activity, this species is likely excluded from hypoxic waters. Males and females were of similar size and larger individuals were restricted to depths greater than 1100 m. The bathymetric patterns of distribution of *N. occidentalis* were associated with oxygen and temperature, probably because of the interdependence between aerobic capacity and temperature tolerance in ectothermic animals. In addition, surface production enhanced

<sup>\*</sup> Corresponding Author's Email: vpapioln@gmail.com; Tel.: +52(669)9852845; Fax +52(669)9856133.

aggregations of *N. occidentalis* four months later. In the Mexican Pacific, *N. occidentalis*  occurs in environmental conditions with 0.22-0.87 ml  $O_2$  l<sup>-1</sup> and 3.4-4.4 °C. Including unpublished records, a total of 61 localities where the species occurs were compiled and a continuous distribution of *N. occidentalis* along the continental slope of the Eastern Pacific from Mexico (ca. 27ºN) to Chile (ca. 33ºS) was confirmed. The first depth of appearance of *N. occidentalis* slightly decreased southwards and somehow followed the bathymetric distribution of the OMZ, thus confirming the effects of such structure on the distribution of the species. Finally, fishery potential of the species is briefly addressed and compared to what is known about similar deep-water species worldwide.

## **INTRODUCTION**

The family Nephropidae is a relatively diverse taxon in the world's oceans, with 21 species in the Atlantic, 34 species in the Indian Ocean, and 31 species in the Pacific (Wahle et al., 2012). Within the Pacific Ocean, this family presents a very heterogeneous distribution, with as many as 30 species occurring in the western part vs. none in the central Pacific, and only one, *Nephropsis occidentalis*, in the eastern Pacific (Wahle et al., 2012). This species also constitutes the only marine Astacidea species occurring in this region. Moreover, the own genus *Nephropsis* is rather diverse in the Indo-West Pacific (9 species) and the Atlantic (5 species) (Chan, 2010), but not in the eastern Pacific.

Species from the genus *Nephropsis* are burrowers and possess a robust first pair of chelae and small unpigmented eyes (Schiff & Hendrickx, 1997; Chan, 1998) (Figure 1). *Nephropsis*  spp. are mostly distributed from ca. 135 to 2560 m depth, with the majority of species occurring between ca. 500 and 1250 m. From a morphological point of view, within the Nephropidae, the genus *Nephropsis* is closer to *Nephropides* than to the rest of the family's genera (Ahyong, 2006). However, phylogenetic relationships based on molecular analysis indicate that *Nephropsis* is closer to *Metanephrops* (Wahle et al., 2012).

*Nephropsis occidentalis*, commonly known as the Pacific lobsterette, was described by Faxon (1893) (Figure 1A) based on material collected off Acapulco and the Tres Marias Islands. It is a relatively large (up to 135 mm of total length: Hendrickx, 2003) benthic astacid lobster distributed from the southern Gulf of California and the west coast of the Baja California Peninsula to Valparaíso, Chile (Bahamonde, 1959; Manning, 1970; Holthuis, 1991; Hendrickx, 1995; Hendrickx, 2003). It has been recorded at depths from 270 to 1310 m, but in Mexico the bathymetric distribution of this species is restricted to depths between 1050 and 1310 m, below the core of the oxygen minimum zone (Hendrickx, 2003).

Oxygen minimum zones (OMZs) occur worldwide and are large oceanic areas where dissolved oxygen concentration in the water is below  $0.5$  ml  $l<sup>-1</sup>$  (Stramma et al., 2010). Those severely affect the distribution of marine benthic communities and, within OMZ cores, where conditions of severe hypoxia take place, macro- and megafaunal organisms are virtually absent (Levin, 2003; Gooday et al., 2009). At the lower boundaries of OMZs, where oxygen concentration increases gradually, megabenthic and benthopelagic organisms feature massive aggregations (Diaz & Rosenberg, 1995; Levin, 2003; Hendrickx, 2012a) and a rapid taxonomic replacement with depth is observed related with the size and swimming capacity

of taxa (Wishner et al., 1990; 1998; Murty et al., 2009). Below those boundaries, abundance of megafauna decreases with depth despite the continuous increase in dissolved oxygen in the water. Both the patterns in oxygen concentration in the water an in food availability have been repeatedly discussed as the main drivers of fauna bathymetric distribution. However, the works available to date have mainly been performed at a community level, and intraspecific patterns of distribution in OMZ areas and autecology of key species have barely been addressed (Jeffreys et al., 2012; Hendrickx & Papiol, in press).

The largest OMZ of the world's oceans is located in the eastern Pacific (Díaz & Rosenberg, 1995; Levin, 2003) and it distributes from ca. 60ºN to 30ºS (Helly & Levin, 2004). The amplitude of this OMZ varies with latitude, its lower boundary being found at shallower depths southwards, and its intensity being lowest at northern latitudes. Maximum thickness and intensity are observed at latitudes from ca. 25ºN to 8ºN, encompassing the continental margins of Mexico, Guatemala, El Salvador, Costa Rica, and Panama, where the OMZ ranges from ca. 100 to 1000 m depth (Helly & Levin, 2004; Fuenzalida et al., 2009). Below the OMZ off the Mexican Pacific, considerably abundant and diverse communities of benthic invertebrates have been reported across several studies (Zamorano et al., 2007; Méndez, 2007; Massin & Hendrickx, 2011; Hendrickx et al., 2011; Zamorano & Hendrickx, 2012). In this area, *N. occidentalis* is a typical member of the decapod crustaceans' community, which is dominated by some large benthic (e.g., *Heterocarpus affinis*, *Lebbeus scrippsi*) and benthopelagic (e.g., *Acantephyra brevicarinata*, *Nematocarcinus* spp.) shrimps, and large to medium-sized squat lobsters (e.g., *Galacantha diomedae*, *Munidopsis depressa*) (Hendrickx, 2001; 2012a; Papiol & Hendrickx, in press).

Despite its potential as a fishery target (Retamal, 1977; Holthuis, 1991), little additional knowledge on the biology and ecology of *N. occidentalis* is available and, to our knowledge, only some information on the morphometrics of the species has been published (Hendrickx, 2003). A similar situation takes place for the rest of *Nephropsis* spp., for which knowledge is limited to sparse documents dealing with their distribution (Pequegnat & Pequegnat, 1983; Macpherson, 1991; Cartes et al., 2007), morphometrics (Dineshbabu, 2008), and physiology (McAllen et al., 2005).

During exploratory cruises off the west coast of Mexico performed from 1991 to 2014 a relatively large series of specimens of *N. occidentalis* was captured. The present contribution reports the material not cited in Hendrickx (2003) and provides information on the distribution and ecology of this species along the Pacific coast of Mexico. In addition, it integrates the information of the published and unpublished records of *N. occidentalis* across its entire range of distribution. Finally, the fishery potential of the species is briefly addressed comparing it with that of other astacid lobsters.

## **MATERIAL AND METHODS**

## **The Mexican Pacific**

Within the TALUD project, 12 cruises were performed on the Mexican Pacific slope from 1991 to 2014 (Table 1). A total of 170 stations were explored in three main areas: the southern Gulf of California (GC), the western coast of the Baja California Peninsula (WBaja), and the southern Mexican Pacific (SMPac). Samples were obtained within and below the OMZ core (defined herein as the fringe where oxygen concentration is  $<$ 0.5 ml l<sup>-1</sup>), from ca. 700 m to ca. 2200 m in both the GC and the WBaja, and from ca. 850 m to ca. 2200 m in the SMPac.

#### *Sampling of Biological Data*

Two different fishing gear were used for sampling: on the 1991 cruise (TALUD III) a total of 12 hauls were performed using an Agassiz dredge (horizontal length 2.50 m; vertical height 1 m), and in the rest of the surveys samples were obtained using a benthic sledge (horizontal length 2.35 m; vertical height 0.9 m) (see Hendrickx, 2012b). Both sampling gear were equipped with an outer collecting net of ca. 5.5 cm (2 1/4") stretch mesh and an inner net of ca. 2.0 cm (3/4") stretch mesh. Considering the similarity of the two gear and the low mobility of the target species, results obtained by both sampling gear were analysed jointly. All samplings were carried out on board of the R.V. "*El Puma"* at an average speed of 1.75 knots and the time on the bottom of each haul was on average 30 minutes.

Figure 1. (A) Original illustration of *Nephropsis occidentalis* (from Faxon, 1895); (B) *Nephropsis occidentalis*, dorsal view (TALUD) (EMU-9830). C. Same, lateral view.

Once identified, all specimens of *N. occidentalis* were sexed, counted, measured (carapace length, *CL* in mm;  $\pm$  0.1 mm) and weighed ( $\pm$  0.1 g) at the laboratory. Most specimens were preserved in ethanol and deposited in the Regional Collection of Marine Invertebrates (EMU) at UNAM in Mazatlán, Mexico.

## *Sampling of Environmental Data*

Depth was measured with an EdoWestern analogic (TALUD III-VIII) or a Simrad digital (TALUD IX-XVIB) recorder. Temperature, salinity, and oxygen (the latter two only from TALUD VII and on) were measured around 20 m above the sea bottom (20mab) with a Seabird 19 CTD equipped with an oxygen sensor at each station. Rosette-mounted 10 litres Niskin bottles were also deployed and dissolved oxygen content was estimated with the Winkler method (Strickland & Parsons, 1972) during all samplings. Oxygen values obtained with the two methods (CTD and Winkler) were usually similar. Winkler data were used in the statistical analysis and those obtained with the CTD were plotted vs. depth.

## **Table 1. Date, depth range, minimum and maximum latitude and longitude, number of hauls performed and number of** *Nephropsis occidentalis* **specimens collected during the oceanographic cruises conducted within the TALUD research project**

## *Sediment Sampling and Analysis*

Sediments were sampled by means of a Smith-McIntyre dredge or a modified USNEL box core at each sampling station and samples of the top 3 cm were obtained and stored at 4-  $8^{\circ}$ C. At the laboratory, total organic matter contents of sediments (TOM<sub>sed</sub>), calculated as the difference between dry weight (DW:  $60^{\circ}$ C to constant weight) and ash weight (500 $^{\circ}$ C in a furnace for 2 h), were obtained and used as indicators of food availability for benthos (see Beaulieu, 2002).

Phytoplankton pigment concentration (PPC, mg Chla m<sup>-3</sup>) values were obtained from http://reason.gsfc.nasa.gov/Giovanni and were used as an estimate of surface primary production in the area. This was used to assess the response of bathyal decapod crustaceans to surface production processes (Cartes et al. 2004). Monthly average PPC values recorded for each locality on the date of sampling  $(PPC_{sim})$  and 1-6 months before (PPC-1 to PPC-6) were used in order to evaluate the time lag between surface processes and the faunal response.

#### *Data Analyses*

#### **Population Structure**

Geographical patterns of distribution of *N. occidentalis* collected during the TALUD survey in western Mexico were evaluated by plotting the presence/absence of the species on a map. Abundance and biomass of *N. occidentalis* were standardized to a common swept area of 1 hectare (ind ha<sup>-1</sup> and g ha<sup>-1</sup>, respectively). In order to determine the depth distribution of the species, abundance and biomass patterns with depth were analysed for the Mexican Pacific as a whole, grouping samples every 100 m. Statistical differences in bathymetric patterns of abundance and biomass of *N. occidentalis* were tested. All data were tested for normality using the Kolmogorov-Smirnov test. For data that were normally distributed, ANOVA were used. For data that did not satisfy the assumptions of normality, even after transformation, a non-parametric Kruskal-Wallis or Mann-Whitney U test was used.

Sexual and bathymetric differences in *CL* were tested for the whole Mexican Pacific using a Mann-Whitney U and a Kruskal-Wallis test, respectively.

#### **Environmental Variables**

The bathymetric patterns of near-bottom temperature  $(T_{20mab})$ , salinity  $(S_{20mab})$ , and oxygen  $(O_{20mab})$ , and of TOM<sub>sed</sub> in each sampling area where the species was present were examined. In addition, environmental maximum and minimum thresholds of distribution of the species were recorded.

#### **Drivers of Population Structure**

In order to identify which variables explained the patterns of distribution of *N. occidentalis*, values of abundance at all depths were compared with independent explanatory variables by means of generalized linear models (GLM). Abundance values were logtransformed and the distribution family used was Gaussian with identity link function. The models were computed by adding single terms based on minimizing Akaike's Information Criterion and only including variables that were significant ( $p < 0.05$ ). Environmental variables included were:  $T_{20mab}$ ,  $O_{20mab}$ , PPC<sub>sim</sub>, PPC-1 to PPC-6, and TOM<sub>sed</sub>.

All statistical analyses were carried out with STATISTICA 10 (StatSoft Inc.) and R 3.1.2 (http://www.r-project.org/) softwares.

#### *Worldwide Distribution*

Previously published and unpublished records of catches of *N. occidentalis* worldwide were compiled and the geographic distribution of the species was explored. The bathymetric distribution of the species in relationship with latitude was investigated and compared with latitudinal patterns of dissolved oxygen concentration in the water described by Helly & Levin (2004).

Figure 2. Position of the samplings performed during TALUD cruises with presence (●) and absence (○) of *Nephropsis occidentalis* indicated.

## **RESULTS**

## **The Mexican Pacific**

#### *Population Structure*

A total of 85 specimens of *N. occidentalis* were collected in the Mexican Pacific in 18 hauls out of the 170 initially performed (Table 2). Northernmost latitude of collection of *N. occidentalis* was 27.1°N, off Baja California (Table 2; Figure 2).

Within the Gulf of California, *N. occidentalis* was neither collected on the peninsular slope nor at latitudes above 26°N. Therefore, samples obtained above 27.1°N off Baja California (TALUD XVI-B cruise; see Table 1) and samples obtained at the peninsular slope and at the northern sampling sites within the Gulf of California (TALUD VIII, IX, X, XIV) were not considered for abundance and biomass estimations and comparisons. Seventeen of the hauls (= 94%) containing *N. occidentalis* were obtained between 980 and 1310 m, and only two specimens were caught in one haul located at 772-786 m (Table 2). Bathymetric analyses of abundance and biomass for the Mexican Pacific revealed greatest values of both parameters between 1100 and 1300 m (Figure 3). Moreover, on the continental slope of the Gulf of California, all specimens were caught between 1100 and 1300 m, and no specimens were present between 1000 and 1100 m. Main Kruskal-Wallis test for bathymetric changes in abundance (H<sub>13,101</sub> = 42.55;  $P < 0.001$ ) and biomass (H<sub>13,101</sub> = 43.02;  $P < 0.001$ ) were significant. However, the large number of hauls without *N. occidentalis* provided high intrasamples variance which probably led to the lack of statistical significance when testing for bathymetric differences in abundance and biomass across 100 m depth intervals.

All specimens collected were adults. Sex ratio (M : F) was 1:0.65. Overall, sizes of males and females were similar (Mann-Whitney U test,  $n_F = 34$ ,  $n_M = 51$ ,  $P = 0.80$ ) and ranged from 18.3 to 42.3 mm, 84% of the specimens ranging from 24 to 40 mm (Figure 4a). The size of individuals changed with depth (K-W test  $H_{3,85} = 10.83$ ;  $P < 0.05$ ), larger individuals (*CL* > 35 mm) being restricted to depth greater than 1100 m (Figure 4b).

Figure 3. Bathymetric patterns in abundance and biomass of *Nephropsis occidentalis* collected in the Mexican Pacific considering the entire bathymetric interval sampled during the survey.

Figure 4. Cephalotorax length distribution (a) of males and females of *Nephropsis occidentalis* (black = males; grey = females) and (b) by depth range (black =  $1001-1100$  m; white =  $1101-1200$  m;  $grey = 1201-1300$  m).

Catalogue number of each lot, sampling location, date and depth are also indicated**

#### **Environmental Variables**

In the three areas where *N. occidentalis* was present, at depths greater than 700 m T<sub>20mab</sub> decreased with depth while both  $O_{20mab}$  and  $S_{20mab}$  increased with depth (Figure 5), the latter increasing very slightly. O<sub>20mab</sub> started increasing shallower on the slope off WBaja than in the GC and the SMPac. Patterns of  $T_{20mab}$  were similar in the three areas, but  $S_{20mab}$  was in general lower off WBaja. TOM<sub>sed</sub> was not available for 15 samples (i.e.,  $9\%$ ). For the rest of data, both in the GC and the SMPac greatest values of TOM<sub>sed</sub> were found at the shallowest depths sampled (ca. 700-900 m) (Figure 6). Below those depths, TOM<sub>sed</sub> values were stable. Off the WBaja, TOMsed values did not follow any bathymetric pattern and were generally lower than in the other two areas.

Figure 5. Bathymetric profiles of average (and standard deviation) temperature, salinity and oxygen measured for the three areas in which *N. occidentalis* was collected: (a) Gulf of California (Talud VII St. 19), (b) southern Mexican Pacific (TALUD XII St. 10, 13, 23, 28), and (c) western Baja California Peninsula (TALUD XV St. 8, 5C, 13, 2, 24). Upper and lower boundaries of the 0.2 and 0.5 ml  $1<sup>-1</sup>$ dissolved oxygen concentrations (horizontal lines) OMZ and presence of *Nephropsis occidentalis* (arrows) indicated.

Figure 6. Percentage total organic matter in sediments by area (black = continental slope of the Gulf of California; grey=southern Mexican Pacific; white = western Baja California).

Figure 7. Ranges of depth, oxygen, temperature, salinity and organic matter in sediments sampled (light grey) and ranges corresponding to captures of *N. occidentalis* (98% of individuals captured: black; remaining 2% captured: dark grey). WBaja = western Baja California; GC = Gulf of California; SMPac = southern Mexican Pacific.

Ranges obtained for environmental parameters (Figure 7) indicate that *Nephropsis occidentalis* occurred over a relatively narrow oxygen range (0.14-0.87 ml l<sup>-1</sup>), although most specimens (98%; the two specimens collected at 779 m not being considered) were present at O<sub>20mab</sub> > 0.22 ml 1<sup>-1</sup>. Lowest oxygen concentration tolerated by *N. occidentalis* was similar in the three areas analysed. T20mab where *N. occidentalis* were collected ranged from 3.4 to 5.2°C (98% of specimens between 3.4 and 4.39 $^{\circ}$ C). S<sub>20mab</sub> were not available for the continental slope of the GC. In the other areas, *N. occidentalis* was collected at S<sub>20mab</sub> between 34.53 and 34.60 g kg-1 . Regarding TOMsed, both in the WBaja and at SMPac *N. occidentalis* was found from the lowest values measured (ca. 2%) to almost maximum values obtained (8.7% and 13.6%, respectively). In the GC, *N. occidentalis* appeared at greater values of TOMsed, from 12.6% to 15.1%.

#### **Drivers of Population Structure**

The GLMs performed on the abundance data considering all samples explained 15% of the total variation (Table 3), with  $O_{20mab}$ ,  $T_{20mab}$  and PPC-4 as the main drivers of abundance patterns of distribution.

## **Worldwide Distribution**

A total of 61 records of *N. occidentalis* (Tables 2, 4) were compiled, 37 of which were unpublished records. Those confirmed that *N. occidentalis* is an endemic species of the eastern Pacific. The species is continuously distributed from the west coast of Baja California (27.1ºN), Mexico, to Valparaiso (ca. 33ºS), Chile, with confirmed captures from off the coasts of El Salvador, Nicaragua, Costa Rica, Panama, Ecuador, and Peru (Table 4; Figure 8). Considering all captures, *N. occidentalis* is restricted to depths greater than 700 m along its distribution range, except for two specimens collected at 533-569 m off Peru and a single specimen collected at 270 m off Valparaiso, Chile (33ºS), coinciding with its southernmost distribution limit.

The analysis of the bathymetric distribution of *N. occidentalis* with latitude revealed that shallowest depths of occurrence slightly decreased from north to south (Figure 9). Between latitudes of ca. 27°N to ca. 11.5ºN organisms were found at ca. 1000-1300 m; between 11.5ºN and 11.5ºS most samples were obtained at ca. 800-1000 m. At latitudes around 17ºS organisms were distributed along a wider depth range, being observed from 800 to ca. 1250 m. The bathymetric distribution of the species somehow matched the profile of the OMZ described by Helly and Levin (2004) (Figure 9), this being especially noticeable in the Ushaped pattern of distribution from 27.1ºN to ca. 6.5ºN and in the relatively shallow samples collected at ca. 4ºS at 551 m (depth range of haul 533-569 m) and at ca. 33ºS at 270 m.

## **DISCUSSION**

The distribution of a species depends on the influence of a variety of interacting abiotic and biotic factors both at the macro- and the mesoscale (Boschi, 2000; Sexton et al., 2009). Below OMZs, the interaction between dissolved oxygen concentration and food availability has often been discussed as the main driver of species' bathymetric distributions (e.g., Levin et al., 1991; Levin et al., 2009; Mosch et al., 2012; Levin & Sibuet, 2012). However, few studies have established direct relationships between fauna patterns and environmental drivers, especially regarding benthopelagic megafauna. The few existing works have usually been performed at the community level (Murty et al., 2009; Papiol & Hendrickx, in press), and studies on population distribution and ecology are even scarcer (Jeffreys et al., 2012; Hendrickx and Papiol, in press).

In this chapter the patterns of distribution of *Nephropsis occidentalis*, a benthic lobsterette living below the OMZ of the Eastern Pacific Ocean (Hendrickx, 2003), were analysed at the mesoscale level off Mexico, and the environmental factors controlling those patterns were explored. In addition, information on the distribution of *N. occidentalis* at the macroscale was compiled, and bathymetric patterns of distribution along latitude were investigated.

## **Mexican Pacific**

#### *Population Structure*

*Nephropsis occidentalis* is a relatively large benthic decapod crustacean with a unimodal size distribution of the population off the Mexican Pacific ranging from 18.3 to 42.3 mm *CL*. Maximum size coincides with the specimen already reported by Hendrickx (2003), which constitutes the largest specimen known to date.

This lobsterette mainly inhabited depths between 980 and 1310 m, with oxygen concentrations above hypoxic values (i.e., > 0.2 ml 1<sup>-1</sup>; Kamykowski & Zentara, 1990), along the whole Mexican Pacific. Megafauna, such as crabs and shrimps, are rare where oxygen drops below 0.1 ml 1<sup>-1</sup>. Low swimming capacity benthic decapods (e.g., *Munidopsis* spp.; McAllen et al., 2005) with low metabolic rates (Company & Sardà, 1998) proliferate below the OMZ cores at water with oxygen concentration below 0.2 ml  $l<sup>-1</sup>$  (e.g., Wishner et al., 1990; Murty et al., 2009; Papiol & Hendrickx, in press), and more mobile taxa with higher metabolic demands for oxygen are usually found in water with higher oxygen concentration. Although *N. occidentalis* is a benthic species with little natatory ability, *Nephropsis* is a very active genus (McAllen et al., 2005). Therefore, high metabolic requirements of *N. occidentalis* probably exclude it from hypoxic water and its distribution is restricted to depths greater than ca. 1000 m, where water is more oxygenated. Surprisingly, two individuals were recorded in a haul performed at depths of  $772-786$  m and oxygen concentration of 0.14 ml  $1<sup>-1</sup>$ . Temporal excursions into less oxygenated waters for escaping predators or finding food have been observed in other species (Gooday et al., 2009) and seem a plausible explanation for this finding, as some Nephropidae are known to be adapted to short periods of hypoxia (Eriksson et al., 2013).

The peak in abundance of *N. occidentalis* in the lower limit of the OMZ core and its distribution within a narrow depth range of ca. 300 m is somehow parallel to the pattern of distribution observed for decapod crustaceans below OMZs in other regions (e.g., Wishner et al., 1990; Murty et al., 2009). Aggregations of organisms below OMZ cores have been attributed to the large accumulation of food in these areas. The restriction of *N. occidentalis* within such a narrow depth range could be driven by the parallel restriction of its food source to this stratum. It is likely that *N. occidentalis* is sustained by benthic and benthopelagic

macrofauna that peak in narrow bands below OMZ cores (Wishner et al., 1995; 2008; Mosch et al., 2012), as the species' powerful chelipeds and the presence of polychaetes, decapod crustaceans, and fish remains in their stomachs (authors' unp. data) suggest it is an active predator on macrofauna. The paucity of macrofaunal prey at greater depths (Wishner et al., 1995; Levin et al., 2000; Mosch et al., 2012) could cause the parallel disappearance of *N. occidentalis*.

Figure 8. Distribution of *N. occidentalis* in the eastern Pacific including previously published records (solid symbols) and additional records (open symbols). See Tables 2 and 3.

Although the low number of organisms available forces cautious interpretation of the data, results suggest that within the narrow bathymetric range of distribution of *N. occidentalis* there was size structure in which larger individuals were restricted to depths greater than 1100 m. Bathymetric size segregation within a given habitat is usually attributed to food availability together with how species exploit existing food resources (Rowe, 1971; Carey, 1981). The depth pattern observed in *N. occidentalis* could be associated with the presence of different potential food sources (i.e., prey items) through the depth gradient (Wishner et al., 1995; Levin et al., 2009) coupled with ontogenic variations that could take place in the diet of *N. occidentalis*, as reported for other Nephropidae (e.g., *Metanephrops thomsoni*; Choi et al., 2008).

Notwithstanding the relatively large range of sizes collected, all specimens obtained during the TALUD surveys were adults. Although the selectivity of the gear mesh size is biased towards capturing medium to large-size individuals, small specimens (i.e., <15 mm total length) of other species (e.g., *Galacantha diomedeae*, *Munidopsis* spp.,) have been regularly collected using the same net (authors' pers. observ.). The bathymetric distributions of smaller specimens of *N. occidentalis* as well as their recruitment patterns remain therefore unsolved, as occurs with the majority of decapod crustacean species from below OMZs. Little is known about the occurrence of larvae or juveniles of deep-water decapod crustaceans in general and specially within or below the OMZ off the Mexican Pacific (see Hendrickx & García-Guerrero, 2007; Thatje et al., 2005). Besides, only three ovigerous females were obtained, ranging from 34.1 to 37.1 mm CL, which is very close to the maximum known size of the species (42.3 mm CL). These eggs-carrying females were collected in March, August and December, an indication that reproduction probably occurs all year-round.

## **Environmental Drivers of the Distribution of the Pacific Lobsterette**

A large amount of variation was not explained by the models obtained in our study, probably due to the complex and very patchy distribution of megafauna in the Mexican Pacific (Méndez, 2007; Papiol & Hendrickx, in press), which is likely enhanced by the clustering of burrows observed in some species of Nephropidae (Dybern & Höisaeter, 1965). Besides, the availability of information on some additional variables (e.g., salinity, prey availability, or  $\delta^{3}C$  of sediments) that have been identified as important drivers of decapod crustaceans' distribution in other studies (Murty et al., 2009; Papiol et al., 2012; Fanelli et al., 2013) could contribute to increase the amount of variation explained in our models. However, combined effects of both oxygen and temperature partially controlled the distribution of *N. occidentalis* over the depth gradient. As mentioned above, metabolic rates associated with activity level of a species somehow define its minimum oxygen thresholds. Coherently, the active *N. occidentalis* is excluded from hypoxic environments. Also, the positive influence of temperature on metabolic rates (Childress et al., 1990) likely reinforces the exclusion of *N. occidentalis* from shallower, less oxygenated, warmer waters. In addition, aerobic capacity and temperature tolerance are interdependent processes within most ectothermic animals. There are both high and low species-specific critical temperatures that lead to tissue hypoxia through limited ventilation and circulation performance (Frederich & Pörtner, 2000; Pörtner, 2001; Ekau et al., 2010). In the Mexican Pacific, the optimum temperature range for aerobic performance of *N. occidentalis* seems to be between ca. 3 and 5°C at dissolved oxygen concentrations of between  $0.87$  and  $0.22$  ml  $1<sup>-1</sup>$ .

Within OMZ areas, the interaction between oxygen and food availability has often been discussed as main driver of species' distribution. In the present chapter the foremost importance of food was not patent, most probably due to the lack of adequate food indicators (e.g.,  $\delta^{3}C$  composition of sediments or biomass of potential prey; Murty et al., 2009; Fanelli et al., 2013). However, food inputs generated at surface favoured aggregations of *N. occidentalis* four months later. The relationship between fauna patterns and surface production is coherent with the occurrence of short food chains (Fanelli et al., 2013) that have been proposed below OMZ cores (Wishner et al. 1995). Zooplankton taxa potentially inhabiting the lower boundary of the OMZ (Wishner et al., 1995; 2008; Roullier et al., 2013) likely channel the fresh organic matter sinking from surface to megafauna (Fanelli et al., 2011).

Figure 9. Bathymetric distribution (●) of *Nephropsis occidentalis* along a latitudinal gradient from Mexico to southern Chile. The depth range of the OMZ corresponding to upper and lower values of ≤ 0.5 ml  $l$ <sup>-1</sup> is indicated (grey) (adapted from Helly & Levin, 2004).

#### **Worldwide Patterns of Distribution**

The latitudinal range of distribution of *N. occidentalis* was not expanded with respect to previous knowledge, but the 37 additional records compiled in the present chapter confirmed that the species is continuously distributed all along a very large section of the continental slope off western America, from ca. 27º40'N off Baja California, Mexico, to ca. 33ºS, off Valparaiso, Chile. Most works dealing with invertebrate zoogeographic regionalization at the macroscale have been performed on littoral and shelf areas (e.g., Brusca & Wallerstein, 1979; Boschi, 2000; Castillo & Guiñez, 2000), and some studies have been performed at hydrothermal vents (Won et al., 2003; Wolff, 2005) and seamounts (Samadi et al., 2006). Despite the relative scarcity of deep-water samplings, Wicksten (1989) investigated zoogeographic provinces based on decapod crustaceans occurring from 50 m to depths greater than 1500 m. Both shallow and deep-water studies coincided in the segregation of the ocean margin from California to central Chile into several provinces characterised by different species (Wicksten, 1989). *Nephropsis occidentalis* is distributed along this entire coast, and thus its distribution is considered particularly wide.

To our knowledge, *N. occidentalis* has not been reported further north or south of the range reported herein, thus some biotic and/or abiotic factors must be preventing the species' expansion beyond these geographical limits (Sexton et al., 2009). Among those factors, the most important usually listed are the geological history of each area, topographic barriers, physical-chemical gradients, and biological factors (Briggs, 1974; Vermeij, 1978; Wicksten, 1989). The northern and southern limits of distribution of *N. occidentalis* are related with the inflow of low salinity intermediate water masses (i.e., the North Pacific Intermediate Water, NPIW: Fiedler & Talley, 2006; and the Eastern South Pacific Intermediate Water, ESPIW: Schneider et al., 2003). The inflow of the NPIW in the north is coherent with the lower salinity and its greater oscillations observed in the southern Baja California in this study (see Figure 5). We hypothesize that the changes in the salinity due to the presence of haline fronts could be above the tolerance limit of *N. occidentalis*, constituting a barrier for the dispersal of the species. Small changes in the physical properties of the environment especially affect species living in the deep sea, where the environment is usually stable (Gage  $&$  Tyler, 1991). Although the salinity minima of both water masses (NPIW and ESPIW) are located shallower than the range of distribution of *N. occidentalis*, they could still be affecting the distribution of their planktonic larvae.

Inside the Gulf, the distribution of *N. occidentalis* was limited to the continental side of the slope. The sedimentary and less precipitous character of the continental shelf and slope contrasts with the steep and calcareous rocky nature of the peninsular coast (Shepard, 1950; Thunell, 1998), and may provide more suitable habitat for burrowing decapods such as *N. occidentalis*.

Our results (both by Winkler and CTD) suggested a deeper location of the lower boundary of the OMZ ( $O_2 = 0.5$  m l<sup>-1</sup>) for the Mexican Pacific than that reported by Helly & Levin (2004). Nevertheless, the latitudinal pattern of the shallowest depth of collection of *N. occidentalis* was somehow parallel to that of the lower OMZ boundary, with a southward trend of shallower collection of *N. occidentalis*. This distribution pattern is consistent with the above discussed importance of oxygen concentration as a limiting factor for *N. occidentalis* proliferation below the OMZ. In addition, *N. occidentalis* was usually distributed over narrow bathymetric ranges, likely due to the edge effect at the OMZ lower boundary, as described above. In contrast, at latitudes of 15-19ºS *N. occidentalis* occupied a relatively wide bathymetric range. There is no clear explanation for this. The OMZ edge effects caused by the food accumulation and rapid transformation may be significantly reduced in this area where the OMZ is less intense, and there could be no need for *N. occidentalis* to adapt to this particular landscape. However, many other environmental (biotic or abiotic) factors could be causing this different distribution, and further studies would be required to clarify this issue.

## **Fishery Potential**

With a worldwide increasing interest for new fishery resources in deep waters (Roberts, 2002; Norse et al., 2012), many species of decapod crustaceans that had been traditionally ignored are now regarded as potentially important. The "langoustines", "lobsterettes" or "scampi" are no exception to this and recent surveys have been undertaken in order to evaluate the stocks and gather information on their biology (Lynch & Garvey, 2005; Choi et al., 2008; Paramo & Saint-Paul, 2012; Robey et al. 2013). In the specific case of the genus

*Nephropsis*, Pequegnat & Pequegnat (1983) reported three species in the Gulf of Mexico. Densities (orgs ha<sup>-1</sup>) varied considerably according to depth and from one species to another. *Nephropsis agassizii* was collected in depths of 900-1600 m with maximum density (ca. 200 orgs ha-1 ) observed at 950 m. *Nephropsis aculeata* occurred in depths of 350-1350 and ranked second in population density (maximum of ca. 100 orgs ha<sup>-1</sup> at 500 m). The third and less abundant species, *N. rosea* (ca. 25 orgs ha<sup>-1</sup>), was also the shallowest (500-750 m) with population peak at 700 m. Guéguen (2000) reported *N. aculeata* (321-491 m depth) and *N. rosea* (547-854 m depth) as two of the major species of decapod crustaceans from off the coast of Guyana, with catch per hour of trawl comprised between ca. 23 and 637 g. *Nephropsis aculeata* has also been reported as an abundant species off the Mississippi river and East Florida, with captures of up to  $40 \text{ kg h}^{-1}$  (Holthuis, 1991). This species is distributed at depths of 137-824 m in the Gulf of Mexico, Caribbean Province and extended to the north off Massachussets. Another species that has recently caught the attention is *Nephropsis carpenteri*, occurring around India and Japan. This forms part of the by-catch of the deep-sea shrimps' fishery (e.g., *Aristeus*, *Solenocera*, *Metapenaeopsis*, *Heterocarpus*) off Chenia, India, and represents up to 40% of total catch with maximum size of 154 mm total length (Thirumilu, 2011). Morphometric relationships and fishery aspects of the Indian Ocean lobsterette *Nephropsis stewarti* have been documented by Dineshbabu (2008) for the SW coast of India. The species is fished between 250 and 500 m and yields an average annual catch of 23.3 t, with a sharp decrease after a peak of captures in 2001-2002, and is processed together with scylarids lobsters and mostly exported. A survey in the same area in 2006, however, indicated that *N. stewarti* might have a very limited importance because catches are restricted to a rather reduced area (Jayaprakash et al., 2006). Small catches of *N. stewarti* of up to 0.5 kg h<sup>-1</sup> of trawl have also been reported off Madagascar (Crosnier & Jouannic, 1973). Although the maximum size of this species is greater than that of *N. occidentalis* (total length 113 mm in males, 158 mm in females), almost 90% of the catch corresponded to specimens with a length range of 80-105 mm, similar to what has been observed with *N. occidentalis*.

Because information related to the abundance and distribution of *N. occidentalis* in the eastern Pacific is still very limited, it is difficult to evaluate if a profitable fishery could be initiated. Holthuis (1991) referred to a potential interest for this species off the coast of Chile and Retamal (1977) reported this lobsterette as a common by-catch of the *Heterocarpus reedi* fishery. Almost 40 years after this report by Retamal (1977), no fishery has apparently been developed for *N. occidentalis* off Chile (G. Guzman, pers. comm., 2014; M. Retamal, pers. comm., 2014) and captures of this species have been incidental, with only a few specimens available in museums collections (Table 2). Although it is likely that *N. occidentalis* still forms part of the *H. reedi* fishery (that produced a total capture of ca. 4,350 t year<sup>-1</sup> from 2006-2010) (Wehrtmann et al., 2012), no specific information seems to be available on the potential use of this lobsterette in the area or on its ecology (P. Arana, pers. comm. 2014).

Bottom trawling is the major fishery in deep-sea habitats (Kaiser et al., 2002), and technical advances in the last 6 decades have allowed the exploitation of these habitats (Thiel, 2003; Clark et al., 2007; Benn et al., 2010). For example, in the Mediterranean Sea, deepwater bottom trawling targeting *Aristeus antennatus* (400-800 m) is common (Cartes & Sardà, 1989; Cartes et al. 2008). However, it is well known that trawl fisheries have an enormous environmental impact, which is especially notable on deep-water communities (Gray et al., 2006; Althaus et al., 2009, Maynou & Cartes, 2011), and any intention to switch part of the current fishery activity in that direction should be carefully evaluated. Besides, in

the particular case of western Mexico, targeting deep-water crustaceans or other deep-water species (e.g., Holothuroidea, Macrouridae) occurring below the OMZ would imply deployment of fishing gear at depths greater than 700-800 m in most areas, a costly operation with few guarantees of sustainability.

## **OUTLOOK**

The investigation on the distribution and ecology of decapod crustaceans living below OMZ areas is still in its early stages, and further studies are not only necessary but urgently required in order to understand the role of each species within the communities. Additional multidisciplinary studies encompassing samplings of biotic and abiotic data are essential in order to better understand the distribution of *N. occidentalis*. However, considering that both oxygen and temperature are drivers of the bathymetric distribution of deep-water decapods, there is a potential susceptibility to the global pattern of expansion of OMZs resulting of climate change. Consequently, the study of deep-water communities in these areas should be considered a priority.

## **ACKNOWLEDGMENTS**

The authors would like to thank all scientists, students and crew members who helped with the sampling operations aboard the R/V "El Puma" during the TALUD III-XVI-B cruises. Authors also thank Mercedes Cordero Ruiz (Mexico) for preparing Figures 1 and 8, and editing Figures 8 and 9, Ana K. Barragán (Mexico) for laboratory support (SNI III assistant, CONACyT), Francesc Maynou (Spain) and Juan Madrid (Mexico) for their advice in statistical analyses, and our colleagues Jorge López (El Salvador), Albertina Kameya (Peru), Marco Retamal, Guillermo Guzman and Patricio Arana (Chile), and Rita Vargas (Costa Rica) who generously provided information on capture of *N. occidentalis*. Many thanks to M.K. Wicksten (U.S.A.) for her careful reading of the manuscript and useful suggestions. We also thank José Salgado-Barragán (Mexico) for taking the photographs of Figure 1 B, C aboard the R/V "*El Puma*". Ship time of the research cruises TALUD III-XVI-B carried aboard the R/V "*El Puma*" was funded by the Universidad Nacional Autónoma de México and CONACyT (TALUD XV and XVI-B). This study was partly supported by CONACyT (Projects 31805–N and 179467) and PAPIIT, DGAPA (projects IN-217306-3 and INE-203013-2). The authors wish to acknowledge use of the Maptool program for graphics in this paper. Maptool is a product of SEATURTLE.ORG. (Information is available at www.seaturtle.org). One of us (VP) is beneficiary of a DGAPA, UNAM, postdoctoral grant. The use of Figure 2a from Helly  $&$  Levin (2004) is covered by the copyright agreement with Elsevier Science and Technology Journals (Copyright Clearance Center's Rights).

**ABSTRACT**

Sea turtles are migratory vertebrates that are linked to many coastal and marine habitats in different parts of the world depending on the stage of their life cycle. These agencies have given them a higher value as a sentinel species by characteristics such as longevity, size, resilience to environmental changes of the seas, and even changes induced by humans as environmental pollution. One of the main risks to sea turtles is drowning in gill nets or trawl fisheries used in flake or shrimp; it has been extensively analyzed in different regions of the country and the world. However, the effects of environmental pollution on the health of sea turtles is the least studied. The environment has been altered dramatically in recent years by rising temperatures, increased severity, and frequency of storms and rising sea level, where most human settlements have been deforested and changed land use for urban, port and tourist developments. In the case of turtles, these changes affect species differentially throughout his life. For example, climate change and temperature variations can affect the sex ratio of the hatchlings and nesting patterns since they depend on healthy beaches to lay eggs, so the migration patterns of females could be affected significantly by climate change. The dependence of sea turtles of seagrass meadows, mangrove forest, rhodolith beds, Sargassum forest, coral reefs and deep ocean to live, give them the importance of indicators of the environmental health of these ecosystems. Understanding how pollution and climate change may affect these ecosystems not only benefit conservation programs of populations of sea turtles, but also the diversity associated with them. On which they depend on millions of people living along the shores of the world using marine resources and ecosystem services for their economic activities and food safety.

#### **INTRODUCTION**

Several studies claim that over-exploitation of fishery resources, climate change, environmental pollution, and the resulting acidification of the oceans, threatening marine ecosystems. Some of the most common contaminants derived from human activity are pesticides, herbicides, chemical fertilizers, detergents, hydrocarbons, sewage, plastics and other solids. Many of these pollutants accumulate in the deep ocean, except plastic that accumulates mostly on the surface, where they are ingested by small marine organisms introduced in the global food chain (Beltran et al. 2005). The threat of extinction faced by sea turtles worldwide has meant that today all species are included in Appendix I of the resolutions of the Convention on International Trade in Endangered Species of Flora and Fauna Threatened (CITES 2001). The International Union for Conservation of Nature and Natural Resources (IUCN 2006) lists all species and subspecies of sea turtles in danger of extinction, with three of them in critical condition: the olive ridley (*Lepidochelys kempii*), hawksbill turtle (*Eretmochelys imbricata*) and the leatherback turtle (*Dermochelys coriacea*), while the Endangered Species Act of the United States and the Inter-American Convention for the Protection and Conservation of Sea Turtles (IAC) regards them as threatened or endangered. In Mexico, the degree of threat and protection of sea turtles is established in the Mexican Official Standard NOM-059-ECOL (Official Journal, September 2010) while regulations for handling and care laboratory are reflected in NOM -162-SEMARNAT (February 2012).

A species that can illustrate the serious threat that hangs over these agencies is the hawksbill turtle. Exploitation that has made this kind of the value of its shell has caused a reduction in global population by over 80% in the last 105 years, and it is expected that this reduction will continue in the near future due to the activities of gathering of eggs in nesting areas, capture of juveniles and adult individuals for consumption, incidental killing in fishing gear (Gardner and Nichols 2001) or ship strikes both fishing tourism, intensely still happen in different areas where these organisms are distributed. The concern generated by this decline is reflected in different publications like Groombridge and Luxmoore (1989), the volume dedicated in 1999 by the journal Chelonian Conservation and Biology at depth examination of this kind, the "Status Listing Justification for the Hawksbill Turtle (*Eretmochelys imbricata*) as Critically Endangered on the 1996 IUCN Red List of Threatened Animals "by Meylan and Donnelly (1999) and" Status of the Hawksbill Turtle (*Eretmochelys imbricata*) in the Caribbean region "by Meylan (1989).

Currently, it is considered that only five populations exist hawksbill more than 1,000 nesting females annually in the Republic of Seychelles (Indian Ocean), Mexico, Indonesia and two in Australia. Four of these populations (Indonesia, Seychelles and in Australia) show a declining trend. The government of Australia has described the hawksbill populations in its territory as vulnerable; they are considered as the largest populations in the world (CITES 2001). In the last document prepared by the group of experts of sea turtles IUCN / SSC, it is mentioned that worldwide, only Mexico remains positive trends in population recovery (Guzman-Hernandez, 2005) as a result of more than ten years of protection. Cases like that of Mexico show that populations of this species may react positively to programs of long-term preservation (Frazier 2000).

## **BIODIVERSITY OF SEA TURTLES IN MEXICO**

Mexico is considered one of the countries with the highest diversity of reptiles in the world and is considered as an important example sea turtles (Carabias et al. 2005). In the coast are six of the seven species in the world: the olive ridley (*Lepidochelys kempii*) that nests on the coasts of Tamaulipas and in small quantities in the coast of Campeche; hawksbill turtle (*Eretmochelys imbricata*) nesting on the coast of Campeche, Yucatan, Quintana Roo and another Pacific and Atlantic is the largest (Mortimer or Marquez or both) population, the green turtle (*Chelonia mydas*) whose records are in the Gulf of Mexico, Caribbean Sea and the Pacific; the loggerhead turtle (*Caretta caretta*) and the leatherback turtle (*Dermochelys coriacea*) nesting in the Caribbean and Pacific coasts. Since 1993, year in which the dramatic decline of the latter species was observed, actions were initiated along the Mexican Pacific coast looking for possible causes of this decline. For it was signed in 2003 the Tri Convention for the Recovery and Conservation of the Leatherback Turtle in the Eastern Pacific with the main objective to design and establish measures for the conservation and recovery of the stock of Eastern Pacific Leatherback and habitat which it depends, based on the available scientific evidence into account the environmental, socioeconomic and cultural characteristics of the parties. In that agreement it provides that, for the recovery of lutes, should be given full attention to terrestrial factors (alteration and destruction of nesting beaches, illegal collection of eggs, etc.) and marine (mainly the result of fishing activities and pollution), as well as playback or presence of the olive ridley (*Lepidochelys olivacea*) and the black turtle (Chelonia agassizii) whose nests are recorded in the Pacific (Marquez 2002; Guzman-Hernandez 2005; Sarti et al. 2007).

## **THREATS TO SEA TURTLES**

Turtles have certain characteristics that make them particularly vulnerable to environmental disturbances such as:

## **CLIMATE CHANGE**

In our country, it lives about 10% of the diversity of the planet, so it is considered a megadiverse country. The causes of this loss of biodiversity may be falling into two broad categories: 1) immediate causes: habitat destruction and fragmentation, overexploitation of wildlife resources, invasive species, pollution, and 2) structural causes: human population growth and consequent increase in resources mainly for food (Hawkes et al. 2006).

Urban and tourism development that has been taking place in coastal areas where turtles lay their eggs has caused problems at that stage of the life cycle. Buildings such as hotels, breakwater, fillers or sand extraction sites; as well as the elimination of the natural vegetation of the dunes, causing high erosion or soil depletion and affects suitable for sea turtles (Figure 1) environmental conditions.

Figure 1. Playa El Suspiro Turtle camp at Cabo San Lucas, BCS, under the effects of tropical storm Paul 2013.

Figure 2. Contamination by vegetation carried with the water in Playa el Suspiro, Los Cabos B.C.S. México after the storm "Norman" September 2012.

Van Houtan and Halley (2011) showed evidence supporting the damage of climate change on sea turtles. One of the consequences of climate change will increase the frequency and intensity of storms and hurricanes; events seriously harm sea turtles (Van Houtan and Bass 2007). There will also be a loss of their nesting sites as a result of sea level rise caused by climate change (Reece et al. 2013). The damages suffered by turtles are not limited to the influence of the marine environment, but also to the land portion due to the need of land areas

to spawn. Global changes in land use and poor logging practices, biodiversity impact and generate a large amount of organic waste that is carried by rivers to the sea (Fitzherbert et al. 2008). This shift logs and other organic waste can cause side impacts on multiple ecosystems (Foley et al. 2007). One of those ecosystems is the sandy beach where waste spewing from ocean currents and sea barriers are parallel accumulate. An excess of this type of plant residues can alter the nesting sea turtles and the survival of newly hatched individuals on their way from the nest to the sea (Figure 2). However, detailed studies of the effect of organic matter accumulated on beaches on nesting behavior and survival of nests and hatchlings of sea turtles are still as rare as needed on nesting beaches (Quinones et al. 2007).

## **Pollution**

Jakimska et al. 2011b mentioned that turtles are exposed to many pollutants. Pollution is a negative outcome associated with the socioeconomic and technological development of humanity as one of the biggest problems that this development present is the generation of chemicals in various industrial activities have accelerated in recent decades. Some of these substances are released into the environment as byproducts of other processes and are used in different farming and crop protection (Kampalath et al. 2006). The seas and coasts are most affected since most of these chemicals eventually reach the sea. The seas not only receive the discharge of sewage and agricultural activities, but they are also dumped radioactive waste and much rubbish (and Vanegas Espina 2005). Currently there are some studies that have explored the effects of various pollutants on the health of marine turtles and their populations; among them we can mention the research conducted by Fitzgerald (2004) and Act-Quinonez et al. (2009) who determined the presence of heavy metals in marine turtles in northwestern Mexico; Morales-Rodriguez and Cobos-Gasca (2005) used as a biomarker to *Eretmochelys imbricata*, omnivorous species up to the beaches of Campeche each year to lay their eggs, to evaluate the temporal variation of the concentration of DDT and DDE between 1999 and 2000. Rosales et al. (2011) worked on understanding the role of chorioallantois in retaining organochlorine pollutants (pesticides) and their relation to other environmental variables: plasma sediment and olive ridley sea turtle (*Lepidochelys olivacea*) Baja California South. While Labrada and colleagues (2011) are evaluated the health status of the eastern Pacific green turtle (*Chelonia mydas*) inhabiting the coast of Baja California Sur, through physiological biomarkers. Thus, we can see that all these research highlights the extent of contamination affecting sea turtle populations.

#### **Pesticides**

Persistent organic pollutants (POPs) are organic compounds mostly man-made and characterized by its presence worldwide, its stability, the slower biodegradation, their accumulation in fatty tissues and its long half-life, van de Merwe and colleagues in 2010 showed damage *Chelonia mydas* embryos because of Persistent Organic Pollutants (POPs). Polychlorinated biphenyls (PCBs) and organochlorine pesticides (OCs) and dichlorodiphenyl-trichloroethane (DDT) and its derivatives have contaminated many environments, including oceans (Moore et al. 2002;. Labrada et al. 2011), spread over all geographic regions

because of its intensive use in agricultural and industrial activities. PCBs, as persistent organic compounds with a relative mobility, are among the chemicals that can reach any region that this is remote (Moore et al. 2002; Keller et al., 2004). Currently, atmospheric transport is recognized as the leading cause of dispersion and the primary source of pollution in the polar regions and the open sea. However, CBs continue to be detected in different environmental samples and animal tissues besides their use continues in some countries development due to lack of effective regulation (Godley et al. 1999, McKenzie et al. 1999; Lazar et al. 2011; Rosales et al. 2011).

#### **Hydrocarbons**

The study of oil pollution in the oceans and coastal areas, faces two opposite aspects of human activities: 1) the alteration of marine and coastal ecosystems caused by mining operations, refining, transportation, storage and use of oil as the main source of energy, and 2) the undeniable need to preserve and protect marine resources for our current uses and future generations (NAS 1985; Botello 2005). The exploration and extraction of hydrocarbons at sea pose a serious threat to sea turtles to stop their activities foraging and nesting habitat destruction seriously. Dredging not only destroys habitat but incidentally may cause serious injury or even kill sea turtles. The oil in the skin and shell of a sea turtle can affect breathing functions and salt gland and blood chemistry. When the oil slick reaches the beach, this is pasted into each grain of sand and rock affecting the turtles on the beach, at sea or in the sand where they lay their eggs. The latter is polluted and affected the development of embryos, on the other hand, at hatching, the chicks are also contaminated by the oil is on the beach (Figure 4). Ingestion of pellets tar is also of concern that the tar balls are the second most common type of debris ingested (NMFS / FWS 1992, 1998).

Spills in the Gulf of Mexico del Pozo Ixtoc-I off the coast of Campeche deserve special measurement. This spill was considered the largest in the world, because for nine months over 3'100,000 barrels of crude oil in marine waters (Botello 2005) were spilled. The oil spill from the platform of British Petroleum (BP) in April 2010 in this area affected the five species of turtles Lora (Kemp's ridley sea turtle), white (*Chelonia mydas*) loggerhead (*Caretta caretta*), leatherback (*Dermochelys coriacea*) and hawksbill (*Eretmochelys imbricata*). Of the seven known species of sea turtles living today, five live in the Gulf of Mexico (Fomix 2010). Sea turtles are not only damaged by direct losses. The daily consumption of petroleum products from shipping, burning coal and wood, as well as combustion motor, producing similar polycyclic aromatic hydrocarbon content of crude oil (Botello 2005).

#### **Heavy Metals**

The accumulation of heavy metals in marine life is of great interest because of the potentially toxic effects that these elements may cause, especially predators located in the highest parts of the food chain (Law-Quinonez et al. 2011) as the turtles.

#### **Sewage and Garbage**

It found the presence of debris such as plastic, Styrofoam, string, rubber, glass, metal, paper and woven in the stomachs of sea turtles are being transported by sea currents fibers. When ingested, these wastes can obstruct the digestive tract, causing health problems such as infections or death (Lazar and Gračan 2011).

#### **Damage Caused by the Lights on Nesting Beaches**

Alteration of nesting habitat has increased significantly (Witherington 2000). The beaches have been the pressure of growing demand (Chacon & Arauz 2001) for the development of tourism activities, construction of hotels, restaurants and residences (Lutcavage et al. 1997, Parra 2002), involving changes in the physical structure and an increase artificial light (Chacon  $\&$  Arauz 2001). It has been documented that artificial lighting on nesting beaches affect sea turtles and produces disorientation of hatchlings emerging who diverted their way to the sea to follow the light signals (Kamrowski et al. 2012).

Other threats caused by the presence of man in the turtle habitat are the presence of domestic animals such as pigs, cats and dogs can become predators of eggs and chicks, and the use of motorized vehicles on beaches which crush eggs and hatchlings in addition to compact the sand difficult and output spawning nests (Day et al. 2007). Anthropogenic impact and beach erosion significantly impact the complex and delicate coastal and marine ecosystems, contributing significantly to the reduction of nesting habitat and therefore on populations of these organisms, since the females return to their natal beaches to nest (Márquez et al. 2007).

With these processes of biomagnification (being predators stops) and bioaccumulation (being lived animals), we can estimate the type and degree of exposure that are subject populations and from there information of interest for conservation and/or survival. It is known that sublethal exposures for extended periods of time can cause long-term toxic effects, such as reproductive disorders, decreased the ability of the immune defense system against infections and infestations, nervous and behavioral alterations and an increased risk of developing certain cancers (López-Castro et al. 2010; Law-2013 Quinonez et al.). These effects have been described in a considerable number of species, both terrestrial and marine, which leads us to believe that similar effects are also observed in marine turtles (García-Fernández et al. 2009; Páez-Osuna et al. 2010).

We start by defining marine pollution, biomarkers and sentinel species. Many of these terms can refer to several concepts, however, use the more accepted. Marine pollution is the introduction of substances and energy by the entry of water used for cooling industrial plants in the marine environment, which is harmful to live resources, it constitutes a risk to human health, harm marine activities as fishing damages the quality of sea water and reduces recreational activities (definition proposed by the experts of the United Nations (GESAMP 1980). The biomarkers are living organisms that are exposed to contaminants, or that may be useful for predict future damage and even may themselves present harmful effects. The context in which a biomarker falls to be interpreted in the biochemical, physiological, morphological or behavioral level (Badii-Zabeh et al. 2005, Cajaraville et al. 2000). The species bioindicators used to detect environmental changes through a stress response that can be extended to other groups. They are used to reflect the biotic or abiotic state of the environment, reveal evidence of impacts caused by environmental changes or to indicate the diversity of other species, groups or communities in an area (Tabor and Aguirre 2004; Badii-Zabeh et al. 2005, Rendon 2005). Tabor and Aguirre said in 2004 that the use of biomarkers in the diagnosis of alteration of ecosystems has several advantages: a) the response of biomarkers can indicate the presence of pollutants biologically available, b) with a suitable battery set or biomarkers You can ascertain the presence of pollutants that had not been considered, c) can detect intermittent pollution events and integrate in time and space exposure, d) they can detect induced by complex mixtures of pollutants effects. In many cases, the use of biomarkers is much easier and cheaper to implement than other options, such as chemical analysis (Handy et al. 2003). Mayer et al. 1992 states that it is necessary to know the biochemistry and physiology of the organism, set the size and reproductive status, which is simple sampling, which is available in sufficient number and ages, know their trophic level and mainly delivering social and ecological importance. This is necessary to give a complete diagnosis of the condition of the body, and that serves to monitor environmental problems.

They can give examples of sea turtles as sentinels, so we have the leatherback turtle that may be a biomarker of changes in the short and long term food networks and the availability of resources in the overexploited marine ecosystems (Saba et al. 2008; Fossette et al. 2010). They are used to monitor the effects of dredging (McRae 2014).

Sea Turtles: Sentinels of Climate Change: Temperature determines the sex of the turtles. An increase in the average temperature could cause a bias in the sex ratio that could be used as evidence of climate change. The increase of air temperature will advance the date of nesting (Weishampel et al. 2004). The use of stable isotopes to identify the foraging area for turtles. Changes of places to eat in conjunction with the measurement of other variables can be indicators of climate change (Rodriguez Baron 2010; Strang et al., 2012.).

Sea Turtles: Sentinels of Pollution Contaminants Biocumulan (Jakimska et al. 2011a, 2011b.). Since a correlation was found between fibropapilloma tumors and highly polluted areas, it has been proposed to the disease as contamination indicator (Aguirre et al. 2004). The fibro papilloma tumors can cause weakening and eventually death of turtles green (C. mydas). From the 1980s, the incidence increased and has become the biggest threat to the green turtle (Gamache and Horrocks 1991) and has already been detected in other species.

There is evidence for maternal transfer of persistent organic pollutants into the eggs so that they can be used as indicators of pollution (Alava et al. 2011; Sakai et al., 1995).

Perfluorinated compounds (PFCs) are water-repellent properties oil are hardly degraded in the environment and can bio Cuma arse. They pose a threat to many organisms because they are toxic and endocrine disruptors. Evidence of their presence in turtles (Guerranti et al. 2013). Vitellogenin as a biomarker of endocrine disruption in turtles (Zaccaroni et al. 2010). Gonadal development partnership between the turtle and the concentration of the herbicide atrazine (De Solla et al. 2006).

Sea turtles are considered as potential indicators of the health of the marine, coastal habitats and local environments in which they live in temporary, annual or even decadal scales (Aguirre and Lutz 2004; Wallace et al., 2004). The longevity of individuals of sea turtles, the residence time on land or water, and the variety of marine habitats by traversing along his life story, return to these organisms susceptible to exposure to multiple stressors and Pollutants (Milton and Lutz 2003). Several studies have explored the vulnerability of the

turtles to these two factors, being that this will depend directly on their longevity (Milton and Lutz 2003; Aguirre et al. 2006)., Ecological niche, including diet and feeding strategy

(Gardner et al. 2006 ; Kampalath et al. 2006), concentration and duration of exposure (Talavera-Saenz et al. 2007) and metabolic processes and homeostatic (Gardner et al. 2003;... Sakai et al. 2000).

Sea turtles are becoming one of the most popular icons of the environment. Taking advantage of his charismatic image, a remarkable variety of stakeholders including scientists, conservationists, community-based organizations, corporations and governments have sought to use sea turtles to motivate people to consider issues surrounding the health of the marine ecosystem, warning while a potential danger situation as demonstrating the presence of contaminants in the environment in which they live and the degree of exposure, the sustainability of fisheries, the potential benefits of protected areas, indigenous cultural value (often involving nationalism and cultural) pride, biodiversity and the desirability of cooperation and the multilateral management of shared marine and terrestrial species (Eckert and Hemphill 2005). In the context of the use of sea turtles as sentinel species it has been proposed to generate databases on parameters for: how to make environmental monitoring using sea turtles using data and analysis eggs in search of contaminants, and which it is an effective technique that causes little damage to the populations studied (Alava et al. 2011, Schneider et al. 2011). Use of tissue carapace has proven useful in the study of pollutants (Komoroske et al. 2011). Analysis of blood samples to detect contaminants such as lead, selenium and mercury (Burger et al. 2009) and has the advantage of being a minimally invasive technique (Labrada et al. 2011, Lara-Uc et al. 2011). Tissue analysis of recently dead turtles can be useful (da Silva et al. 2014.) To make the following analysis: in vitro culture of stem cells, for example, liver cells green turtle has potential in monitoring and evaluation of mercury contamination (Wang et al. 2013). Determining the affinity trophic by stable isotopes (Rodriguez Baron 2010; Strang et al., 2012). Antioxidant enzyme activity. This may be a good biomarker of contamination in turtles (Labrada-Martagón et al. 2011). The search for biomarkers that reveal the exposure of organisms to endocrine disruptors, for example, the presence of vitellogenin in males. Satellite tracking to monitor populations (Schofield et l. 2013), and the unborn tracking (Mansfield et al. 2014).

Advantages and disadvantages of using turtles as bioindicators. Is it easy sampling? A collecting permit is required; this is handled with the undersecretary for environmental protection management (Directorate General of Wildlife) specifying the objectives of the study and whether it is a research project or teaching purposes. They should have experience in sampling either blood, tissue, etc. Because if you do not have to experience results that are issued are be as reliable, on the material used, the shape of the blood collection, in which means of transport the fabrics are, as time has shown to the analysis from which the sample was drawn until delivery to the laboratory. A feature is a sentinel species that react very quickly to environmental disturbances. However, to be ancient turtles, the impact of these disturbances on the size of the populations occurs slowly so it does not reflect the effects of the unrest on short-lived species (disadvantage). At the same time a long-lived species can bioaccumulate more polluting than short-lived species, the latter exacerbated by being the top predators turtles.

#### **Challenges**

Develop a reliable method for sexing turtles and to estimate the proportions of sexes. As very long-lived, the impact of environmental stressors on the population size may be delayed. Such delay would cause the indirect environmental stressor effects could not be detected on time in species with a short life.

# **SIMILARITY IN MOLLUSK ASSEMBLAGES ASSOCIATED WITH CONSPICUOUS HABITAT FORMERS IN NORTHWEST MÉXICO**

## *María del Carmen Méndez Trejo\* and Rafael Riosmena-Rodríguez*

Programa de Investigación en Botánica Marina, Departamento Académico de Biología Marina, Universidad Autónoma de Baja California Sur, La Paz, B.C.S. México

## **ABSTRACT**

Mollusks mesograzers are an important ecological factor in subtidal environments. We analyzed conspicuous habitats from Gulf of California and Mexican Pacific littoral in northwest to answer: 1) How are formed the associated mollusks assemblages? 2) Is taxocenosis structure maintained over time and space inside habitats? 3) How does biodiversity change between habitats? Mollusks were found in critical habitats *Zostera marina*, rhodoliths and *Sargassum* forest, and invasive red seaweed *Acanthophora spicifera*. We made clusters about their presence in different geographical sectors and surveys using qualitative and quantitative data. 75 small species were recorded. Rhodoliths was the habitat with higher richness (25) and diversity, as well eelgrass beds (24). The grouping shows one assemblage that contains localities with eelgrass, the second rhodoliths, and the third seaweeds. Small gastropods *Acteocina*, *Alabama,* and *Barleeia* were essential components in all hosts. The structure changed over time and between habitats. Results suggest similar assemblages in eelgrasses and distant regards brown/red seaweeds as well rhodolith beds. This study highlights the importance of *Zostera marina* beds by evidence of similarity even localities inside and outside gulf; coralline beds by preserving atypical diversity and brown/red seaweeds as transitional microhabitats and temporary corridors subject to further change. These interactions are more complex than estimated, but this contribution helps to understand these critical habitats as biological corridors and implications on mollusk distribution.

#### **INTRODUCTION**

Eelgrass and seaweed constitute a sort of biodiversity as micro-habitats, are significant for recruitment, settlement, and development of fishes and invertebrates (Morse 1992; Russo 1999; Christie 2009), in which mollusks are part of mesograzers inhabiting and one of the major groups interest of them. In addition to the structure complexity for shelter, another reason is food availability (Albano & Sabelli 2012). Sometimes mesograzers enhance host condition by removing epiphytes or redirecting nutrients to the sediments (Fong et al. 2000; Rakocinski et al. 2008), another reason to highlight its importance is because they are contributors to secondary production. Despite this, studies remain poor in assessed spatial composition and variation of this group on subtidal habitats (Wernberg et al. 2008).

In the Gulf of California and Pacific Coast, researchers have documented marine and brackish-water molluscan biodiversity in geographical scaling using the whole of the substrates (Hendrickx et al. 2007), another, in particular, localities but overall fauna (Quiroz-Vazquez et al. 2005;Hinojosa-Arango y Riosmena-Rodríguez et al. 2004; Foster et al. 2007). This region contain several relevant ecosystems: *Sargassum* forest, rodolith and eelgrass beds actually are considered as critical habitats (Steller et al. 2003; Riosmena-Rodríguez 2009; Ávila et al. 2010; López-Calderón et al. 2013; Hinojosa-Arango et al. 2014) by establishment and development for abundant associated fauna and their ecosystemic services (Hinojosa-Arango & Riosmena-Rodríguez 2004; Foster et al. 2007; Riosmena-Rodríguez & Medina-López 2010; Suarez-Castillo 2014), therefore, arises the need to analyze predominantly these ecosystems.

Recently, in addition to the historical or natural process of colonization (Muñíz-Salazar et al. 2005), the anthropogenic factor (shipping and contamination) is influencing the species presence and dispersal around the world, as the actual situation of the invasive seaweed *Acanthophora spicifera* (Russell 1992; Schaffelke & Hewitt 2007), which was observed inside the gulf in 2006 by first time (Ávila et al. 2012) and has since then spread and established throughout Bahía de La Paz, making it one of the most conspicuous ecosystems and potentially invasive along the gulf.

We observed that one of the most significant and fluctuant taxa associated whit this conspicuous habitat in Mexican Pacific Northwest is Mollusca, however, recently beginning to be studied. The aim of this study analyzes if there a similarity in mollusk assemblages between the most distinct habitats recorded in northwest Mexican Pacific by the response: 1) How are formed the mollusk assemblages each habitat? 2) Is taxocenosis structure maintained over time and space inside habitats? 3) How does biodiversity change between habitats? This research is to understand the mollusk taxocenosis dynamic inside the distinct habitats recorded, which involve critical habitats and the most invasive seaweed by the moment.

## **STUDY SITE**

Peninsula coast and the Gulf of California maintain the border of geographical distribution of *Zostera marina* along northeast Pacific (Muñíz-Salazar et al. 2005; Riosmena-Rodriguez et al. 2012), as well *Sargassum* (Suarez-Castillo et al. 2013) and the major rhodolith beds (Steller et al. 2003; Ávila & Riosmena et al. 2011). The invasive seaweed *Acanthophora spicifera* by the moment is distributed in Bahía de La Paz (Ávila et al. 2012). Pacific Coast communities are not only separated geographically from communities in the Gulf of California but are also exposed to different environmental conditions (Cabello-Pasini et al. 2003). The Gulf of California is a semi-enclosed sea where the exchange with Pacific waters occurs only in the south of the gulf via cyclonic circulation (Castro et al. 2000). We analyzed localities at these critical habitats, as well the invasive species *A. spicifera*. Sampling was conducted at different sites each locality, from 1-5 m depth by SCUBA, to collect most of the mobile organisms for concurrent studies.

Samples were taken from *Zostera marina* in San Ignacio (SI): 26º55' N; 113º10' W North (N), 26º49' N; 113º15' W, Media (M), 26º42' N; 113º60' W, Pitahaya (P). Bahía Magdalena in *Zostera* (BMZ): CFE, Las Tijeras (T1), Cancún (C1), El Muerto (EM1), Punta de Gato (PG1). Sonora in *Zostera* (SZ): Punta Arenas (PA1), Coniic (C1), Bajo Callero (M1), Punta Xpanams (PX), Punta Chueca (SR), Punta Tormenta (PT), Palo Fierro (PP), Estero San Miguel (SM), Punta Ohna (PO), El Álamo (BA), Bajo Media Luna (ML), Bajo Canal (MC). Rhodolith beds from Bahía Magdalena (BMR) 24º15' N; 111º30' W (CFE) and 25º20' N; 112º15' W (PED). *Sargassum* forest throughout Bahía de La Paz (BLP): L1 (24º45'37"N; 110º40'24" W), L2 (24º35'52" N; 110º44'48" W), L3 (24º28'29" N; 110º41'37" W), L4 (24º18'59" N; 110º38'24" W) and L5 (24º12'15" N; 110º32'6" W) in June 2011 and May 2012. Invasive seaweed *Acanthophora spicifera* in Ensenada de La Paz (ELP) 24º12'07" N; 110º17'59'" W.

#### **Field Sampling**

Samples were taken every two months from April to August. 2010 in *A. spicifera* from holdfast using a sampling square of  $0.00625$  m<sup>2</sup> over three beds, nine replicates each one. June 2011 and May 2012 from *Sargassum* in 5 beds, sampling 15 replicates each site from the holdfast. June 2011 in two rhodolith beds, 20 replicates each one using a square of 0.0625 m<sup>2</sup> (same for the next three localities). October 2009, March, April and August 2010 from *Z. marina*, Sonora in 12 sites, sampling three replicates each one from the rhizome and the sediment surface (same for the next two localities). June, April, and September 2009 and December 2010 from *Z. marina,* San Ignacio in 4 sites, three replicates each. June 2011 from *Z. marina*, Bahía Magdalena in 5 locations, three replicates each.

#### *Laboratory Analyses*

The samples were separated by sieved through a 0.5 mm mesh and preserved in ethyl alcohol (70%). Each sample were examined for the record and counted all organisms possible. Mollusks were sorted quantitatively and identified as a group possible using particular references. Some species required further identification.

#### *Feeding Habits and Feeding Guilds*

The next feeding habits and guilds were considered: carnivores (C) herbivorous (H) Omnivorous (O). Deposit feeders (D) feeding on organic particles contained in the sediment, filter feeders (F) intercepting nutrient particles with their gills and/or mucous strings, Suctorial parasite (Sp), Grazer (Gr) feeds by scraping, either on algae or sessile animals, and Browsing (feeds by tearing or gathering particular items (Br), we selected sorts of Rueda et al. (2009). Trophic information was mined from the literature for each species wherever possible. If the feeding behavior of a particular species was unknown, it was assumed to feed in a similar manner to species within the same major group.

#### **Data Analysis**

Mollusk taxocenosis structure and dynamics were analyzed by the number of specimens (N), the number of species (S), the Shannon index (H', using the log formula) and Pielou's evenness index  $(J')$ . Before all data were converted to  $m<sup>2</sup>$  for comparison. After were tested for KS normality and homogeneity of variances by Cochran's test, and log-transformed as necessary. Component Principal Analyses (CPA) were made each habitat to detect and compare the most variable data corresponding with the species. We performed a cluster analyzes and non-metric multidimensional scaling (MDS) in different geographical sectors and surveys using qualitative and quantitative data (presence/absence and Ind  $m<sup>2</sup>$ ) and the Jaccard similarity index. Before analysis, data were the fourth root transformed abundance data, to minimize the effect of extremely abundant species. The SIMPER routine was then used to locate which species contribute most to the differences between habitats or, conversely, which species contribute most to the similarities within the same group. Multivariate analyzes were performed using R software and PRIMER.

## **RESULTS**

#### **Fauna Composition**

An almost total of assemblages were dominated by mollusks in most of the surveys (Figure 1), except in *Sargassum*, the transitional habitat in BLP, which usually is occupying by crustaceans, and the next abundant group is polychaetes. We recorded 42 families and 73 species of mollusks across all sites and time surveys (Appendix 1). The material was identified as level possible. Species abundance was different between sites inside habitat along time, due to the location, but we chose the total abundance all surveys for the show the principal components and abundant species each locality (Figure 2). In most of the habitats dominated the carnivorous guild, except in Sonora due to the high abundance of the detritus feeder *Caecum* in soil (Figure 1).

#### **Similarity and Taxocenosis Structure**

Main species contribution consistently accounted for greater than 70% of the total dissimilarity among the different habitats and localities (Table 1). The taxocenosis in eelgrass beds and brown/red seaweed is characterized by high abundance of less dominant species than rhodolith beds (Figure 2).

Figure 1. Contribution of Invertebrates in the different habitats: Bahía de La Paz *Sargassum* (BLP S), Roca Caimancito *Acanthophora* (LC A), San Ignacio *Z. marina* (SI Z), Sonora (S Z) and Bahía Magdalena in *Z. marina* (BM Z) and Bahía Magdalena in rhodolith beds (BMR).

Taxocenosis structure in *Acanthophora* was relatively consistent over time but differ between sites, the greatest abundances were found to in this invasive seaweed (Figure 2), *Assiminea* were the most abundant species in this habitat. Rhodolith bed shows less abundance but greatest S, J' and H'; the species recorded in this habitat were entirely different to eelgrass taken the same date and lagoon, only three species share both. BLP contains fewer species and only the dominant *Alaba supra lira ta* (Figure 2). *Alabimia, Barleeia, Acteocina, Caecum* and *Alaba* were the most related taxa in almost all habitats. Several particular taxa

less abundant were found only inhabiting eelgrass beds, even one locality inside gulf and two outside as well: *Alabina, Nassarius*, *Anachis*, *Neopilina*, *Cerithiopsis*, *Mitrella*, *Turbonilla*, *Elephantelum*, *Hipponix, Calyptraea,* and *Biv 1* (Table A1).

The mollusk assemblages grouped among similar habitats represent by eelgrass and distant respect to seaweed beds (Figure 3). Taxocenosis composition in *Sargassum* was near to *Acanthophora* group; these localities are cited in Bahía de La Paz both. Clustering in rhodolith beds was far to the other groups since most of the species were only found in these habitats. A significant nMDS ordination is detected; stress values for the analyzes were 0.146, the plots show some clustering of habitats (Figure 4)*.* SZ is near to SIZ and BMZ, even if these last is situated outside gulf.

Figure 2. Representative species each habitat, selected by high abundance and principal components after Component Principal Analyses each habitat.

#### **Table 1. Results of SIMPER analysis on the percent contribution of benthic categories, testing dissimilarity between zones**

#### **DISCUSSION**

Olds et al. (2012) have shown that connectivity is essential in conservation planning and this is extremely difficult to find in many planning process in marine protected areas. Also is a consideration lacking in environmental impact reports who needs to evaluate the synergic impacts of assemblages in any given project. Strong differences were found among the major habitats studied in relation to feeding habits and in relation to diversity (Figure 1). Steller et al. (2003) have found strong differences between Rhodolith beds and sandy areas, our analysis extend this observations to other habitats. Seagrasses meadows and Rhodolith beds seems to be the most diverse areas but less abundant (Figure 5) comparing among them.

Foster et al. (2007) have found rich and diverse biota associated to *Sargassum* forest in Bahia Concepcion and our results are contrasting with less species and less abundant. This situation might be related to geographical position because our sampling is from Bahia de La Paz. However, when comparisons with the *Zostera marina* meadows are made strong similarities among sites are clearly present. In the case of Rhodolith beds it is clear that no significant differences have been found in the associated species from what we know. Our study is unique because no one has compare this ecosystems before, we have found indicators for further analysis with the whole invertebrate community.

Figure 3. Cluster analyzes. The key is arrangement in the next order: localities: BLP (Bahía de La Paz), Roca Caimancito (LC), Bahía Magdalena (BM), Sonora (S) and San Ignacio (SI); hosts: *Zostera marina* (Z), *Acanthophora spicifera* (A), *Sargassum* (S) and rhodolith beds (R); year, month and sites inside each locality.

Figure 4. Nonmetric Multidimensional Scaling (nMDS) biplot on the Jaccard similarity matrix of transformed benthic taxocenosis data (the fourth root transformed abundance data) showing physical means for all habitats and sites. Bahía Magdalena *Zostera marina* (BM Z), San Ignacio *Zostera marina*, Sonora *Zoster Marina* (S-Z), Bahía de La Paz *Sargassum* (BLP A), Bahía Magdalena rhodolith beds (BM-R) and Roca Caimancito *Acanthophora spicifera* (LC A).

Figure 5. Ecological attributes. Bahía Magdalena *Zostera marina* (BM Z), San Ignacio *Z. marina*, Sonora *Z. marina* (S-Z), Bahía de La Paz *Sargassum* (BLP A), Bahía Magdalena rhodolith beds (BM-R) and Roca Caimancito *Acanthophora spicifera* (LC A).

# **A CRITIQUE OF THE ENVIRONMENTAL IMPACT STUDIES IN MÉXICO BASED ON TWO STUDY CASES**

*Rafael Riosmena-Rodríguez1,\* and Rocío Marcín-Medina2,†*

<sup>1</sup>Programa de Investigación en Botánica Marina, Departamento de Biología Marina, La Paz, México

<sup>2</sup>Asociación de Investigación y Conservación de Mamíferos Marinos y su Hábitat (AICMMARH), A.C. La Paz, México

## **ABSTRACT**

By means of behavioral studies it has been determined for the first time in Mexico the critical habitat of a semi-resident group of coastal dolphin *Tursiops truncatus* (bottlenose dolphin) in Ensenada de La Paz and the south-southeast of Bahia de La Paz. In this zone it is more frequent to observe small groups of mothers with calves and juvenile dolphins. Through the years it has been recorded a habitat shift of these cetaceans induced by environmental and anthropogenic factors: loss of southwest basin in Ensenada de La Paz due to silting, dredging and tropical cyclones; similarly a reduction of the feeding activity has been observed in the northwest basin due to fisheries and the increase of nautical traffic which overlaps with the main transit route of bottlenose dolphins near El Mogote, thus affecting their conduct. The disturbance could increase because of dredging realized in 2012 by the touristic development Paraiso del Mar to build a dock for a marina in El Mogote, affecting particularly zones where females teach juvenile dolphins to feed next to mangroves. Unfortunately, the ecological, social and economic importance of these coastal wetlands it is not considered, subject to a stress and risk increase in the last decades due to non-regulated deforestation and dredging, as a consequence of the mentioned touristic development for the construction of a golf course, and affecting the mangrove zone. It is imperative a decree by SEMARNAT stating Ensenada de La Paz and south of Bahía de La Paz as a critical habitat for dolphins, based on the scientific information available; given the current threats on this Ramsar site and its communities, the lack of acknowledgement as a critical zone, and the need to be included in the environmental impact evaluation for coastal developments. By including

## **INTRODUCTION**

The Article 2 of the Mexican Constitution ensures that natural resources are owned by the nation (and its citizens) have developed concessions to the implementation of productive projects (whether public or private) where it could impact the ambient. Based on this constitutional mandate the General Law of Ecological Balance seeks to preserve ecosystems and their processes to human actions. These processes are extracting water from wells, rivers and lakes through land use for different purposes to the way we use the oceans with its highly productive ecosystems. When a country assumes a model of sustainable development you are able to meet current needs without putting at risk the resources continue to be used long term for the same population. To this end, they require environmental instruments to support us in order to determine whether the activity to be developed could have an impact on ecosystems or significantly affect its processes. This is key, you can use the environment but what you intend to do has to be friendly to the future development and not necessarily destroy the natural capital that exploits.

Although its origins are in the 70's, the instrument used in Mexico to assess the potential impacts of human activities began to be used effectively in 2000 arising from both changes in environmental policy and the commitments the country signing international treaties. It is when it is proposed that all development projects will have to submit an Environmental Impact Statement taking two forms: private or regional which is related to the size of the project. There is also what is called Preventive Report being used in very specific cases. Although it seems that these manifestations seem to name only assess potential impacts on the environment which would also have to consider are social, economic, cultural and even political aspects (since the project in question could cause some instability). It is also necessary to consider that even developed in two modes have to keep in mind the potential synergistic impacts both the quantity and the size of other nearby projects that can be generated.

To give an award to a particular is very necessary that the Environmental Impact Statement develop a detailed description of the environment or ecosystems in the area of interest. This is a key point for any project since being a concession to a certain time what could hope for is that development does not cause a drastic change in the environment where the grant is completed changes are as small as possible. However, there is no classification of terrestrial ecosystems consistent between different secretariats in the SEMARNAT (i.e., that each agency secretariat terrestrial ecosystems are recognized differently). However, the seriousness of the matter is that on aquatic ecosystems seems to be marine or freshwater is the biggest difference possible. There is an inclusive classification of all marine ecosystems leaving defenseless internationally recognized for any administrative or procedural protection of ecosystems in Mexico but we have not yet dared to protect (including seagrass beds, maerl beds, kelp/Sargassum forests, marsh meadows, hydrothermal vents, gorgonian forests, etc ... among many others). This generates a lot of controversy of how to develop an environmental statement if you do not have a complete catalog of the "environment" of the country. Perhaps this is related to the number of professionals in the marine sciences have been trained and employed in different spheres of the productive life of the country.

But as it is assumed that the MIA will seek to assess whether the processes to be carried out to make an impact on these ecosystems should know some of its dynamic aspects. These should be at least biodiversity (species in the area), ecological processes (reproduction, recruitment, breeding or feeding, etc. ...) and participation in geological processes (stability of beaches, soil, sediment origin, etc. ... ). Now if this is not well understood in developing the EIS then it is not possible to propose measures to compensate or mitigate the impacts making it impractical to say that a project is feasible or not, right? It is something that needs to be worked intensively gathering critical information that you have in the country on this issue both in research centers and universities, it is not possible that information of this nature is generated and is not used. Although there are very serious academic exercises like those made by the National Commission for the Use and Conservation of Biodiversity (CONABIO) to understand the Natural capital to understand their gaps or omissions not covered there are still some corners that need to be evaluated priority.

But consider that these deficiencies are already covered in these fundamental inputs that the process requires. The next thing to ask for this instrument to fulfill its roles is: who makes the demonstrations and who evaluates them. It is disturbing to know that is supposed to be to draw up a register of providers of this service are properly credited to the demonstrations but this one is at the state level (where differences to be accredited are evident), in some cases to levels City (counted) but we could not find a single federal standard or features should have this provider. Subsequently, although SEMARNAT you have a direction to make assessments of these studies it seems that they must have a wide range of professionals to cover the topic of each and every one of the evaluations. However, it does not seem to be the case and has not touched me that these offices require advice or support from academics who might have information on the project or subject knowledge to support decision making. This would be necessary to conduct some sort of survey data verification so as to delineate dispute that projects might have. The figure of the expert is not well defined at both the federal and state levels. It requires a profile of each position to ensure that the process will be well qualified professionals who achieve the goal of having fewer disputes arising in these processes.

Within this instrument it has been considered that the public consultation and the reports are objective elements where you can clarify any doubts regarding the project. But experience with public consultations in Baja California Sur (and we are sure in other parts of the Republic) tell us that this has been a media circus than an exercise of reflection on the true intentions of the petitioner. We think there should be other elements from previous assessment that the petitioner could use to assess the chances of their proposal well before starting to invest in studies that did not represent support decision making. Then you end up with the wrong idea about the interest in the protection and conservation of the environment losing sight of the nuances that this may have on the approaches of each organization. In this area at country level absent the professional associations in Marine Sciences (perhaps with the honorable exception of Oceanographers organizations in the North state) that could be guarantors in the process of evaluation. Perhaps the key point is that it has not properly stimulated private organizations environmental assessment (like has happened with Civil Society Organizations) profiles which are desirable for the development of the EIS. This would stimulate the development of professionals in the area of knowledge and would provide with the necessary feedback to professional associations, removing the temptation to involve public institutions that, through your profile, may have conflicts of interest to develop these demonstrations.

A well implemented MIA monitoring may be evaluated to assess the observed impacts against the predicted and to adjust or modify the planned mitigation in each process. Clearly this represents an additional cost that often do not want to pay but if you want to know the state of the ecosystems as a project (or several projects) is necessary to have this ongoing assessment. That is why in other countries environmental monitoring program that measures are developed, registers and makes available to the public a series of crucial data in the development environment in the region. These are also used by insurance companies working with large companies assuring its activities related compensation and any potential impact.

Thus, the paradigm of sustainable development are not the windows of opportunity that should have different organizations or companies. But the way they achieve, or not accredit an environmental impact study due to lack of renovation of processes and the limited view of its scope. It would be important that the permanent dialogue that should have all sectors in the country could discuss adjustments to existing procedures. They may implement alternative assessment systems that represent relative cost differentials and the size of the project but at the same time give certainty to investors, CSOs and government processes that will achieve the objectives of environmental policy. The experience gained in these collective processes might achieve that decisions are at least controversial and politicized that current net profit for the ecosystem. Because of that we are presenting here 2 study cases in La Paz Bay who serve as examples to show how the actual model is not working and the urgent need of a review.

#### **DOLPHINS, MANGROVES AND EL MOGOTE**

Mangrove structure, functioning and permanence are singular, given that it is an ecosystem located at the threshold between marine and terrestrial environments. On one hand it is dominated by oceanic factors like tidal regime, marine currents, salinity, temperature, and nutrient availability; on the other hand atmospheric factors like humidity, wind, temperature and irradiance determine its physiological status and survival. From an anthropocentric point of view, mangroves experience significant changes due to land use modifications, deforestation, and pollution (1). Unfortunately, anthropogenic agents have had a determinant effect on this coastal ecosystem, reducing its spatial coverage. It is estimated that in the last two decades, approximately 50% of the mangroves of the world have been lost (Santamaría-Gallegos et al., 2011). FAO (2007) determined that the worldwide coverage of mangrove was 150,000 km<sup>2</sup> between 1980 and 2005. A recent assessment by Giri et al. (2011) states that worldwide mangrove coverage in year 2000 was 137,360 km<sup>2</sup>, 12% less that estimated by FAO.

From an ecologic and economic point of view, mangrove of the Baja California Peninsula are acknowledge as valuable ecosystems, and protected by the Mexican legal framework. Despite of this, currently they are highly threatened by the construction of real estate development with urban and tourist purposes: golf facilities, marinas and roads. In order to carry out mangrove conservation in Mexico it is required that they are considered in management plans, that authorities enforced the law strictly during the inspection and authorization of building activities along the coastal zone, and that public policies at the federal, state, and municipal level acknowledge the economic value of the environmental services provided by mangrove forests.

The municipality of La Paz, Ensenada de La Paz, and Bahia de La Paz in its Eastern portion have 14 wetlands with mangrove forests (Mendoza-Salgado et al., 2011). Inside Ensenada de La Paz the sandy bar known as El Mogote has two wetlands with mangrove forests: Zacatecas and El Mogote. Zacatecas mangrove has been subject to a management proposal by federal authorities to be preserved for being the habitat of least tern (*Sternula antillarum*) an endangered migratory bird species that uses this habitat as reproductive area (Amador & Mendoza, unpublished data; Mendoza 1994; Mendoza-Salgado et al., 2011). While mangrove El Mogote has a series of mangrove forests separated by dune zones, the total length along the shore of these mangroves is 6 km. Mangrove El Mogote constitutes the central subject of this chapter, given that mangroves along El Mogote form a fundamental ecological connection with a population of coastal dolphins known as tursiones (*Tursiops truncatus*) in Ensenada de La Paz.

It is known that between 1973 and 1981 Ensenada de La Paz lost more than 44 ha of mangrove, 21.5% of its total coverage (Mendoza-Salgado et al., 1984), the purpose of this deforestation was to obtain firewood, build roads to access the coast by mangrove-oyster fishermen, and to develop recreational areas (Mendoza-Salgado et al., 2011). Mendoza-Arrambídez et al. (2007) developed and applied a Coastal Environmental Quality Index (ICAC) at Bahia de La Paz, which shows that a wide spectrum exists in terms of conservation status of coastal wetlands with mangrove forests. These values go from good environmental quality (ICAC = 58%) to an environmental alert status (ICAC =  $31\%$ ) (Mendoza-Salgado et al., 2011). Unfortunately, more that 30% of the surveyed sites show environmental alert indexes, thus mangrove forest at those sites have ecophysiological problems in its remineralization capacity of organic matter (Mendoza-Salgado et al., 2011).

Lack of community awareness is another serious problem for the preservation of mangrove forests, because a large sector of the population thinks of this coastal ecosystem as illegal dumps, breeding ground for mosquitoes, free source of firewood, and bad odor. It is necessary to strengthen a dissemination campaign in all levels of society so that people know that these forests are fragile ecosystems on which hundreds of resident and migratory species rely on, and where key biogeochemical processes take place that have an important role in the recycling of carbon, nitrogen, and phosphorous through the terrestrial-marine system. This promotion of environmental culture will bring a new approach to social conscience: healthy mangrove forests mean a reduction of  $CO<sub>2</sub>$  in the atmosphere, healthy fisheries, biodiversity preservation and a higher environmental quality for Bahia de La Paz.

Dolphins (*Tursiops truncatus*) are known as bottlenose dolphins or toninas, they distribute in almost every ocean, except at higher latitudes (Leatherwood & Reeves, 1983), they are gregarious animals that form herds (Walker, 1981; Leatherwood & Reeves, 1982; Mead & Potter, 1990). Females reach maturity between 5 and 12 years old, while male does it between 10 and 15 years old (Sergeant et al., 1973; Mead & Potter, 1990; Wells, 1991). Gestation in these animals last approximately 12 months (McBride & Kritzler, 1951; Hansen, 1990; Wells, 1991; Mann & Smuts, 1999), females give birth in any season of the year, with one calf every 2 or 3 years (Shane et al., 1982). A strong binding forms between mother and

calf that lasts 3 to 10 years; calves do not interact with males (Shane et al., 1986; Wells et al., 1987; Buckstaff, 2004). Social organization in dolphins is based on age and sex and the association mother - calf and between adult males is very stable. Size and composition of groups it is related with different parameters, characteristics, requirements and attributes of each animal *per se*, intra- and inter-specific relationships, availability and use of resources. It also varies seasonally, according to the structure of habitat, activity patterns, food availability, reproductive stage, and protection against predators (Caldwell, 1955; Wells et al., 1980, 1987; Shane et al., 1986; Ballance, 1990; 1992; Wells, 1991; Mann & Smuts, 1999; Connor et al., 2000; Bearzi, 2005).

Coastal zone is the home range for bottlenose dolphins, reaching permanent social groups (Wells et al., 1980; Ballance, 1985). The preference for this zone could be a result of prey abundance supported by coastal systems and the protection offered by this zone against predators. In this zone bottlenose dolphins reproduce, breed, and feed their offspring, therefore their presence in the coastal zone can be used as an indirect indicator of productivity. Bottlenose dolphin distribution is also related to other factor such as bathymetry, tidal regime, type of bottom, and prey diversity, thus they can be found in a wide range of environments (Wells et al., 1980; Irving et al*.*, 1981; Shane et al*.*, 1986; Ballance, 1992; Wilson et al*.*, 1997; Hastie et al., 2004). They feed on fish of 5 to 30cm in length; their diet includes individuals of the families Mugilidae, Scianidae, Clupeidae, Scombridae, Batrachoidae and Haemulidae, among others. Also octopus, squid, shrimp, crab, and in some cases sharks can be present in their diet (Gunter, 1942; Barros and Odell, 1990; Corkeron et al., 1990; Corkeron and Ross, 1990; Mead and Potter, 1990).

Human impact has increased on coastal ecosystems in the lasts decades, mainly because of anthropogenic activities and settlement developments such as fisheries, tourism, marine traffic (Wells et al., 1980; Shane et al., 1986; Wilson et al., 1997; Barco et al., 1999; Bristow and Rees 2001; Nowacek et al., 2001; Prideaux, 2003; Lemon et al., 2006). As a consequence of these worldwide impacts a measure adopted for the protection and conservation of bottlenose dolphins is the declaration of critical habitats, formed by regions of high presence of bottlenose dolphins where feeding, socializing, and resting activities take place (Higham and Lusseau, 2004; Hoyt, 2005). This declaration promotes protection of core areas to preserve critical habitat for the species as well as their prey and marine ecosystems; establishing that only non-invasive research and periodic environmental surveys are allowed, conducted by specialist in the species studied or under their supervision (Hoyt, 2005). Habitat use pattern is different between localities, so it is important to know species behavior and its relation with environmental and anthropogenic factors in order to establish a critical habitat as a function of feeding, socializing, resting, and breeding areas (Wells and Scott, 1997; Nowacek et al., 2001; Ingram and Rogan, 2002; Higham and Lusseau, 2004; Pierpoint and Allan, 2004).

For northwest Mexico, research focused on bottlenose dolphins in the Gulf of California and Pacific Ocean has focused on subjects like community structure, distribution, abundance, morphology, genetics, feeding, home range, movements, behavior, group organization, distribution, size and population structure, photoidentification, residence patterns, reproduction and birth, human impacts and strandings. In Ensenada de La Paz and south of Bahia de La Paz there is a semiresident population of bottlenose dolphins that can be observed almost the whole year and that has been one of the population most studied in Mexico since 1987 through 2006 (Acevedo-Gutiérrez, 1989; Marcín-Medina, 1997; 2010;
Díaz-Gamboa, 2001; Rojo-Arreola, 2002; Valadéz-Suárez, 2002; Salinas-Zacarías, 2005). In 2005 and 2006 a survey was conducted regarding its behavior (Figure 1) and it was determined that this region represents a portion of its critical habitat (Figure 2). Several of their activities take place near the coastline of El Mogote (feeding, breeding, reproduction, socialization, resting), including the outer margin to the Bahia as well as the inner margin to the Ensenada. It is worth mentioning that this is the first time in Mexico that a critical habitat is determined for coastal dolphins. These cetaceans can be observed in groups from 2 to 40 individuals, however small groups (2 to 10 animals) predominate, formed by females with calves and juvenile dolphins which are the ones observed inside the Ensenada; constituting a breeding lagoon (Figures 3 and 4). Its distribution range goes from 1 to 5 m from the coastline and from 1 to 7 m depth, shallow waters where they protect their offspring. Mothers teach their calves to hunt by playing, the mother and the calf throw a fish several in the air until the calf learns to eat it. It is important to mention that juvenile dolphins do not have and innate hunting instinct, it is an acquired trait taught only by its mother. Such a conduct has been frequently observed in the Ensenada channel and in shallow waters near the El Mogote mangrove; small fishes inhabit this area and represent an easy prey. It should also be highlighted that reproductive activity has been observed mainly in the Ensenada channel and in Ensenada mouth (Marcín-Medina, 2010).

Figure 1. Critical habitat polygon and buffer zone base on bottlenose dolphins (*Tursiops truncatus*) sightings and behavioral studies during 2005 and 2006 in Ensenada La Paz and southeast of Bahia de La Paz (Marcín-Medina, 2010).

Figure 2. Mother and calf traveling in the Ensenada de La Paz channel. Picture by Alberto León-Gómez-Villacorta.

Figure 3. Juvenile dolphins near to El Mogote in Ensenada channel. Picture by Rocío Marcín-Medina.

This behavioral study was compared with a previous one made on 1995-1996 using the same methodology in Ensenada La Paz (Marcín-Medina, 1997; 2010), finding a habitat shift in 2005-2006 induced by environmental factors and anthropogenic disturbances (Figure 4). Southeast basin was lost (zone 1) due to sedimentation associated with tropical storms, hurricanes and dredging; reduced feeding activity in the northwest basin (zone 2) as a consequence of fisheries and increase in marine traffic superimposed on bottlenose dolphins main route near El Mogote; this affects dolphins' behavior particularly the mothers. This species is very sensitive to noise, in July 2005 it was recorded that a group of females with their calves were feeding when dredging activities of marina Singlair in Fidepaz began (zone 1). Dolphins were scared by sound and never returned to the zone, at least during the whole

year that the survey continued; it is an example of negative effects caused by noise pollution which implies loss of habitat (Marcín-Medina, 2010).

In La Paz city there has been an increase in mega-projects to create more touristic facilities (hotels, marinas) in the last 12 years. Among them there are the "Costa Baja" development in Bahia de La Paz, and the "Paraiso del Mar" development in Ensenada de La Paz; the latter was planned to occupy an area of 504.31 ha with 3,922 residential units, 2,050 hotel rooms in a 6 stories building, two 18-holes golf courses, a desalination plant, 5 wastewater plants, an outer marina with capacity for 535 docking stations, a pier with a building at the end, and a boardwalk (39 ha of marine development in a zone adjacent to Ensenada de La Paz). Clearly, this marina will obstruct the secondary navigation channel of the bottlenose dolphins, and the circulation of vessels will increase the noise pollution in their main transit route, specially where females teach their calves how to feed. Therefore, the construction of this marina poses a threat inside the critical habitat for this species protected by NOM-059-SEMARNAT-2001.

Figure 4. Bottlenose dolphin seasonal feeding zones in Ensenada and south of Bahia de La Paz in summer 2005 and spring 2006. Points represent dolphin feeding location (Marcín-Medina, 2010).

Grounds where this mega-project is planned (over 500 ha) were owned by the state, but in February 2004 a land use change was authorized from forests grounds and several vegetal species were removed from the area. In the written project it was stated that mangrove forest will be removed only in an area of 1.19 ha in order to build both the dry marina and the touristic marina, and that a buffer fringe 100 m wide will be established between the remaining mangrove forest and every construction made by this mega-project. This was not so, even when a group of scientific researchers (including some authors of this chapter) sent letters to the SEMARNAT delegacy (Secretary of Environment and Natural Resources) at La Paz and to the President of Mexico to denounce the damage on mangroves and probably dolphins as well, one month later DGIRA (General Directorate for Environmental Risk Impact) at SEMARNAT authorized the MIA (Environmental Impact Declaration) of this mega-project without the public consultation process required by law. In the resolution of the MIA it was consider that deforestation of 1.19 ha of mangrove forest did not put at risk the ecosystem and that petitioner's proposal for restoration of Enfermeria and El Grande estuaries (only the latter located at El Mogote, where the mega-project is planned) will be enough to mitigate the impact. As for the impact of vessel traffic on the feeding zone of dolphin community DGIRA only manifests that petitioner will be conditioned to develop a protection program for the environmental imbalance and a "survey program of the project's environmental performance" including: indicators for the incidence of nautical activity on main components of marine biota in the area with emphasis on the marine mammal population (*Tursiops truncatus*) present in Ensenada de La Paz, and to include as an indicator the results of the survey program for water quality. Include concrete preoperative actions to the activities of the touristic marina anticipating possible affectations that can occur due to nautical activities inherent to the mega-project to marine biota preservation. Emphasizing on transit routes, feeding and refuge zones for marine mammals, fishes like whale shark (*Rhincodon typus*) and manta (*Manta birrostris*). All this created discontent among some researchers and civil society organizations (OSC), thus a decision to appeal on a long environmental litigation to impugn the authorization of the MIA, defending organisms, values, and ecosystem services of El Mogote was made.

The OSC "Ciudadanos Preocupados A.C." on July 2005 showed the review resource for the violation to the NOM-022-SEMARNAT-2003 for the mangrove affectation, violation to the NOM-059-SEMARNAT-2001 for the detriment to species like whale shark, breeding zones without mitigation measurements, and for considering that proposed measures by the petitioner of the MIA are insufficient to mitigate the damage to Enfermeria and El Grande estuaries. SEMARNAT resolution was unfavorable, stating that the arguments were unfounded without sustenance and insufficient to declare the nullity of the contested resolution. In October 2006 "Ciudadanos Preocupados A.C." replied recurring to an annulment of judgement before the TFJFA (Federal Court of Fiscal and Administrative Justice) where it was requested the impugnment of this development for the violations of NOM-059-SEMARNAT-2001 and NOM-022-SEMARNAT-2003 and because DGIRA did not considered the existence of a presidential mandate declaring protected forest zone the grounds surrounding the city and port of La Paz, publish on August 24, 1938 in the DOF (Federation Official Diary). The mandate includes El Mogote and forbids the use and extraction of live wood, only dead wood extraction is allowed. In February 2008 "Paraiso del Mar" realized without clearance dredging activities and installation of sewage pipelines on the shore of La Paz city where Reforma Street is located. In June of the same year they

repeated the operation, this time where Nayarit Street is located. Although official complaints were stated no authority took action nor penalized those actions in any way. In response, judges from S11M (Metropolitan Hall #11) of TFJFA emitted the record 32183/06-17-11-3 on April  $3<sup>rd</sup>$ , 2010 which cancels the clearance granted by DGIRA to the real-estate megaproject "Paraiso del Mar" regarding environmental impact. They were no longer authorized to perform any operation or development including the marina and its environmental effects given that the permission previously granted violated protection regulations for mangrove forests (NOM-022-SEMARNAT-2003) ignoring that the 500 ha grounds for such project are located in a zone declared as a wetland of international importance by the Ramsar convention (site #1816). Petitioners presented two legal appeals which were both denied by PJF (Federal Judicial Power), meanwhile it was expected that SEMARNAT through DGIRA emitted a resolution against "Paraiso del Mar" thus denying any development to this mega-project. Surprisingly SEMARNAT disrespectfully ignored judges' decision violating legal order, while real-estate enterprise continued working. Despite all above mentioned, during March 2011 Paraiso del Mar started illegally to dredge, construct and operate of the marina in the Ensenada de La Paz channel adjacent to the mangrove zone (Figures 5 and 6). Although organizations like CEMDA (Mexican Center of Environmental Right), AICMMARH, A.C. (Research and Conservation Association of Marine Mammals and their Habitat), and ConCiencia denounced this activities to SEMARNAT at local and federal level, as well as to PROFEPA (Federal Attorney for Environmental Protection), neither authority took action to stop such activities. One of PROFEPA's guidelines established on June 1st, 2009 states that when an enterprise performs an activity that requires environmental clearance without authorization it will be closed. Nevertheless this development continued with the construction of a pier for 25 vessels. After several months the activities ceased because of the complaints; nowadays the hotels zone, and the golf course still operate; and the residential zone is inhabited. In March 2014 Guillermo Haro Belchez, head of PROFEPA, stated that this project will be reviewed and that if it does not comply with the required specifications it could be closed or even be demolished (2).

In October 2008 another mega-project named "Entremares" presented its MIA in the modality regional. This development was planned at El Mogote adjacent to "Paraiso del Mar", with a property size of 390.76 ha to construct touristic, residential and hotels infrastructure. Development included construction of a system of tidal channels, a docking for 440 vessels, an 18-holes gulf course, shooting practice field, commercial and residential lots, hotels, duplex houses, single-family houses, villas, commercial areas, clubhouse, with a total of 3,420 housing units or its equivalent to 6,840 hotel rooms. Tidal channels will serve for vessels to circulate and dock inland. In order to develop this project, the petitioner required a deforested area of 285.99 ha, 73.2% of the total surface of its property. Tidal channel system would be formed by smaller channels in an area of 4.3 ha in the salitrales zone and/or in the restriction zone specified in the numeral 4.16 of the NOM-022-SEMARNAT-2003 (minimum of 100 m to the mangrove fringe). The larger navigation channels forming the touristicresidential complex would cover an area of 37.68 ha, including two main flow channels inside Ensenada de La Paz 50 m wide on the sea, and 30-40 m wide on the land with a depth of 2- 3m. In the adjacent lots to the tidal channels, floating docks is planned with 9 to 18 m long for a total of 440 docking facilities. For this mega-project DGIRA did make a public consultation and a public meeting in November. Different opinions were exposed against this development like damage to mangroves, Marcin-Medina delivered data regarding the critical habitat of

dolphins and the impact of vessels on its main transit route where frequent feeding and socializing activities take place. In November 2009 in the resolution made by DGIRA, 7 state and federal agencies opposed to this project, like CONANP (Natural Protected Areas Commision) in consideration of articles 3 and 4 of Ramsar Convention did not consider feasible any deforestation, digging, and dredging activities for the opening and construction of channels for the "Entremares" mega-project inside the Ramsar polygon wetlands Mogote-Ensenada de La Paz. In an unprecedented action, the DGVS (General Directorate for Wildlife) a branch of SEMARNAT, declares for the first time the damage to dolphins stating that the petitioner does not indicate the dates when the field surveys were realized, which could limit the identification of environmental impacts. For example, information about the presence of bottlenose dolphins and how they utilize the region was presented, but it was not considered which would be the impacts from vessel use over bottlenose dolphin's populations, as well as for whale sharks, given the fact that the mega-project plans the construction of piers inside the navigation channels; thus it is to be expected that these vessels do not only use the projected channels but the whole Ensenada de La Paz region as well. Despite all these arguments, DGIRA approved the mega-project with some conditions; one of them was land use change, which was denied by the municipality of La Paz. Meanwhile organizations like AICMMARH, A.C., CEMDA, Tiburon Ballena Mexico, and ConCiencia pointed out the risks that this project represented to local species; these opinions where written in the annulment of judgment before the Federal Court of Fiscal and Administrative Justice. In September 2012 the TFJFA permanently nullify the Environmental Impact Authorization (AIA) of "Entremares" and determined that the petitioner did not consider in the project the possible damage caused to endangered species, like California sea lions, coyotes, gray foxes, and raccoons, all of them inhabitants of the forested protected zone El Mogote, located in front of La Paz city in Baja California Sur. Petitioner appealed legally but in November 2013, the Eleventh Collegiate Tribunal confirmed the nullity of the AIA, resolving to deny the appeal for considering that the 1938 decree that declares the port of La Paz area as a forested protected zone, is valid as a natural protected area (ANP) in the category "protection area for flora and fauna", according to LGEEPA (Ecologic Equilibrium General Law).

# **MARINA AZUL AND THE ACCUMULATIVE AND SYNERGIC IMPACTS**

Another case is the fact that during the development of the Environmental Impact Study of the Project Marina Azul the consultant did not made a good evaluation because some relevant issues were not taking in consideration. Direct, synergistic, cumulative and residual ecological corridor in the southern Bay of La Paz impacts because we believe there are omissions, methodological faults, flaws and gaps in the Environmental Impact Statement filed. In the case of omissions, you can make a direct reference to the literature review of the relevant area as a list of species cannot be restricted to the exclusive area of the project and should be included in the zone of influence of the project as They focused on the development zone but not in the region. This project was categorized as REGIONAL so the information should be presented as part of the MIA. The document was presented with a list of some pretty grim and updated references.

It represents an omission the fact that there was a collection of diverse taxa marine, coastal and land that should be considered in the report. Within my count there are about 3000 species inhabit ecosystems corridor Bay La Paz-Bay Window (considering the Archipelago of Isla Espiritu Santo and Isla Cerralvo) where they have at least 50 endemic species and at least 500 species NOM ECOL are 059. There are at least 8 ecosystems (mangrove forests, rocky reefs, coral reefs, forests of seaweed, maerl beds, seagrass, sacrocaule scrub and marsh grasses) that did not show appropriate information distribution in the region. The project is located in the fishing 7 Bay of La Paz and represents an important area for fishermen in the region. The document does not present a single analysis of the situation of coastal fisheries. information relevant to the project are ignored as the winds relationship with respect to the movement of marine sediments pair raised. The Pleistocene terrace which covers almost 50% of the project was not considered. It is not considered the presence of invasive species in the project area (at least 2 species of invertebrates in the area and at least 4 of macroalgae in the vicinity) that could increase your coverage by leaks resulting nitrogen-rich water Golf Equestrian Club and pastures. So this project could well be causing direct impacts to ecologically and economically important populations.

The study data have methodological errors as the data collection were not raised using widely accepted standards in academia so that the data presented have presented interpretative vices. This is particularly evident in the methodology for determining the coverage of corals, macroalgae, density of vertebrates and fish for sea area but could set the same standard for the land area. The major mistakes I find in these data are in the design of sampling as no samples were statistically significant aftershocks in which clearly show that the project area is homogeneous in this biological corridor. Having no appropriate sampling design and not having a robust database we could not calculate the residual impact that could estarse generated as part of the development.

This Environmental Impact Statement has gaps in information and in the vicinity of this project there are 6 projects already approved and some of them already in operation shown in Figure 7: Maravia (adjacent), Punta Blanca (adjoining), El Judio (next), Azul del Cortes (next), The Saltito (next) and Vista Cerralvo (near and longer active). There is at least one mining concession adjacent and in addition to the desalination plant proposed in this project, there are two more: one in Maravia (adjacent) and another planned for the south of the CNA

#### 632 *Rafael Riosmena-Rodríguez and Rocío Marcín-Medina*

project. This set of projects having at least 4 sea which would add to the already operational in 5 Peace and plan tourist Megacruceros input. In addition there are two thermal power projects in close and marine aquaculture area. All these projects will promote the increase in population along with the frequency of visitors to the ANP: Sloop Gulf Islands and ANP in a first stage but most certainly to other areas such as Cabo Pulmo ANP by increased traffic in the calculation boats least 2 thousand boats continuously circulating. This was not evaluated as part of the MIA and displayed synergistic and cumulative impacts that have not been evaluated or resolved herein. All these projects represents the increase in population which also put pressure on the aquifer of La Paz, La Ventana and Dam Buena Mujer.

#### **CONCLUSION**

The way in which Mexican environmental authorities like SEMARNAT have authorized touristic-nautical developments like Paraiso del Mar and Entremares in La Paz, B.C.S. shows a clear systematic violation of our environmental law (LGEEPA) resulting in the deforestation of mangrove forests, modification of the coastline and damage to protected species.

There are 5 wetlands inside Ensenada de La Paz with mangrove forests; El Mogote is one of them affected by deforestation, garbage, construction for touristic activities, and dredging of water channels. As it could be observed, main threat is the establishment of touristic facilities like Paraiso del Mar or Entremares, the potential impact of the latter was higher; because the petitioner pretended to remove the mangrove to build the inner channels so residents could board their vessels outside their houses. El Mogote is bordered by red and black mangrove, is considered a highly fragile environment, acknowledge as Ramsar site #1816 on February 2<sup>nd</sup>, 2008 (Wetlands Mogote-Ensenada de La Paz).

Ensenada de La Paz and south of Bahia de La Paz are part of the critical habitat for groups of female's bottlenose dolphins, which they use during most of the year for feeding as well as nursing, protect them against predators, socialize and rest. One potential threat that can affect this protected species is coastal touristic nautical development, with an increase in the number of constructions and marinas along the coast. The latter will influence habitat quality due to the increase in the number of vessels traveling in the zone, with a concomitant increase in marine noise; hearing system is the most important sense for the development of different biological activities in cetaceans.

In Mexico critical habitats are mentioned in articles 63 and 64 of the LGVS (General Law for Wildlife), those articles were reformed by the Commission of Environment, Natural Resources and Fish from the Republic Senate (DOF, 2010), stating that SEMARNAT has the authority to declare critical habitats by means of a secretariat agreement, based on scientific information of species. Critical habitats are specific areas in which organisms develop their essential biological processes (feeding, reproduction, socialization, and resting). Physic, chemical or acoustic pollution, as well as risk of collision with vessels can affect populations of coastal marine mammals. Therefore SEMARNAT with the aid of researchers specialized in such species and their behavior must decrete zones as critical habitats and consider management measures for the conservation of species. Without a doubt, one of these zones is Ensenada de La Paz and south of Bahia de La Paz, that should be legally acknowledged as a critical habitat for dolphins; this will help for the protection and conservations of the whole ecosystem. By means of management programs, human activities that could impact the critical habitat of bottlenose dolphins must be regulated; this impact is higher for mothers with calves and juvenile dolphins, which according to the environmental laws of our country should be protected.

# **THE KEY ROLE OF THE SPECIES** *HEDISTE DIVERSICOLOR* **(POLYCHAETA, NEREIDIDAE) IN ESTUARINE ECOSYSTEMS**

# *Patrick G. Gillet , PhD, Mohammed Mouloud, PhD and Catherine Mouneyrac, PhD*

Department of Biology Environment, UCO University, Angers, France

### **ABSTRACT**

The ragworm *Hediste diversicolor* (O. F. Müller, 1776) is a widespread species of coastal lagoons and estuaries from Morocco to Scandinavia. Population dynamics of *H. diversicolor* from the Atlantic coast of Morocco were studied in the Bou Regreg Estuary (Gillet, 1993), in the Souss Estuary (Aït Alla et al., 2006); in Spain, in the Bay of Cadiz (Arias & Drake, 1995); and in Portugal in the estuarine systems (Sprung, 1994; Fidalgo e Costa et al., 1998; Abrantes et al., 1999). In the North Atlantic Ocean, *H. diversicolor* was studied in the Severn Estuary (Mettam, 1979; Mettam et al., 1982); in the North Sea, in the Ythan Estuary, Scotland (Chambers & Milne, 1975); in North East England (Olive & Garwood, 1981); and in the North Norfolk (Nithart, 1998). *H. diversicolor* is a major link in food webs and of economic importance as bait for fishing in several European countries. This species was chosen because it has a key role in the functioning of estuaries, a major link in benthic food webs and through sediment reworking by bioturbation activity. In France, the population dynamics of *H. diversicolor* was first studied in the Loire Estuary (Gillet, 1990; Gillet & Torresani, 2002) and the bioturbation activity (Gillet et al., 2012). This is a preliminary work to a large scale research program on *H. diversicolor* in different estuaries with the PNETOX '*National Program of Ecotoxicology*'. In the framework of the French National Program of Ecotoxicology, environmental quality was assessed in the multi-polluted Seine Estuary and the comparatively clean Authie Estuary, France (2002-2004), by determining contaminant levels in water, sediments and the infaunal worm *H. diversicolor* (Durou et al., 2003; Amiard-Triquet et al., 2007; Gillet et al., 2008). A scientific project comes under the

# **1.INTRODUCTION**

The endobenthic ragworm *Hediste diversicolor* (O. F. Müller, 1776) is a widespread species of coastal lagoons and estuaries from Morocco to Scandinavia. Population dynamics of *H. diversicolor* from the Atlantic coast of Morocco was studied in the Bou Regreg Estuary (Gillet, 1993), in the Souss Estuary (Aït Alla et al., 2006); in Spain, in the Bay of Cadiz (Arias and Drake, 1995); and in estuarine systems of Portugal (Sprung, 1994; Fidalgo e Costa et al., 1998; Abrantes et al., 1999). In the North Atlantic Ocean, *H. diversicolor* was studied in the Severn Estuary (Mettam, 1979; Mettam et al., 1982); in the North Sea, in the Ythan Estuary, Scotland (Chambers and Milne, 1975); in North East England (Olive and Garwood, 1981); and in the North Norfolk (Nithart, 1998). *H. diversicolor* is a major link in food webs and of economic importance as bait for fishing in North Atlantic Ocean. This species was chosen because it has a key role in the structure and functioning of estuaries. It plays a major link in benthic food webs and through sediment reworking by bioturbation activity. In France, the population dynamics of *H. diversicolor* was first studied in the Loire Estuary (Gillet, 1990; Gillet and Torresani, 2002) and the bioturbation activity (Gillet et al., 2012). This is a work to a large scale research program on *H. diversicolor* in different estuaries through the PNETOX 'National Program of Ecotoxicology'. In the framework of the French National Program of Ecotoxicology, environmental quality was assessed in the multi-polluted Seine Estuary and the comparatively clean Authie Estuary, France (2002-2004), by determining contaminant levels in water, sediments and in the infaunal worm *H. diversicolor* (Durou et al., 2003; Amiard-Triquet et al., 2007; Durou et al., 2007; Gillet et al., 2008). A scientific project comes under the framework of the International network Nereis Park Experiment gathering 27 laboratories from all over the world. The experiments were carried out concurrently in spring 2007 using a common protocol to study the bioturbation activity of *H. diversicolor* (Gillet et al., 2012; Gilbert et al, in press).

#### **2. MATERIALS AND METHODS**

A survey within the French National Program of Ecotoxicology was carried out in 2002, 2003 and 2004 to study the responses of *H. diversicolor* populations to the impact of pollution in the multi-polluted Seine Estuary comparatively to the reference Authie Estuary (non-contaminated site). Samples of *H. diversicolor* (Figure 1) were collected in both sites: Authie Estuary (Station: 50°22,217'N; 1°36,484'E) and in the Seine Estuary, (Station: 49°26,823'N; 0°14,628'E) in 2002 – 2004 (Figure 2). Four quadrats at 25 cm<sup>2</sup> to a depth of 20 cm were taken in order to calculate density and biomass of the target organisms. Quadrat sediment was placed on mesh wire pan and sieved. *H. diversicolor* samples were measured

for fresh weight and then placed in ethanol tubes. Each individual was then tested to measure the length of L3 (Gillet and Torresani, 2003; Ait Alla et al., 2006; Durou et al., 2007). L3 corresponds to the length measurement of the first three segments: prostomium, peristomium and first chaetiger. The length of these first three segments is positively correlated with the fresh weight and used to determine trends in size within the population. The size frequency histograms were treated by the SAEM (Simulated Annealing Estimating Mixture). The algorithm EM (Dempster et al., 1977; Redner et al., 1984) was used for the identification of parameters of a mixture and replaces the methods based on the analysis of the modes of the histograms. An amelioration of the algorithm EM consisted to base on methods of recuit simulated where result the name SAEM (Simulated Annealing E, M), to introduce one random perturbation of the probabilities -a posteriori- of affectation (Soubiran et al., 1991; Celeux et al., 1995). This method presents numerous developments to study the size frequency histograms to determine cohorts within a population (Robert, 1996).

Figure 2. Locations of sampling site in the Authie and Seine estuaries, France. National Program of Ecotoxicology.

#### **3. POPULATION DYNAMICS OF** *HEDISTE DIVERSICOLOR*

In 2002, the density of *H. diversicolor* ranged from 1,084 to 3,584 individuals  $m<sup>2</sup>$  in the Authie Estuary and from 136 to 920 ind  $m<sup>2</sup>$  in the Seine Estuary. In 2003, the densities varied from 912 to 3,328 ind.m<sup>-2</sup> in the Authie Estuary and from 80 to 288 ind.m<sup>-2</sup> in the Seine Estuary. A decrease of the density was observed in the Seine Estuary with  $920$  ind.m<sup>-2</sup> in February 2002 and only 80 ind.m<sup>-2</sup> in November 2003. In 2002, the biomass of  $H$ . diversicolor showed temporal variations with a maximum of 32.66 g.m<sup>-2</sup> in July and lower values in February with  $B = 21.55$  g.m<sup>-2</sup> in the Authie Estuary. The biomass varied from 3.42 g.m<sup>-2</sup> in February to 0.68 g.m<sup>-2</sup> in September in the Seine Estuary. In 2004, the density varied from  $672$  to  $3,512$  ind.m<sup>-2</sup> in the Authie Estuary and from 120 to 192 ind.m<sup>-2</sup> in the Seine Estuary. Biomass varied from  $3.94 \text{ g.m}^2$  (dry weight) in February to  $26.77 \text{ g.m}^2$  in August in the Authie Estuary and from 0.56  $g.m<sup>-2</sup>$  in February to 1.25  $g.m<sup>-2</sup>$  in August in the Seine Estuary. Density and biomass are greater in the uncontaminated site of the Authie Estuary than in the contaminated site of the Seine Estuary (Figure 3). When the data was compared to mean historical values (from 2002 to 2015) collected overlapping the site of collection (radial 3 and 5) (Figure 4) values showed that the highest recorded density was  $1,293 \pm 850$  ind.m<sup>-2</sup> in 2001 and the lowest recorded value was  $25 \pm 12$  ind.m<sup>-2</sup> in 2010. Results showed that the average density for *H. diversicolor* was higher than previous collections between the years 2009-2013. The density of *H. diversicolor* was also compared to historical data collected at Authie and Seine estuaries in February (2002, 2003 and 2004) (Gillet et al., 2008). Results showed that the density of individuals collected was lower than values observed in the previous study when compared to Authie, as demonstrated in Figure 4.

Figure 3. Density (A) and biomass (B) of *Hediste diversicolor* in the Authie and Seine estuaries, France. National Program of Ecotoxicology carried out in 2002-2004 (Gillet et al., 2003).

With the same size, the individuals from the Seine Estuary have a low biomass. For the individuals from the Authie Estuary, the relationship between Dry Weight (DW) and length (L3) was DW = 4.2205 L3<sup>2.9832</sup> with r = 0.66 (N = 57 individuals). For those from the Seine Estuary, the relation between Dry Weight and L3 was DW =  $0.4697 e^{1.7209L3}$  with r = 0.38 (N  $= 32$  individuals) (Figure 5).

The size frequency histograms of the length L3 were separated into size classes from 0.3 to 4.3 mm (Figure 6). Most of the size frequency histograms were plurimodal with 2 or 3 cohorts. In 2002, we observed three cohorts C1, C2 and C3 in February in the Authie Estuary.

From April to September, there were two cohorts C2 and C3 then two cohorts C3 and C4 in the Authie Estuary. In the Seine Estuary, we observed two cohorts C2 and C3 in February but only one cohort C3 in April and July and two cohorts C3 and C4 in September 2002. The individuals of *H. diversicolor* from the Authie Estuary belonged to eight different cohorts instead of six cohorts for those from the Seine Estuary. The life time for a cohort was 13 months in the Authie Estuary and varied from 6 to 11 months in the Seine Estuary (Figure 7). These differences of the number of cohorts could be attributed to the effect of pollution on the population of *H. diversicolor* (Durou et al., 2007).

Figure 4. Comparison of *H. diversicolor* density to historical data acquired from Seine (polluted) and Authie (non-polluted) Estuary.

Figure 5. Comparison of individual size and weight of *H. diversicolor* from Seine (polluted) and Authie (non-polluted) Estuary.

Figure 6. Comparison of size frequency histograms of *H. diversicolor* from Seine (polluted) and Authie (non-polluted) Estuary (2002).

Figure 7. Number of cohorts of *H. diversicolor* from Seine (polluted) and Authie (non-polluted) Estuary (2002).

In 2002, the mean size L3 of the cohorts varied from 1.04 mm to 2.65 mm in the Authie Estuary and from 1.32 mm to 1.94 mm in the Seine Estuary. In 2003, the mean size L3 of the cohorts varied from 1.08 mm to 2.27 mm in the Authie Estuary and from 1.27 mm to 1.82 mm in the Seine Estuary. In 2004, the mean size L3 of the cohorts varied from 1.01 mm to 2.41 mm in the Authie Estuary and from 1.07 mm to 1.77 mm in the Seine Estuary. The size of individuals was lower in the Seine Estuary than in the Authie Estuary. These differences of the mean size could be attributed to the effect of pollution on the population of *H. diversicolor* (Durou et al., 2007).

#### **Comparison with Other Estuaries**

The density of the population of *H. diversicolor* observed in the Seine Estuary was similar to those observed in the Loire Estuary in 1987 with 800 to 3,200 ind.m<sup>-2</sup> (Gillet, 1990) and in 1999 with 300 to 2,560 ind.m<sup>-2</sup> (Gillet and Torresani, 2003). The biomass observed in the Authie Estuary was higher than biomass observed in the Loire Estuary in 1987 with 16 g.m-2 (Gillet, 1990). In the Seine Estuary, density and biomass decreased from 2002 to 2003 and seemed to show a regression of the population of *H. diversicolor*. The lower densities of *H. diversicolor* were comparable with densities from polluted parts of the Tees Estuary (Gray, 1976). In the Ems Estuary, North Sea, Essink et al., (1985) found decreasing densities of *H. diversicolor* toward a point of discharge of organic waste. They suggested two causes: mortality and migration. Such a migration was observed in the oued Souss Estuary in Morocco by Aït Alla et al., (2006). Two recruitment periods were detected each year. These results were similar to the data of Gillet (1990) and Gillet and Torresani (2003) in the Loire Estuary. In Southern regions, the populations of *H. diversicolor* presented a longer spawning period and two recruitment periods in spring and autumn Abrantes et al. (1999), Aït Alla et al., (2006). In Northern regions, the populations of *H. diversicolor* had a short spawn and only one recruitment period, usually in spring or summer. Thus migration and low recruitment were likely to be involved in the disappearance of the worms in the Seine Estuary. Pollution might affect the recruitment of juveniles, the number of cohorts and the growth of individuals (Durou et al., 2007).

#### **4. BIOTURBATION ACTIVITY OF** *HEDISTE DIVERSICOLOR*

This scientific project comes under the framework of the International network Nereis Park Experiment gathering 27 laboratories from all over the world (Figure 8). The experiments were carried out concurrently in spring 2007 using a common protocol to study the bioturbation of *H. diversicolor* (Figure 9). Sediments and polychaetes were sampled in 18 locations around the world from May to July, 2007. Based on a common experimental protocol, surface sediments (0-5 cm depth) were sampled and handled similarly in the 18 participating laboratories, i.e., sieved through a 1-mm mesh to remove large animals and debris, and then homogenized. Subsamples of sediments were collected for organic matter (OM) content and for sediment grain size determination. *H. diversicolor* was used by 16 laboratories. All laboratories obtained worms at natural sampling sites. The worms were

weighed individually and sorted to obtain samples with a biomass representative for local natural populations. They were kept in homogenized sediments with aerated water, under a 12: 12 dark: light cycle and at *in situ* temperature until experimental use. Four PVC or Plexiglas core tubes (height: 20 cm; internal diameter: 10 cm) were filled with homogenized sediments (15 cm deep sediment column) and incubated for a week in experimental containers under the previously described conditions. Four worms were introduced in each of three cores, leaving the last core as a control. Worms were allowed to establish burrows for 7 days before the addition of particle tracers. Two g of fluorescent inert particles  $(63-125 \mu m)$ ; Partrac Ltd., Glasgow, UK) were suspended in water into a tube and homogeneously deposited through the overlying column on the surface of each sediment column (resulting in a visible layer of  $\leq 1$  mm thick). After 10 days of incubation, the overlying seawater was removed and the experimental cores were carefully sectioned into 0.5-cm thick layers from the surface down to 2 cm depth, and 1-cm thick layers down to 15 cm. The sediment from each layer was freeze-dried, homogenized and shipped to EcoLab (Toulouse, France) for further analysis. At EcoLab sediment subsamples were processed for counting of luminophores under UV-light (light peak at 365 nm; digital camera Olympus C-2500L; image analysis software Image-Pro Plus).

Figure 9. Reworking activity of *Hediste diversicolor* in the sediment of estuarine ecosystem.

#### **4.1. Bioturbation Activity of** *Hediste diversicolor* **in the Loire Estuary**

In the Loire Estuary, samples were collected in the intertidal zone of the Saint-Nazaire Bridge (Figure 10). During the field experiment, we estimated the surface area of the burrow walls (Sb) value varied from Sb = 0.26 m2.m-2 to 2.18 m<sup>2</sup>.m<sup>-2</sup> (mean Sb = 0.75 m<sup>2</sup>.m<sup>-2</sup>), and the pumping rate (Pr) value from Pr = 0.9 l.d<sup>-1</sup>m<sup>-2</sup> to 7.7 l.d<sup>-1</sup> m<sup>-2</sup> (mean value Pr = 2.7 l.d<sup>-1</sup>m<sup>-</sup> 2 ). The density and the biomass of *H. diversicolor* populations largely controlled the amount of reworked sediment (Figure 11).

In the laboratory, we estimated the pseudo-diffusive mixing,  $D_b$  value varied from  $D_b$  = 1.2 to 1.6 (mean  $D_b = 1.5$ ). The non-local transport (*r*) from the upper layers to the bottom of the tubes varied from  $r = 1$  to 7.2 (mean  $r = 4.3$ ) (Figure 11). A positive relationship could be established between  $D_b$  and the temperature while on the contrary a negative relationship could be established between the  $D<sub>b</sub>$  and biomass. It seems that small individuals were more efficient reworkers than bigger ones.

Figure 10. Location of the sampling site in the Loire Estuary, France for the Nereis Park Experiment.

#### **Comparaison Hediste site1/site2**

Figure 11. Luminophore profiles obtained with the gallery-diffusor model *H. diversicolor* in the Loire Estuary, France (Gillet et al., 2003).

#### **4.2. Bioturbation Activity of** *Hediste diversicolor* **in the Nereis Park Experiment**

The results provided by this study allowed ranking of the global sediment reworking intensity by *H. diversicolor* populations between different geographical locations. In an attempt to investigate the possible causes of this ranking, correlations between sediment mixing proxies (MPD, *D<sup>b</sup>* and *r*) and the registered experimental, biological and environmental parameters were tested. The apparent biodiffusion-like coefficient  $D<sub>b</sub>$  and the non-local coefficient *r* allowing the best fit with the modelled profile according to the least square method were obtained for each experimental luminophore profile (Figure 12). In addition, the maximum penetration depth of luminophores (MPD) was used as a proxy to estimate sediment reworking depth.

Figure 12. Luminophore profiles (diamonds) and corresponding modelled profiles (dotted lines) obtained with the gallery-diffusor model *H. diversicolor* in the Nereis Park Experiment (Gilbert et al., in press).

Figure 13. Sediment reworking score integrating the values of both the biodiffusion-like coefficient *Db* and non-local coefficient *r* obtained for the sixteen *Hediste diversicolor* laboratory experiments involved in the Nereis Park Experiment (Gilbert et al., in press).

The global sediment reworking intensity among experiments (i.e., geographical locations) involving *H. diversicolor* was ranked according to the sediment reworking scores integrating the values of both the biodiffusion  $(D_b)$  and non-local  $(r)$  coefficient. The highest score (i.e., the highest global sediment reworking intensity  $= 1.42$ ) was found for UB (France) and the lowest for SAMS (Scotland) (score = 0, i.e., the lowest values of  $D_b$  and  $r$  for the whole study) (Figure 13).

However, beyond the specific results obtained on *H. diversicolor* sediment reworking, this inter-laboratory work highlighted the usefulness of joint experiments in functional ecology. Indeed, in order to investigate some process at a global scale while integrating a set of biological and environmental parameters which differ locally over more or less large gradients, this comparative approach had good merits in comparison to what could be achieved with a single experimental study at one location to assess the same range of factors, due in part to the numerous experimental conditions to be considered which would require the set up an extremely complicated experimental design. Covering large, natural ranges in such a comparative study compensates for the correlative nature of the results obtained. Due to its high physiological plasticity, the ragworm *H. diversicolor* appears to be able managing burrow construction and sediment reworking within a wide range of soft bottoms. The sediment reworking intensity by this species has been shown to be quite variable at a global scale and to be governed by both biological and environmental parameters.

# **HOX-GENES IN THE ONTOGENESIS OF POLYCHAETES**

# *Milana A. Kulakova\**

Department of Embryology, Saint Petersburg State University, Saint Petersburg, Russia

#### **ABSTRACT**

The basic plane and evolution of bilateral animals (Bilateria) are closely associated with Hox-genes. These genes usually exist in the genome in the form of clusters, gene complexes with a conservative position of individual genes inside them. These genes encode transcription factors containing a homeodomain, and their expression is ordered along the main body axis in accordance with the rule of colinearity. This means that the position of a gene in the cluster determines its spatial and, sometimes, temporal expression in the embryo. In vertebrates and arthropods, which are studied in most detail, Hox-genes define the morphological distinction between different regions of the body (tagmas). Boundaries of Hox-genes expression often coincide with the borders of tagmas. In addition, these genes also function in adult organisms, where they are involved in regeneration processes and the maintenance of tissue homeostasis. In recent years, there has been an surge of interest in the study of Hox-genes in animals that are not traditional models of molecular biology. Polychaetes are the most intriguing objects of such studies. They belong to a poorly studied evolutionary branch of Bilateria, the Lophotrochozoa, which is enough to make them attractive for both molecular and developmental biologists. Among polychaetes, there are both families with morphologically specialized segments grouped into tagmas (Chaetopteridae) and families with numerous identical segments (Nereididae). There are polychaete species with impressive abilities to regeneration of the head and the tail and those incapable of regeneration at all. In addition, the life cycle of polychaetes often includes the larva, which may be essentially different from an adult worm. How do the Hox-genes work in so different systems? Can we compare some of their functions with those of homologous genes in insects and vertebrates? What is their place in the hierarchy of molecular regulators controlling developmental processes in polychaetes? If we answer these questions, many pieces of the jigsaw puzzle representing the earliest evolution of bilaterian animals would fall into

 $\overline{a}$

place. In this review, I present an up-to-date information about Hox-genes in polychaetes and make some cautious assumptions about the ancestral functions of the Hox-cluster.

**Keywords**: Annelida, Hox-genes, UrBilateria, larval development, regeneration

# **1.INTRODUCTION**

In this chapter, I describe Hox-genes of polychaetes, their structural organization and functional features in the ontogenesis. Among hundreds of evolutionary conservative gene families, Hox-genes are especially important for understanding the relationship between individual development and macroevolution. Edward B. Lewis, an American geneticist scientist (Nobel Prize in Medicine 1995), was the first to discover this relationship. In 1987 he published the results of his long-term studies of the segmentation control pattern in *Drosophila* in *Nature* (Lewis, 1987). He used mutation analysis to consider the structure and the function of specific *bithorax* locus (a gene complex bithorax or BX-C). Calvin Bridges, who worked in the laboratory of Thomas Hunt Morgan, isolated and described a strange *bithorax* mutation at this locus in *Drosophila* as early as in 1915. This was a classic homeotic mutation, with the third thoracic segment being partially transformed into the second one. In this case, the anterior part of the halter became the anterior part of the wing (Bridges and Morgan, 1923).

Lewis knew nothing about the nature of factors encoding the BX-C sequence but made several important conclusions, most of which proved true. Some of them are as follows:

- 1) BX-C genes form a cluster, a complex of genes, which resulted from tandem duplications of an ancestor gene with subsequent mutational divergence of its offspring;
- 2) The position of the gene on the chromosome is directly connected with the spatial order of the gene's activation (this link is now referred to as colinearity);
- 3) *Diptera* originated from primitive four-winged ancestors, while insects originated from primitive arthropods, which had legs on all abdominal segments. In the course of evolution, "leg-suppressing" genes emerged, which suppressed the development of legs on abdominal segments. "Halter-promoting" genes suppressing wing development on the third thoracic segment also evolved. The loss-of-function mutation in BX-C may lead to the recapitulation of the primitive state, i.e., the emergence of four-winged and many-legged flies.

Now we know that insects evolved no new Hox-genes. Instead, "old" genes assumed new control functions of the development program. In general, however, the logical reasoning suggested by Lewis proved correct.

After the publication of this seminal article, the researchers obtained a tool directly linking the molecular control of development and phylogenetic evolution. A new science, evolutionary developmental biology or EvoDevo, was born.

BX-C sequences and other *Drosophila* genes causing homeotic transformation were found, cloned and sequenced independently by three research teams in California and Indiana (the USA) and Basel (Switzerland) (cit. ex Papageorgiou, 2007). As Lewis had predicted, these genes appeared to be serial homologs. They encode transcription factors with a

distinctive DNA-binding protein domain, the *homeodomain*. The nucleotide fragment encoding it, the *homeobox*, consists of 180 base pairs. The name *Hox*-genes is derived from "homeotic" and "homeobox." In *Drosophila* they are organized in two complexes, ANT-C and BX-C. A set of homologous Hox-genes was later found in vertebrates (Ranginib et al., 1989; Godsave et al., 1994; Burke et al., 1995). Their mutations also result in spatial shifts of structures located along the body axis. It was suggested that Hox-genes originated not in insects but much earlier, in the Precambrian (ca. 600 million years ago), when the last common ancestor of chordates and arthropods supposedly lived.

The analysis of Hox amino-acid sequences of homeodomains and flanking areas in animals from different evolutionary branches dramatically altered the phylogeny of bilateral animals (de Rosa et al., 1999). The evolutionary tree of Bilateria is divided near the basement into two branches, *Deuterostomia* (Chordates, Hemichordates, Echinoderms) and *Protostomia*. The latter, in turn, are divided into *Ecdysozoa* (Arthropoda, Onychophora, Nematoda, Priapulida and others) and *Spiralia* (Brachiopoda, Nemertea, Annelida, Mollusca, Platyhelminthes, Rotifera and others) (de Rosa et al., 1999). The name Ecdysozoa derives from the Greek word *ecdysis* meaning molting. All ecdysozoans are covered by hard cuticle, and their growth is accompanied by periodical molting, when old covers are discarded and the animal grows quickly or, rather, expands, until the new covers harden. *Spiralia* branch is named after the type of early embryonic cleavage. This branch is very heterogeneous. It include Lophotrochozoa, Platyhelminthes, Gastrotricha, Syndermata and Gnathostomulida (Struck et al., 2014). Lophotrochozoa are an especially intriguing group for evolutionary biologists because of the great variability of body organization plans. An octopus, a murex and an oyster belong to the same taxon Mollusca but this is hard to believe judging from their appearance. The term Lophotrochozoa derives from two other zoological terms: Lophophorata and Trochophora. Lophophorata (Brachiopoda, Bryozoa and Phoronida) are animals with the lophophore, an organ of suspension feeding. Earlier the group Lophophorata was included in Deuterostomia. The trochophore is a spherical ciliated larva typical of the Lophotrochozoa (Annelida, Mollusca).

This new "molecular" phylogeny fitted well the previous phylogenies based on 18s rDNA (Field et al., 1988, Aguinaldo et al., 1997) and mitochondrial DNA (Cohen et al., 1998). A comparative study of Hox-genes sequences suggested that the common ancestor of bilateral animals (located at the basement of all the three evolutionary branches) already had at least seven Hox-genes (de Rosa et al., 1999). Modern studies of metazoan evolution focus on the morphology of this common ancestor, its origin and the reasons behind a great evolutionary radiation of its descendants.

In the last decade, mechanisms underlying morphological evolution have mostly become clear. Remarkable new methods, made it possible to fine-tune the functioning of a certain gene, to turn it off at a certain moment of development, to stimulate its ectopic expression and even to edit the genome *in vivo* (CRISPR/Cas9 technology). However, our knowledge about the functions of Hox-genes and even the patterns of their expression in different branches of Bilateria is very uneven. While the functions of Hox-genes in Deuterostomia and Ecdysozoa are studied in detail (at least as concerns vertebrates and arthropods), similar studies of Lophotrochozoa arejust starting. The set of molecular tools for controlling morphogenesis in these animals is same as used in studies of fruit flies or humans. The difference is in the strategy of using these tools. Studies of Hox-genes in Lophotrochozoa can provide fascinating insights into regulatory evolution and epigenetics.

### **2. POLYCHAETES: WHAT ARE THEY?**

Before starting to discuss the Hox-genes of polychaetes, it is necessary to make clear what these animals are. The phylum Annelida was previously divided into two monophyletic branches, Polychaeta and Clitellata (Clitellata = Oligochaeta + Hirudinea) (Rouse and Fauchald, 1997). This division was based on a convincing body of morphological evidence. However, the classification of annelids changed dramatically as soon as nucleotide and amino-acid sequences were applied. At first, there were just a few genes and gene families, then mitochondrial genomes became available, then scientists had at their disposal expressed sequence tags (ESTs) libraries and even whole transcriptomes read with the aid of NGS platforms (Illumina) (Zrzavy et al. 2009; Shen et al., 2009; Struck et al., 2011; Weigert et al., 2014, Andrade et al., 2015). This approach revealed several counter-intuitive connections within Annelida and showed that their classification was much more complex than previously thought (Figure 1).

Figure 1. Annelid relationships based on combined results from larger phylogenomic studies. The stem of phylogenetic tree is divided to two big branches: Sedentaria and Errantia. The data about the compound and the structure of Hox-clusters are distributed very irregularly. White circles mean genes, for which there isn't data. Circles with X mean lost genes. Heavy lines mean proved physical connection between genes. The line's absence means proved absence of connection. Dotted lines mean hypothetic connection between genes (according to two reviews (Weigert and Bleidorn, 2016; Barucca et al., 2016) and several original articles (Irvine and Martindale, 2000; Andreeva et al., 2001; Frobius et al., 2008; Simakov et al., 2013; Zwarycz et al., 2015).

It appears now that polychaetes are paraphyletic. The term "polychaetes" fell out of taxonomic register, becoming the synonym of annelids (Struck et al., 2011; Weigert and Bleidorn, 2016). We continue, however, to use the name "polychaetes" for sea annelids from two different monophyletic branches, Errantia and Sedentaria, because this use is firmly rooted in tradition. Importantly, these two branches had a common ancestor in the remote past. Petrified mandibles (scolecodonts)resembling the jaws of modern eunicid polychaetes (Errantia) have been found in strata at the border of Late Cambrian and Early Ordovician, i.e., they are at least 485 million years old (Weigert and Bleidorn, 2016). The last common ancestor of Errantia and Sedentaria might have lived even earlier. Some of its traits were recapitulated based on phylogenetic reconstructions and paleontological data from Middle-Cambrian sediments of Burgess Shale (Middle Cambrian; ~508 mya) (Struck et al., 2011; Parry et al., 2015). This was a macroscopic epibenthic worm with paired palps, biramous parapodia and simple (capillary) bristles. It might also have had aciculae (supporting chitinous rods within parapodia) (Struck et al., 2011) but this is uncertain. Annelids from the Burgess Shale have no aciculae (Parry et al., 2015), while a fossil worm from earlier sediments has them (Liu et al., 2015).

Errantia and Sedentaria are the crown group of Annelids, with the largest number of species and the greatest diversity of shape. There are among them both segmented and unsegmented worms, forms with a simple life cycle and with complex life cycles involving several larval stages. Besides these two groups, Annelida also includes six basal branches: Oweniidae, Magelonidae, Chaetopteridae, Sipuncula, Amphinomida, and Lobatocerebrum (Weigert and Bleidorn, 2016). There are also both segmented and unsegmented worms among them. This circumstance complicates considerably the search for the ancestor of the crown group of annelids.

#### **3. SET AND STRUCTURE OF HOX-CLUSTERS IN POLYCHAETES**

Hox-genes of annelids are the best studied among Lophotrochozoa. However, superimposing the data about the Hox-cluster set and the transcription pattern of Hox-genes on the phylogenetic map, we can see that they are fragmentary (Figure 1). Clitellate are studied better than other lines (Wysocka-Diller et al., 1989; Aisemberg et al., 1993; Snow and Buss, 1994; Cho et al., 2004, Cho et al., 2012; Simakov et al., 2013; Zwarycz et al., 2015; Endo et al., 2016), which is probably due to an easier maintenance of cultures of terrestrial and freshwater annelids. At the same time, molecular phylogeny and the fossil record indicate that the Clitellata evolved in late Paleozoic, not earlier than in the Permian period. They are very different from the ancestor of the crown group and basal annelids (Parry et al., 2015).

Almost full sets of Hox-genes were cloned from *Urechis unicinetus* (Sedentaria, Echiura), *Ctenodrilus serratus* (Sedentaria, Cirratuliformia) and *Myzostoma cirriferum* (Errantia, Mizostomida) (Barucca et al., 2016) but there are no data about their expression yet. The first five Hox-cluster genes were cloned from the only studied representative of the basal group, *Chaetopterus variopedatus* (Irvine and Martindale, 2000). Their transcription patterns are well-known, and we will discuss them later.

The most complete data are available for two polychaetes from the Errantia branch (*Alitta virens* and *Platynereis dumerilii;* Family: Nereididae) and one polychaete from the Sedentaria branch (*Capitella capitata;* Family: Capitellidae). Though two families from nearly a hundred cannot, of course, represent the entire crown group of annelids, the studied species were at least not from the same branch.

The full set of Hox-genes characteristic of Lophotrochozoa was first described in *Alitta virens* (formerly *Nereis virens*) (de Rosa et al., 1999). In *Alitta* genome there are eleven Hoxgenes: *Hox1*(PG1), *Hox2*(PG2), *Hox3*(PG3), *Hox4*(PG4), *Hox5*(PG5), *Lox5*(PG6−8), *Hox7*(PG6−8), *Lox4*(PG6−8), *Lox2*(PG6−8), *Post2*(PG9+) and *Post1*(PG9+). This set is considered as an ancestral complement of Mollusca, Brachiopoda and Annelida (Barucca et al., 2016). In the second nereid polychaete (*Platynereis dumerilii*) only nine genes were initially cloned (Kulakova et al.2007; Pfeifer et al., 2012) but missing orthologs were later found (*Hox7*, *Lox4*) (Bakalenko N., unpublished data). The size and the structure of Hoxcluster in nereid polychaetes has not been described in detail yet. According to preliminary data obtained by pulsed field electrophoresis (PFE) (Andreeva et al., 2001), the Hox-cluster of *Alitta* is situated in a single locus not exceeding  $2.4 - 2.5$  Mb. This indicates that Hoxgenes are not scattered in the genome, i.e., the cluster is not atomized as it is in the urochordate *Oikopleura* or the octopus (Seo et al., 2004; Albertin et al., 2015). However, the resolution of PFE does not allow one to determine the exact size of the cluster and the pattern of its organization (whether it is organized, disorganized or split *sensu* Denis Duboule, 2007). In *Platynereis* Hox-genes are also localized on one chromosome and, moreover, in one linkage group with some "extended" Hox-genes (*eve* and *mox*) and genes from EHGbox (*en, hb9/mnx1, gbx*). These genes, which often flank Hox-clusters in Deuterostomia, are considered as a part of an ancient synteny between the ancestral gene clusters from the Megacluster of homeobox-containing genes of the Antennapedia class (ANTP-class) (Pollard and Holland, 2000; Hui et al., 2012).

A similar set of Hox-genes was found in the polychaete *Capitella capitata* (Frobius et al., 2008). The structure of the cluster is studied in detail. It is localized in three different scaffolds. In the first scaffold in the region of 243 kbp genes *CapI-lab* (PG1), *CapI-pb* (PG2), *CapI-Hox3* (PG3), *CapI-Dfd* (PG4), *CapI-Scr* (PG5), *CapI-lox5* (PG6−8), *CapI-Antp* (PG6−8), and *CapI-lox4* (PG6−8) are placed. The remaining genes, *CapI-lox2* (PG6−8) and *CapI-Post2* (PG9+), occupy 21.6 kbp in the second scaffold. *Post1* lies within the third scaffold surrounded by non-Hox sequences. This suggests that Post1-ortholog is not part of the Hox-cluster in *Capitella*. All Hox-genes in this polychaete have the same transcriptional orientation and have no ORFs between them. If we summarize Hox-coding areas, the total size of the cluster will be 345 Kb. The genome of *Capitella* has been sequenced (Simakov et al., 2013) but the gap between scaffolds is unfortunately still present. This probably indicates that there is a region difficult to read and to assemble or that the distance between Hox-cluster fragments is very large.

It is interesting that the studied species of Clitellata (oligochaetes and leeches) often have Hox-cluster reconstructions leading to the loss or duplication of certain genes (Simakov et al., 2013; Barucca et al., 2016). For example, leeches have no *Post1* orthologs, and *Hox2* is present only in the earthworm *Perionyx excavatus*. Another earthworm, *Eisenia fetida*, has multiple duplications possibly involving the entire genome. Owing to them, the number of Hox-genes in the genome is increased up to 28 (Zwarycz et al., 2015).

Orthologs of the first five Hox-genes of polychaetes were found in Deuterostomia and Ecdysozoa. These genes seem to have been inherited from the common ancestor of Bilateria, the UrBilateria (de Rosa et al. 1999). They are the most conservative Hox-genes. The central
Hox-genes of annelids (*Lox5*, *Hox7*, *Lox4* and *Lox2*) have no definite orthologs among those of vertebrates (*Hox6*, *Hox7*, *Hox8*) and arthropods (*Antp*, *Ubx*, *abd-A)* (de Rosa et al. 1999; Hueber et al., 2013; Frobius et al., 2008). To solve complicated phylogenetic relationships within this group of sequences, a detailed analysis of signature amino acid motifs was necessary (Hueber et al., 2013). It revealed that the last common ancestor of Protosomia had at least two central Hox-genes, Antp/Hox7-like and abd-A-like. The first sequence is the most conservative; it was inherited from the ancestor of Protostomia/Deuterostomia (Hueber et al., 2013)*.* Antp/Hox7-like gene gave rise, by independent duplications, to *ftz* and *Antp* in Arthropoda and to *Lox5* and *Hox7* in Annelida. The second central gene, abd-A-like gene, evolved shortly before the division of UrProtostomia into Ecdysozoa and Spiralia. This ancestral gene gave rise to *abd-A* in Arthropoda and to *Lox4* and *Lox2* in Annelida. It is interesting that the key gene responsible for the development and evolution of insects, *Ubx*, evolved relatively late in the arthropod line, probably by duplication of the ancestral *abd-A* sequence (Hueber et al., 2013). The affinity between the central Hox-proteins of Deuterostomia and Protostomia can be traced at the level of the single sequence type, Antp/Hox7. It suggests that UrBilateria had one central Hox-gene, Antp/Hox7, which was duplicated and diverged in a specific manner in each evolutionary branch.

The posterior genes of annelids are *Post1* and *Post2*. They are representatives of PG9+ and are characteristic of Spiralia. Until recently, *Post1* was believed to have evolved after the duplication of the *Post1/Post2* ancestral sequence at the level of the last common ancestor of Mollusca, Brachiopoda and Annelida. This belief was based on the fact that only one posterior gene similar to *Post2* was found in the genome of nemerteans and flatworms (Barucca et al., 2016). However, a single *Post-1* gene and four *Post-2* paralogs have recently been reported from *Schmidtea mediterranea* (Tricladida) (Currie et al., 2016). It is possible that *Post1* evolved earlier than previously thought but has been lost repeatedly.

Thus, orthologs of central and posterior genes duplicated and diverged independently in each evolutionary branch of Bilateria (Deuterostomia, Ecdysozoa and Spiralia). This makes them useful phylogenetic markers for studies of animals with an uncertain taxonomic position (Chaetognatha, Rotifera etc.). Besides, structural evolution of the Hox-cluster is inseparable from its functional evolution. Below I will show how the expression of Hox-genes is associated with morphogenesis in polychaetes.

# **4. EXPRESSION PATTERNS OF HOX-GENES**

#### **4.1.** *Chaetopterus variopedatus*

Hox-genes transcription patterns in polychaetes were first studied in *Chaetopterus variopedatus* (Irvine and Martindale, 2000; Peterson et al., 2000). This polychaete has a world-wide distribution. It builds U-shaped burrows and gathers food particles by specialized organs while pumping water through the burrow. Though it belongs to basal annelids, *Chaetopterus* has a very complex heteronomous organization. The body of the adult worm has three functionally and morphologically different parts, tagmas (A, B and C). Tagma A consists of a presegmental prostomium and a peristomium, which are fused together. The peristomium has ten chaetae-bearing segments, setigers (A1-A9). They have certain morphological differences (A4 bears a bundle of dark spines, while A9 bears neuropodial uncini) (Irvine et al., 1999). Tagma B consists of five specialized segments (B1-B5) used for the collection of food particles by filtration and the pumping of water through the burrow. Each of these segments has a unique morphology (Figure 2a). Tagma C consists of a variable number of uniform segments, where gametes are formed.

The function of five genes cloned in *Chaetopterus* (*CH-Hox1*, *CH-Hox2*, *CH-Hox3*, *CH-Hox4* and *CH-Hox5*) intrigued the researchers a lot. First of all, it was important to understand how the transcription of the Hox-genes is related to the time when a segment is set up along the body axis and with the morphological boundaries of the tagmas. If the Hoxgenes of *Chaetopterus* followed the rule of spatial colinearity characteristic of vertebrates and arthropods, this would mean that this rule probably operated in their common ancestor. The pelagic larva of *Chaetopterus* was another intriguing aspect. Is the Hox-gene cluster used for its formation? If so, what happens during the formation of definitive structures?

The place, the time and the intensity of transcription were determined by the WMISH (Whole Mount In Situ Hybridization) method (Irvine and Martindale, 2000) and by the quantitative assessment of the amount of CH-Hox-genes transcripts in the organism (Peterson et al., 2000). All Hox-genes in *Chaetopterus* appear to start functioning in the posterior zone of the larva long before any visible segmentation. Topologically, this zone corresponds to the growth zone. All larval and definitive segments are formed later. *CH-Hox1* and *CH-Hox3* begin to transcribe after 24 hpf (L1), the initial transcription level of *CH-Hox3* being lower than that of *CH-Hox1*. *CH-Hox4* and *CH-Hox5* are activated after 48 hpf (L2), and *CH-Hox5*  transcription level at this stage is lesser than that of *CH-Hox4*. At later stages, the signal intensity for all these genes become equal. This might indicate the presence of a temporal gradient (Irvine and Martindale, 2000), and quantitative analysis confirmed this assumption (Peterson et al., 2000). Thus, 3'-associated genes of *Chaetopterus* are activated according the rule of temporal colinearity with the only exception: *CH-Hox2*, which has the maternal matrix, is present in embryo from the start (Peterson et al., 2000). The authors note that other animals with teloblastic growth (leeches, crustaceans, insects with a short germ band) have no such early Hox-expression in the growth zone. This may be a characteristic feature of polychaetes or an ancestral condition, that was lost in the studied representatives of other groups (Irvine and Martindale, 2001).

By the time the larva reaches stage L5, the areas of Hox-genes expression are not limited by the growth zone anymore and spread to the setigers. As a result, *CH-Hox1*, *CH-Hox2*, *CH-Hox3*, *CH-Hox4*, and *CH-Hox5* have anterior boundaries in segments 2, 1, 3, 4, and 5, respectively. The rule of spatial colinearity obviously applies to CH-Hox-genes. The only gene that violates both rules (temporal and spatial colinearity) is *CH-Hox2*.

During larval growth and development, CH-Hox-genes begin to be involved in the formation of the nervous system, in parapodia and in the superficial ectoderm of segments. Besides, *CH-Hox1* and *CH-Hox2* are expressed at the foregut/midgut boundary. This domain persists for *CH-Hox1* until the metamorphosis and is localized at the caudal end of the pharynx (Irvine and Martindale, 2000).

The transcription boundaries of CH-Hox-genes are related to the morphological boundaries of the tagmas. It is especially true of the posterior boundaries of transcription. So, the posterior boundary of *CH-Hox1* and *CH-Hox2* is located at the ninth segment, where tagma A ends. The posterior boundary of *CH-Hox5* is located at the level of B2 segment, coinciding with the anterior morphological boundary of subsequent palette-bearing segments

B3-B5, which generate the water flow. The anterior boundaries of all the five genes pass through relatively homogeneous tagma A. However, a certain correlation is observed here as well. A4 is the only setiger where *CH-Hox3* domain is not covered by *CH-Hox4* as well as the only segment bearing the bundle of dark spines.

Unfortunately, there are still no data about central and posterior genes of Hox-cluster in *Chaetopterus*, which was Hopefully, a recent discovery that *Chaetopterus* belongs to the basal annelids (Weigert and Bleidorn, 2016) will rekindle the interest of researchers in this object.

#### **4.2.** *Capitella teleta*

The polychaete *Capitella teleta* (formerly known as *Capitella sp. I*) belongs to Sedentaria. Unlike *Chaetopterus*, it has a feeble tagmization. The body of this polychaete is divided into the thoracic and the abdominal part, with all the segments being similar. However, chaetae on the thoracic and the abdominal segments are morphologically different, the thoracic ganglia are placed more closely that abdominal ones, FMRF-amid immunoreactive neurons lie only in the fifth segment (de Jong and Seaver, 2016). Embryogenesis and larval development in *Capitella* occurs inside the brood tube. A female produces 100-250 synchronously developing offspring. Non-feeding free-swimming larvae come out of the tube on the 8<sup>th</sup>-9<sup>th</sup> day after fertilization (Stage 9). After a short pelagic stage, larvae begin their metamorphosis: they lengthen, loose ciliary bands (the prototroch, the telotroch, and the neurotroch), settle and begin to feed. Subsequent growth is ensured by the prepygidial (subterminal) growth zone. A juvenile polychaete has 13-14 segments. It matures within 8-10 weeks, reaching the size of 55-65 segments. Embryonic and larval development of *Capitella* was described in detail, the fate of single blastomeres was traced, and the cell lines were mapped (Seaver et al., 2005; Meyer et al., 2010). Many of its developmental molecular markers were cloned. All this information makes *Capitella* much easier to work with (Seaver and Kaneshige, 2006; Frobius and Seaver, 2006; Shimeld et al., 2010; Meyer et al., 2015). In addition, it can regenerate its posterior body part.

Larval morphogenesis in *Capitella* is noteworthy. Its sophisticated larva consists of 13 segments (Seaver et al., 2005). According to the BrdU-labeling data, initial larval segments are formed in the bilaterally-symmetric growth zone, which is placed ventro-laterally (Seaver et al., 2005). This growth zone, covering almost the entire length of the embryonic anteriorposterior axis, produces the first ten larval segments within a short time period ( $\sim$ 24 h). The remaining larval segments (A2-A4) originate from the posterior growth zone. They are formed slowly, one segment a day. Late pelagic larva emerges from the brood tube and does not undergo further segmentation until the end of metamorphosis (Frobius et al., 2008). Several questions arose in connection with *Capitella*. How is the expression pattern of Hoxgenes related with the positional segment identity in a polychaete with a poorly defined tagmosis? Is larval expression different from the postlarval one? Do annelids from different evolutionary branches share common traits of the Hox-genes transcription pattern?

All these questions were answered in 2008, when the expression of all Hox-cluster genes in *Capitella*, from the early larval stage to the third day after metamorphosis, was analyzed by WMISH (Frobius et al., 2008). All larval CapI-Hox-genes transcripts seem to form wide gradients with a different intensity in the nervous system and in the setiger ectoderm. Their

anterior expression boundaries are located along the anterior-posterior body axis according to the rule of spatial colinearity (Figure 2b). The only gene that violates this rule is *CapI-pb* (PG2). It begins to work in the subesophageal ganglion at T1 level, while the boundary of *CapI-lab* (PG1) lies at T2 level. Posterior boundaries of most genes are localized at the level of the last larval segments and the ectodermal growth zone. This rule also has exceptions. So, *CapI-Hox3* is probably the only gene that works in the mesodermal part of the growth zone, while CapI-*Hox5* is the only gene with a distinct larval posterior boundary at the level of thoracic segments T7-T8. In the late larva, all Hox-genes are down-regulated, with a weak transcription persisting in the nervous system and the growth zone.

*CapI-lab*, *CapI-pb*, *CapI-Hox3* begin to transcribe almost simultaneously, before segmentation. After this, *CapI-Dfd* and *CapI-Scr* become consecutively activated, then *CapIlox5*, *CapI-Antp*, and *CapI-lox4* and finally, in the end of larval stage, *CapI-lox2* and *CapI-Post2* (Frobius et al., 2008). Generally, the rule of temporal colinearity holds. However, in some cases the transcription signal of 5'-genes is brighter and more complex than that in the 3'-neighbours at the same stage. For example, the patterns of *CapI-lox5* and *CapI-Post2* are brighter and more detailed than those of *CapI-Scr* and *CapI-lox4*/*CapI-lox2*, respectively.

Besides an axial transcription in the nervous system and the ectoderm, additional domains have been found for some *Capitella* Hox-genes. So, *CapI-lab*, *CapI-pb*, *CapI-Hox3*, and *CapI-Antp* are expressed in the presumptive foregut (Frobius et al., 2008). The expression of *CapI-lab* begins in the dorsal part of the stomodaeum and later is localized in the esophagus; *CapI-pb* is transiently expressed in the dorsal part of the pharynx; *CapI-Hox3* is weakly detected in the pharynx and in the esophagus; *CapI-Antp* is weakly and transiently expressed in the pharynx, more ventrally than *CapI-pb*.

*CapI-lab* is transiently expressed in two cell clusters in the cranial epidermis of the larva in the middle of development, while *CapI-Hox3* and CapI-Antp are weakly expressed in the brain. *CapI-Post1*, falling out of the Hox-cluster, contributes to the specification of chaetaebearing cells, chaetoblasts (Frobius et al., 2008).

This sophisticated and dynamic pattern of expression reduces dramatically by the start of the worm's postlarval life. Spatial expression domains of all Hox-genes are weakened and become restricted by the CNS (Central Nervous System) ganglia. Moreover, transcription of all genes except *CapI-Hox3*, *CapI-Dfd* and *CapI-lox5* disappears in the growth zone (Frobius et al., 2008; de Jong and Seaver, 2016). The anterior boundaries of expression generally remain stable (the expression of *CapI-Antp* shifts anteriorly by half a segment in the juvenile worm). It is interesting that the posterior boundaries of Hox-genes expression between the thorax and the abdomen are established precisely at this stage. Those of *CapI-lb*, *CapI-Hox3*, *CapI-Dfd*, *CapI-Scr*, and *CapI-lox5* are located, in juveniles, at the anterior edge of T9, and that of *CapI-Antp*, at the posterior edge of T9. *CapI-lox2* and *CapI-Post2* have anterior boundaries at A1 (Frobius et al., 2008).

#### **4.3.** *Alitta virens* **and** *Platynereis dumerilii*

Nereid polychaetes *Platynereis dumerilii (Pdu)* and *Alitta virens (Avi)* (formerly known as *Nereis virens*) belong to Errantia. Unlike *Chaetopterus* and *Capitella*, they are homonomously segmented worms, that is, all their segments are similar. The number of segments is nearly 70 in an adult *Pdu*and slightly more than 200 in an adult *Avi*. These worms grow by formation of new segments in the prepygidial growth zone. They breed once in their lifetime, producing numerous offspring (~2000 in *Pdu* and about a million in *Avi*). Both species are capable of caudal regeneration.

The ontogenesis of *Pdu* and *Avi* includes two consecutive larval stages: a spherical lecithotrophic trochophore and a segmented nectochaete (Figure 2c). The nectochaete sinks to the bottom and after a long pause (5 days of development for *Pdu*; 16–17 days of development for *Avi*) begins to form postlarval segments from the subterminal (prepygidial) growth zone. The temperature optimum for the development of a normal larva is different in these two species (18<sup>0</sup>С *Pdu*; 10.5 <sup>0</sup>С *Avi*). On the average, *Pdu* develops three times faster than *Avi*. The presence of two larvae with an essentially different organization (segmented and non-segmented) in the ontogenesis of these polychaetes has attracted much attention of embryologists, zoologists and development biologists (Wilson, 1892; Fischer et al., 2010; Starunov et al., 2017).

After the discovery that the genome of nereids contained 11 Hox-genes (de Rosa et al., 1999), the scientists began to suspect that these genes might work in a different way than in other segmented animals. It was unclear whether Hox-genes were involved in larval morphogenesis. If they were, a large set of regionalizing genes looked obviously redundant for a four-segment nectochaete and even more so for a spherical trochophore. It was also unclear what Hox-genes were doing at the postlarval stage. Indeed, what is such a large Hoxcluster needed for, if all body segments are equal?

Most Hox-genes in *A. virens* and *P. dumerilii* seem to be expressed during metamorphosis of the spherical trochophore into the nectochaete (Kulakova et al., 2007). The expression is colinear to anterior-posterior axis of the larval body and involves segmental ectoderm, neuromeres of the neural cord and the pygidium, i.e., all derivatives of the primary somatoblast (2d-micromere). Based on the general larval expression pattern, these genes may be classified into the four groups.

The first group contains *Hox1, Hox4, Hox5, Lox5* and *Post2.* Early expression of these genes does not fade during the development and appears colinear. There are reasons to think that they are used in the regionalization of the larval body. The anterior expression boundaries of *Hox1, Hox4, Hox5,* and *Lox5* are consecutively bound to the boundaries of three chaetaebearing segments and their neuromers (Figure 2c). *Post2* expression marks the pygidium and pygidial cirri (Kulakova et al., 2007).

*Hox2* and *Hox3* belong to the second group. They are activated in 2d derivatives much earlier than other Hox-genes. Their dynamic transcription accompanies the complex process of the establishment of the definitive axis in the larval body. Later their expression pattern becomes similar to the well-ordered axial expression pattern of the genes from the first group. At this time, the anterior boundary of *Hox2* expression lies at the level of the cephalic segment, i.e., more anteriorly than that of *Hox1* expression. The anterior expression boundary of *Hox3* passes at the level of the first chaetae-bearing segment, coinciding with the *Hox1* boundary. In the end of the metamorphosis into the nectochaete, the expression of *Hox2* and *Hox3* fades gradually and becomes limited by the subterminal zone (the future growth zone of the juvenile worm).

The third group is formed by central Hox-genes (*Hox7*, *Lox4* and *Lox2*), which are not activated until the nectochaete stage. They work in a thin subterminal zone. In the beginning of postlarval growth, they become involved into the patterning of new segments.

The last group is represented by a single gene, *Post1*, which lost its Hox-function and is responsible for the formation of chaetal sacks (Kulakova et al., 2002).

Figure 2. The scheme of Hox-gene transcription domains in studied polychaetes. The explanation is within the text. Solid lines mean boundaries of tagmas in *Chaetopterus* and *Capitella.*

Hox-genes of some nereids have additional expression domains, as do Hox-genes of *Capitella* and *Chaetopterus*. For example, *Hox1* and *Hox2* genes are expressed in the pharynx and at the esophagus-midgut boundary. Besides, *Pdu-Hox1* (but not *Avi-Hox1*) is expressed in the apical tuft (Kulakova et al., 2007; Bakalenko et al., 2013).

The expression of postlarval Hox-genes in *Avi* is studied in detail (Bakalenko et al., 2013). Data obtained by our research team indicate that in *Pdu* Hox-genes are involved in the same processes, and their patterns do not differ much from those in *Avi* (Novikova, Bakalenko, unpublished data). All Hox-genes of nereids operate during postlarval ontogenesis. Their expression (except that of *Hox3*) is represented by wide differently directed gene-specific gradients in the superficial tissues of segments, neural ganglia and parapodia.

*Hox3* orthologs are expressed in juvenile nereids only in the ectodermal growth zone. An intermediate pattern is described for *Avi-Hox2*. This gene has a strong transcription in the mesodermal growth zone and a weak one in some ectodermal clusters positioned on the median line of each chaetae-bearing segment (Bakalenko et al., 2013).

The postlarval expression of Hox-genes in nereids is very different from the larval, hinting at the presence of two different morphogenetic programs of the body construction: one for the larva and another for the worm. The first program is responsible for the formation of the larval oligomerous body according to the rule of spatial colinearity. Each of the four segments has its own stable Hox-code. Anterior boundaries of transcription become established in larval segments and remain unchanged throughout the lifetime of the worm.

The second program forms a polymer, constantly growing body, which has no tagmas. The only difference between postlarval segments is their position in relation to the body ends. Transcription gradients of Hox-genes change proportionally with the worm's growth, in other words, they are zoomed. This suggests that the same segment is placed in a different Hoxcontext in relation to the growth zone (Figure 3). Each postlarval segment expresses a full set of Hox-genes but these genes are expressed at different times, and the expression boundaries are unstable.

Figure 3. Hox-genes expression gradients scheme in postlarval body of nereid polychaetes. These gradients change in proportion to worm's growth. The same segment gets into different "Hox"-contexts depending on its position toward the head and toward the pygidium.

Such a complex system must be there for some purpose. It is possible that a juvenile polychaete uses Hox-genes to assign and maintain the position value of each segment of the many. The polychaete "numbers" segments with the use of the Hox-protein set to control their growth and quantity. If this is true, then a position failure would affect the functioning of Hox-genes. Indeed, in *Avi* most of the Hox-genes quickly reorganize their pattern during regeneration (Novikova et al., 2013). Expression boundaries of these genes rapidly shift into new spatial coordinates of the regenerating worm to restore normal proportional relations between the domains of their activity. It was found that a position failure smoothens within less than 8 hours. A segment which is nearest to the cut line acquires a "Hox-code" of the posteriormost segment. After that, a new structure begins to form from the cells of the regeneration blastema: a pygidium and a new growth zone (Novikova et al., 2013).

It is still unknown how often polychaetes use Hox-cluster for the maintenance and the restoration of position values in a regenerating body but there are reasons to think that this is not a unique phenomenon among nereids. For example, a shift of anterior expression boundaries for three genes, *CapI-lox4*, *CapI-lox2* and *CapI-Post2*, occurs during regeneration in *Capitella* (de Jong and Seaver, 2016). Crucially, in this case *CapI-lox4* and *CapI-Post2* shift to the thoracic area, which never occurs in the normal condition. The shift happens at a different time for different genes. The stronger the failure in the normal position of the Hoxgene expression, the earlier transcription begins. All this evidence points to the existence of a common mechanism of position value restoration in polychaetes, even those divided by 500 million years of evolution.

# **5. WHAT DO POLYCHAETES TELL US ABOUT URBILATERIA?**

Our attempts to reconstruct traits of the common ancestor of bilateria with the help of extant model objects are in some respects similar to an attempt to reconstruct the acorn's appearance on the basis of an oak's saw cut. Nevertheless, the search of similarities and differences in development programs of polychaetes, arthropods and vertebrates is certainly not useless. Within the gene regulatory network we can identify circuits so closely related to the bilateral body architecture that they are unlikely to have ever changed.

The Hox-cluster is one of such hyper-conservative functional control levers of bilaterian development. Its most prominent feature is colinear transcription. Spatial colinearity or traces thereof are almost always detected, even if the cluster is scattered (atomized) within the genome (Seo et al., 2004). Temporal colinearity is strictly associated with the cluster's continuity (Monteiro and Ferrier 2006) and is obviously present only in vertebrates, with their compact and ordered clusters (Denis Duboule called them "organized" — Duboule, 2007). Not only colinearity but even local exceptions can tell us about the ancestral condition of the cluster and control ways at the dawn of bilaterian evolution.

In the basal polychaete *Chaetopterus*, spatial and temporal transcription colinearity of the first five Hox-genes in larval segments was shown. In *Capitella*, spatial colinearity of Hoxexpression is preserved at all ontogenesis stages but strict temporal colinearity is doubtful because the stages of development in this polychaete have too broad time boundaries, and a detailed analysis of the dynamical Hox-pattern is impossible. Besides, *Capitella* has a gap in the Hox-cluster (Frobius et al., 2008). In nereid polychaetes, Hox-expression was shown to be

divided into two stages. Some of the genes (*Hox1, Hox2, Hox3, Hox4, Hox5, Lox5* and *Post2*) pattern the four-segmented body of the larva, demontsrating spatial but not temporal colinearity. These genes, together with the remaining *Lox7*, *Lox4* and *Lox2*, begin to work in juvenile nereids according to absolutely different rules (Kulakova et al., 2007; Bakalenko et al., 2013). If we assume that *Chaetopterus* is indeed a basal polychaete, this state of things appears to be secondary. On the other hand, we do not know how the entire complex of Hoxgenes in *Chaetopterus* works at the stage of segmented larva. Neither do we know anything about the work of the CH-cluster in postlarval segments (tagma C).

An ontogenetic difference in the expression patterns of Hox-genes in nereids is obvious. It provokes a question about the presence of functional traces connecting the structural evolution of the Hox-cluster with that of developmental programs.

According to molecular phylogeny data, the last common ancestor of Bilateria had at least seven Hox-genes: five anterior genes (*PG1-5*), one central gene (Hox6-8/Antp/Hox7) and one posterior gene (Hox9-14/Abd-B/Post2-1) (de Rosa et al., 1999; Hueber et al., 2013). If this is true, the formation of the segmented larva in *Avi* and *Pdu* is accompanied by the expression of Hox-genes from the most ancient paralog groups (Kulakova et al., 2007).

Single exceptions from the colinearity rule and additional domains of some Hoxorthologs transcription were found in polychaete larvae. Such a secondary involvement of genes into an unusual morphological program is referred to as co-option (True and Carroll, 2002). For example, *Post1* is expressed in chaetae-bearing sacs in nereids and *Capitella* (Kulakova et al., 2002; Frobius et al., 2008). The evolutionary age of this co-option is comparable with that of the common ancestor of brachiopods and annelids, because in the brachiopod *Terebratalia transversa* the Hox-gene *Post1* was also transiently detected at the late gastrula stages in four ectodermal chaetal sacs of the larva (Schiemann et al., 2017).

The second important exception from the the rule of spatial colinearity is a floating boundary of *PG2* expression. *CH-Hox2* has an anterior expression boundary rostral to that of *CH-Hox1*. The same relationships between PG2-orthologs is present in *Capitella*, *Alitta*, and *Platynereis* (Frobius et al., 2008; Kulakova et al., 2007; Bakalenko et al., 2013). In the amphioxus *Branchiostoma floridae* (Cephalochordata), Hox-genes are activated consecutively but *Amphi-Hox2* violates the rule of spatial colinearity, its anterior expression border being shifted anteriorly of *Amphi-Hox1* (Wada et al., 1999). This feature was noted for Hox2-orthologs in all studied vertebrates (Krumlauf, 1993; Prince et al., 1998). In *Drosophila pb* domain also gets out of the common register but its anterior boundary lies more posteriorly than that of *lab* and *Dfd* (Rogers and Kaufman, 1997). Interestingly, Hox-genes studies in Cnidaria (Hydrozoa, *Clytia*) suggest that *PG2* and *PG3* may have evolved earlier than *PG1* (Quiquand et al., 2009). If so, then an early and a more anterior expression of *Hox2* and *Hox3*  may be a trace of their true ancient function. Some anterior Hox-genes of polychaetes are involved in the foregut development program. Surprisingly, in vertebrates *HoxB1*-*HoxB5* genes are expressed in overlapping domains in the developing foregut (Bogue et al., 1996), while in the lancelet *Amphi-Hox2* is expressed in the preoral pit (Wada et al., 1999).

Thus, some Hox-genes have several conservative pan-bilaterian functions, which are not related directly with their axial regionalizing activity within a united vector tool, the Hoxcluster. Calling these functions "co-options," we might be missing the point. They could have emerged at the earliest stage of bilaterian evolution. If so, the co-option of these genes is a coordinated expression within the Hox-cluster rather than the specification of separate cell lines. In all probability, UrBilateria already possessed time- and space-ordered Hox-genes

transcription, which depended on the continuity of the cluster. Were this not the case, there would not have been undivided clusters in different animal lines. On the other hand, such a coordinated common regulation was accompanied by individual regulation of separate, probably the most ancient genes. All exceptions to the colinearity rule (including a complete change of Hox-function or an additional pan-bilaterian transcription domain) most often concern *PG1-PG5*.

The germinal layer in which the Hox-cluster of UrBilateria first became active is another important question. In echinoderms and vertebrates, Hox-genes start their work in the mesoderm (Arenas-Mena et al., 2000; Barak et al., 2012), whereas in arthropods they do so in the ectoderm (Hughes and Kaufman, 2002). In some cases the expression of Hox-genes begins almost simultaneously in the ectoderm and the mesoderm (Brena et al., 2006). Spiralia might shed some light upon this question. During the development of *Capitella*, Hox-genes are sequentially activated in the larval ectoderm (Frobius et al., 2008). In *Chaetopterus*, Hoxpatterning is more complex. Hox-genes are activated in the posterior part of the L1 larva, according to the temporal colinearity rule. Later, as the larva elongates, Hox-expression translates into a spatial colinear pattern in the nervous system (Irvine and Martindale, 2000). We have recently discovered an early cryptic expression of *Hox2*, *Hox4* and *Lox5* in mesodermal bands of *Avi* (Kulakova et al., 2017). This short-time expression is initiated in the embryo and the early trochophore (Figure 2c). It is colinear in space and time and occurs before the expression of the same orthologs in the ectoderm. The difference between the time of initiation for each of the three genes is approximately two hours, and a synchronous culture of slowly developing larvae is necessary to reveal the start of transcription. A similar early transcription stage can probably be identified in other polychaetes, too. Besides, an early staggered expression of the Hox-genes *pb*, *Hox3*, and *Dfd* was found along the anteriorposterior axis of the developing larval mesoderm in two brachiopod species, *Terebratalia transversa* and *Novocrania anomala* (Schiemann et al., 2017). Indications of the colinearity of Hox-expression in brachiopods can be seen only at the level of the mesoderm.

# **6. HOX-GENES AND LARVAL DEVELOPMENT**

The boundaries between larval and postlarval ontogenesis in polychaetes are not always obvious. The stage of the trochophore, an unsegmented ciliated larva, is relatively clear. Larvae of this type are called primary. They consist of a few cells, which specialize early into relatively few cell types (Peterson et al., 1997). Trochophore larvae of the studied polychaetes (*Chaetopterus*, *Platynereis*, *Alitta*) do not use the Hox-cluster for body patterning. A similar situation has been described for the sea urchin and nemerteans, which activate the axial transcription of the Hox-cluster only during metamorphosis and only in the presumptive tissues of the developing definitive body (Arenas-Mena et al., 2000; Hiebert and Maslakova, 2015). It has been suggested that the regulation programs responsible for the development of primary bilaterian larvae may have emerged at the time when the Hox-cluster still included few genes, which did not take part in the regionalization but were involved into tissuespecific differentiation (Davidson, 2001).

Polychaetes may also have a secondary segmented larva, whose organization is similar to that of the definitive organism. Secondary larvae of all studied polychaetes use the Hoxcluster for the regionalization of the body. Both *Capitella* and nereid polychaetes turn on Hox-genes colinearly at the stage of the segmented larva. However, larval and postlarval ontogenesis of these phylogenetically distant polychaetes is not similar. *Capitella* has no trochophore, and its secondary larva consists of many segments formed in two growth zones (Seaver et al., 2005). Some of these segments form almost simultaneously in the lateral growth zone, while others form consecutively in the subterminal growth zone. The secondary larva of nereids (the nectochaete) consists of a few segments, all of which derive from the ventral somatic plate.

Unexpectedly, the expression patterns of Hox-genes were found to be similar in juveniles of *Alitta* and late larvae of *Capitella*. In both cases, these genes are transcribed as wide gradients and many of them mark a growth zone. The parallel with the expression patterns of ortholog genes is visible (Figure 2bc). A heterochronic shift seems to have transferred a nereid-like definitive development program to the larval period of *Capitella* development. In this case, the postlarval program of *Capitella* appears to be an independent add-on, which is absent in nereids. Another possibility is that the definitive stage was closer to the postlarval stage of *Capitella*. In this case, Hox-genes were involved in specification of single neural ganglia, and their wider functions are shifted to the larval stage. If so, the nereid ancestors lost the definitive stage, and the breeding time shifted to an earlier stage. This idea is supported by the fact that in Rotifera and Chaetognatha (basal Spiralia) Hox-genes are involved almost exclusively in the linear neuron specification (Papillon et al., 2005; Frobius and Funch, 2017). In this light, a complex secondary larva of *Capitella* and a juvenile nereid are homologous stages of the life cycle, which intercalated between the primary larva and the definitive stage. In nereids, the definitive stage was lost during evolution.

Evidence from the studied polychaetes shows that the same animal may use different developmental programs during its ontogenesis: an embryonic program for the formation of the primary larva, a larval program for the formation of the secondary larva, and a postlarval program for the formation of the definitive body. All the above-mentioned features of polychaetes' ontogenesis indicate a high modularity of their developmental programs. Ontogenetic modules in polychaetes consist of Gene Regulatory Networks (GRNs), which interact weakly and can evolve independently. They are, in fact, separate epigenomes packed into a common genome. Unlike epigenomes of different cell lines (for example, those operating in mammalian fibroblasts), they have a complete hierarchic structure, which is not constrained by epigenetic limitations. This hypothesis perfectly explains the remarkable somatic embryogenesis of polychaetes. In these animals, heterochronies and heterotopies of the developmental program involve all levels of the GRNs hierarchy and therefore can shift entire ontogenetic modules. If these shifts occur in space, this is a good prerequisite for somatic embryogenesis. If they occur in time, a new ontogenetic stage may emerge or an old one may be lost.

A vast morphological variety of Spiralia is a direct consequence of their multi-level ontogenesis, which is evolutionarily flexible at each level. The marks of structural and functional evolution of the Hox- genes are tracked quite well. The more objects from various groups are studied in this respect, the better understanding of evolutionary ways we may hope to achieve.

# **DYNAMICS OF THE STRESS PROTEIN CONTENT IN THE WHITE SEA MUSSEL** *MYTILUS EDULIS* **L. IN COURSE OF SALINITY ADAPTATION**

*Yulia I. Podlipaeva\* and Andrew V. Goodkov*

Institute of Cytology, Russian Academy of Sciences, St. Petersburg, Russia

# **ABSTRACT**

Mussels inhabiting the littoral/sublittoral zones of seas and oceans are regularly exposed to osmotic stresses. Although the mussels are rather prevalent and of a high economic value, little is known about their capacity to adapt to changes in environmental salinity, especially in terms of cell and molecular mechanisms of salinity adaptation. It is still not clear, whether changes in the environmental osmolarity (water salinity, concentration of various ions and/or organic osmolytes) do cause stress (heat shock) proteins to emerge in the cells, particularly, the heat shock protein of 70 kDa (Hsp70).

This article comprises a study on the adaptation to alterations of the environmental salinity in the White Sea mussel *Mytilus edulis*, the research having been conducted for several years and involving both long-term acclimation and exposure to stress salinity.

In the first series of experiments, the mollusks were acclimated to salinities within the range of their salinity tolerance (14-35‰). The composition and level of HSPs in their gill epithelium were examined by the method of immunoblotting; constitutive stress proteins of about 70 and 40 kDa were revealed. A mass-spectrometry analysis confirmed that the revealed mussel protein with a molecular weight of about 70 kDa belongs to heat shock proteins of the 70 kDa family. After a long-term (11-14 days) acclimation to salinities at the limits of the salinity tolerance range (14‰ and 35‰), the level of Hsp70 in gill epithelium cells was higher than that in the control group mussels contained in normal sea water of 24-26‰. Hsp70 induction was also observed in the cells of isolated gills that had been exposed to salinity shock. These results suggest that the chaperone system of mussel gills can react to salinity changes more or less independently, and is able to function when not controlled by the whole organism.

The second series of experiments was performed on mussels acclimating to a salinity of 10‰, which is outside of their salinity tolerance range. Osmolarity of the extravisceral liquid of the mussels was measured in course of acclimation. This study showed that the induction of stress protein synthesis in *M. edulis* is a response to salinity changes in the internal medium of the mollusks, but not to the changes in their surrounding medium.

The adaptive changes of the Hsp70 content in mussel gills took different time depending on the salinity gradient. The increased level of Hsp70 in the acclimated/ adapted mussels as compared to the intact ones allows to conclude that this stress protein participates in the adaptation of the White Sea mussel to the salinity changes.

**Keywords**: stress proteins, Hsp70, *Mytilus edulis*, mussel, salinity, adaptation

# **INTRODUCTION**

This work deals with the influence of the salinity changes on the content of the heat shock protein (Hsp70) in the White Sea mussels *Mytilus edulis* after their acclimation to low and high salinities.

Several issues prompted us to unite some of our theoretical and experimental data in this research. These issues are considered to be of large importance when studying the behaviour of the stress (heat shock) proteins that accompanies the adaptation of an organism to a factor.

No need to mention that in the recent decades much attention has been paid to the function of heat shock proteins (HSPs) in the adaptation process. Numerous, namely tens of thousands, studies have been carried out on various organisms, from microorganisms and protozoa to human beings, demonstrating that the adaptation to temperature is accompanied by an induction of heat shock proteins, first of all, of the Hsp70, a protein of 70 kDa molecular weight (see reviews: Feder and Hofmann, 1999; Margulis and Guzhova, 2000, 2009; Hochachka and Somero, 2002; Ermylova, 2007).

However, until now studies on the acclimation to the changes of the environmental salinity and on the adaptation to such changes have been incomparably fewer than those on the temperature adaptations. It is still poorly understood whether the Hsp70-family proteins play any role in the adaptation of an organism to altered salinity. Even when studying marine intertidal organisms, including mussels (*Mytilus galloprovincialis, M. trossulus, M. californianus*), authors give preference to temperature as an abiotic factor affecting the mollusks (Hoffman and Somero, 1996; Helmuth and Hoffman, 2001; Buckley et al., 2001; Halpin et al., 2002; Sagarin and Somero, 2006; Fitzgerald-Dehoog et al., 2012).

It seems that not only does temperature dominate salinity in the current researches due to a tradition to connect "heat shock proteins" particularly with the "heat", but also because of the popular "global heating" and "climate changes" issues.

When examining the constitutive level, expression, or induction of a stress protein in the setting of acclimation and/or adaptation, it is impossible to ignore the fact that each species has its own tolerance range (a set of environmental conditions within which it can best survive and reproduce) of every abiotic factor. It is important to whether know or determine this range before choosing the values of a stress factor, as the organism experiences stress in the conditions approaching the upper or lower limits of the tolerance range. We even assume that the evidence of induction of the stress proteins may be used as a marker of the limit points of the tolerance range (Goodkov et al., 2010). These data were deemed crucial in the

1970s discussion of the step-wise acclimation and of possibilities to widen the tolerance range (Alderdice, 1971; Khlebovich and Kondratenkov, 1973); in the last decades, though, this aspect has been considered in occasional works only (Smurov and Fokin, 2001; Filippov and Filippova, 2006; Komendantov et al., 2006; Komendantov and Smurov, 2009), some of such studies also turned out not to be able to avoid the popular topic of the climate changes (Tomanek, 2008; Zerebecki and Sorte, 2011).

Previously, the Hsp70 induction had been registered in isolated gills of the *Mytilus edulis* mussels from the White Sea placed into water with a reduced salinity (Kharazova, 1999). This fact is important for investigations of the *M. edulis* reaction to any harmful impact, as this species tends to pressurise its mantel cavity in stressful conditions. Our intention was to prove if an isolated gill can react to the salinity conditions independently from the whole organism, and thus to confirm or reject a possibility to use the isolated gills in the experiments on the salinity acclimation and salinity stress.

It is worth mentioning that the results of investigations on the salinity effect in mollusks have been rather contradictory. For example, *Mytilus edulis* mussels from the North Sea (salinity of 29‰) had a higher constitutive content of Hsp70 than those inhabiting the Baltic Sea with its 6‰ salinity (Brown et al., 1995). The stress proteins level in the euryhaline clam *Potamocorbula amurensis* from the San Francisco Bay was lower at a salinity of 0.3‰ than at 27‰ (Werner and Hinton, 2000); the reduced environmental salinity inhibited the temperature-caused induction of Hsp70 (Werner, 2004). However, Hsp70 content remained unchanged by the salinity alterations in *Mytilus galloprovincialis* from the Mediterranean (Li et al., 2009). In a study of the relative sensitivity to pollution in two populations of mussels, *M. edulis* from the Baltic Sea and that from the North Sea, the stress response to the salinity changes in those two populations was compared to that in water with the diesel oil infused in it along with the salinity changes. It appeared that respiration and NH4-N excretion change synergistically when the salinity decreases in the Baltic mussels, but not in the North Sea mussels. A more pronounced decrease of O/N-ratios in the Baltic mussels at ambient salinities indicates that these are more sensitive to the additional stress of oil pollution combined with the already existing salinity stress (Tedergen and Kautsky, 2012). In a study performed by O.A. Muraeva and colleagues (2015) on proteomics of the gastropod mollusk *Littorina saxatilis* exposed to the experimental hypoosmotic stress, it was observed that the expression level of the 70 kDa protein increased and reached its maximum on the 3<sup>rd</sup> to 5<sup>th</sup> day of exposure. However, this protein had not been mass-spectrometrically characterised, and for this reason the authors did not discuss neither its chaperon function, nor its role in the adaptation to salinity in the *Littorina* in the study mentioned.

It is clear from the information above that there is little data on the role of the heat shock protein when an organism adapts to the environmental salinity. As the salinity changes have a gross influence on the marine inhabitants, different strategies of their chaperone system and expansion/speciation capacities may be revealed. The mechanism that triggers the salinity adaptations having already been discussed (Berger, 2005), further data on the participation of the heat shock protein in this mechanism are required.

## **MATERIAL AND METHODS**

Experiments were performed during several years, each time from July to September, at the White Sea Biological Station, Zoological Institute, Russian Academy of Sciences, located in the Chupa inlet of the Kandalaksha Bay in the White Sea.

The *Mytilus edulis* L. mussels were collected at a depth of 1–2 m. The water temperature varied from 7 to 15°C, and the salinity ranged from 24 to 26‰, which was within the common seasonal fluctuations in this area (Babkov, 1998). The mussels were placed into aquariums with seawater of a 24–26‰ salinity in isothermal cameras at  $10 \pm 1$ °C. Some animals (control group) or their isolated gills were constantly contained in these conditions. Others (or their isolated gills) were acclimated for various periods (from several hours up to 14 days) to water with a different salinity (14-35‰ in the first series and 10‰ in the second series) at  $10 \pm 1^{\circ}$ C. In the case of the low-salinity acclimation, samples were taken on the 1st, 5th, 9th, and 14th day of keeping the mussels in the 10‰ water. The aquarium water was changed every 2 days; the mussels were not fed. Several hundred mussels were used in the experiment.

The mussels tolerance to the altered seawater salinity was estimated by the number of specimens that had sealed the mantle cavity under the unfavourable salinity conditions. For this purpose, the animals were placed in crystallisers with seawater of a salinity from 0 to 50‰ and, in 1 h, the number of such mussels (the percentage of the total number of experimental mollusks with open shells and siphons) was calculated. Thus, the range of salinity tolerance in the mussels (Figure 1) was determined.

SPs were identified in the homogenates of gills from 3-5 mussels per experimentation point. The term "dissected gills" (DG) is employed, when a gill of an acclimated or a control mollusk was used in an experiment, while the term "isolated gills" (IG) means that the gill itself was treated by a control or stress salinity, separately from the whole organism.

The tissue was homogenised in a glass homogeniser with a Teflon pestle in the extraction buffer (20 mM Tris\_HCl, pH 7.5, 20 mM NaCl, 0.1 mM EDTA, 0.5 mM dithiothreitol, and 0.2 mM phenylmethylsulfonyl fluoride to inhibit protease activity). The homogenates were either immediately centrifuged at 12000 rpm for 20 min or frozen at –20°C to obtain samples, and then thawed and simultaneously centrifuged. In the further assays, supernatants were used.

The protein composition was assayed by an SDS-electrophoresis in 10% PAAG in the Tris-glycine Laemmli system. The supernatant was mixed  $(3:1)$  with  $4 \times$  Laemmli buffer (1% SDS, 5% β-mercaptoethanol, 10% glycerine). The probes were boiled at 100 °C in a water bath for 3–4 min. The electrophoresis was performed in the Mini-PROTEAN BIORAD System at  $10-12$  mA for  $1-1.5$  h and then at  $20-25$  mA for  $2-2.5$  h. Before the electroblotting, calibrating electrophoreses were carried out, and a control gel staining was performed after the protein transfer to the cellulose; after the electrophoresis/electroblotting, the gels were fixed in a mixture of formaldehyde, ethanol and acetic acid, stained with 0.25% Coomassie Brilliant blue R 250 solution for 1 h, and differentiated by 7% acetic acid. Also, an equal amount of the gill material was used to level the protein content loaded for the electrophoresis. In addition, the gel loading control was done by cutting and staining the lower part of the gel (the zone containing proteins with the molecular weight varying from 30

to 10 kDa), from which the analyzed proteins were transferred to the nitrocellulose membrane.

To reveal the HSPs, the separated proteins were transferred onto nitrocellulose by electroblotting (Towbin et al., 1979). The nitrocellulose was incubated with monoclonal antibodies SPA 822 obtained against chicken Hsp70 (Stressgen Technologies, Enzo Life Sciences), cross reactive in a wide variety of uni- and multicellular organisms. The antibody binding on the nitrocellulose was monitored by the enzyme reactions of secondary antibodies conjugated with the alkaline phosphatase (Sigma, Aldrich, United States), as well as of the secondary biotin-conjugated antibodies (Sigma-Aldrich, United States) and the alkaline phosphatase-conjugated ExtrAvidin (Sigma-Aldrich, United States). The molecular weight of the separated proteins was identified with the ColourBurst (Sigma-Aldrich, United States) markers of the protein molecular weight and the Prestained Protein Ladder (10–170 kDa) (Fermentas, Lithuania).

Figure 1. Mussels activity in water of various salinity. Vertical bars – 0.95 confidence intervals.

The protein bands visualised by Coomassie staining corresponding to the 70 kDa protein were excised and prepared for mass spectrometry (Shevchenko et al., 1996). The mass– spectrometric assay was performed on a MALDI TOF Bruker reflex IV mass spectrometer with positive ions and in the reflectron mode. The peptide spectra were treated with the Swiss PROT database (http://prospector.ucsf.edu).

The salts content in the extravisceral liquid of the mollusks was determined using an electric conductivity outfit (Khlebowich and Berger, 1965). The extravisceral (mantle cavity) liquid samples were first diluted 200 times. The conductivity outfit was graduated using sodium chloride solutions with concentrations varying from 5 to 30 mg/L. The obtained data were statistically processed. The table contains mean arithmetic values for the results of  $4 - 7$ measurements and the corresponding 95% confidence intervals.

#### **RESULTS**

First, the range of the mussel resistance to the salinity was estimated. It was found that the siphons and shells of the animals remained open at a wide range of salinities, from 14 to 35‰ (Figure 1). At a salinity below 8 and above 42‰, all animals shut their shells, thus sealing their mantle cavity. Further experiments on the mussels acclimation to the environmental salinity were based on these observations. In this series of experiments the water salinity varied between 35 and 14‰, i.e., was within the range where 100% of the animals remained active, or, in other words, within the salinity tolerance range of the species *M. edulis*.

The immunoblotting with antibodies to Hsp70 revealed constitutive stress proteins with molecular weights of 70 and 40 kDa in the gill epithelium of the control mussels (Figure 2, *lane* 1). The electrophoretic mobility of one of these proteins corresponded completely to that of the marker protein of the Hsp family with a molecular weight of 72 kDa. The massspectrometry assay confirmed that the protein revealed by the immunoblotting was Hsp70. MALDI-TOF mass spectra demonstrated the presence of the proteins identified with the Swiss PROT database as mouse, rat, and pig HS71L; hamster, bovine, mouse, rat, goat, and human HSP72, and mouse HS71A and HS71B. Since all these proteins belong to the Hsp70 family, which is highly conservative in various species (Feder and Hofmann, 1999; Margulis and Guzhova, 2000; Hochachka and Somero, 2002), we may suggest that the mussel 70 kDa protein also belongs to this family.

Figure 2. Heat shock proteins in the cells of gill epithelium of *Mytilus edulis* in control mussels and in mussels after their long-term acclimation. *Lanes: 1* – control mussels, maintained in control salinity 24 – 26‰; *2* and *3* – 14 days acclimation in 14 и 35‰ respectively.

Figure 3. Hsp70 in gill epithelium of control mussels, mussels after long–term (11 days) acclimation and isolated gills of mussels after reciprocal salinity shocks. *Lanes: 1* - control mussels maintained at salinity 26‰, *2 -* after acclimation to salinity 14‰, *3* - after acclimation to salinity 35‰, *4* - isolated gills from mussels acclimated to 14‰ after salinity shock (35‰, 1 h), and *5* - isolated gills from mussels acclimated to 35‰ after salinity shock (14‰, 1 h).

After a long-term (14 days) acclimation to the salinities of 14 and 35‰, the Hsp70 level in the mussel gill epithelium increased. This increase, as compared to the control animals, was evidenced in the specimens acclimated both to 14 (Figure 2, *lanes* 1, 2) and 35‰ (Figure 2, *lanes* 1, 3). Similar data were obtained in another year – the mussels had enhanced the expression of Hsp70 (Figure 3, *lanes* 2, 3) after having been acclimated to the salinity of 14 and 35‰ for 14 days.

To examine the reaction of the isolated gills to the salinity stress, the isolated gills of the mussels which had acclimated to 14 and 35‰ salinity for 11 days were placed for 1 h into water with a cross-changed salinity (35 and 14‰, respectively). In both cases, the Hsp70 content increased (Figure 3, *lanes* 1, 4, 5).

In the other experiments performed in two different years, the isolated mussel gills were placed into water of 14, 24 (control), and 35‰ salinity for 1, 3, and 24 h (Figure 4, a, b). An increased level of Hsp70 was observed in the isolated gills contained in the water of 14‰ salinity for 3 and 24 h (Figure 4a*, lanes* 1, 3, 4 and 4b, *lanes* 1, 2 and 4, 5). The content of Hsp70 did not change neither in the gills placed into water of the same salinity but for a shorter period (1 h) (Figure 4a, *lanes* 1, 2), nor in water of 35‰ salinity. Salinity of 35‰ even reduced the expression of Hsp70 as compared to control: it was most evident after an exposure for 3 h (Figure 4a*, lanes* 1, 6 and 4b, *lanes* 1, 3).

Figure 4. Hsp70 in the gill epithelium of the *Mytilus edulis* after maintaining their isolated gills in control conditions and in stress salinities in two (a, b) different seasons. a – *lanes*: 1 – isolated mussel gills after 24 hrs maintenance in control salinity; 2–4 – isolated mussel gills after their maintenance in 14‰ during 1, 3 and 24 hrs, respectively; 5–7 – isolated mussel gills after their maintenance in 35‰ during 1, 3 and 24 hrs, respectively;  $b - \text{lanes}$ :  $1 - 3$  hrs in control salinity;  $2 - 3$  hrs in 14‰;  $3 - 3$  hrs in 35‰; 4 – 24 hrs in control salinity; 5 – 24 hrs in 14‰; 6 – 24 hrs in 35‰.

The second series of experiments was performed in order to reveal whether the Hsp70 amount in the gill epithelium cells of the *M. edulis* mussel changes in course of the acclimation to the low salinity conditions (10‰), such conditions having provoked an isolation reflex in the mollusks examined. We also aimed to find out, in case if such changes take place, when they occur and how they correlate with the osmolarity of the internal

medium of the mussels (the mantle cavity liquid). Upon exposing the mussels to a salinity outside of their salinity tolerance range, we again counted the active mollusks in the low salinity water; the number of mollusks that remained active upon being moved from the 25‰ salinity water (control) to diluted seawater with a salt content varying from 14 (lower limit of salinity tolerance range, Figure 1) to 0‰ is shown in the Table 1.

The data obtained confirm that the White Sea mussels are able to actively exchange water and salts with the environment at water salinity levels of 14‰ and higher. At the salinity levels ranging from 8‰ to 12‰, only a certain portion of the experimental mollusks was active, while others isolated themselves from the environment. At lower salinity levels, all the mollusks obturated their tubes and closed their shells. These results are in agreement with those published earlier (Berger and Lukanin, 1985; Podlipaeva and Berger, 2012).

. - - .		.				$\sim$ $\sim$ ---	$-$

Note: Arithmetic means are provided for the results of 4–7 measurements and the corresponding 0.95 confidence intervals.

Changes of the salt content in the extravisceral (mantle cavity) liquid of the mussels placed into the 10‰ salinity water (Figure 5) were analyzed. The analysis showed that the mollusks had for a long time retained a high salt content in their mantle cavity liquid, by blocking to a certain degree the exchange of water and salts with the surrounding seawater. In the control group, the mollusks were kept in seawater of a 25‰ salinity, and the salt content in their mantle cavity liquid was  $25 \pm 0.4$  g/L. On the fifth day of the acclimation to 10‰ salinity, the salt content in the mantle cavity liquid was still significantly higher than in the surrounding medium, namely, 15  $g/L$  (Figure 5), which corresponds to the 15‰ seawater salinity. The difference between the salt concentrations in the external and internal media diminished gradually until the ninth day when the concentrations finally became equal. By this time, all the mollusks that were kept in the water with the salinity levels of 10‰ had partly opened their shells and were filtering seawater. The salt content in their mantle cavity liquid was 10 g/L.

The immunoblotting and subsequent enzymatic reaction revealed a weak double band corresponding to the polypeptides with a molecular weight of about 70 kDa (Figure 6a, *lane* C) in the samples of the dissected gills obtained from the mollusks that had been kept in water of the control salinity. In this series of experiments, we did not detect the protein with the molecular weight of about 40 kDa that had earlier been found in the dissected gills of the control mollusks and had not subsequently been observed neither after the exposure to osmotic shock or long-time acclimations to an increased/ decreased salinity, nor in the isolated gills (Podlipaeva and Berger, 2012). This may have been caused by changes in abiotic and/or biotic factors that occurred since the earlier seasonal observations. Hsp70 is also represented in all the analyzed samples by a double band (Figures 6a, 6b), a phenomenon that has not been previously mentioned in the mussels, but, for example, was observed in the *Tetrahymena* (Podlipaeva et al., 2008). It also may be a result of using the biotin-conjugated antibodies.

Figure 5. Salt content in the mantle cavity liquid of mussels in the course of acclimation to 10‰ during 11 days. Vertical bars – 0.95 confidence intervals.

Figure 6. Hsp70 in the gill cells of mussels kept in 25‰ (control) and 10‰. *a – lanes*: DG—Hsp70 in the dissected gills of the mussels which were kept for 1 day in control salinity (25‰); IG—Hsp70 in the isolated gills which were placed into the water of control salinity (25‰) for 1 day; MM—molecular weight marker; *b – lanes*: MM—molecular weight marker; IG—isolated gills placed into salinity 10‰ for one day; C—control (24–25‰, dissected gills); 1, 5, 9, and 14— mussels (dissected gills) after being kept in 10‰ salinity for 1, 5, 9, and 14 days, respectively.

After 1 day of keeping the mussels in water with a salinity of 10‰, no perceivable changes were observed in the Hsp70 content in the cells of the dissected gill epithelium, as compared to the control (Figure 6b, *lanes* C and 1). At the same time, in the isolated gill cells, a noticeable induction of the Hsp70 expression was observed 1 day after the gills being placed in the water of the same (10‰) salinity (Figure 6b, *lanes* IG and C). In an independent series of experiments, we have demonstrated that the Hsp70 content in the epithelium of the isolated gills placed into the water of control salinity (25‰) did not exceed the Hsp70 content in the dissected gills of the mollusks kept under the same salinity conditions (Figure 6a, *lanes*

DG and IG). Then, on the fifth day of acclimation to 10‰ salinity, we clearly observed the Hsp70 induction in the cells of the gill epithelium (Figure 6b, *lanes* C and 5), and on the 14th day of acclimation the Hsp70 content reached its maximum level (Figure 6b, *lane* 14). The data obtained do not provide grounds to claim that the Hsp70 content increases in the gills of the mussels acclimated to 10‰ salinity in a linear mode; it may only safely be said that the Hsp70 content indeed increases within the period from the  $1<sup>st</sup>$  to the  $14<sup>th</sup>$  day of acclimation (Figure 6b, *lanes* 1, 5, 9, and 14).

#### **DISCUSSION**

We found that the cells of the mussel gill epithelium had constitutively expressed 70- and 40 kDa proteins. Electrophoresis, immunoblotting with antibodies to Hsp70, and mass spectrometry identified the mussel 70 kDa protein as a member of the Hsp70 protein family.

Some preliminary evidence is available for the other protein with a molecular weight of about 40 kDa, which was identified in one series of experiments only by the same antibodies to Hsp70 in intact mussels, but not in isolated gills. Previously, a heat shock protein of 38 kDa had been reported to be present constitutively and induced as a result of the temperature acclimation in the mollusks of the genus *Tegula* (Tomanek and Somero, 2000), and induction of the stress protein of about 40 kDa as a result of thermal stress had also been revealed in the red seaweed *Porphyra* (Podlipaeva et al., 2014).

In the mussels, after a long-term acclimation to salinities very close to the limits of their natural tolerance range, the Hsp70 content in the cells of the dissected gill epithelium increased (Figures 2, 3). This shows that the heat shock proteins of the 70 kDa family are involved in the salinity adaptation of the osmoconformers, such as mussels.

As for the experiments using the isolated gills exposed to water of different salinities, they are in a good accordance with the experiments on the Hsp70 induction in the isolated mussel gills acclimated to variable environmental salinity (Kharazova, 1999), and at least three conclusions can now be drawn. First: we can ascertain that in some conditions (acute test, p.e.) isolated mussel gills can be used in the experiments with salinity changes together with dissected gills of the mollusks examined. Second: the chaperone system of the mussel gill is rather autonomous and functions more or less independently of the control from the whole organism.

This second conclusion confirms the autonomous adaptation in the mollusks and other osmoconformers in terms of: inorganic ion content regulation, volume regulation, variations in the adaptive rearrangements of RNA, protein synthesis, isozyme spectra, and others (Berger, 1986; Berger and Kharazova, 1997).

Our third conclusion from the data obtained is that different time is needed for the adaptive changes in the content of the stress proteins in the mussel cells, depending on the salinity gradient. These changes occurred in 3 h at 14‰ salinity (Figure 4, a, b). At a higher salinity (35‰) and with a more extended exposure (24 h), no changes in the amount of Hsp70 were observed, although it was increased in the dissected gill after a longer (11–14 days) acclimation of the mussels to the same salinity.

It looks like the factor dose impact on the length of the period required for the Hsp70 induction might provide an explanation why, in some cases, no stress proteins were registered to participate in the salinity adaptation in various hydrobionts (Black and Bloom, 1984; Li et al., 2009). Further data are needed to confirm this assumption. However, it is rather clear that, to study the response of the cell chaperone system to environmental variations in salinity, both acute experiments and an analysis of the long-term adaptive changes are required. The advantage of such an approach was shown, for example, in a research of the stress protein content in the mollusks of the *Tegula* genus exposed to a long-term thermal acclimation (Tomanek and Somero, 2000).

In course of the acclimation of the White Sea *M. edulis* to low salinity, a nonlinear dynamics of the Hsp70 content was detected (Figure 6b). It is worth mentioning that such nonlinearity is typical for the adaptive reorganizations of the metabolism. Nonlinear changes had been repeatedly observed earlier when examining the variations in the RNA and protein synthesis rate, as well as in the oxygen uptake rate in cells of some mollusks undergoing acclimation to water salinity changes (Kharazova and Berger, 1974; Lukanin, 1979; Berger, 1986). Similar dynamics reflects the staging of the adaptation processes and a delay of feedback in the corresponding regulatory mechanisms (Grodins, 1963).

A comparison of the results obtained for the salts content variations in the mantle cavity liquid (Figure 5) and for the Hsp70 content dynamics in the gill epithelium cells (Figure 6b) allowed us to conclude that the induction of the Hsp70 family proteins detected in the mussels on the fifth day of exposure to 10‰-salinity represents, in fact, a response of the cells and their chaperone system to the salinity level of  $15 \pm 1.6\%$  (Figure 5), this level being at the extreme point of the mussels 100% activity range (Table 1). The effect of the 10‰ salinity, which for *M. edulis*, that is, for its organs and cells, is more stressful than a salinity of 15‰, could be observed on the ninth day of acclimation only, when the salinity of the mussels' internal medium became equal to that of the surrounding water. This stressor factor also led to an increase in the Hsp70 level as compared to the control (Figure 6b, *lanes* C and 9). Therefore, for a proper comparison of the Hsp70 content on the  $5<sup>th</sup>$  and  $9<sup>th</sup>$  days of acclimation to 10‰ salinity, shorter intervals between the experimental points should apparently be chosen both for the analysis of the salt content in the mantle cavity liquid and the analysis of the Hsp70 levels in the gill epithelium of the experimental mussels.

Both in case of the acclimation to a salinity within the tolerance range and to a lower salinity, we observed an increase in the Hsp70 content in the mussels after the adaptation, as compared to the control mollusks. Thus, we may conclude that the stress protein of 70kDa participates in the process of acclimation and contributes to salinity adaptation of the White Sea M. edulis.

It is very important to emphasise that it is the salinity changes not in the surrounding, but in the internal medium of the mollusks, that the *M. edulis* respond to with an induction of the stress proteins synthesis. These changes, in turn, are an indirect response to the external stressor, at least when the isolation reflex is provoked by a salinity change, as was the case when the salt content was decreased to 10‰ in the present study. This idea is further supported by the results obtained in the experiments on the isolated gills, where expression of the 70 kDa stress proteins was induced as early as after a day of the mollusks exposure to a 10‰ salinity level (Podlipaeva et al., 2016). In fact, this induction may even occur earlier, as we may expect based on the data obtained by A. Kharazova (1999) for the isolated mussel gills, and as it was shown in this work (Figures 3, 4, 6).

Thus, when studying the dynamics of the Hsp70 expression in the mollusks gills in course of the mollusks acclimation to an environmental salinity beyond their salinity

tolerance range, data on the changes in the salts content in their mantle cavity liquid should always be taken into account. Depending on how remote the values of the experiment points are from the tolerance range limits, it will take the mussels a different time to equalise the salt content in the environment and that in their internal medium. This should also be kept in mind when setting time frames of the analysis.

#### **ACKNOWLEDGMENT**

We are extremely thankful to Prof. Viktor Ya. Berger for his invaluable help in writing this manuscript.

# **NOVEL FIBRINOGENOLYTIC METALLOPROTEASE FROM THE ANTARCTIC SCALLOP (***ADAMUSSIUM COLBECKI***)**

# *Nataliia G. Raksha\* , Tetiana I. Halenova, Tetiana B. Vovk, Tetiana V. Ishchuk, Oleksii M. Savchuk and Lydmila I. Ostapchenko*

Educational and Scientific Center "Institute of Biology and Medicine" Taras Shevchenko National University of Kyiv, Kyiv, Ukraine

# **ABSTRACT**

Novel fibrinogenolytic metalloprotease from Antarctic scallop *Adamussium colbecki* was purified and characterized in terms of substrate specificity and enzyme kinetics. A three-step chromatographic procedure which included affinity chromatography on SBTI Sepharose 4B and Blue Sepharose 6FF columns as well as size exclusion chromatography on Superdex 200 PG column was used for purification of the fibrinogenolytic enzyme. The enzyme had an apparent molecular weight of 40 kDa, as shown by sodium dodecyl sulfate-polyacrylamide gel electrophoresis. The  $A\alpha$ - and the Bβ-chains of fibrinogen were completely cleaved by the enzyme within 2 and 4 h, respectively. However, the γ-chain was much more resistant to digestion by the enzyme. The fibrinogenolytic enzyme also exhibited activity toward fibrin, cleaving the  $\alpha$ - and  $\beta$ chains of fibrin, but did not effectively digest the  $\gamma$ - $\gamma$  polymer. The fibrinogenolytic enzyme showed detectable amidolytic activity on chromogenic substrates for activated protein C and factor XIa  $(S_{2366})$ , thrombin  $(S_{2238})$ , factor Xa  $(S_{2222})$ , and plasmin  $(S_{2251})$ . Among the various divalent ions tested,  $Zn^{2+}$  and  $Cu^{2+}$  showed strong inhibitory effects on enzyme activity. The activity of enzyme was unaffected by  $Ca^{2+}$  and slightly activated by  $Mg^{2+}$ . The optimal pH was found to be 10.0 when S<sub>2238</sub> was used as a substrate. The enzyme activity was also inhibited by treatment with EDTA but not with PMSF suggesting that the fibrinogenolytic enzyme was a metalloprotease and not a serine protease. Activity of the fibrinogenolytic enzyme was inhibited by cysteine, indicating the significance of SH-groups for the structural and functional enzyme integrity. The

fibrinogenolytic enzyme significantly prolonged activated partial thromboplastin time, prothrombin time and thrombin clotting time and inhibited ADP-induced platelet aggregation in platelet-rich plasma. The enzymatic parameters  $K_M$ ,  $k_{cat}$  and  $k_{cat}/K_M$  were estimated to be 0.023 mM,  $0.25 \text{ sec}^{-1}$  and 10.8 mM<sup>-1</sup>sec<sup>-1</sup>, respectively, when  $S_{2238}$  was used as a substrate.

# **INTRODUCTION**

Hemostasis is the physiological process that involves in maintaining of blood fluidity and prevention of blood loss following injury through the formation of blood clots. Various systems work in strong coordination to provide the delicate balance between all of the compounds. A disruption of this balance may induce hypercoagulation or hypocoagulation state resulting in thrombosis or hemorrhage, respectively. At the present time, cardiovascular diseases (CVDs) such as acute myocardial infarction, ischemic heart diseases, and stroke are the leading cause of the human mortality worldwide. Intravascular thrombosis due to abnormal fibrin accumulation in the blood vessels or a fibrin clot adhering to the unbroken vessel walls of the endoepithelium is one of the main causes of CVDs. Fibrinogen as one of the key molecule of blood clotting system plays an essential role in many physiological processes, including blood clotting, fibrinolysis, wound healing, inflammation, matrix and cellular interactions et al. But high plasma fibrinogen levels are associated with an increased risk for coronary heart diseases, myocardial infarction and peripheral arterial diseases. Fibrinogen is related to both preclinical atherosclerosis and to most of the cardiovascular risk factors. Anticoagulant, antithrombotic and thrombolytic agents have been extensively used in the therapeutic treatment of hemostasis disorders. Up to date, a lot of effective thrombolytic agents have been isolated and well-studied from plants (latex, fruits, and seeds) and animals (bee, snake, scorpion and spider venoms). Despite their wide spread use, most of them have some serious shortcomings, including limited efficacy, short plasma half-life, large therapeutic dose or allergic response, and are also relatively expensive. Therefore, there is a strong rationale for searching new molecules with reduced side risk for their use in human therapeutics. Recognition that clot fibrin formation stronger depends on present in bloodstream intact fibrinogen or its early high-molecular degradation products led to the creation of alternative enzyme-mediated approaches based on direct action on fibrinogen. In this case, fibrinogenolytic enzymes have been a topic under debate in several studies for its clinical relevance in the treatment of thrombotic diseases. These enzymes act directly on fibrinogen molecule, do not require any other additional factors for the manifestation of activity and therefore may be potentially promising as preventive means for the development of complications caused by the activation of pro-coagulating level as well as in treatment of diseases associated with excessive thrombosis.

Extremely promising objects for the search of new compounds with unique properties are marine organisms. Among the products of their life activities were found a number of compounds that have antibacterial, antifungal, antiviral, anti-inflammatory, immunostimulating, anti-tumor, anti-apoptotic effects [1, 2, 3]. However, in spite of such a structural and functional diversity of metabolites, only a few works are devoted to the study of the influence of compounds from marine hydrobionts on hemostasis. For example, peptides with significant anticoagulant activities were isolated from *L. aspera* [4], *U. unicinctus* [5], *M. edulis* [6], *S. broughtonii* [7].

The current paper described the purification of the fibrinogenolytic enzyme from the crude tissue extract of *Adamussium colbecki* as well as some results of biochemical characterization of this enzyme.

# **CONCLUSION**

The specimens of *A. colbecki* (n = 35) about 7-8 cm long were sampled near the island Galindez (geographical coordinates - 65°15' south latitude, 64°15' west longitude) of Argentine Islands archipelago. After collection the scallops were immediately frozen in liquid nitrogen to prevent enzyme deterioration and stored at -80<sup>0</sup>C. Shells were removed, tissues were rapidly cut into small pieces, weighed, and then were powdered by a blender with addition of liquid nitrogen. The powder  $(1:2, w/v)$  was suspended in the extraction buffer 0.1 M Na-phosphate (pH 7.4), containing 0.15 M NaCl, 0.15 mM ethylenediaminetetraacetic acid (EDTA), 2 mМ phenylmethylsulfonyl fluoride (PMSF), 0.1% Triton X-100 and stirred continuously at  $4^{\circ}$ C for 1 h. Afterwards, the sample was centrifuged at 10 000 g for 60 min at 4<sup>0</sup>C to remove the tissue debris. The supernatant was collected and lyophilized.

Purification of the fibrinogenolytic enzyme from *A. colbecki* employed a three-step procedure including two-step of affinity chromatography and one step of size exclusion chromatography. The progress of purification was followed by determining the following for each fraction: general proteolytic activity on casein, activity on chromogenic substrates pyroGlu-Pro-Arg-*p*NA, *N*-α-benzoyl-DL-Arg-*p*NA and fibrinogenolytic activity. The lyophilized-crude tissue extract powder of *A. colbecki* (50 mg/mL) was dissolved in 5 mL 10 mM Tris-HCl (pH 8.0) and allowed to stand for 30 min at  $4^{\circ}$ C. After centrifugation at 10 000 g for 5 min the supernatant was used for purification procedure. In step 1, an affinity chromatography, SBTI-sepharose 4B column was pre-equilibrated with 10 mM Tris-HCl (pH 8.0) containing 5 mM CaCl2. The supernatant was loaded on column at flow rate of 3 mL/min. Elution was carried out with the 50 mM glycin-HCl ( $pH$  3.0) containing 5 mM CaCl<sub>2</sub> and 1М NaCl at the same flow rate. The unbound fraction was collected and analyzed for the presence of activity to casein, chromogenic substrates and fibrinogen. In step 2, an affinity chromatography, Blue Sepharose 6 FF column was pre-equilibrated with 10 mM Tris-HCl (pH 8.0). The unbound fraction was loaded on Blue Sepharose 6 FF column at flow rate of 1 mL/min, the bound proteins were eluted from the affinity matrix by washing with the same buffer but containing 1M NaCl at a flow rate of 1 mL/min. After removing of NaCl and concentrated the obtained fraction was dissolved in a small volume of 10 mM Tris-HCl (pH 8.0), containing 0.13 M NaCl and subjected for next step of chromatography - size exclusion chromatography. HiLoad 16/60 Superdex 200 PG column was pre-equilibrated with 10 mM Tris-HCl (pH 8.0), containing 0.13 M NaCl. The fraction was loaded and collected at a flow rate of 0.5 mL/min. Elution was carried out with the same buffer. As result, nine fractions were obtained (Figure 1).

Despite the presence of caseinolytic activity in fractions 2-8, the fibrinogenolytic activity was found only in fractions 6 and 7. These fractions were further analyzed by SDS-PAGE, according to that the purified enzyme appeared as a single protein band with molecular weight of 40 kDa (Figure 2).

Figure 1. The elution profile of the fibrinogenolytic enzyme purification by size exclusion chromatography on HiLoad 16/60 Superdex 200 PG column: 1-9 – fraction number. Shaded zone contains the fibrinogenolytic enzyme.

Figure 2. SDS-PAGE of the fibrinogenolytic enzyme. SDS-PAGE was carried out in 10% gel. Lane 1 molecular weight markers: myosin (200 kDa), β-galactosidase (116 kDa), phosphorylase b (97 kDa), serum albumin (66 kDa), ovalbumin (45 kDa). Lane 2 – the purified fibrinogenolytic enzyme.

Based on this result, the fractions 6 and 7 were pooled, lyophilized and further investigated as the fibrinogenolytic enzyme. The molecular weight of the purified enzyme was about 40 kDa which correlated with the clear area presented at substrate gel electrophoregram (Figure 3).

Figure 3. Substrate SDS-PAGE of the fibrinogenolytic enzyme. Activity was assayed by using fibrinogen (1 mg/mL) as substrate in 10% SDS-PAGE. Clear area in the gel indicated region of enzymatic activity. Lane 1 - molecular weight markers: plasmin (86 kDa), mii-plasmin (36 kDa). Lane 2 – the purified fibrinogenolytic enzyme.

Table 1 summarized the purification procedure for the fibrinogenolytic enzyme. The final step resulted in an overall yield of 4.95% and the specific activity of the purified enzyme was 35.5 Units·mg-1 , corresponding to a purification factor of 9.8.

It is well known that blood coagulation is brought about by enzymatic cascade consisting of intrinsic and extrinsic pathways which join at the step of factor IX or factor X activation, and then the coagulation process eventually terminates in fibrinogenesis [8]. To clarify the site(s) of action of the fibrinogenolytic enzyme, the effects of the enzyme on the clotting activities of human plasma were examined as the measurement of clotting times in three different tests such as activated partial thromboplastin time (APTT), prothrombin time (PT) and thrombin time (TT).

**Table 1. Purification of the fibrinogenolytic enzyme from the crude tissue extract of** *A. colbecki*

#### **Table 2. Effect of the fibrynogenolytic enzyme on plasma clotting time in chronometric tests**

One-way analysis of variance (ANOVA) was used to compare the means among different groups. Differences were considered to be statistically significant when  $p < 0.05$  in comparison with control value. Data were reported as mean  $\pm$  standard deviation (SD) (n = 5).

As shown in Table 2, the fibrinogenolytic enzyme prolonged APTT and PT in a dosedependent manner. By comparing the results of both tests, the most logical assumption is that the effect of the fibrinogenolytic enzyme is realized at the stage of the general path, in particular, the transformation of fibrinogen into fibrin. Therefore, the thrombin time (TT) was determined further, which allowed to assess the final stage of the coagulation process, namely the formation of fibrin. The indicators of thrombin time directly depend on the concentration of fibrinogen, its properties, the presence of abnormal forms, and fibrin stabilization, so the using of this test allows us to speak, first of all, about the functional integrity of the fibrinogen. Our studies have shown a significant prolongation of thrombin time during the action of the fibrinogenolytic enzyme in all investigated concentrations (10, 20, 40 μg/mL). At the same time for all concentrations there was an excess of the interval of measurements. Obtained results may suggest a significant fibrinogen deficiency and the development of a state of deep hypofibrinogenemia. Taking into account the ability of the fibrinogenolytic enzyme to cleave the fibrinogen, it can be explained by the presence of fibrinogen with impaired polymerization capacity.

The substrate specificity of the fibrinogenolytic enzyme was assessed by using chromogenic *p*-nitroanilide substrates, which are widely used to study the properties of hemostasis enzymes. This includes H-D-Phe-Pip-Arg-*pNA* (S2238), pyroGlu-Pro-Arg-*pNA* (S2366), Bz-Ile-Glu(γ-OR)-Gly-Arg-*p*NA (S2222), and H-D-Val-Leu-Lys-*p*NA (S2251). *N*-αbenzoyl-DL-Arg-*p*NA (BA*p*NA) was also used. Nevertheless being metalloprotease the investigated enzyme was able to hydrolyze substrates specific for serine proteases which could indicate the broad substrate specificity of the fibrinogenolytic enzyme. In accordance with the obtained results (Table 3), the fibrinogenolytic enzyme from *A. colbecki* exhibited the activity against all tested substrates, but the effectiveness of the hydrolysis of the substrates contained at the  $P_1$ -position of arginine residue was significantly higher than that of the substrate, which in this position had lysine residue. The fibrinogenolytic enzyme exhibited a higher activity for the substrates pyroGlu-Pro-Arg-*p*NA and H-D-Phe-Pip-Arg-*p*NA. The activity on Bz-Ile-Glu(γ-OR)-Gly-Arg-*p*NA which is very sensitive to trypsin, and the activity on H-D-Val-Leu-Lys-*p*NA were in 3.4 and 3 times lower comparing to the activity toward pyroGlu-Pro-Arg-*p*NA. It should be noted that the fibrinogenolytic enzyme did not hydrolyze BA*p*NA – specific substrate for trypsin. This observation can serve as an indirect
confirmation that the fibrinogenolytic enzyme from *A. colbecki* did not belong to trypsin family.

### **Table 3. Activity of the fibrinogenolytic enzyme from** *A. colbecki* **towards chromogenic substrates**

Data were reported as mean $\pm$ standard deviation (SD) (n = 5).

## **Table 4. Effect of protease inhibitors on activity of the fibrinogenolytic enzyme from** *A. colbecki*

One-way analysis of variance (ANOVA) was used to compare the means among different groups. Differences were considered to be statistically significant when  $p < 0.05$  in comparison with basal activity. Data were reported as mean  $\pm$  standard deviation (SD) (n = 5).

## **Table 5. Effect of divalent metals ions, cysteine and β-mercaptoethanol on activity of the fibrinogenolytic enzyme from** *A. colbecki*

One-way analysis of variance (ANOVA) was used to compare the means among different groups. Differences were considered to be statistically significant when  $p < 0.05$  in comparison with basal activity. Data were reported as mean  $\pm$  standard deviation (SD) (n = 5).

For clarifying the nature of the purified enzyme the effect of main class-specific inhibitors like EDTA and PMSF on the enzyme activity was assessed. The enzyme activity was significantly inhibited by metal-chelating agent EDTA, indicating that it was a metalloprotease (Table 4).

Thus, treatment with EDTA at concentration 2 and 5 mM decreased the enzyme activity by 55% and 75%. In contrast, PMSF, an inhibitor of serine proteases, had no effect on activity of the fibrinogenolytic enzyme. These observations indicated that the fibrinogenolytic enzyme from *A. colbecki* was not serine protease, but confirmed that it was metalloprotease.

In order to determine the sensitivity of the fibrinogenolytic enzyme to the action of natural inhibitors, we have incubated the investigated enzyme with blood plasma, which contains endogenous protease inhibitors. Pre-incubation of the fibrinogenolytic enzyme with blood plasma resulted in significant inhibition of enzyme activity evaluated by using chromogenic substrate pyroGlu-Pro-Arg-*p*NA. Thus, at the concentration of 10 µg/mL, there was an inhibition of enzyme activity in 8 times. Increasing the concentration of the enzyme to 80 µg/mL was accompanied by a somewhat less pronounced, but still significant inhibition of enzymatic activity - under these conditions there was an inhibition of the enzyme activity in 4.6 times. Our results are consistent with the literature on the activity of α-fibrinogenases in terms of their incubation with plasma [9]. It well-known fact, that  $\alpha$ -fibrinogenases are markedly inhibited by plasma protease inhibitors. On the other hand, β-fibrinogenases are less suppressed by plasma inhibitors. Since the fibrinogenolytic enzyme is metalloproteases, it is unlikely that the inhibition of the activity of the enzyme in the conditions of our experiment may be due to the effect of serine proteases inhibitors (serpins) which effectively control the activity of the most enzymes of the hemostasis system and present in plasma in sufficient concentrations. The exception may be α2-macroglobulin, which is a universal inhibitor of plasma proteases, regardless of their class. The effect of divalent metals ions on enzyme activity was also investigated. Metals are known to serve as important cofactors for the catalytic activity of several enzymes, they mediate efficient substrate binding and take part in protein folding. Among the major metals ions that are required for enzymatic reactions are  $Zn^{2+}$ ,  $Ca^{2+}$ ,  $Mg^{2+}$ ,  $Cu^{2+}$ . It is likely that  $Ca^{2+}$  and  $Mg^{2+}$  are quite essential for the stabilization of enzyme structure, while  $Zn^{2+}$  may actually participate in catalysis. The effect of some metals ions, at a concentration of 2 and 5 mM, on the activity of *A. colbecki* fibrinogenolytic enzyme was examined. According to obtained result (Table 5),  $Ca^{2+}$  did not affect activity of the fibrinogenolytic enzyme, whereas  $Mg^{2+}$  increased activity by 17 % and 34 % at concentration of 2 and 5 mM  $Mg^{2+}$ , respectively. The increase of the enzyme activity may be due the link substrate and enzyme by this ion. It was found that the activity of the fibrinogenolytic enzyme was inhibited by  $Zn^{2+}$  and  $Cu^{2+}$ . The activity of the fibrinogenolytic enzyme from *A. colbecki* was inhibited by 28 % and 40% after pre-incubation with  $Zn^{2+}$  at 2 mM and 5 mM concentration, respectively. Similar result regarding the effect of  $\text{Zn}^{2+}$ on activity of the fibrinogenolytic enzyme was detected in [10, 11].  $Cu^{2+}$  was found to be more effective inhibitor of the enzyme activity.

The activity of the investigated enzyme was abolished by the reducing agent  $\beta$ mercaptoethanol, indicating that disulfide bonds may be fundamental to the structural and functional integrity of *A. colbecki* fibrinogenolytic enzyme. There are some reports highlighting the significance of disulfide bridges for enzymatic activity of snake venom metalloproteases [12]. The addition of cysteine caused the inhibition of enzyme activity by 10% and 25% at the concentration of cysteine, respectively, 2 mM and 5 mM. Such results allowed to assume the importance of free SH-groups for the manifestation of the enzymatic. In general, our data on inhibition of cysteine exposure are consistent with the data presented in the literature [13], where the authors also found significant inhibition of the activity of fibrinenolytic metalloproteinases when they were incubated with cysteine.

The pH influence on the activity of the purified enzyme was monitored from pH 2.0 to 13.0 using pyroGlu-Pro-Arg-*p*NA as substrate. The pH at which enzyme had maximum activity was 10.0 (Figure 4). Therefore, the fibrinogenolytic enzyme was regarded as a basic protease. This result was similar to other fibrinogenolytic proteases described in the literature, since most of the fibrinogenolytic enzymes have optimum pH at neutral and alkaline values [14]. The increase of pH values to 11.0 and 12.0 led to a slight inhibition of enzyme activity. Under these conditions, the enzyme retained 96% and 90% activity, respectively. However, at pH 13.0, the activity of the enzyme was half of the maximum. The enzyme activity decreased rapidly at levels below pH 6.0 and at pH 4.0 and 5.0 was about 9.5% of its initial activity.

To evaluate the catalytic characteristics of the fibrinogenolytic enzyme, the main kinetic parameters were estimated. The determination was performed using a chromogenic substrate H-D-Phe-Pip-Arg-*p*NA in respect of which the fibrinogenolytic enzyme showed one of the highest activity. For the study, the substrate was used in the range of final concentrations from 0.01 to 0.3 mM. Kinetic constants  $K_M$  and  $k_{cat}$  for the fibrinogenolytic enzyme were calculated from a Lineweaver-Burk double-reciprocal plot (Figure 5) and shown in Table 6.

Figure 4. Effect pH on activity of the fibrinogenolytic enzyme. The relative activity was measured in a series of buffers using H-D-Phe-Pip-Arg-*p*NA as substrate at 37<sup>0</sup>C and varying pH from 2.0 to 13.0. Percentage of enzyme activity was estimated considering 100% the highest activity detected in this assay.

Figure 5. Lineweaver–Burk plot (double reciprocal) for the fibrinogenolytic enzyme kinetics. Kinetic constants were calculated at pH 10.0 and 37<sup>o</sup>C by varying H-D-Phe-Pip-Arg-*p*NA substrate concentration between 0.01 and 0.3 mM.

### **Table 6. Kinetic parameters for hydrolysis of chromogenic substrate H-D-Phe-Pip-Arg***p***NA** by the fibrinogenolytic enzyme  $(M \pm m, n = 5)$

Data were reported as mean  $\pm$  standard deviation (SD) (n = 5).

According to the calculations, the maximum velocity of the enzymatic reaction was 0.99 µM⋅s<sup>-1</sup>. The concentration of the substrate at which the velocity of the enzymatic reaction is equal to half of the maximum for the fibrinogenolytic enzyme from *A. сolbeckі* was 0.023 mM. Comparing the values of  $K_M$  for the studied enzyme and  $K_M$  for fibrinogenolytic enzymes, isolated from the snake venom, we can note that the fibrinogenolytic enzyme from *A. сolbeckі* had a higher affinity for the H-D-Phe-Pip-Arg-*p*NA. Thus, the affinity of the fibrinogenolytic enzyme to this substrate was 2 and 20 times higher when compared with the K<sup>M</sup> for the fibrinogenolytic enzymes from *T. jerdonii* and *T. stejnegeri* [15]. Given that H-D-Phe-Pip-Arg-*p*NA is a synthetic substrate widely used in the study of thrombin and thrombinlike enzymes, it was interesting to compare the value of  $K<sub>M</sub>$  for the fibrinogenolytic enzyme from *A. colbecki* with the value for thrombin. It should be noted that we did not calculated  $K_M$ for thrombin, but used the data of Chromogenix catalog  $[16]$ . The K<sub>M</sub> value for the studied fibrinogenolytic enzyme was 2.3 times higher, and therefore its affinity for the thrombin substrate was as many times as low as compared with the corresponding value for thrombin. The parameter describing the efficiency of catalysis was catalytic efficiency  $k_{\text{cat}}/K_M$ . As can be seen from Table 6, the catalytic efficiency of H-D-Phe-Pip-Arg-*p*NA hydrolysis by the fibrinogenolytic enzyme was  $10.8 \text{ mM}^{-1} \cdot \text{s}^{-1}$ .

An important feature of fibrinogenolytic enzymes is their specificity with respect to fibrinogen chains. Serine proteases cleave fibrinogen from the N-terminal end of the А- or Вchains, causing the release, respectively, of the fibrinopeptide A or B. Metaloproteases, on the contrary, are characterized by the specificity to the C-terminal end of the A $\alpha$ -chain of fibrinogen and do not act on the N-terminal end of molecule. All fibrinogenolytic enzymes can be classified as being either α- or β-fibrinogenases according to their proteolytic preference toward the fibrinogen chains. The α-fibrinogenases preferentially attack the Aαchains of fibrinogen and are metalloproteases, whereas β-fibrinogenases cleave the Bβ-chains and are serine proteases [17]. Identification as either a  $\alpha$ - or β-fibrinogenase is not absolute since there is significant degradation of the alternate chain with increasing time of incubation. These enzymes are directly acting endoproteases which do not require any other factors for their activity. Although fibrinogenases can cleave fibrinogen actively, they do not induce the release of fibrinopeptides A or/and B. In contrast to thrombin, they degrade the chains of fibrinogen with formation of truncated fibrinogen which has reduced clotting ability.

Therefore, in order to assess the nature of obtained fibrinogenolytic enzyme we analyzed its specificity towards the chains of fibrinogen. Fibrinogenolytic degradation assay was carried out using fibrinogen solution mixed with the fibrinogenolytic enzyme from *A. colbecki* at a ratio 100:1. At different time intervals (0, 1, 2, 3, 4, 6 and 24 h), the reaction mixture was removed and SDS-PAG electrophoresis was performed. As can be seen in Figure 6 reduced fibrinogen was separated into the Aα-, Bβ- and γ-chains, and showed three bands on the electrophoregram.

Figure 6. SDS-PAGE analysis of fibrinogen after incubation with the fibrinogenolytic enzyme. SDS-PAGE was carried out in 10% gel. Lane F - control of fibrinogen sample without incubation with the fibrinogenolytic enzyme. Lanes  $0-24$  - fibrinogen samples after incubation at  $37^{\circ}$ C with the fibrinogenolytic enzyme for 0, 1, 2, 3, 4, 6 and 24 h, respectively.

When fibrinogen was incubated with the fibrinogenolytic enzyme, the  $A\alpha$ -chain started to disappear after 1 h of incubation and essentially disappeared within 2 h. Fibrinogen Aαchains are almost twice as long as the Bβ- and γ-chains, and their C-terminal domain ( $\alpha$ Cdomain), which protrude from the fibrinogen molecule, is more susceptible to proteolysis by fibrinogenolytic enzymes. The С-domain of fibrinogen plays an exclusively important role in lateral aggregation and cross-linking of protofibrils during the formation of a fibrin clot [18].

Figure 7. Concentration of functionally inactive fibrinogen. 1- control. 2, 3, 4 - samples after incubation with the fibrinogenolytic enzyme for 1 h (2), 3 h (3), and 6 h (4). \*p < 0.05 significantly different from basal activity.

Moreover, С-domain mediates the interactions with some plasma proteins, in particular, this domain contains binding sites for fibronectin, FXIII, plasminogen, and tissue plasminogen activator. When linked to the С-domain of fibrinogen, the plasma proteins are included in the fibrin clot. Fibrinogen, nicked in its  $\alpha$ C-domain, forms a loose fibrin clot that is more prone to lysis. The band corresponding to the Bβ-chain of fibrinogen disappeared in about 4 h of incubation with the fibrinogenolytic enzyme. Such results do not contradict the literature, because, as already noted, despite the expressed specificity to one of the fibrinogen chains, fibrinogenolytic enzymes are also able to hydrolyze another chain of fibrinogen under continuous incubation. Degradation of the  $\gamma$ -chain occurred after 6 h of incubation. Most of the γ-chain was digested after 24 h of incubation. The degradation of the γ-chain by the fibrinogenolytic enzymes is a rare phenomenon. To date, in literature presented a few work on fibrinogenases capable of hydrolyze the  $\gamma$ -chain. Thus, enzymes isolated from the snakes venom of *A. acutus, B. moojeni, B. isabelae* [19, 20] possesses the ability to cleave the γchain of the fibrinogen, and its complete degradation was observed at relatively early terms of incubation (up to 8 h), and as well as after 18 h of incubation. Afterward, the fibrinogenolytic enzyme completely digested all fibrinogen chains in 24 h. Hydrolysis of fibrinogen by the fibrinogenolytic enzyme resulted in the appearance of low molecular weight fragments. The major degradation product was a fragment about 40 kDa. In addition, some amounts of 30 and 35 kDa polypeptides appeared after 24 h incubation. Thus, on the basis of obtained results, we could suggest that the fibrinogenolytic enzyme from *A. colbecki* belonged to the αfibrinogenase. It is important to emphasize that the fibrinogenolytic enzyme treatment did not result in clotting of fibrinogen per se, despite the fact it could degrade fibrinogen; therefore, it is unlikely that this enzyme produces fibrinopeptides A and/or B, which are required for the initiation of fibrin polymerization. The ability of *A. colbecki* fibrinogenolytic enzyme to cleave fibrinogen without the initiation of the polymerization process, may serve as a confirmation of the belonging of the enzyme to fibrinogenases. Our observations also indicated that the fibrinogenolytic enzyme could not clot plasma by itself, suggesting that this enzyme was unable to activate prothrombin into thrombin, as do other  $\alpha$ -fibrinogenases from snake venom [21].

The conversion of fibrinogen into fibrin plays an important role in coagulation and hemostasis. The fibrinogen cleavage due to the action of fibrinogenolytic enzymes impairs

the ability of fibrinogen molecules to polymerize and it directly depends on the depth of hydrolysis of the fibrinogen and the nature of the fibrinogenolytic enzyme. Taking into account the ability of the fibrinogenolytic enzyme to cleave the fibrinogen, we determined the concentration of fibrinogen lacking ability to form fibrin monomers after incubation with the fibrinogenolytic enzyme. For this purpose, fibrinogen was incubated with the fibrinogenolytic enzyme for 1, 3 and 6 h prior to the addition of thrombin. Obtained fibrin clots were dissolved in 0.125% acetic acid and fibrinogen concentration was determined by optical absorption at 280 nm. The concentration of the fibrinogen lacking ability to polymerization was calculated as the difference between the total concentration of fibrinogen (0.5 mg/mL) and the concentration of fibrinogen in the acetic lysates of the fibrin clots. In accordance with the obtained results (Figure 7), the incubation of fibrinogen with the fibrinogenolytic enzyme was accompanied by the accumulation of functionally inactive fibrinogen, the concentration of which increased depending on the time of incubation. The concentration of functionally inactive fibrinogen in the control sample was  $0.062 \pm 0.008$  mg/mL, which corresponded to 12% from the total content. After 1 h incubation, the concentration of functionally inactive fibrinogen increased in 7 times and amounted to  $0.439 \pm 0.06$  mg/mL. The extension of the incubation time to 3 hours resulted in the further accumulation of fibrinogen cleavage products, the concentration of which was already  $0.483 \pm 0.08$  mg/mL. Our findings of changes in the concentration of fibrinogen were confirmed by a visual assessment of the fibrin clot, that formed after the addition of thrombin - the size of the clot decreased with incubation time and the addition of thrombin after 6 h of incubation with the enzyme did not cause the formation of a fibrin clot at all, which may serve as a confirmation of the lack of a functionally active fibrinogen.

Figure 8. SDS-PAGE analysis of incubation medium (3-5) or fibrin clots (6-8) after incubation with the fibrinogenolytic enzyme. SDS-PAGE was carried out in 10% gel. Lane 1 - molecular weight standards: phosphorylase b (97 kDa), serum albbumin (66 kDa), ovalbumin (45 kDa), carbonic anhydrase (31 kDa), trypsin inhibitor (21.5 kDa), and lysozyme (14.4 kDa). Lane 2 - control of fibrin sample without incubation with the fibrinogenolytic enzyme. Lanes 3–6 - samples after incubation with the fibrinogenolytic enzyme for 1 h. Lanes 4–7 - samples after incubation with the fibrinogenolytic enzyme for 6 h. Lanes 5–8 - samples after incubation with the fibrinogenolytic enzyme for 24 h.

The resultant fibrin monomers spontaneously polymerize to form fibril strands that undergo linear extension, branching and lateral association, leading to the formation of a 3D network of fibrin. A number of fibrinogenolytic enzymes, in particular those which are metalloproteases, along with the ability to cleave the fibrinogen also have fibrinolytic activity. To determine whether the fibrinogenolytic enzyme exhibits fibrinolytic activity, fibrin clots are incubated with the fibrinogenolytic enzyme for 1, 6 and 24 h. The reaction was stopped by addition of SDS-PAGE sample buffer in the presence of β-mercaptoethanol and immediately subjected to  $95\degree$ C for 5 min. The hydrolysis pattern of fibrin clot as well as incubation medium was analyzed by SDS-PAGE (Figure 8).

Degradation of fibrin clot by the fibrinogenolytic enzyme resulted in cleavage of  $\alpha$ - and β-chains. Thus, bands corresponding to these chains of fibrin were appeared in incubation medium upon incubation for 1 and 6 h. We found that with increasing time of incubation to 24 h, bands related to γ-chains were also detected, confirming the presence of fibrinolytic activity. We also revealed the presence of a number of protein bands with molecular weights above 100 kDa. In addition, the fragments with molecular weights of 11 and 15 kDa were also identified. Electrophoretic analysis of samples of fibrin clots after their incubation with the enzyme showed the presence of clearly expressed protein bands with molecular weights of 67 and 55 kDa in all investigated time intervals. Given the molecular weight and the correspondence to the fibrin chains in the control sample, we can say that these bands are  $\alpha$ and β-chains of fibrin. The absence of the band that corresponds to the γ-chain can be partially explained by the formation of  $\gamma$ -γ-polymers. It is known that the covalent firmware of fibrin monomers is carried out with the participation of a ХІІІа factor that catalyzes the formation of a specific bond between the ε-amino groups of lysine residues and the γcarboxyl groups of glutamine residues of the corresponding chains. Despite the fact that we did not use factor XIIIa to initiate the formation of a fibrin clot its certain amount is always present in preparations of fibrinogen and can cause the firmware of chains. Comparison of the electrophoretic profile of the samples obtained after incubation of the fibrin clot with the fibrinogenolytic enzyme from *A. colbecki* during different time intervals suggested a slight hydrolytic activity of the enzyme in relation to α-α-polymers of fibrin. The intensity of the band corresponding to  $\alpha$ - $\alpha$ -polymers (Figure 8) was somewhat reduced with an extension of the incubation time up to 6 h, but the complete cleavage was not observed even after 24 h of incubation. A certain confirmation of fibrinolytic activity of the investigated enzyme was the accumulation of a number of fibrin degradation products that are visualized in the region between 45 and 31 kDa. Despite the ability of the fibrinogenolytic enzyme under long-term incubation with fibrinogen, cleave its γ-chain, the enzyme was not hydrolysed γ-γ-polymers of fibrin, as evidenced by the presence on the electrophoregram of bands with a molecular weight of about 90 kDa. Similar results were obtained in works [22, 23, 24], where the authors showed that the fibrinogenolytic metalloproteases preferentially cleave the the Aαand Bβ-chains of fibrinogen, however, they cannot exhibit any effect on the  $\gamma$ -chains of fibrinogen and γ-γ polymer of fibrin. According to literature, fibrinolytic activity is predominantly characteristic of metalloproteases, whereas serine enzymes from snake venoms, as a rule, do not possess such activity. To sum up, *A. colbecki* fibrinogenolytic enzyme has higher affinity to fibrinogen than to fibrin.

Several lines of evidence support the fact that metalloprotease from snake venom often cause the development of hemorrhagic syndrome [25]. Hemorrhagic activity is predominantly characteristic of fibrinogenolytic enzymes belonging to the class of metalloproteases and related not so much to the presence of a catalytic or metal-protease domain in the enzyme molecule, as with the presence of disintegrin (for PII class metalloproteases) or cysteine-rich (for PII and PIII class metalloproteases) domains [26]. These domains contain the SECD

sequence required for binding to collagen and other proteins of the extracellular matrix [27, 28]. The hemorrhagic activity of fibrinogenolytic metaloproteases depends on their ability to hydrolyse proteins of basement membrane and extracellular matrix. Hemodynamic forces, imposed by blood streaming through the vessel, ultimately disrupt the damaged vessels. Since *A. colbecki* fibrinogenolytic enzyme was metalloprotease, and due to its molecular weight (about 40 kDa) it may contain a disintegrin domain, therefore we tested whether this enzyme can cleave collagen, which is an important component of the basement membranes and the extracellular matrix. The degree of hydrolysis of collagen samples was evaluated by electrophoresis in 8% SDS-PAAG after incubation of the fibrinogenolytic enzyme with collagen for 1, 2, 3, 4, 6 and 24 h. According to obtained results (Figure 9), the studied fibrinogenolytic enzyme did not possess the ability to cleave the collagen, since in the control sample and samples after incubation with the enzyme the collagen remained intact throughout the entire incubation period.

Figure 9. SDS-PAGE analysis of collagen after incubation with the fibrinogenolytic enzyme. SDS-PAGE was carried out in 18% gel. Lane 1 - control of collagen sample without incubation the fibrinogenolytic enzyme. Lane 2 - molecular weight markers: myosin (200 kDa), β-galactosidase (116 kDa), phosphorylase b (97 kDa), serum albumin (66 kDa), ovalbumin (45 kDa). Lanes 3-5 - collagen samples after incubation at 37°C with the fibrinogenolytic enzyme for 1, 2, 3 and 24 h, respectively.

Under physiological conditions, the platelets are inactive and circulate in the bloodstream as separate cells that have limited ability to interact with both the endothelium of the vascular wall and other blood cells, including with each other. Expression of the adhesive properties of platelets occurs in response to the action of a number of the stimulating agents, in particular, ADP. It is well-known that for platelet aggregation, one of the necessary conditions is the presence of fibrinogen, which, through the formation of fibrinogen bridges, provides the connection of individual platelets to a fluff platelet during the first phase of aggregation. Therefore, the fibrinogen is considered to be a mandatory cofactor for platelet aggregation. Taking into account the ability of the fibrinogenolytic enzyme from A. сolbeckі to cleave the fibrinogen, further we investigated whether the enzyme could influence on ADP-induced platelet aggregation. The purified enzyme was assayed for platelet aggregation inhibitory

effect using platelet-rich plasma, which allowed to assess whether the effect of the enzyme due to cleave of fibrinogen. The results of the studies convincingly indicate the ability of the enzyme to inhibit ADP-induced platelet aggregation (Figure 10).

Figure 10. Effect of the fibrinogenolytic enzyme on ADP-induced platelet aggregation: 1 – control.  $2 - 6.25$  µg/mL.  $3 - 12.5$  µg/mL.

The fibrinogenolytic enzyme mediated a dose-dependent inhibition of platelet aggregation. Thus, when the enzyme was used at concentrations of  $12.5 \mu g/mL$  and  $6.25 \mu g$ µg/mL, only 8% and 28% aggregation was observed compared to 41% which was recorded in control sample. Obtained results are fully consistent with the data presented in the literature, according to which the ability to suppress platelet aggregation is predominantly characteristic of α-fibrinogenases, whereas for the β-fibrinogenase, this effect is not typical. A similar effect has been shown for α-fibrinogenolytic enzymes from the snake venom [29, 30]. The inhibitory effect of α-fibrinogenase depends on the concentration of the enzyme and the time of incubation, which may indirectly indicate that their action is associated with the manifestation of enzyme activity. Since fibrinogen plays an important role in platelet aggregation, we supposed that the fibrinogenoloytic enzyme inhibited aggregation by destroying intact fibrinogen to prevent fibrinogen from combining with fibrinogen receptor (GPIIb-IIIa) on platelet membrane.

In conclusion, in view of the specificity towards chains of fibrinogen and effects of inhibitors, the fibrinogenolytic enzyme from *A. colbecki* can be classified as a metaldependent α-fibrinogenase with platelet aggregation inhibitory activity. This enzyme due to its effects on hemostasis may be used as a biological tool to explore many facets of hemostasis.

*Chapter 30*

# **INVESTIGATION OF MARINE BIOTOXINS AND HUMAN TOXICITY**

# *Pierina Visciano\* and Maria Schirone*

Faculty of Bioscience and Technology for Food, Agriculture and Environment, University of Teramo, Teramo, Italy

## **ABSTRACT**

The marine biotoxins are correlated with a proliferation of harmful algal blooms (HABs) and can accumulate in the seafood products, with severe consequences both on the fishery industry and consumer health. Recently, an increase of HABs occurred worldwide due to climate change or anthropogenic activities such as discharge of nutrients from domestic and industrial waste, shellfish translocation and global shipping. Different types of food poisoning are described, i.e., Amnesic Shellfish Poisoning (ASP), Diarrhetic Shellfish Poisoning (DSP), Neurologic Shellfish Poisoning (NSP), Paralytic Shellfish Poisoning, (PSP) and Ciguatera Fish Poisoning (CFP). The symptoms are dependent on the specific biotoxin, and maximum levels have been established for some of them in the global legislation. Moreover, acute reference doses are reported for some marine biotoxins, whereas tolerable daily intakes cannot be determined due to the absence of appropriate toxicological data. The real incidence of poisoning events is often underestimated because the symptoms are similar to viral or bacterial infections as well as allergic reactions. In addition, the lack of knowledge aiming at the diagnosis and treatment of human patients can represent a serious problem for communities and educational programs are considered efficient tools to prevent these events. The majority of human intoxications are related to the consumption of live bivalve molluscs, which are filter feeders and concentrate the marine biotoxins produced by toxic phytoplankton species, but these substances may increase at higher trophic levels in the food chain and therefore also other marine organisms can be involved in foodborne outbreaks. Most marine biotoxins are not destroyed by food technologies like freezing or cooking, and their presence cannot be perceived because they give no specific taste, flavor or smell to food. The monitoring plans are generally performed to assess the risk of seafood

contamination, and *in vivo* assays and chemical analysis are the most frequently used tests. In addition, other rapid methods have been developed, such as ELISA tests, receptor binding or antibody-based lateral flow assays and *in vitro* tests.

In this chapter, the authors described the main foodborne illnesses linked to the marine biotoxins, their toxicity, detection methods and prevention strategies. In particular, they reported the results of the monitoring analyses carried out in the samples of *Mytilus galloprovincialis* collected along the Central Adriatic Coast, Italy.

#### **ABBREVIATIONS**

# **IMPACT OF THE HARMFUL ALGAL BLOOMS IN THE MARINE ECOSYSTEMS**

The harmful algal blooms are natural phenomena developing mainly near coastal waters due to nutrient composition changes (excess of nitrogen and phosphorus) and anthropogenic activities such as discharges from domestic, industrial and agricultural sources, fertilizers usage, aquaculture farms and marine traffic (Narale and Anil, 2017; Park et al., 2017). Moreover, the increase of HABs is also the consequence of climate change (alterations of temperature, ocean acidification, stratification) that influences the marine planktonic systems (Faggio et al., 2011). The global warming is one of the main causes of increase in frequency and severity of HABs, favouring the growth of toxic dinoflagellates of genera *Alexandrium* and *Dinophysis* in both the Atlantic and Pacific Oceans (Gobler et al., 2017) and diatom *Pseudo-nitzschia* spp. (Zhu et al., 2017).

The HABs can have negative effects on the marine ecosystems through two ways of action. The first one is due to the sheer number of microalgae cells that create a barrier between the surface and deeper waters, while the second type is linked to the production of marine biotoxins and their metabolites. The exposure of the marine organisms can be attributed to the environmental conditions during the algal blooms and their potential contact with the toxins. The last event can be significantly reduced by the physical and chemical properties of seawater, especially when the volume of water is large and dilutes its concentration (Lopes et al., 2013).

The bioaccumulation of the marine biotoxins is a dynamic process because they are produced by different phytoplankton species (Table 1) and transferred to the marine organisms through the food chain. It is well known that the marine biotoxins accumulate above all in the bivalve molluscs as filter-feeding organisms, but they can also be found at higher trophic levels through the bioaccumulation in fish, marine mammals, seabirds and humans (Orellana et al., 2017). Several benthic species such as gastropods, bivalves and echinoderms have been described as new vectors of some marine biotoxins (Silva et al., 2013). Turner (2014) described that the HABs can be concentrated in some upper-trophic level pelagic consumers such as fish and marine mammals. Costa et al. (2010) also reported that fish can accumulate the marine biotoxins without signs of toxicity or transfer them up to piscivorous predators such as marine mammals. AZA have been found in shellfish and crabs mainly in Europe (Álvarez et al., 2010), whereas PSP toxins accumulated in Atlantic horse mackerel over a bloom of *Gymnodinium catenatum* (Lage and Costa, 2013).

The main economic losses due to the HABs and marine biotoxins in shellfish are related to the closure of coastal fisheries, implications on international trade, reduction of job in seafood industries and recreational activities (McPartlin et al., 2016). Furthermore, the marine biotoxins are toxic also for animals belonging to the marine food web (Franchini et al., 2010). Therefore, the HABs have adverse impact on the aquatic ecosystems, fisheries and public health due to the production of the marine biotoxins that can be classified on the basis of their toxic effects or their chemical structure and solubility in solvents (Gobler et al., 2017).

<b>HAB</b> taxa	<b>Marine biotoxin</b>	<b>Human toxic syndrome</b>
Pseudo-nitzschia spp.	Domoic acid	Amnesic Shellfish Poisoning
Gambierdiscus spp.	Ciguatoxin	Ciguatera Fish Poisoning
Dinophysis spp. Prorocentrum spp.	Okadaic acid Pectenotoxin	Diarrheic Shellfish Poisoning
Gonyaulax spinifera Azadinium spinosum	Yessotoxin Azaspiracid	
Karenia brevis	Brevetoxin	Neurotoxic Shellfish Poisoning
Alexandrium spp.	Saxitoxin	Paralytic Shellfish Poisoning

**Table 1. Origin and classification of the marine biotoxins affecting human health**

The European legislation set the maximum levels in the live bivalve molluscs by Regulations (EC) No 853/2004 and (EU) No 786/2013. These regulatory limits correspond to:

- 160 μg OA/AZA/PTX equivalent/kg;
- $\bullet$  800 μg/kg for STX;
- 3.75 mg YTX equivalent/kg;
- $\bullet$  20 mg/kg for DA.

The Codex Committee on Fish and Fishery Products developed the standard for live and raw bivalve molluscs for 5 toxin groups, with the same above reported values for STX, OA, DA and AZA, and 200 mouse units/or equivalent/kg for BTX (Botana et al., 2017).

The consumption of the contaminated seafood generally causes acute and short-term events in humans, therefore ARfD have been established by EFSA for the marine biotoxins, corresponding to the concentration per kg of shellfish meat (400 g) that can be safely consumed. In some cases, the ARfD are lower than the existing limits to ensure food safety. The lowering of the maximum limits could have implications for the shellfish industries, but besides the regulatory limits the monitoring programs are necessary to prevent outbreaks due to the marine biotoxins (Nicolas et al., 2017).

Some marine biotoxins are characterized by the presence of analogues in the same group that can have dissimilar toxic potencies. In that case, a potential approach aiming at defining and applying TEFs could be essential for the monitoring and control of the regulatory limits set for the related compounds (Botana et al., 2017).

Another important aspect is related to the non-bivalve organisms that can be toxin vectors, such as echinoderms, tunicates and marine gastropods as well as crustaceans, as reported in human poisoning incidents occurred worldwide. Therefore, their relevance or potential threat for the public health should also be considered in the monitoring and regulatory surveillance plans (Costa et al., 2017).

## **HUMAN TOXICITY OF THE MARINE BIOTOXINS**

The marine biotoxins need to be monitored in the fishery products because they cause food poisoning outbreaks in humans. The symptomatology varies from some gastrointestinal (nausea, vomiting, diarrhea or abdominal cramps) or neurological (confusion, lethargy, disorientation, paresthesia) signs up to a permanent neuropathy or death (Botana et al., 2017; Visciano et al., 2016).

The marine biotoxins can be classified on the basis of the adverse effects observed after the consumption of the contaminated seafood. Most of them are well known, even if there is a great number of recent studies reporting emerging toxicity mechanisms and some organ/system damages.

DA is the main toxin responsible of ASP, characterized by neurological symptoms such as disorientation, confusion, hallucinations and memory loss. It is structurally related to the kainic acid, an analogue to the neuro-transmitter L-glutamate, and can cause the apoptotic and necrotic neuronal cell death. Further studies reported the enhancement of its neurotoxicity due to the involvement of glial cells, with inhibition of glutamate uptake as secondary effect of the glutamate-receptor activation, intracellular acidification or free-radical formation (Ross et

al., 2000). The interaction between the glia and neurons is particularly important during the brain development and neonates have been shown to be more sensitive than adults (Hogberg and Bal-Price, 2011). However, Crespo et al. (2015) reported that the affected people showed other symptoms than neurological, such as unstable blood pressure and arrhythmias or gastrointestinal disorders.

Among the marine biotoxins belonging to the DSP group, OA and its analogues are responsible of some gastrointestinal disorders, i.e., nausea and severe diarrhea (García et al., 2016), whereas AZA, PTX and YTX show still unclear effects in humans (Ferron et al., 2016). In particular, the OA group toxins have citotoxic effects on the intestinal cell lines through a disruption of the cell cycle, apoptosis, inflammatory response and DNA damage (Ferron et al., 2014). Moreover, other toxicological studies reported also neurotoxicity, immunotoxicity, genotoxicity and carcinogenicity (Valdiglesias et al., 2013). A recent study (Espiña et al., 2010) demonstrated that the methyl ester derivative of OA could be considered more toxic for the metabolism of primary cultured hepatocytes.

The AZA group toxins represent an emerging human health risk. Besides gastrointestinal symptoms with a severe and protracted diarrhea, they can affect also other organs and have been shown to be cytotoxic, carcinogen in mice and teratogen to developing fish (Twiner et al., 2012a). AZA1 has been described as lung tumors inducer (Ito et al., 2002), whereas AZA2 showed acute arrhythmogenic potential *in vivo* (Ferreiro et al., 2014a) and *in vitro* chronic effects on a specific cardiac potassium channel (Ferreiro et al., 2014b). In particular, an open-state hERG (human *ether*-*a*-*go*-*go*-related gene) blocking activity has been reported for AZA1, AZA2 and AZA3 by Twiner et al. (2012b). The alteration of hERG function is linked to the ventricular repolarization disorders (Ferreiro et al., 2014b) and the electrophysiological changes at cellular and tissue levels triggering a form of arrhythmia with the QT interval prolongation of electrocardiogram (Ferreiro et al., 2014a).

The adverse effects of the PTX and YTX groups are still unclear even if PTX have been shown to induce an actin depolarization with following disruption of the cytoskeleton (Espiña and Rubiolo, 2008). YTX and its analogues show cardiotoxicity with a mitochondrial damage in the cardiomyocytes after repeated exposures (Ferreiro et al., 2016), but also some changes of the intracellular calcium and cyclic AMP levels and alteration of adhesion molecules like E-cadherin (Tubaro et al., 2010). The selective disruption of E-cadherin system can cause a potential loss of its tumor-suppressing activity (Schirone et al., 2013). Ferreiro et al. (2016) reported a marked bradycardia and hypotension associated to the ultrastructural cardiac damage due to repeated exposures to YTX. Other *in vitro* studies (Fernandez-Araujo et al., 2015) showed some histopathological alterations and cytotoxicity in many cell lines after the acute exposure to this marine biotoxin. Recently Ferreiro et al. (2017) studied the subacute immunotoxicity in rats by evaluating some plasmatic inflammatory cytokine biomarkers and alterations in spleen and thymus. This study suggested that the exposures to low amounts of YTX could affect the health of the consumers especially if immuno-compromised.

STX, BTX and CTX are different neurotoxins causing a nervous and muscular deficit (Cocilova et al., 2017). STX is one of the most potent natural neurotoxins that cause a severe illness in humans known as PSP. Further 57 analogues have been described since its discovery in 1957, when it was isolated from the butter clam *Saxidomus giganteus* (O'Neill et al., 2016). The members of this group can be found both in the marine environments, during HAB events characterized by the proliferation of dinoflagellates of the genera *Alexandrium*, *Gymnodinium* and *Pyrodinium*, and in the freshwater environments, where they are produced by prokaryotic cyanobacteria, resulting in the contamination of drinking and recreational water resources (Wiese et al., 2010). The mechanism of action of STX is linked to the interaction with the voltage-gated sodium channels, and the consequent inhibition of ion conduction across the plasmatic membrane of the neurons and muscle cells (Cusick and Sayler, 2013). Among the PSP symptoms there are muscle weakness, tingling or numbness around mouth and limbs, paraesthesia, incoordination, headache, shortness of breath, dysarthria, dysphagia, hypotension and potential fatality due to the respiratory paralysis (O'Neill et al., 2016; Wharton et al., 2017).

BTX induces a syndrome known as NSP with severe gastrointestinal disorders, reversal of temperature sensation and paresthesia (James et al., 2010). BTX has been also associated with marine mammal deaths and mass mortalities in manatees, seabirds and fish. The human exposure can occur through the consumption of contaminated molluscs as well as by aerosols during the red tide events. In the last case, a respiratory symptomatology can be observed (Chen et al., 2017) showing more severe symptoms in asthmatics (Fleming et al., 2009). It has been reported that BTX binds to and opens voltage gated sodium channels in the excitable cells, causing a continuous depolarization of the excitable membranes. So, the neuronal, muscular and cardiac systems can be affected, with ataxia, muscle twitching, from partial to the complete paralysis and potential long-term behavioral changes (Cocilova et al., 2017). At low concentrations, BTX can cause the depression of the pulmonary and cardiac function, inflammation (Baden et al., 2005) and immune function suppression (Perrault et al., 2016). A recent study (Chen et al., 2017) showed the inhibition of the thioredoxin-reductase system in mammalians, but this effect could be supposed also in humans because this system is present in almost all living organisms.

CFP is the most common non-bacterial cause of human disease due to the consumption of fish containing relatively high concentrations of CTX. This is a group of lipophylic neurotoxins produced by dinoflagellates of the genera *Gambierdiscus* and *Fukuyoa* (Kibler et al., 2017). These dinoflagellates can be consumed by herbivorous and omnivorous fishes and bioaccumulated in the food web in piscivores (Catania et al., 2017). Even if the occurrence of ciguateric fish is more frequent in the tropical and sub-tropical areas, a spread of dinoflagellates into the temperate climate zones has been observed in recent years and CFP has become a global human health concern (Mattei et al., 2014). The disease presents several symptoms, that can be gastrointestinal (diarrhea and/or vomiting) and neurologic (estremity paresthesias, weakness and fatigue). While the gastrointestinal disorders can be resolved within 48 h, the others can persist for several weeks and some patients can develop a chronic form characterized by fatigue and long-term disability (Lopez et al., 2016).

## **METHODS OF DETECTION OF THE MARINE BIOTOXINS**

The main assay used worldwide for the detection of the marine biotoxins is the MBA where mice are intraperitoneally injected with a sample extract and the toxic effects, above all lethality, are observed to reveal their presence. However, this test presents some ethical problems and can give also false-negative or false-positive results (EFSA, 2009). While the false-negative results can cause some dangerous problems to the human health, the falsepositive results can involve economic loss for the shellfish industry.

MBA is also limited because it is poor sensitive and does not provide information as to the exact toxin present in the sample (McPartlin et al., 2016). In recent years, Regulation (EU) No 15/2011 substituted the MBA with a validated technique of LC-MS/MS as the reference method for the detection of the lipophilic toxins, to be used as matter of routine, whereas the biological methods should be applied only during the periodic monitoring of the production areas for detecting new or unknown marine biotoxins.

However, LC-MS/MS methods can present some difficulties due to the lack of the certified standards and/or reference materials for many toxins. For instance, only 20–30 certified reference standards are currently available, even if 24 STX analogues, 13 OA-ester derivatives, 90 YTX analogues, 15 BTX analogues and around 30 AZA analogues have been described. For these reasons, many countries prefer to adopt other assays such as *in vitro* tests able to detect both known and new emerging marine biotoxins (Bodero et al., 2017). The methods of detection currently in force according to the European legislation are often expensive and time consuming, so that other faster techniques such as the use of biosensors, that target both marine biotoxins and the toxin-producing micro-algae, could be used for the implementation of their monitoring programs. These assays are based on the naturally high binding affinity of the marine biotoxins to their cellular target, e.g., voltage-gated sodium channel receptors for PSP, BTX, CTX, glutamate receptor for DA, or protein phosphatase for OA (McPartlin et al., 2016).

Another interesting aspect to be considered during the monitoring regards the significant amounts of algal biotoxins dissolved in the seawater when toxic species are present (MacKenzie et al., 2010), even if the current regulation fixed maximum levels only in seafood but not in seawater. MacKenzie et al. (2004) first demonstrated that the passive adsorption of dissolved toxins from seawater, coupled to sensitive analytical technologies such as LC-MS/MS and ELISA assays, provided a simple means of monitoring that simulated a biotoxin contamination of the filter feeding bivalves.

Many recent studies (Blay et al., 2011; Domènech et al., 2014; García-Altares et al., 2014) demonstrated that the UHPLC-HRMS is an excellent tool to detect the marine biotoxins in algae and seafood. These techniques could be particularly useful to assess a potential exposure to a multi-toxin mixture. As a future perspective, a confirmatory identification of potential toxins by studying their fragmentation spectra (using new tools such as hybrid quadrupole Q-ExactiveTM Orbitrap-MS) is designated (Orellana et al., 2014, 2015).

# **THE MONITORING PROGRAMS IN MOLLUSCS FROM THE ADRIATIC SEA,ITALY**

In recent years, the increase of HABs has led to the need of new strategies aiming at the monitoring of the marine biotoxins in coastal waters, that vary among the geographical locations and HAB types (Asnaghi et al., 2017). According to the food legislation currently in force in the European Union, sampling plans are periodically applied in the production areas of the live bivalve molluscs. The frequency is generally to be weekly during the periods at which the harvesting is allowed, but it can be reduced if a risk assessment on the marine

biotoxins and/or toxin-producing plankton occurrence suggests a very low risk of intoxication, as reported in Regulation (EC) No 854/2004.

In our study (Schirone et al., 2011) a total of 415 specimens of *Mytilus galloprovincialis* were collected from some shellfish aquaculture plans located along the coasts of the Central Adriatic Sea (Abruzzo and Molise regions) during the monitoring programmes of the years 2006-2009 (Figure 1). The MBA was applied on extract from whole body or edible part of the molluscs to investigate the presence of OA, DTX, PTX, AZA and YTX, whereas DA was determined by HPLC-UV. No biotoxins were detected and these results demonstrated a good condition of the marine area as well as the safety of the bivalve molluscs.

The detection of YTX in specimens of *M*. *galloprovincialis* was performed by an *in vitro* functional assay based on the fragmentation of the cell-adhesion molecule E-cadherin in cultured cells. The samples were collected from three regions (Abruzzo, Molise and Emilia Romagna) along the Central Adriatic coasts and grouped in two aliquots in a sufficient number to obtain pools of 100 g whole flesh. All samples were analyzed in duplicate. The mean values of YTX in samples coming from Abruzzo and Molise regions ranged from 0.20 to 0.67 mg of YTX equivalent/kg, whereas in those collected along the coasts of Emilia Romagna they were higher up to 1.80 mg of YTX equivalent/kg (Schirone et al., 2013).

Figure 1. Sampling area (Abruzzo and Molise regions) of specimens of *Mytilus galloprovincialis*.

Samples of *M*. *galloprovincialis* collected from several shellfish aquacultural plans (n = 15) located along the coasts of Abruzzo, Molise and Emilia Romagna regions, were analyzed for YTX content by three different methods, i.e., MBA, the *in vitro* functional test described by Schirone et al. (2013), and a LC-MS/MS method. The results obtained by MBA showed that the specimens coming from Abruzzo and Molise regions were all negative, whereas all the samples coming from Emilia Romagna region caused the death of mice, except for one that could be considered negative because only one of the three mice died after 16 h. The

concentrations of the investigated marine biotoxins were detected by the *in vitro* functional assay and ranged from a minimum of 0.24 mg to a maximum of 1.63 mg of YTX equivalent/kg, with the highest values in the specimens derived from Emilia Romagna region. The samples analyzed by LC-MS/MS showed YTX concentrations only in the molluscs coming from Emilia Romagna region, whereas in all the other samples the values were below the LOQ. More in detail, the major detected analogues were carboxy homo YTX (ranging from 0.227 mg to 1.934 mg of YTX equivalent/kg), followed by homo YTX (ranging from 0.239 mg to 1.023 mg of YTX equivalent/kg). These results seemed to confirm the eutrophic phenomena that have been frequently reported in the Northern Adriatic Sea, and could have an economic impact on shellfish industry considering that this area covered about 90% of the Italian mussel production (Visciano et al., 2013).

Also other authors (Ciminiello et al., 2010) found YTX concentrations ranging from 0.001 to 0.032 μg/g in samples of *M*. *galloprovincialis* coming from Emilia Romagna coasts. These values could vary due to different reasons such as mussel metabolisms, their physiological conditions, water temperature, season and presence of phytoplankton species (Amzil et al., 2008). Bacchiocchi et al. (2015) found levels of OA, YTX and AZA in *M. galloprovincialis* collected along the North-Central Adriatic Sea of Marche region. The highest concentrations were detected always in autumn-winter periods probably due to the increased inflow of freshwater from the Po river.

#### **CONCLUSION**

Several food poisoning outbreaks associated with the consumption of seafood contaminated with marine biotoxins have been reported worldwide and therefore a regular and periodic monitoring of the marine waters especially during well-defined periods, i.e., when the environmental conditions are favorable to HABs, could serve to prevent these events. The presence of the marine biotoxins should be also investigated in molluscs and other potential vectors above mentioned, because most of them cannot be destroyed by freezing or cooking and the contaminated food generally do not present any alteration or specific taste capable to alert the consumers for this health hazard. A recent study (Rodríguez et al., 2016) demonstrated that DTX3 was destroyed by heat under steaming conditions (i.e., 2 min at 105°C and 3 min at 100°C) depending on the matrix environment. Moreover, a 50% decrease in total toxicity was reported for OA and DTX2 after sterilization at 121°C for 20 min.

There is often an underestimation of the real incidence of fish/shellfish poisoning due to the marine biotoxins, especially because the symptoms are similar to allergic reactions and viral or bacterial infections (Iwamoto et al., 2010). Besides the official LC-MS/MS methods used for the detection and the quantification of the marine biotoxins, sensitive and high throughput effect-based *in vitro* assays should be developed and validated to allow the identification of unknown toxins that could cause new adverse effects in consumers.

## **ABSTRACT**

Marine sponges (Phylum Porifera) have consistently been a prolific source of new marine natural products with unprecedented chemical scaffolds and potential pharmaceutical applications. Other than their chemical diversity, these compounds possess remarkable bioactivities. This great potential has aroused applications of sponge natural products as therapeutics against important diseases, such as cancer, a range of viral diseases, malaria, and inflammations and at present, a number of promising compounds are in clinical and preclinical trials. Although the molecular mode of action of most of these metabolites is still unclear, for a substantial number of compounds the mechanisms by which they interfere with the pathogenesis of a wide range of diseases have been reported. Research on marine sponges continues in the hope that drugs of the future will be culled from different parts of the oceans. Though research on marine sponge-derived bioactive compounds are increasingly promising in drug discovery, multiple technical issues are yet to be addressed prior to turning the wide-scale

bioprospecting of marine sponges into a reality. This chapter focuses on some novel compounds having antioxidant, antimicrobial, anti-inflammatory, anticancer and other bioactive properties identified and isolated from marine sponges, which could serve as leads for drug discovery. We also discuss the factors that contribute to new discoveries and the challenges associated with translating marine sponge-derived compounds into clinical trials. In addition, providing an outlook into the future, we examine the advances that may further expand the promise of drug discovery from marine sponges.

**Keywords:** bioactivity, drug discovery, natural products, sponges

#### **1.INTRODUCTION**

Nature represents an infinite reservoir of novel chemotypes and pharmacophores, as well as blueprints for drug development against a multitude of disease indications including cancer, diabetes and infectious diseases. Throughout history natural products (NPs) have been the cornerstone of traditional system of healing worldwide. Although the use of bioactive NPs as herbal drug preparations dates back hundreds, even thousands, of years ago, their application as isolated and characterized compounds to modern drug discovery and development started only in the 19<sup>th</sup> century (Veereshen, 2012). Examples of early identified NPs are undoubtedly the isolation of morphine from *Papaver somniferum* poppies, first reported in 1803, and the discovery of the first antibiotic penicillin from the fungus *Penicillium notatum* in 1929 by Flemming (Carter, 2011). To date approximately 60% of the drugs currently on the market are of natural origin (Newman and Cragg, 2012). Although the pharmaceutical industry turned to combinatorial chemistry and high throughput screening in the 1980s, NPs have again attracted the attention of drug hunters in recent years because they have proven to be a more promising source of drugs than combinatorial synthesized chemicals (Baker et al. 2007, Corson and Crews, 2007, Harvey, 2007, Hostettmann, 2007, Li and Vederas, 2009, Kumar and Walmann, 2009). Today, with a movement into a modern era of biotechnology and automation, natural product-based compounds have an immense impact on modern medicine with a number of top selling drugs such as vincristine from *Vinca rosea*  and Taxol from *Taxus brevifolia* (Newman and Cragg, 2012). The natural product-based drug discovery depends largely on the continuous supply of novel natural agents, especially those with novel scaffolds. Since natural building blocks and biosynthetic strategies are rather limited, natural products are highly redundant. Therefore, although the unexplored natural product universe is still ample, it is not an easy task to find novel agents from nature (Li and Vederas, 2009). Accordingly, research must continue to progress to improve existing therapies and to develop novel cures. Since ancient civilizations, research has essentially focused on edible and natural sources such as fruits, vegetables and plants, mainly because these specimens are easily available and folk traditions have described beneficial effects from their use. However, in contrast to these described terrestrial sources of drug molecules, a completely unexplored potential source of bioactive natural agents is represented by the sea (Schumacher et al. 2011, Beesoo et al. 2014). Although oceans have attracted the attention of researchers since the 1950s with the discovery of the *Cryptotheca crypta* sponge-derived anticancer spongothymidine and anti-viral spongouridine, the technical difficulties of collecting marine organisms together with the poor knowledge of their habitat and identification of the true sources of the bioactive agents have posed relevant obstacles. Nevertheless, the implementation of modern scuba diving tools such as remotely operated vehicles and the development of instruments for the isolation of NPs from marine organisms have rejuvenated research in the arena of marine natural product (Gerwick and Moore, 2012).

## **2. MARINE NATURAL PRODUCT**

The world's ocean, covers 70% of the earth's surface and 95% of its tropical biosphere is home to nearly one million multi-cellular (plants and animals) and one billion unicellular organisms surpassing that of the terrestrial diversity (Minh et al. 2005, Burgess, 2012, Romano et al. 2017). Living in such a highly competitive environment, marine organisms have evolved biochemical and physiological mechanisms that include the production of secondary metabolites in direct response to environmental stressors and thus act as protective and/or adaptive agents. Such responses include up-regulation of toxic compounds as protection, or in response to damage or predator attack; adaption to heat, mechanical deformation, salinity, pH, or cold; aggression (stinging) or other environmental stressors such as UV irradiation, overgrowth, competition for mates, tissue damage, local lack of essential nutrients (Minh et al. 2005, Monaco and Quinlan, 2014). A number of sessile benthic organisms including Porifera, Cnidaria, Bryozoa, and Tunicata produce a myriad of secondary metabolites as their defense mechanism. As these organisms typically lack the physical attributes to escape (fins, legs), fight (claws, spines), or protect (shells), it is of little wonder that they have experienced both the selection pressure and time to evolve chemicals to enhance survival (Capon, 2010). These chemical adaptations generally take the form of structurally unique "marine natural product" (MNPs) that involve well known chemical classes as terpenoids, alkaloids, polypeptides, peptides, shikimic acid derivatives, sugars, steroids, and a multitude of mixed biogenesis metabolites (Firn and Jones, 2003). In addition, and unique to the marine environment, these metabolites possess a diverse mix of novel chemical features endowed with an amalgam of bioactivities such as anti-tumor, antimicrotubule, anti-proliferative, photoprotective, antibiotic and anti-infective (Vinothkumar and Parameswaran, 2013, Beesoo et al. 2014). So far 300 patents have been issued on marine natural products, many of which have shown potentials as pharmaceuticals, cosmetics, dietary supplements, and agrochemicals (Sukarmi and Sabdono, 2008). In view of the great chemical diversity, one is tempted to suggest that further marine bioprospecting may lead to novel therapeutics for the management of health diseases. Nevertheless, the marine habitat is still poorly explored. It is estimated that, in spite of 250 years of taxonomic classification and over 1.2 million species already catalogued in a central database, some 91% of species in the ocean still await description (Mora et al. 2011).

Although this "silent world" has a much richer biodiversity than that of the terrestrial areas, efforts to exploit marine organisms for drug discovery is still at a relatively early stage. Nevertheless, extensive research in the past 30-40 years on MNPs have been very productive and has led to the discovery of many potently active agents worthy of further clinical applications. Few marine plants, animals and microbes have already yielded more than 22,000 novel natural products (compared to 131,000 from terrestrial sources) (Shumacher et al. 2011). A large proportion of these natural products have been extracted from marine

invertebrates including cone snails, soft corals, sponges, sea squirts, marine worms, bryozoans, sea slugs and other marine organisms which not only produce a great number of MNPs currently known but also show the largest diversity of natural products (Bharate et al. 2013). Their low effective dosage, better selectivity against target malignant tissues and relative non-vulnerability to resistance development as compared to compounds of terrestrial origin, render them useful target molecules. According to US National Cancer Institute estimates, more than 1% show antitumour properties as against only 0.01% amongst their terrestrial counterparts (Beesoo et al. 2014).

A cursory review of the literature reveals that marine sponges (Porifera) are the richest sources of novel marine natural products. (Sipkema et al. 2005, Perdicaris et al. 2012, Leal et al. 2012, Mehbub et al. 2014). In 2012, Leal et al. (2012) compiled scientific studies about existing MNPs and classified them according to phyla of their invertebrate source. They found that approximately 80% were into the phyla Porifera (47.1%) and Cnidaria (33.5%). The rest of them were in the phyla Echinodermata (7.4%), Chordata (6.0%), and Mollusca (5.0%). This makes sponges the most prolific marine producers of compounds. Consequently, there is a renewed interest in exploring the marine sponges, with the aim of identifying novel chemical entities as sources for new lead compounds. This chapter gives a general overview of the global marine pharmaceutical pipeline drug, focusing particularly on some of the most interesting novel secondary metabolites/extracts having antioxidant, antitumour, antimicrobial, anti-viral, anti-coagulants and other bioactive properties identified and isolated from marine sponges, which could represent potential lead compounds for drug discovery. The factors that contribute to new discoveries and the challenges associated with translating sponge-derived compounds into clinical trials are also discussed. In addition, providing an outlook into the future, the advances that may further expand the promise of drug discovery from marine sponges are also examined.

## **3. MILESTONES IN RESEARCH ON MARINE NATURAL PRODUCTS**

Throughout history, the use of marine organisms as drug source has played a minor part in the development of traditional medicines and is not as heavily documented as terrestrial organisms. While the terrestrial environment boasts a rich historical association with human therapeutics, evidence of MNPs derived therapeutical products is rather scarce. Historical records show that human beings have been aware of the venomous nature of some sea creatures for at least 4000 years (Colwell, 2002). The few historical references include the use of seaweed extracts by the San Blas Indians of Panama and ancient Chinese people for pain relief, abscesses and cancer. During the Roman times, physicians recommended the use of marine sponges against sunstrokes, wounds, fractures, infectious diseases and testicular tumors and even as implants after breast operations (Sipkema, 2004). Ancient maritime people, notably the Chinese and Japanese, used to eat a variety of iodine-rich seaweeds that undoubtedly accounted for their low incidence of goiter (Thakur et al. 2005). Coral reef products have also been traditionally used for treating various disorders in Taiwan, Japan, China and India. In the  $19<sup>th</sup>$  and early  $20<sup>th</sup>$  centuries, cod liver oil was used as a nutritional supplement (Colwell, 2002). However, only in the middle part of the  $20<sup>th</sup>$  century did scientists begin to systematically probe the oceans for medicines. In the early 1950s, Ross

Nigreli of the Osborn Laboratories of the New York aquarium extracted a toxin from cuvierian organs of the Bahamian sea cucumber, *Actynopyga agassizi*. This toxin was named "Holothurin", and showed some antitumour activities in mice (Nigreli et al. 1967). These few anecdotal references aside, the marine world has been largely regarded as a source of food and a medium of transport, instead of a source of healing.

# **4. CURRENT MARINE PHARMACEUTICAL PIPELINE**

The website "*The Global Marine Pharmaceuticals Pipeline*", maintained by Alejandro M. S. Mayer of Midwestern University, IL, USA, tracks marine-derived drugs and gives summarizing information about licensed drugs and those in clinical trials (Mayer, 2016). Presently, there are seven therapeutic agents (four anti-cancer, one anti-viral, one pain control, and one for hypertriglyceridemia) that derive from the marine environment (Figure 1). Of these, two are the actual chemical structure as isolated, and five others are synthetic agents that capture their chemical idea from a marine product. In addition, a further 13 agents are in phase I, II, or III clinical trials. Table 1 summarizes the collected sources of organisms that have yielded these agents and reveals that sponges, molluscs, and tunicates are the richest collected sources of bioactive MNPs. However, as noted above, the collected source has often times been shown or is strongly suspected of harboring or feeding upon microorganisms that are the actual producers of the bioactive agent.

Figure 1. Clinical development timeline for marine drugs on the market.

An early finding in the marine drug discovery field was Cytarabine (Ara-C) and vidarabine (Ara-A), the first FDA-approved marine-derived drugs. These are synthetic pyrimidine and purine nucleosides, respectively, derived from nucleosides originally isolated from the Caribbean sponge *Cryptotheca crypta*. Cytarabine gained FDA approval in 1969 as an anticancer drug, whereas vidarabine was endorsed in 1976 as an anti-viral agent (Mayer et al. 2010) and is currently being used in the form of eye drops for the treatment of acute kerato conjunctivitis, recurrent epithelial keratitis caused by herpes simplex type 1 and 2. However, in the USA, its approval has been discontinued since June 2001 due to its restricted therapeutic window (Mayer et al. 2010, Anjum et al. 2016). Crucially, more than 40 years

after its approval, cytarabine, is still in the forefront of cancer drug treatment. By 2007, the global revenues of cytarabine and vidarabine were estimated at \$93 M each (Martins et al. 2014). More than 20 years after the entry of cytarabine into the market, ziconotide (commercial name Prialt®) was granted FDA and EMEA approval in 2004 and 2005 respectively, for the management of severe chronic pain associated with cancer, AIDS and neuropathies. Ziconotide was synthesized in 1987 (Molinski et al. 2009) after its equivalent ω-conotoxin, a naturally occurring peptide, isolated from the venom of the marine gastropod *Conus magus.* In 2010 Prialt® sales reached \$6.1 M (Elan, 2010) and its development prompted the investigation on other *Conus* peptides, several of them having reached human clinical trials (Olivera, 2006). On the other hand, Trabectedin (ET-743 Yondelis®), is the first marine anticancer agent to obtain approval by the European Union (EU) for the treatment of soft tissue sarcoma and relapsed ovarian cancer, and is currently awaiting Food and Drug Administration (FDA) approval. Trabectedin is a marine alkaloid isolated from the tunicate *Ecteinascidia turbinata* and was registered as anticancer agent in 2007 (Mayer et al. 2010, Beesoo et al. 2014, Beedessee et al. 2015). Eribulin mesylate  $(Halaven^m)$  is the third anticancer agent from the marine biome, which gained FDA approval in November 2010 for metastatic breast cancer. It is a structurally simplified macrocyclic ketone analogue of the potent cytotoxic compound halichondrin B, which was initially isolated from the marine sponge *Halichondria okadai* in 1986 (Mayer et al. 2010, Beesoo et al. 2014, Beedessee et al. 2015). The most recent addition to the arsenal of approved anticancer agents from the marine environment is brentuximab vedotin (SGN-35), an antibody chimerized through the addition of a dipeptide This agent is used for the treatment of Hodgkin's lymphoma and anaplastic large cell lymphoma (Katz et al. 2011). This agent is used for the treatment of Hodgkin's lymphoma and anaplastic large cell lymphoma (Katz et al. 2011). On their way to the pharmacological market, there are 13 other marine-derived drugs in clinical trials including cytotoxic compounds such as hemiasterlins, plitidepsin, bryostatin 1, salinosporomide A, pseudopterosins, etc. In addition, there is a continuous supply of marine compounds in the preclinical pipeline, which is continuously feeding the global marine clinical pipeline (Beesoo et al. 2014). Table 1 highlights the evolution of this pipeline to date (Blunt et al. 2010, 2011, Mayer, 2016).

# **5. SPONGES (PORIFERA) AS A SOURCE OF DRUG TREASURE TROVE**

Sponges (phylum Porifera) are primitive invertebrate metazoans that are found in all parts of the world's oceans. They have consistently been the richest source of new natural products reported in the marine natural products literature since the early 1970s, and the majority of the novel natural product chemotypes reported from sponges have no close analogs in terrestrial plant and microbial natural products or in natural products isolated from other marine organisms (Anderson, 2017). The biological effects of new metabolites from sponges have been reported in a number of scientific research papers. Highly cited reviews have been published in the last decades on the sponge-derived chemicals with bioactive properties which have the potential to be used for future pharmaceutical applications (Higa et al. 1994, Haefner, 2003, Sipkema et al. 2005). Scientists have been investigating the ecological role of sponge metabolites and the reasons behind sponges producing so many bioactive components that can be potentially useful to treat a great range of human diseases.

Table 1. Seven marine natural products and thirteen marine natural products inspired compounds that are<br>FDA-approved agents or in clinical trial with details of their collected source, predicted biosynthetic source, **Table 1. Seven marine natural products and thirteen marine natural products inspired compounds that are FDA-approved agents or in clinical trial with details of their collected source, predicted biosynthetic source,**  molecular target, and disease treated (adapted from Mayer et al., 2016) **molecular target, and disease treated (adapted from Mayer et al., 2016)**

Marine sponges are an important component of benthic communities throughout the world, regarding its biomass as well as their potential to influence benthic or pelagic processes (Higa et al. 1994, Haefner, 2003, Sipkema et al. 2005). They are among the oldest multi-cellular animals (Metazoa) and show relatively little differentiation and tissue coordination (Bergquist, 1978, Simpson, 1984, Leys and Meech, 2006). More than 8,000 species of sponges have been described; they inhabit a wide variety of marine and freshwater ecosystems and are found throughout tropical, temperate and Polar Regions (Proksch, 1994). They are sessile invertebrates with a wide variety of colours, shapes, and consistencies. Sponges consist of small pores, called ostia. Ostia draw water into them, and circulate it throughout their body by the action of cells called choanocytes. These choanocyte cells contain whiplike structures called flagella that move around and push water through the sponge. As water is drawn in and out, food and oxygen are brought to the sponge and waste and carbon dioxide is removed. The presence and abundance of spicules in marine sponge is variable: some species have dense or fused siliceous skeletons and thus a hard consistency, while other species have few or no spicules, thus lacking physical defenses (Figure 2) (Pawlik et al. 1995). Instead, they have evolved to develop chemical defenses against environmental stress factors such as predation, overgrowth by fouling organisms or competition for space (Rohde and Schupp, 2011, Pawlik, 2011). Studies showed that the highest concentration of toxic sponge metabolites are found in habitats such as coral reefs that are characterized by intense competition and feeding pressure from carnivorous fish. The adaptive significance of sponge's chemical constituents is derived from the observation that their chemical defences are highly effective against most species of fish, shell-less gastropods, and nudibranchs that feed on sponges (Perdicaris et al., 2013).

Figure 2. Sponge anatomy.

By producing different types of toxins or malevolent tastes and odors, sponges protect themselves against predators or inhibit coral overgrowth. In addition, sponges are one of the most efficient sessile filter feeders: they can filter up to 24 m<sup>3</sup>⋅kg<sup>-1</sup> day<sup>-1</sup> (Hentschel et al. 2002). Bacterial numbers in sponge tissue often exceed those of the surrounding seawater by two to three orders of magnitude as the sponge mesohyl provides a unique ecological niche for particular bacterial species. In many cases, sponge mesohyl harbours the bacterial symbionts (30%–60%) (Selvin et al. 2007). Bacteria provide their hosts with products of their metabolism, thereby granting the sponge access to bacteria-specific traits such as autotrophy, nitrogen fixation and nitrification (Wilkinson and Fay, 1979). Other examples show that sponge-associated bacteria can process metabolic waste compounds, stabilize the sponge skeleton and provide protection against UV radiation (Lee et al. 2001, Diaz and Rutzler, 2001, Thoms et al. 2003). The most prominent example of sponge bacterial symbiosis, however, is the involvement of bacteria in the production of bioactive metabolites (Thoms and Schupp, 2005) that have a role in defense (Proksch, 1994). Many of these compounds are very potent because the diluting effect of the ocean drives the construction of molecules that are highly active and stable in saline conditions (Abad et al. 2011).

These highly intensive, constant interactions with the environment have given sponges a unique biochemistry to produce a high diversity of metabolites that can either help them survive or prompt them to evolve. In an ecological context, sponges have developed special mechanisms to protect themselves from pathogenic bacteria, viruses, parasites, fungus and other predators that include both chemical defense mechanisms and physiological responses. Chemical defense mechanisms help to protect sponges against certain deleterious bacteria (Paul et al. 2001, Mahon et al. 2003, Paul et al. 2006). In this way, sponges provide novel leads against viral, fungal and parasitic diseases (Unson et al. 1994).

# **6. MARINE SPONGES AND NATURAL CHEMICAL COMPONENTS**

Among all the marine organisms investigated, marine sponges (Porifera) are recognized as the richest sources of novel MNPs, with about 4851 compounds to date, contributing to nearly 30% of all marine natural products discovered so far. It should be noted that of these, 1499 new compounds were isolated in the five years from 2008 to 2012 (Blunt et al. 2010, 2011, 2012, 2013, 2014). This makes sponges the most prolific marine producers of compounds with more than 200 new compounds reported each year for the last decade (Laport et al. 2009). The chemical diversity of sponge natural products is remarkable, including unusual nucleosides, bioactive terpenes, sterols, cyclic peptides, alkaloids, fatty acids, peroxides, and amino acid derivatives (which are frequently halogenated) (Blunt et al. 2008). With this myriad of MNP available, numerous studies have revealed a broad spectrum of biological activities for these compounds, including anti-cancer, anti-viral, anti-bacterial, anti-fungal, anti-protozoal, anthelmintic, anti-inflammatory, immunosuppressive, neurosuppressive, neuro-protective, antifouling and a range of other bioactivities (Blunt et al. 2005). Studies showed that different components affect the targeted disease by different mechanisms (e.g., microtubule stabilization or interaction with DNA to combat tumors). Natural chemical products that can act as inhibitors of transcription factors may be effective against both malignant neoplasms and viral diseases. Most bioactive metabolites from

sponges proved to be inhibitors of certain enzymes, which often mediate or produce mediators of intracellular or intercellular messengers involved in the pathogenesis of a disease (Sagar et al. 2010, Villa and Gerwick, 2010, Frota et al. 2012). Therefore, bioactive natural products isolated from marine sponge extracts have a solid track record as inspiration for drug discovery and the drug lead potential of this largely unexplored chemical diversity pool has been the primary motivation for our ongoing focus on sponge natural products.

# **7. PHARMACOLOGICAL POTENCY OF MARINE SPONGES**

The scientific literature records numerous examples of bioactive extracts/compounds from marine sponges that were assessed for their anti-oxidant anti-inflammatory, anti-tumour, immune-suppressive, neuro-suppressive, anti-microbial and anti-viral properties. Therefore, this section focuses on the discoveries of sponge derived natural products which displayed interesting pharmacological potential both *in vitro* and *in vivo* as well as their underlying mechanism of action by which they interpose at different points during human pathogenesis. Our objectives are to highlight the compounds by disease type, their mode of action and the greatest potential to drive towards the development of clinically useful drugs.

### **7.1. Anti-Oxidant Activity**

Antioxidants play an important role in the protection of human body against damage by reactive oxygen species (ROS) and reactive nitrogen species (RNS) (Govindarajen et al. 2005). Antioxidant system includes enzymatic and non-enzymatic components. Superoxide dismutase (SOD), glutathione peroxidase (GPx) and catalase (CAT) are the major antioxidant enzymes whereas non antioxidant antioxidants consist of endogenous components (uric acid, reduced glutathione and albumin) in addition to dietary antioxidants such as carotenoids, flavonoids, ascorbic acid and  $\alpha$  tocopherol (Rietveld and Wiseman, 2003). Highly reactive free radicals and oxygen species including singlet oxygen, hydrogen peroxide, superoxide, nitric oxide anion radical and hydroxyl radical are present in biological systems from a wide variety of reactions. These free radicals are known to oxidize nucleic acids, proteins, lipids, or DNA resulting in oxidative stress, a condition implicated in the pathogenesis of various diseases such as atherosclerosis, ischemic heart disease, cancer, Alzheimer's disease, Parkinson's disease and in the aging process (Shahbudin et al. 2011). Therefore, exogenous antioxidants may have positive effects in the removal or suppression of the generation of ROS/RNS. Based on that, many studies have been driven towards the assessment of the antioxidant properties of natural products through both chemical (*in vitro*) and biological (*in vivo*) methods.

Despite the large number of antioxidants revealed, the search for new chemical entities with antioxidant activity from the marine biome still remains a burgeoning field. Marine organisms particularly micro/macro algae have been widely studied as rich sources of polyphenols, astaxanthin, fucoxanthin, phlorotannins and fucoidans with antioxidant potentials (Lordan et al. 2011). While marine antioxidants are primarily from algae, very few studies have focused on marine animals. Similar to various algal species, marine sponges

particularly those inhabiting the intertidal zones are exposed to stressful vagaries of nature. To fight the stress posed by the high level of ROS, which is triggered through a combination of photosynthesis, symbiont oxygen production, intense light intensities and UV radiation, marine sponges are known to produce numerous antioxidant compounds (Brouwer et al. 2004, Almeida et al. 2005, Jiang et al. 2009). As such, microorganisms living as exobionts and endobionts in the tissue of such organisms are implicated in combating the oxidative stress that causes damage to host cells and tissue (Velho-Pereira et al. 2015).

In recent years, the antioxidant activity of marine sponge derived extracts has garnered enormous attention in food industries as they can be used as functional ingredients in food formulations to promote consumer health and improve shelf life of food products. A number of novel metabolites derived from marine sponges, such as indole derivatives, aromatic alkaloids, aromatic polyketides, and phenolic compounds have exhibited strong antioxidant potential compared to vitamin E and ascorbic acid (Kim et al. 2012). Aromatic polyketides isolated from the marine sponge-derived fungus *Aspergillus versicolor* have shown significantly higher antioxidant capacity than that of butylated hydroxytoluene (BHT) (Li et al. 2009). Another scientific study reported that marine sponge-derived yeasts are capable of producing anti-oxidative indole derivatives which can scavenge free radicals and ROS. These findings were very attractive since these sponge microbes are culturable, and there is a possibility of reproducing the compound in large scale (Sugiyama et al. 2009). Extracts from the sponge *Smenospongia* sp, and *Stylissa* sp collected from Red Sea at Egyptian coasts also showed appreciable radical scavenging activity against DPPH and INOS radicals. Subsequent chemical characterizations of these sponge extracts revealed the presence of numerous antioxidative compounds including di-isobutyl phthalate, di-n-butyl phthalate, linoleic acid, β-sitosterol, and cholesterol from the *Smenospongia* sp while *Stylissa* sp. produced bis-[2 ethyl]-hexyl-phthylester and triglyceride fatty acid ester (Shabaan et al. 2012). Furthermore, an *ex vivo* study on albino rats revealed that phenolic rich ethyl acetate extracts from the sponges *Rhabdastrella globostellata* and *Spirastrella inconstans* increased the level of almost all antioxidant related enzymes including glutathione peroxidase, glutathione reductase, catalase and superoxide dismutase, accelerating the removal of ROS (Chairman et al. 2012). Hence, these data argue that the marine fauna can be important sources of anti-oxidative agents with potential application as pharmaceutical or nutraceutical agents for prevention and control of degenerative diseases.

# **7.2. Anti-Bacterial Activity**

The optimism of the 1950s and 1960s of a world without infections is gradually being replaced by an era of pessimism characterized by widespread emergence of anti-bacterial resistance (Raghunath, 2008). Even today, infectious diseases including HIV/AIDS, tuberculosis, and malaria continue to elude the prospect of morbidity and mortality worldwide killing around 700, 000 people annually (O'Neill, 2016). Of all the major infectious diseases, bacterial infections present a major threat to human health. Tuberculosis caused by the bacteria *Mycobacterium tuberculosis*, for instance, ranks among the world's leading causes of death (Mohajan, 2015). *Streptococcus* (Group B *Streptococcus*), another bacterium, continues to be a frequent cause of life-threatening infection during the first three months of life (Edwards and Baker, 2001). Food borne and waterborne bacteria such as *Salmonella* and *Campylobacter* are responsible for the increase in diarrheal disease (Fletcher et al. 2013). Meanwhile, during the last decade, scientists discovered many new organisms and new strains of many familiar bacteria, such as *Escherichia coli*. Diseases from these emerging bacterial strains present a clear challenge to biomedical researchers. The complexity of this challenge is becoming even clearer as researchers begin to appreciate the many mechanisms associated with antibiotic resistance (NIAD, 2012). Resistance is often a result of expression of efflux pumps, modification of drug targets, modulation of transcription factors, and biofilm formation. Moreover, gene transfer among different strains of bacteria, and even between different species of bacteria, is now understood to be a common means whereby these organisms acquire resistance to antibiotics (Laport, 2009).

The importance of drug-resistant bacterial infection has produced an imperative requirement for the quick and sustained development of new antibiotics classes, which may keep pace with the varying face of bacterial antibiotic vulnerability. Continuous development of new antimicrobial drugs with multiple targets and potentials is expected to efficiently combat Multi Drug Resistant (MDR) microorganisms (Anjum et al. 2016). Several studies have focused on the mechanisms by which natural compounds, which attack the microorganisms' cell walls and cell membranes, resulting in release of various intracellular constituents (example; ribose and Na glutamate) (Sabir, 2007, Hasan, 2012, Rahman, 2014). Another mode of action is by interfering with the electron transport, nutrient uptake, protein, nucleic acid synthesis and enzyme activity (Bajpai et al. 2007) (Figure 3). Synergism of drug therapy and natural products may also give optimum results in the fight against existing and emerging infectious diseases. Regarding the application of natural products on bacterial infections, besides their direct antimicrobial activity, natural extracts have also been studied as antimicrobial drug resistance modifiers (Beesoo et al. 2017).

Figure 3. General mechanisms of antibiotic resistance and target of sponge derived anti-bacterial compounds.

Table 2. Selected examples of antimicrobial compounds isolated from marine sponges **Table 2. Selected examples of antimicrobial compounds isolated from marine sponges**

Contributing to the global search for new antimicrobials to combat antibiotic-resistant strains of pathogenic bacteria, marine ecological niches have been described recently as "particularly promising" (Fischbach and Walsh, 2009). Many new molecules with antibiotic properties are discovered every year, but in marine sponges their ubiquity is remarkable. Their complexity enables them to interact with multiple molecular targets thus conveying accrued difficulty for target microorganisms to develop resistance due to multiple response sites (Lagunin et al. 2016). So far a medley of studies on screenings of marine sponges for anti-bacterial activity has led to the isolation and characterization of a wide range of active compounds, including some promising therapeutic leads (Munro et al. 1999, Berlinck et al. 2004, Mayer and Hanann, 2004, Sipkema et al. 2005). An early preliminary anti-bacterial screening by Marihno and his group revealed that 10 out of 12 sponge species screened exhibited anti-bacterial activity with a large action spectrum over Gram-positive *cocci* (Marinho et al. 2006). This is in congruence with most of the available reports on antibacterial property of sponges that revealed that Gram-positive bacteria are more susceptible to sponge extracts as compared to Gram negative ones (Liu et al. 2004). For example, extracts derived from 28 marine sponge species collected along the French coast had high antibacterial activity against Gram positive bacteria (77%) than Gram negative bacteria (53%) (Lippert et al. 2003). Similarly, McCaffrey and Endean (1985) also showed that Grampositive bacteria were more sensitive to sponge extracts of subtropical and tropical species than Gram-negative.

The importance of marine sponges as a source of novel alkaloids, in particular those with anti-bacterial activity, has largely been recognized. The axinellamines B-D from an Australian marine sponge, *Axinella* sp, had bactericidal activity against *Helicobacter pylori*, a Gram-negative bacterium associated with peptic ulcer and gastric cancer (Urban et al., 1999). Another compound active against *H. pylori*, petrosamine B, an inhibitor of the enzyme aspartyl semialdehyde dehydrogenase, was isolated from an *Oceanapia* species (Gulf of Carpentaria, Australia) (Caroll et al. 2005). In bacteria, this enzyme is involved in the production of 25% of all amino acid residues that are required for protein synthesis (Hadfield et al., 2005). Inhibition of enzyme aspartyl semialdehyde dehydrogenase is thus considered to be an important target for the development of anti-bacterial agents. Noteworthy were reports of three novel manzamine-type alkaloids, 12,3,4-oxamanzamine E, 8-hydroxymanzamine J, and 6-hydroxymanzamine E, which were isolated from an *Acanthostrongylophora* species from Indonesia. All three manzamines were active against *Mycobacterium tuberculosis* with minimum inhibitory concentration (MIC)  $\leq$  12.5 μg/ml, with 6- hydroxymanzamine E having the most potent antituberculosis activity (MIC =  $0.4 \mu g/ml$ ) (Rao et al. 2004). The added value of some new sponge-derived antibiotics was also shown by the inhibitory effect of arenosclerins A–C from *Arenosclera brasiliensis* on 12 antibiotic- resistant bacteria isolated from a hospital (Torres et al. 2002). Likewise, Vik and colleagues (2006) also have shown that purine derivatives including Agelasine D isolated from marine sponges of the genus *Agelas* display a broad spectrum of anti-bacterial activities including effect on *M. tuberculosis*, Gram-positive and Gram-negative bacteria. Leone et al. (2008) isolated exiguaquinol from the sponge *N. exigua* which inhibited the bacterial enzymes *Helicobacter pylori* (Glutamate racemase that inter converts L- and D- glucose) needed for the construction of bacterial cell walls. Renieramycin J, tetrahydroisoquinoline alkaloid and araguspongine M, both of which showed strong anti-fungal activities were also isolated from the same species from Japanese waters. A *Synechococcus*-like cyanobacterium has been detected in the tissue

of *Neopetrosia exigua* by visible and fluorescent microscopic observations (Oku et al. 2003). Hence these compounds or their precursors may be produced by these symbiotic microorganisms. It has been widely reported that synergism of drug therapy and natural products may also give optimum results in the fight against existing and emerging infectious diseases. Recently our group showed that ethyl acetate fraction from the Mauritian *N. exigua* displayed interesting antibiotic potentiating activity against a panel of Gram positive and Gram negative bacterial isolates (Beesoo et al. 2017). Till date marine sponges have produced up to 800 antibiotic substances (Torres et al. 2002) but no sponge derived anti-bacterial product has yet entered the global pharmacological market. However, many of them are currently under preclinical investigation as potential anti-bacterial therapeutics (Table 2).

## **7.3. Anti-Fungal Activity**

The incidence of fungal infections has increased rapidly over the past decades, in part as a result of increasing number of immunocompromised patients and invasive procedures (Sydnor and Perl, 2011). Several fungal species that often cause human infections include *Candida albicans*, *Candida glabrata*, *Cryptococcus neoformans* and *Aspergillus fumigatus* (Shapiro et al. 2011). Fungicides that are currently used are less diverse than antimicrobials, and the use of many of them is restricted because of toxic effects to humans, animals, and plants (Sipkema et al. 2005). Therefore, the lack of some new anti-fungal agents and the emergence of resistance to anti-fungal therapy, leads to greater research and interest of optimal and new anti-fungal agents. Screening for anti-fungals is often focused on finding compounds active against *Candida albicans*, the prominent agent for candidiasis. Invasive candidiasis is accounted as the most common nosocomial fungal infection resulting in an average mortality rate between 25%–38% (Dimopoulos et al. 2008).

Jasplakinolide is the first example of cyclodepsipeptide 19-membered macrocyclic depsipeptide isolated from the sponge *Jaspis* sp which has a selective *in vitro* anti-fungal activity with MIC of 25 μg/ml against *C. albicans* while *in vivo* topical activity of a 2% solution against *Candida* vaginal infection in mice (Crews et al. 1986, Zabriskie et al. 1986). Callipeltins are another group of anti-fungal peptides isolated from the marine sponge *Latrunculia* sp. collected off Vanuatu islands. Callipeltins (F-I) inhibit the growth of *C. albicans*, with MICs of 0.1-0.15 μg/ml (Sepe et al. 2006). The peptides callipeltin K (Grkovic et al., 2014) and J (Abad et al. 2008), which were isolated from the sponge *Latrunculia* sp., from Emae, Vanuatu, South Pacific, inhibited the growth of *C. albicans* (ATCC 24433), with MIC values of 0.15 and 0.07 μg/ml (D'Auria et al. 2007). Anti-fungal activity was also detected from the sponge-associated fungus *Phoma* sp. Q60596. The sponge-derived fungus produced a new lactone compound, YM-202204 (Nagai et al. 2002), which was effective against *C. albicans* (MIC: 6.25 µg/ml), along with *Cryptococcus neoformans* (MIC: 1.56 µg/ml), *Saccharomyces cerevisiae* (MIC: 1.56 µg/ml) and *Aspergillus fumigatus* (MIC: 12.5 µg/ml). Furthermore, Nagai et al. (2002) showed that YM-202204 was able to block the glycophosphatidylinositol (GPI) anchor, an important structure for protein attachment in the membrane of eukaryotic cells and one of the targets in developing anti-fungal drugs (McLellan et al. 2012, Butts et al., 2012). Theonellamide G is a bicyclic glycopeptide isolated from the polar fraction of the organic extract of the Red Sea sponge *Theonella swinhoei*. The latter exhibited anti-fungal activity against wild and amphotericin-B-resistant strains of *C. albicans*, with MIC values of 7.84 and 3.49 μg/ml, respectively (Youssef et al. 2014). Nishimura and his colleagues previously revealed that the anti-fungal theonellamides represent a new class of sterol-binding molecules that induce membrane damage and activate Rho1-mediated 1,3-*β*-*d*-glucan synthesis (Nishimura et al. 2010). As part of a continuing investigation of new manzamine-related alkaloids with activity against infectious disease, new manzamine homologues were isolated and characterized from *Acanthostrongylophora* sp. The manzamines: neokauluamine, manzamine A, 8 hydroxymanzamine A, 6-deoxymanzamine and manzamine F showed potent activity against *C. neoformans*. Oral and intravenous pharmacokinetic studies of manzamine A in rats indicated that the substance has low metabolic clearance, a reasonably long pharmacokinetic half-life, and good absolute oral bioavailability of 20.6%, which supports the value of this substance as a potential lead for further preclinical assessment and possible drug development (Yousaf et al. 2004). Many sponge derived anti-fungals are currently being investigated for further clinical trials and drug development (Table 2). However, most of them have proved to be cytotoxic. Consequently, they have not been considered promising anti-fungal agents for clinical development. Therefore, in many cases, the assessment of whether anti-fungal activity outweighs cytotoxic effects is required, followed by rational modifications to improve the therapeutic index for these molecules (Donia and Hamann, 2003).

### **7.4. Anti-Viral Activity**

Viral infections play an important role in human diseases, and recent outbreaks in the advent of globalization and ease of travel have underscored their prevention as a critical issue in safeguarding public health. Several hard-to-cure diseases and complex syndromes including Alzheimer's disease, type 1 diabetes, and hepatocellular carcinoma have been associated with viral infections (Hober et al. 2012, Ball et al. 2013, Morgan et al. 2013). Despite the progress made in immunization and drug development, many viruses lack preventive vaccines and efficient anti-viral therapies, which are often beset by the generation of viral escape mutants. Examples include the recent emergence of dengue virus, influenza virus, measles virus, severe acute respiratory syndrome (SARS) virus, and West Nile virus outbreaks (Christou, 2011, Cascio et al. 2011, Grais et al. 2011). Thus, identifying novel antiviral drugs is of critical importance and natural products are an excellent source for such discoveries.

The officially clinically approved anti-viral drug armamentarium contains approximately 40 lead compounds (Da Silva et al. 2006). Some new approaches are being employed to introduce novel anti-viral agents from the marine biome. In an overview of 132 natural products from marine sources obtained during the period 2002-2011, which exhibited anti-HIV activity, it was reported that sponges contributed more than half of all anti-HIV natural products from marine organisms (Zhou et al. 2013). Among the most interesting anti-viral sponge metabolites, manzamines (Yousaf et al. 2004) Papuamides C and D (Ford et al. 1999), haplosamates A and B (Qureshi and Faulkner, 1999), and avarol (Muller et al. 1987) represent promising potential and future anti-viral drugs. Avarol, isolated from sponge *Dysidea avara* is one of the few compounds for which the mechanism by which it inhibits progression of HIV infection has been elucidated to quite some extent. *In vitro* and *in vivo* experiments show that it increases humoral immune response (Muller et al. 1987).

Mechanistically, avarol inhibits HIV by (almost completely) blocking the synthesis of the natural UAG suppressor glutamine transfer tRNA. Synthesis of this tRNA is upregulated after viral infection, and it is important for the synthesis of a viral protease, which is necessary for viral proliferation (Muller and Schroder, 1991). Moreover, the derivatives of avarol such as 6′-hydroxy avarol and 3′-hydroxy avarone were noted as very strong inhibitors of HIV reverse transcriptase. This enzyme has a key role in the early stages of HIV infection and is a specific target for anti-viral drugs (Loya and Hizi, 1990). Manzamine A, 8 hydroxymanzamine A, 6-deoxymanzamine X, and neokauluamine are manzamine-related alkaloids isolated from an Indo-Pacific sponge. These bioactive agents showed significant anti-HIV-1 activity with  $EC_{50}$  of 4.2, 0.59, 1.6, and 2.3 M, respectively (Yousaf et al. 2004). Several of these compounds have a great potential for drug development (Table 2). Among these compounds, preclinical assessments were started for avarol and manzamine A. Overall, the most important anti-viral discovery from marine source reported so far is the nucleoside Ara A (vidarabine) which was originally isolated from *Cryptotethya crypta* sponge and first synthesized in 1960. Adenine arabinoside is rapidly converted into adenine arabinoside triphosphate, which inhibits viral DNA polymerase and DNA synthesis of herpes, vaccinia and varicella zoster viruses. Vidarabine (Vira-A) received FDA approval in 1976, however, its marketing status is currently listed as discontinued by the FDA in the US market which was possibly associated with the lower therapeutic window of vidarabine relative to newer anti-viral compounds currently on the market (Mayer et al. 2010).

## **7.5. Anti-Malarial Activity**

Malaria is one of the most prevalent parasitic diseases in the world. According to the report, there were 212 million new cases of malaria worldwide in 2015 (range 148–304 million). The WHO African Region accounted for most global cases of malaria (90%), followed by the South-East Asia Region (7%) and the Eastern Mediterranean Region (2%) (WHO, 2015). The disease is caused by several protozoans belonging to the genus *Plasmodium* (*P. falciparum*, *P. ovale*, *P. vivax*, *P. malariae*), with *P. falciparum* being the parasite responsible for most severe diseases and most fatal cases. The global importance of this disease, current limitations of vector control and increasing resistance among *Plasmodium* strains towards anti-malarial drugs such as chloroquinone, pyrimethamine, and sulfadoxine, makes the development of anti-malarial therapeutics the main strategy of malaria control (Shrikant and Bhimanna, 2016).

During last decades, a few anti-malarial compounds have been isolated from sponges (Table 2). Kalihinol A from *Acanthella* sp. (Miyaoka et al. 1998) and a number of terpenoid isocyanates, isothiocyanates, and isonitriles from *Cymbastela hooperi* (Konig et al. 1996) display selective *in vitro* anti-malarial activity against *P. falciparum*. Also a number of free carboxylic acids from *Diacarnus levii* were used as precursors to yield new cyclic norditerpene peroxides after esterification. These epidioxy-substituted norditerpenes and norsesterterpenes displayed selective activity against both chloroquine-sensitive and chloroquine-resistant *P. falciparum* strains (D'Ambrosio et al. 1998). The manzamines, which are the most promising marine anti-malarial compound, have been discovered in a number of sponges (Sakai et al. 1986, Yousaf et al. 2002). Manzamine A, and its 8-hydoxy derivative, were found to potently inhibit the growth of *P. falciparum* both *in vitro* (IC<sub>50</sub> = 5.0 ng/ml) and

*in vivo* (a parasitemia suppression of the same order of magnitude of that of artemisinin). It has been suggested that the anti-malarial effect of manzamine A is due to an enhanced immune response. Unfortunately, its therapeutic index is somewhat narrow (gastrointestinal distress) and further studies are needed to improve this value.

Figure. 4. Diagrammatic process of inflammatory cascade inside the cell. Phospholipase A2 (PLA2) catalyzes the release of membrane-bound arachidonic acid (AA) to free arachidonic acid. Arachidonic acid is then converted to leukotrienes and prostaglandins by lipoxygenase (LOX) and cyclooxygenase-2 (COX-2), respectively. Sponge derived anti-inflammatory compounds such as manoalide (a) are mainly inhibitors of PLA2 or LOX, while nonsteroidal anti-inflammatory drugs (NSAID) inhibit COX-2, but also the constitutive COX-1 (Adapted from Sipkema et al. 2005).

## **7.6. Marine Invertebrates with Anti-Inflammatory Properties**

Inflammation is responsible for many widespread diseases including rheumatoid arthritis, osteoarthritis, atherosclerosis, diabetes, neuro-degeneration, allergy, infection and cancer. Multiple signaling pathways form a network of pro-inflammatory, immune-modulatory and pro-resolving cascades, which define the physiological and pathophysiological aspects of inflammation. Hence, it becomes evident that, an interference with multiple targets is superior to targeting a single key factor regarding drug efficiency, side-effects and adverse compensatory mechanisms involved in inflammation related diseases (Koeberlie and Andwerz, 2014). Accumulating epidemiological and clinical study indicates that various bioactive MNPs suppress pro-inflammatory pathways by inhibiting the expression of proinflammatory cytokines (tumor necrosis factor-α (TNF-α), intercellular adhesion molecule expression and pro-inflammatory mediators (inducible nitric oxide synthase (iNOS) and cyclooxygenase 2 (COX2), master transcription factors (nuclear factor-κB), reactive oxygen species (ROS) and by improving the antioxidant activity (Pan, 2011, Debnath, 2013, Senthikumar and Kim, 2013).

Manoalide (Figure 4(a)), previously described as an important antimicrobial agent (Da Silva and Scheuer, 1980) has been studied extensively for its anti-inflammatory properties (Bennet et al. 1987). Its anti-inflammatory action is based on the irreversible inhibition of the release of arachidonic acid from membrane phospholipids by preventing the enzyme phospholipase A2 from binding to the membranes (Glaser et al. 1989). A rise in the intracellular arachidonic acid concentration would lead to upregulation of the synthesis of inflammation mediators as prostaglandins and leukotrienes (Figure 4). Phospholipase A2 inhibition has been recorded for many sesterterpenes from sponges of the order Dictyoceratida (Jacobs et al., 1994). The mechanism by which they affect the inflammation process is different from commonly used nonsteroidal anti-inflammatory drugs. Only a few sponge-derived terpenoids have been found to inhibit lipoxygenase, another enzyme that is involved in the inflammatory response (Carroll et al. 2001). Indole alkaloids including aplysinopsin-type compounds (Aoki et al. 2001), manzamines (El Sayed et al., 2008), and carteramine A (Koyabashi et al. 2007) isolated from various sponge species have also been reported to have anti-inflammatory activities. In an early study, Kossuga et al. (2008) showed that the polyketide plakortide P isolated from the Brazilian sponge *P. angulospiculatus*, potently decreased the release of thromboxane B2 from activated rat brain microglia. Moreover, a novel dimeric oroidin derivative carteramine A in the marine sponge *Stylissa carteri*, also inhibited neutrophil chemotaxis (Koyabashi et al. 2007). The anti-inflammatory sponge products are selective inhibitors of specific enzymes of a range of diseases, like psoriasis or rheumatic arthritis. The currently used nonsteroidal anti-inflammatory drugs often fail to control the disease and present important side effects such as risk of gastrointestinal bleeding and renal complications (De Rosa, 2002). These are caused by unselective inhibition of cyclooxygenases, some of which are also involved in the promotion of the production of the natural mucus that protects the gastrointestinal tract (Bjarnason et al. 1993).

## **7.7. Anti-Coagulating Activity**

Some of the very common blood-related diseases such as thrombosis and atherosclerosis are unquestionably the main cause of death in the world. For example, the World Health Organization stated that in 2015 alone, approximately 15 million people have died from ischemic heart disease and stroke - the two top causes of mortality reported for that year (WHO, 2015). Based on these numbers, it is evident that there is a high demand for anticoagulant/antithrombotic agents in the global pharmaceutical market. The mechanism of blood coagulation is managed by a complex photolytic cascade that leads to the production of fibrin. Fibrin, a major component responsible for blood coagulation has been generated by the peptide cleaving of fibrinogen by thrombin (Kołodziejczyk and Ponczek, 2013). Cyclotheonamide A, derived from the sponge *Theonella* sp (Maryanoff et al. 1993) is an unusual class of Serine protease (an enzyme responsible for the conversion of fibrinogen into fibrin) inhibitor and is a drug of choice for thrombosis (Maryanoff et al. 1993, Schaschke and Sommerhoff, 2010). Eryloside F derived from *Eryltus formosus* sp. was found to be a potent Thrombin-receptor antagonist (Kalinin et al. 2012) (Figure 5). Thrombin receptor plays a central role not only in thrombosis but also the main agent to cause atherosclerosis (Chackalamannil, 2001, Ikenaga et al. 2016). Atherosclerosis is a disease in which plaque (fats, cholesterol, and calcium, etc.) builds up layer by layer inside the arteries and resulting

by narrowing of the arteries, causing a barrier to blood circulation leading to serious problems including heart attack, stroke or maybe death (Zapolska-Downar et al. 2001, Ikenaga et al. 2016).

Figure 5. Molecular targets of sponge derived anticoagulant compounds.

# **7.8. Marine Sponges with Anti-Tumour Properties**

Cancer figures among the high ranking causes of deaths worldwide, accounting for approximately 8.8 million global deaths in 2015 (GBD, 2015). However, projections based on the GLOBOCAN 2012 estimates predict a substantive increase to 19.3 million new cancer cases per year by 2025, due to growth and ageing of the global population (GLOBOCAN, 2012). This no doubt translates into one of the largest epidemic in human history. Although advances in the field of chemo-preventive and therapeutic medicine have been made regularly over the last ten years, the search for novel anticancer treatments continues. Despite the efforts of numerous researchers worldwide to ameliorate the dismal outcomes of cancer, it still continues to be huge burden on mankind (Shumacher et al. 2011). Cancer is a multifactorial disease that arises as a consequence of alterations in many physiological processes. Recently, hallmarks of cancer were suggested that include sustaining proliferative signalling, evading growth suppressors, resisting cell death, enabling replicative immortality, inducing angiogenesis, and activating invasion and metastasis, along with two emerging hallmarks including reprogramming energy metabolism and escaping immune destruction. In addition, tumors exhibit another dimension of complexity; they contain a repertoire of recruited, ostensibly normal cells to create the "tumor microenvironment" and contribute to the acquisition of hallmark traits (Hanahan and Weinburg, 2011). Understanding these concepts will provide new insights into the development of novel effective therapies to treat human cancer.

Marine chemotherapy is well recognized nowadays and profound development has been achieved by researchers to deal with different molecular pathways of tumors (Shwartsmann et al. 2011). During the search for novel and natural anticancer compounds, crude extracts and pure isolated compounds from marine sponges have been the subject of several investigations. An important feature of sponge- derived compounds is their ability to induce apoptosis by interacting with different molecular targets that are implicated in carcinogenesis. Cytoskeletal elements, nuclear factor-kappa B (NF-kB), hypoxia-inducible factor-1 (HIF-1), breast cancer resistance protein (BCRP), nuclear receptors, P-glycoproteins (P-gp), topoisomerases, matrix metalloproteinases (MMPs) and protein kinase C (PKC) are some examples of targets that have been identified to be modulated by sponge-derived compounds (Sipkema et al. 2005). Till date, more than 2500 cytotoxic compounds isolated from sponges have been reported, several of which are now in clinical trials against various cancers. A review Beesoo et al. (2014) collected the most important marine natural compounds which were already available in the pharmacological market or undergoing clinical trials (I, II, III) for anticancer activity. Among the compounds from sponges were the following:

#### *Cytarabine*

The first successful sponge-derived pharmaceutical drugs were the nucleosides spongothymidine and spongouridine which were isolated from the sponge *Cryptotheca crypta*  (Newman et al. 2012). Derivative of these nucleosides, Ara-C also known as 1-beta-D-Arabinofuranosylcytosine or cytarabine is documented as the first marine derived anticancer agent that is currently being used for the treatment of leukemia and approved by the Food and Drug Administration (FDA, MD, USA) in 1969. Cytarabine (Figure 6(i)) is an S-phase specific anti-metabolite cytotoxic agent, which when converted intracellularly to cytosine arabinoside triphosphate competes with the physiologic substrate deoxycitidine triphosphate, thus resulting in both inhibition of DNA polymerase and DNA synthesis. At present it is being screened for the treatment of acute myeloid neoplasms in combination with Daunoribicin and other anticancer drugs (Mayer et al. 2010).

Figure 6. Chemical structures of marine natural products/derivatives thereof isolated from sponges approved for use by the FDA or EMEA and currently in the clinical and preclinical pipeline in the area of cancer.

#### *Halichondrin B*

The halichondrins are a family of polyether macrolides that were originally isolated in small quantities from the rare Japanese sponge *Halichondria okadai* (Uemura et al. 1985). Many studies have reported the cell growth inhibitory activity of Halichondrins at nanomolar concentrations (1 x  $10^{-9}$  M) (Pettit et al. 1991). Among the Halichondrin family, Halichondrin B (Figure 6(ii)) was identified as the most potent congener which exhibited high *in vitro*  $IC_{50}$ value of 0.3 nM against L1210 Leukemia and remarkable *in vivo* activities against various human solid tumour xenografts, including LOX melanoma, KM20L colon, FEMX melanoma and OVCAR-3 ovarian tumours. Following the discovery of potent anticancer activity of Halichondrin B, it was tested and compared with other known antimitotic and anticancer agents using the United States (US) National Cancer Institute's (NCI) 60 cell line screen (Bai et al. 1991, Towle et al. 2001). While anti-proliferative patterns of Halichondrin B were found similar to those of other antitubulin drugs, its biochemical mechanism interaction with tubulin was unique (Bai et al. 1991). Differential cytotoxicity data indicated that halichondrin B binds tubulin at the vinca peptide binding site (Bai et al. 1991, Dabydeen, 2006). Induction of mitotic arrest by Halichondrin B leads to multisite phosphorylation and inactivation of antiapoptotic protein Bcl-2, cytochrome c release from mitochondria, proteolytic activation of caspase-3 and -9, and cleavage of the caspase-3 substrate poly(ADP-ribose) polymerase (PARP) eventually stimulating cell death via apoptosis (Kuznetsov et al. 2004) (Figure 7). Currently, the synthetic derivative of this compound namely Eribulin is in phase II trials for non small lung cancer, pancreatic, prostate, head and neck cancer and bladder and ovarian and related gynaecological tumours and Phase III clinical trial as second line therapy for the

treatment of advance breast cancer. The trials are taking place across the world under the sponsorship of Eisai (Mayer et al. 2010).

### *Hemiasterlins*

Hemiasterlins comprise a small family of naturally occurring tripeptides containing three highly modified amino acids which were originally isolated from the marine sponge *Hemiasterella minor* by Kashman and co workers in 1994 (Talpir et al. 1994) and subsequently from other unrelated sponges such as *Cymbastella* sp., *Siphonochalina* sp., and *Auletta* sp.(Coleman et al. 1995). All hemiasterlins have shown cytotoxicity in the nanomolar range (concentration  $1x10^{-9}$  M) against a variety of cultured human and murine cell lines. The related isomers hemiasterlin A and B, as reported by Anderson and co workers are the most potent members in the hemiasterlin group (Coleman et al. 1995). Their potent cytotoxicities are due to induction of mitotic arrest in metaphase with similar dynamics to those of known tubulin binders such as paclitaxel or vinblastine (Anderson et al. 1997). The antimitotic activity of hemiasterlin is mediated via a tubulin-based mechanism that leads to tumor cell apoptosis**.** It binds to the *Vinca*-peptide site in tubulin and induces G (2)-M arrest, caspase-3 activation and poly ADP ribose polymerase cleavage (Figure 7), which are typical biochemical markers of apoptosis (Kuznetsov et al. 2009). Extremely limited quantities of hemiasterlins hampered development of this series of compounds, particularly in animal models where limited testing has been reported (Coleman et al. 1995). The optimal analog was considered to be HTI-286 (Figure 6 (iii)) that retains potency in cellular models resistant to several chemotherapeutics, including taxanes and *Vinca* alkaloids (Coleman et al. 1995). Preclinical studies has shown that HTI-286 causes tumour regression and growth inhibition of human xenografts in mice. Even cell lines expressing P-glycoprotein or resistant to paclitaxel were shown to be sensitive to HTI-286 inhibition, but required higher doses than nonresistant cell lines (Loganzo, 2003). An open-label Phase I clinical trial was completed in patients with advanced solid tumours; however there were no objective responses and common toxicities observed included neutropaenia, nausea, alopecia and pain (Ratain, 2003). Phase II trials have been halted. Nevertheless, there is still interest in view of recent results including high antitumour activity in androgen-dependent and androgen-independent mouse models of refractory prostate cancer and in a newly established *in vitro* taxane resistant prostate PC-3 cell lines (Ratain, 2003).

### *Discodermolide*

Discodermolide is a marine sponge derived polyketide lactone, first isolated from the deep water sponge *Discodermia dissoluta* (De Souza, 2004). Crude extracts of the sponge showed strong potency against the murine P388 lymphocytic leukemia cell line and bioassay guided fractionation resulted in the purification of discodermolide. Discodermolide (Figure 6 (iv)) acts as an immunosuppressant and induces G2/M Phase cell cycle arrest and apoptosis in various tumor cell lines. Investigations into the mechanism of cycle-arrest by discodermolide competitively bind to tubulin and stabilize microtubules with another tubulin binding agent, paclitaxel. Fortunately discodermolides bind with a higher affinity for tubulin and have effects even in paclitaxel-resistant cell lines. Despite their competitive behaviour, discodermolides and paclitaxel show synergistic effects (Martello et al. 2000). This contradictory effect may be caused by overlapping rather than identical binding sites. Although both compounds bind to the taxane binding pocket, taxol interacts with the M-loop and discodermolide orients itself away in the direction of S1-S2 loop. Furthermore, the two compounds seem to show a complementary stabilising effect on microtubules (Khrapunovich-Baine et al. 2004). Discodermolide treatment causes a late activation of caspase 3 and caspase 8 as well as a cleavage of PARP in NSLCS cells (Figure 7). Treatment with discodermolide also leads to an efflux of cytochrome c from the mitochondria. Despite these findings, neither overexpression of Bcl-2 nor FADD-negative cells or inhibition of caspases could prevent cells from undergoing apoptosis (Broket et al. 2002). However, although discodermolide has shown more potent effects in tumour cells than paclitaxel and has also shown promising effects in murine models, the pharmaceutical company Novartis has withdrawn it from Phase I trials due to cytotoxicity problems (Molinski et al. 2009). However potentials remain for its use in combination drug therapy.

Figure 7. Interaction of marine sponge derived compounds on apoptotic signaling molecules. Regulation of this pathway with marine compounds; arrow indicates activation and blocked arrow indicates inhibition of the molecules.

### *Spongistatin 1*

The spongistatins comprise an important family of marine macrolides that display extraordinarily antitumour activities against a variety of human cancer cell lines. These unique marine compounds were isolated from the sponge *Spirasterella sp.* (Pettit et al. 1993). The spongistatin family includes 9 macrolides all of which possess remarkable cytotoxic activity against the US National Cancer Institute's panel of sixty human cancer cell lines.

Table 4. Current status of sponge-derived anti-tumour products in the drug development process **Table 4. Current status of sponge-derived anti-tumour products in the drug development process**

Discontinued from further development. \* Discontinued from further development.

Spongistatin 1 (Figure  $6(y)$ ) is known as the most cytotoxic member of the spongistatin family and has an average IC<sub>50</sub> value of 2.5-3.5 x  $10^{-1}$  against a subset of highly chemoresistant tumor types (Bai et al. 1993, Pettit et al. 1993). Spongistatin 1 shows interesting apoptotic features in various tumour cells. In leukemic cell lines it triggers caspase dependent apoptosis through the release of cytochrome c, Smac/Diablo and Omi/HtrA2 (Figure 3) from the mitochondria into the cytosol. Spongistatin 1 also leads to the degradation of the anti-apoptotic X-linked inhibitor of apoptosis protein (XIAP) thus positioning itself as a promising drug for the treatment of chemoresistance due to overexpression of XIAP (Schyschka et al. 2008). Moreover spongistatin 1 induces apoptosis more efficiently in human primary leukemic cells of children suffering acute leukemia at low nanomolar concentrations than clinically applied conventional drugs used in micromolar concentrations (Schyschka et al. 2008). Besides leukemic cells, spongistatin showed promising apoptotic potential in mammary cancer cells including the treatment-resistant cell line MCF-7 lacking caspase 3. Spongistatin-1 -induced cell death mainly caspase independent, involves the pro-apoptotic proteins AIF and endonuclease G. Both proteins translocate from mitochondria to the nucleus and contribute to spongistatin-1 mediated apoptosis as shown via gene silencing (Figure 7). Second, spongistatin acts as a tubulin depolymerising agent and is able to free the pro apoptotic Bcl-2 family member Bim from its sequestration both by microtubular complex and by the anti-apoptotic protein Mcl-1 (Schneiders et al. 2009). Silencing of Bim by siRNA leads to a diminished translocation of AIF and endonuclease G to the nucleus and subsequently reduces rate of apoptosis. By using spongistatin as a chemical tool, Bim has been suggested to be an important factor upstream of mitochondria by executing a central role in the caspase-independent apoptotic signalling pathway induced by spongistatin 1 (Schneiders et al. 2009). These different apoptotic features indicate that the apoptosis signalling is cell line specific.

The robustness of the global marine pharmaceutical pipeline in the area of cancer is evident by two FDA approved compounds isolated from marine sponges namely cytarabine and eribulin mesylate and many others such as hemiasterlin, discodermolide and spongistatin 1 (Table 4) being currently investigated under different phases of the clinical trial as the next possible clinical candidates.

# **8. FUTURE PROSPECTS OF SPONGE-DERIVED NATURAL PRODUCTS IN DRUG DISCOVERY**

The above examples illustrate the intense excitement which surrounds the achievement particularly in the area of infectious diseases and cancer research from marine sponges. A substantial number of bioactive lead compounds isolated from sponges are progressing through the development process, primarily with indications in cancer. Sponge chemicals span a wide range of chemical classes (e.g., terpenoids, alkaloids, peptides and polyketides) with an equally variety of biotechnologically relevant properties (e.g., anti-oxidant, antibacterial, anti-fungal, anti-viral and anti-tumour). There are now some significant reports of activities from a particular class of metabolites, the manzamines from marine sponges and/or associated bacteria as potential drugs or leads to drugs that might be effective against HIV, tuberculosis, malaria, and other infective agents. Cytarabine, halichondrin B, hemiasterlins

and discodermolide isolated from different sponge species are all examples of interesting sponge anticancer agents of potential relevance in cancer therapy.

These promising sponge (or microbial symbiont) -derived compounds in advanced stages of clinical trials emphasize the potential of sponges as auspicious source for drugs against various diseases. However, compared to the vast number of over 4,000 compounds isolated from sponges during the last three decades, the number of sponge derived drugs that have so far entered the market is surprisingly small. There are three major reasons for this phenomenon: one is the extremely long time frame involved in the process of drug development. For example, the development of the famous anticancer drug Taxol® from its initial description in the yew tree (Wall et al. 1995) to its approval as a commercial pharmaceutical took over 20 years. Thus, since many interesting sponge-derived substances were initially reported in the 1980s and early 1990s, there is hope that in not too far future the number of commercially available "marine drugs" will considerably increase. The second reason is that Big Pharma programs mostly avoid looking at marine invertebrate natural products as potential lead compounds because of the legal and logistical difficulties encountered in accessing the source organisms in the ocean waters of foreign countries, combined with the challenges associated with solving the compound supply issues involved in turning a structurally complex invertebrate natural product into a commercial drug. Conversely, the lack of Big Pharma interest in marine invertebrate natural products as a source of chemical diversity for their drug discovery efforts has made the examination of marine invertebrate natural products as potential cell biology tools and drug leads a very attractive area for academic research. University researchers do not face the same timeline pressures found in industry and bioactive natural product discovery projects are excellent interdisciplinary training platforms for the next generation of drug discovery scientists. Academic drug discovery research on bioactive marine invertebrate natural products is complementary to Big Pharma drug discovery efforts because it facilitates the exploration of an important drug discovery chemical diversity resource that would not otherwise be exploited (Koehn et al. 2005, Andersen et al. 2017).

The third and major reason is the unfortunate fact that most pharmaceutically interesting compounds found in sponges or microbial symbionts are available only in minute amounts from their natural sources. To develop *in vitro* screening assays, small amounts are needed; however, in preclinical studies, hundreds of grams to kilograms are often required for testing purposes. Perhaps this is the most important factor challenging in the development of products from the sea. Indeed, in order to obtain 300 mg of halicondrins, close to 1 metric ton (wet weight) of the sponge (*Lissodendoryx* sp) has to be collected and extracted. (Proksch et al. 2002, Minh et al. 2005). Consequently, the application in clinical is extremely difficult because of the low productivity of these compounds. Clearly, natural exploitation of these compounds cannot be reasonably envisaged without causing the destruction of marine ecosystems. Synthesis of marine bioactive compounds remains therefore the alternate method. However, due to the high complexity of certain structures their synthesis, in many cases, is not feasible. One successful example of the synthetic production of a marine-product drug in unlimited quantities is the conus toxin ziconotide, because of its peptide nature (Mayer and Gustafson, 2000). Another alternative to exploit natural products is marine culture. The aquaculture of the source organisms, including sponges, tunicates, bryozoans, with the aim of securing a steady supply of drug product, has progressed notably in cancer applications. For example, by culturing *B. Neritica*, American groups have obtained large amounts of

bryostatin 1 and the latter was produced at reasonable cost (Mendola, 2000). On the other hand, the majority of pharmaceutically interesting marine organisms, especially sponges, cannot be cultured under artificial conditions. Better understanding of living conditions in natural environment is necessary to develop alternative cultivation methods and to maintain the metabolite production over a long time. Culture of sponge cells and, more likely, primmorphs can become a future source of metabolites, cell and primmorph cultures are not feasible at present for producing large amounts of biomass (Belarbi et al. 2003).

Another limiting factor in the use marine sponges in the discovery of novel drug leads is the potential presence of toxins from the organisms or of environmental origin and the presence of inorganic salts. These species may compromise the use of raw extracts for *in vitro* screening purposes. Often, the production of toxins by a sponge is an indicator that this organism is a candidate source of bioactive compounds. Therefore, an effort should be made to characterize the possible contaminants (inorganic salts and toxins) in order to make marine extracts compatible with in vitro testing. Many analytical techniques are currently available for the analysis, isolation, characterization and separation of active compounds in marine extracts (Grienke et al. 2014). Moreover, analysis of drug development programs has shown that only 5-10% of experimental drugs with new chemical scaffolds hitting new cellular targets that enter phase I clinical trials will succeed, so the failure rate is high (Kola and Ladis, 2004, Schumacher et al. 2016). The major causes of failure are lack of efficacy and/or toxicity, as was described above for HTI-286. There is a constant effort to find new ways to increase the success rate for new drug candidates, but simple solutions to reducing the high rate of attrition are elusive. Ideally, marine natural product lead compounds must have biological activity that addresses an unmet medical need by hitting a new molecular target, or represent a completely new approach to modulating an already highly validated target. Therefore, robust pipelines of new drug candidates are essential and marine/sponge natural products can make meaningful contributions to these pipelines.

A long-standing and perplexing question in marine natural products chemistry has been the identification of the metabolite producing organism or potentially metabolite biotransforming organism, in systems involving an invertebrate host and symbiotic microorganisms. Many studies have successfully provided data to support the involvement of microorganisms including actinomycetes, cyanobacteria, microalgae such as dinoflagellates, and others in the biosynthesis of natural products isolated from invertebrates. For instance, the structural study on ET-743 has led to the identification of a congener named safracin B from *P.f luorescens*. Also Symbostatin 1, a similar skeleton to dolastatin 10 was isolated from the green alga *Symploca hydnoides* (Minh et al. 2005). In a sense, this is quite fortunate, for the biosynthetic pathways that code for natural compounds in prokaryotes are better understood and more amenable for study than those in eukaryotes. Progress in understanding how these biosynthetic pathways operate at the genetic and biochemical levels is opening new doors for harnessing this potential, and the future looks very optimistic for realizing tangible benefits from such efforts, such as new designer molecules with improved biological and pharmaceutical properties (Beesoo et al. 2014).

# **CONCLUSION**

This chapter summarizes the current pipeline of marine sponge natural products that are currently being evaluated in clinical and pre-clinical trials as well as it provides a view into the promise that these compounds pose to improve the diversity of our pharmacopeia to treat a wide variety of human diseases. Presently, two FDA approved drugs from marine sponges namely the anticancer citarabine and anti-viral vidarabine are on the market while many are rowing the different phases of the clinical trial. Clearly, marine sponges will play an important part in the future control of the global disease burden. Although substantial progress has been made in identifying novel drug leads from sponge's resources, a major frontier will be the application of metagenomic and genomic tools which will allow identification of the true sources of bioactive compounds. Fast evolving technologies and the increasing knowledge of molecular processes and mechanisms at the base of secondary metabolite production will continue to improve possibilities of mining for novel natural products from marine sponges and their exploitation for clinical applications.

## **ABSTRACT**

The incubation period, emergence, and dash of freshly emerged hatchlings to the sea is a critical period in the life cycle of sea turtles, although it is short compared to their life span. Predators can claim up to 100% of sea turtle eggs or hatchlings, depending upon the site, time of year, or location. We examined the foraging behavior of black vultures (*Coragyps atratus*) on an *arribada* beach of the olive ridley (*Lepidochelys olivacea*) sea turtle at Ostional, Guanacaste, Costa Rica. We address the following: 1) What methods of foraging do vultures use? 2) How successful are they in obtaining food? and 3) What factors affect their foraging, and we speculate on the possible effects of vultures on olive ridley reproductive success. The number of black vultures feeding on a 1500 m beach averaged 643 + 104 (max of 1243). Vultures foraged by hunting (nests with eggs or embryos, emerging or crawling hatchlings), social parasitism (using other birds or dogs to locate foraging opportunities), parasitism (eating eggs or hatchlings at nests other vultures found first), piracy, and scavenging of washed up adults, eggs, and dead hatchlings. Foraging opportunities included finding nests at eroded stream banks, nests uncovered by tides or wind, nests dug up by dogs, eggs thrown up by digging female turtles, and hatchlings emerging on their own. Overall, almost half the vultures gathered around exposed nests ate eggs/embryos (mean number of vultures was 10.6), while 64% obtained hatchlings at nests with emerging hatchlings. Both the number of vultures, and

<sup>†</sup> Corresponding Author's Email: gochfeld@eohsi.rutgers.edu.

the percent feeding, varied by foraging opportunity, with the highest percent feeding on and below vertical banks of eroded streams, and the lowest percent feeding with dogs. Interference competition with wood storks (*Mycteria americana*) resulted in significant decreases in the number of foraging vultures within 5 m of an exposed nest, and a significantly lower percent were able to feed, when storks were present at nests exposed at stream banks and by tidal action, and when hatchlings were emerging. 82% of the variance in the number of vultures feeding was explained by feeding location (foraging opportunity), number of storks, number of vultures present, and time of day. Although the turtles are supporting a healthy population of black vultures, most of the vulture food source on the beach are eggs that would not otherwise hatch, including inviable eggs, developing embryos and nearly-developed hatchlings that were exposed by stream bank collapse, tidal erosion, dogs or Wood Storks, digging female turtles during *arribadas*, and human egg-harvesters.

**Keywords**: reptilia, testudines, cheloniidae, *Lepidochelys olivacea,* olive ridley sea turtles, hatchlings, marine debris, foraging, predation, Costa Rica; conservation

All seven species of sea turtles are listed on the International Union for Conservation of Nature (IUCN) Red List of Threatened Animals (IUCN 2011). The threats facing sea turtles are many, both on land and at sea, including habitat loss, predation, and human exploitation (Plotkin 2007). The olive ridley (*Lepidochelys olivacea*), the most numerous sea turtle species, has a pantropical distribution (NRC 1990). It exhibits two breeding strategies: solitary nesting, and *arribadas*, in which up to hundreds of thousands of turtles nest on a single beach over the course of a few nights (Pritchard 2007).

Predator swamping is the hypothesis proposed to explain the latter phenomena. The superabundance of prey in a short period of time makes it impossible for predators to take them all (Gochfeld 1980; Ims 1990). In olive ridleys, the mass laying and hatching results in the emergence of large numbers of hatchlings at one time (over a period of a week), and predators may become sated, allowing some hatchlings to safely reach the sea. When millions of hatchlings crawl to the sea, terrestrial predators (including nocturnal ones) can consume only a small proportion of the young (Cornelius et al. 1991). Thus, the evolution of *arribada* behavior is ascribed to the predator-satiation hypothesis (Eckrich and Owens 1995).

However, an *arribada* has drawbacks. Predators may be recruited in large numbers, and the mass nesting facilitates the harvest of adults and eggs. In some places, the harvest of eggs has led directly to declines and elimination of *arribada-*nesting populations (Campbell 2007a,b; Cornelius et al. 2007), and *arribadas* are rare among turtles. *Arribadas* can attract a range of predators, both on land and at sea. At sea, hatchlings are vulnerable to fish and to avian predators, such as frigatebirds (Witherington and Salmon 1992; Lagarde et al. 2001). On land, nests, eggs, and hatchlings are vulnerable to reptilian, avian, and mammalian predators, the latter mainly at night (Santidrian et al. 2010).

Most hatchlings emerge at night (Drake and Spotila 2002). Predation rates on sea turtles nests can be as high as 95% (Engeman et al. 2003), and in some cases, 100% of hatchlings observed diurnally were taken by predators (Lagarde et al. 2001). In Costa Rica, Fowler (1979) reported that feral dogs, raccoons (*Procyon lotor*) coatis (*Nasua narica*), black vulture (*Coragyps atratus*) and turkey vultures (*Cathartes aura*) preyed on the eggs and hatchlings of sea turtles. Vultures also prey on hatchling sea turtles in other places, such as Trinidad (Safina 2006). Although mammalian and avian predation on turtle eggs and hatchlings is well-known, studies normally concentrate on the adult sea turtles, and do not specifically examine the behavior of the birds or mammals, their foraging strategies, and the potential positive effects of their foraging on sea turtle eggs and hatchlings.

In this paper we examine the foraging behavior of black vultures when feeding on olive ridley sea turtle (*Lepidochelys olivacea*) eggs and hatchlings at Ostional, Guanacaste, Costa Rica. Our objectives were to 1) describe the foraging behavior of black vultures on sea turtle eggs and hatchlings, 2) describe their foraging success using different types of foraging opportunities, and 3) describe the factors affecting foraging success. We were particularly interested in the potential effects of vulture foraging on nests and hatchlings, and in the abundance and behavior of vultures on the *arribada* beach. While the presence of vultures, and their scavenging and predation on eggs and hatchling sea turtles in Costa Rica was well known (Fowler 1979; Valverde et al. 2007), the number of vultures present on the beaches, their foraging behavior, and their effect on eggs and hatchling sea turtles at Ostional had not been examined.

## **METHODS**

*Study Species*. - Black vultures range from northeastern and southern United States through most of the neotropics to northern Argentina. Their main foods are dead animals, including refuse. They locate food mainly by soaring and watching for other vultures. Although their food occurs sporadically, landfills and turtle beaches like Ostional provide some guarantee of food. Wood storks (*Mycteria americana*) were also present regularly on the beach, and also foraged on sea turtle eggs and hatchlings. The other diurnal predators at the Ostional beach were turkey vultures (*Cathartes aura*), crested caracaras *(Caracara cheriway),* and great-tailed grackles (*Quiscalus mexicanus*). Although turkey vultures and caracaras preyed on turtle eggs or young, there numbers were small and their influence on black vultures probably negligible. All observations reported below are for black vultures, other birds are discussed in detail elsewhere (Burger and Gochfeld, 2014a).

Olive ridleys nest both solitarily and in *arribadas* that occur approximately monthly on traditional beaches in Central and South America, Africa, India, and Australia (Plotkin and Bernardo 2003). Even on *arribada* beaches, solitary turtles come up to nest in between *arribadas*. During a study from 2006 to 2010 at Ostional, the largest *arribada* occurred in October 2008, when an estimated 476,550 female turtles nested (Valverde et al. 2012; (Figure 1). *Arribadas* at Ostional occur in every month, although those early in the year are the smallest (Pritchard 2007). Ostional *Arribadas* ranged from 3,564 to 476,550 egg-laying females, with the largest occurring in the rainy season (August to December). The olive ridley *arribadas* at Ostional are the second largest nesting assemblages of sea turtles in the world (Valverde et al. 2012). The mass nesting of turtles has provided the opportunity for harvesting of turtles and eggs, much of it illegal (Cambpell 1998; Campbell et al. 2007a; Bernado and Plotkin, 2007). However, egg harvesting is legal at Ostional, and is allowed for the first 2.5 days of an *arribada*. People harvested an average of 21.2% of the clutches laid during their study, and there is some suggestion that this nesting assemblage has decreased over the last two decades (Valverde et al. 2012).

Figure 1. The Ostional (Costa Rica) arribada of Olive Ridley Sea Turtles in November 2012. Shown are 125 turtles.

*Study Area*. - The *arribada* beach at Ostional National Wildlife Refuge (Guanacaste, Costa Rica, lat 9.993913 N, long 85.700403 W) is 7 km long, with a variable width (typically less than 100m). Permanent markers established every 50 m allowed us to accurately census vultures along the beach and associated trees and shrubs at the edge of the upper beach. Windrows of logs and driftwood of varying sizes litter the beach. Ostional village (population of 450) has established the Association for the Integral Development of Ostional (Asociación de Desarrollo Integral de Ostional= ADIO) that legally has authority to harvest olive ridley sea turtle eggs from the beaches (Valverde et al. 2012) (Figure 2a and 2b).

*Behavioral Observations*. - Observations on foraging in vultures were made from October 19 to November 8, 2012, supplemented with data from refuge personnel and on-site collaborators. Our observations were obtained during a one month cycle at the height of the rainy season. The November 2012 *arribada* was considered the largest of the year, with over 110,000 females nesting the first night (7-8 November). We collected data on 1) number of vultures, 2) foraging methods, and 3) factors affecting foraging behavior and success. In addition, observations were made of the protective measures of the Association for the Integral Development of Ostional (ADIO) with regard to influence on vulture predation. Observations were made from 04:30 AM until 17:30 PM daily, with periodic observations at night. Vultures arrived from their nocturnal roost around 5:00 AM and were flying to roost by  $17:00 \text{ PM}$ 

Figure 2a and 2b. The people of Ostional have CITES permits to harvest turtle eggs, and protect the beaches, emerging hatchlings, and nesting turtles from predators, poachers, and beach debris.

We conducted censuses of the number of vultures present on the beach, and in the shrubs/trees at the top of the beach, in the morning and afternoon every day to determine the species and numbers that were present and actively engaged in hunting or foraging on eggs, nests, or hatchlings. We also recorded the number of dogs (using photographs for individual recognition) that dug down to nests, ate eggs or hatchlings, and then abandoned the nests to vultures and other birds. Data recorded included: date, time of day, transect segment (pole number), and number of vultures by location (beach, trees/shrubs at top edge of beach). During the peak hatchling period (6 days), vultures and other birds were scared from the beach from 05:00 AM to 07:30 AM by members of ADIO. Thus, vulture numbers were analyzed only for censuses where there were no people keeping them from the beach. Vultures began returning to the beaches within minutes of the departure of beach protectors, but during that six day period, their numbers never reached the high numbers recorded before the peak hatchling period.

Behavioral observations on predation of nests, eggs, and non-emerged and emerged hatchlings were made by walking the same transects in the morning and afternoon each day. We recorded the following information for all nests where vultures were foraging: date, time of day, transect segment, depth the nest was open (sand depth), type (eggs, hatchlings with or without residual yolk sac), the number of birds within 3 m, number of birds eating/30 sec, number of chases (or defensive behaviors)/30 sec, and handling times when vultures ate hatchlings (time from when it picked up the hatchling until it finished eating). We also recorded the number of wood storks, caracaras, grackles and other birds present along transects (Burger and Gochfeld, unpubl data). The present ms concentrates on the behavior of foraging black vultures.

Linear regression procedures were used to determine the variables that contributed most strongly to explaining variations in the foraging behavior of vultures (PROC GLM, SAS 2005). We used a stepwise model that adds the variable that contributes the most to the  $\mathbb{R}^2$ , continuing until all significant variables are added. Thus, variables that vary co-linearly are entered only if they add independently to explaining the variation. We used Kruskal Wallis tests to determine significant differences among variables, and Contingency  $X^2$  tests for small samples sizes. Levels of  $p < 0.05$  were considered significant.

## **RESULTS**

*Vulture Numbers*. - Vultures normally arrived at the beach well before sunrise, when light levels were very low (around 05:00AM). While some vultures immediately started foraging at the tideline, others flew to trees and shrubs at the top edge of the beach. The average number of vultures present on the beach was  $643 \pm 104$ , with a maximum of 1243.

*Foraging Behavior*. – Vultures foraged using a number of methods, including hunting on foot or from the air, social parasitism (looking down the beach for groups of vultures that might indicate a prey source), parasitism (eating eggs or hatchlings at nests found by other vultures), kleptoparasitism (piracy from other vultures), and scavenging (Table 1, Figure 3). They flew, walked, or hopped over the beach looking for exposed eggs or hatchlings, flew over the beach looking for live hatchlings emerging or crawling toward the sea, took eggs or hatchlings exposed by people, other birds, or female turtles in full *arribada*, stole eggs or hatchlings from other vultures (piracy), and searched for the presence of a group of vultures or a digging dog that indicated an exposed nest (social parasitism). Thus, in most cases vultures were searching for place-based prey (e.g., eggs and hatchlings at nests, surrounded by groups of other vultures).

Figure 3. Black vultures dig up nests that are near the surface or are exposed by high tides or dogs.

## **Table 1. Foraging strategies of black vultures on olive ridley sea turtles in Ostional, Costa Rica. \*\* = eggs or hatchlings would not make it because of exposures not due to the vultures**

a. This form of predation is partly eliminated by the ADIO because from 05:00AM to 07:30AM or 08:00AM they station people every 50 m to scare or chase Vultures away, effectively removing them from the beach during this time.

The rain-swollen stream cuts were a dynamic system eroded by the continuous pressure of flowing water. The sides were 2-4 m high with 60 to 80 degree slopes. Groups of vultures were lined up at the top of the cut, or in the streambed, waiting for a subsidence event to expose a nest. Anywhere from 10 to 40 vultures would congregate in a frenzied effort to maintain a footing on the steep slope and snatch exposed eggs. Often groups of eggs would roll to the bottom of the slope to be opened and sucked dry by the vultures (Figure 4).

Figure 4. Erosion of stream banks sometimes exposes eggs that are eaten by vultures or wood storks. These are eggs that would never hatch.

Figure 5. (Continued).

Figure 5a and 5b. During the arribada the vultures try to eat eggs thrown up by digging turtles, but only at the edge of the mass of turtles.

The vultures switched foraging strategies depending upon prey available (eggs in nests, embryos in nests, hatchlings emerging). When no hatchlings were emerging, the vultures coursed low over the dunes, searching for exposed nests or eggs, and for groups of vultures that indicated an exposed nest. Once hatchlings began to emerge from nests, vultures switched to solitary hunting in the early morning when they first arrived. When light levels were very low, vultures arrived in small groups, landed at the south end of the *arribada* beach, and followed two strategies: they hopped rapidly on the upper beach, moving in groups down the beach searching for hatchlings still crawling toward the sea, or they hopped or flew low over the surf searching for hatchlings being buffeted by the waves (some hatchlings required several waves before they were carried out to sea). When the beach and surf had been searched, they switched to looking for dogs or groups of vultures that indicated an exposed nest.

While female turtles were digging during an *arribada*, significant numbers of eggs from earlier nests were thrown up by their back flippers while digging. Such nests were from females that nested in the same *arribada*, or in a previous one. Vultures ate these eggs or embryos while the turtles were still on the beach, or after they departed. This occurred only near the top edge of the beach where turtle density was low. The vultures were wary of the digging turtles, kept an eye on them, and ran or flew back when the turtles moved (Figure 5a and 5b). Few turtles were accompanied by vultures, and in the mid-beach there was very little room between turtles. This contrasted with vulture behavior in the two days before the full *arribada,* when fewer than 200 turtles nested, and some were still completing nesting at 05:00AM. Then groups of vultures foraged around each female, waiting for eggs to be thrown up by the digging activity.

Additionally, legal egg harvesting by the local residents resulted in eggs (rotten, not viable) and developing embryos (up to nearly fully formed hatchlings) being left on the sand surface as they harvested only the freshly-laid eggs, but sometimes encountered previously laid clutches. During the early morning harvest, egg-harvesters, nesting turtles, and vultures were all on the beach. When the harvesters moved on up the beach, they left the few turtles behind, providing foraging opportunities for the vultures.

*Eating hatchlings.* – When a vulture discovered a nest with newly emerging hatchlings, there was a frenzy of activity as other vultures flew in and began seizing other hatchlings. Within 15 sec, the initial vulture was joined by half dozen others, or more. Foraging on hatchlings differed from eating eggs because the vultures either swallowed the hatchling whole, removed parts to eat, or removed parts and then swallowed the rest of the hatchling. Further, vultures tried to pirate hatchlings from one other. Total handling times ranged from 9 sec to swallow one, to 409 sec to fail. Although some swallowed a hatchling quickly, most did not. Attempting to eat a hatchling often involved pulling, dropping, defending, dismembering, disgorging, swallowing, and sometimes abandoning it completely. A solitary vulture dismembered a hatchling, removing the head, and often much of the viscera, by holding the turtle body with its foot, and tugging upward vigorously and repeatedly. When we tried this feat, it required great strength, and often we could not dislodge a leg. Any vulture with a hatchling tried to retain control of the hatchling, while trying to remove the legs or swallow it whole.

When hatchlings were abundant (peak of emergence), defense may have been more costly than finding another hatchling and vultures that lost a hatchling to a pirate just looked for another rather than fight for it. Some vultures appeared satiated, and merely pulled off the head and legs to eat, and then reached for another hatchling, or stopped feeding altogether. During this time, we examined 100 dropped hatchlings, and found that: 2 were intact, 7 had the head and viscera missing, 58 had both foreflippers missing, 18 had one foreflipper missing, 7 had hind flippers missing, and 5 were open carapaces only.

We timed 171 hatchling captures by black vultures, but only 127 were complete. It was difficult to follow complete sequences  $(N = 16)$ , and some were abandoned almost immediately  $(N = 28)$ . The mean handling time for 49 adults when they were not interrupted was  $49 + 5.2$  sec. However, when an adult vulture was interrupted by pirates (N = 58), the mean time for the hatchling to be swallowed was  $92.3 \pm 7.7$  sec (X<sup>2</sup> = 18.3, P < 0.001). This involved up to 5 separate chases, by up to 5 different vulture pirates. There were only 20 juvenile vultures that ate hatchlings without interruption, or with one or two apparent parents guarding them, the mean time to swallow was  $74.9 + 12.7$  sec, longer than required by adults  $(P = 0.08)$ . It is likely that the one or two vultures near the juveniles were parents because they did not attempt to pirate from the juveniles, and did not allow other vultures near, Otherwise, juveniles did not pick up hatchlings first, but tried to pirate from others.

*Foraging Opportunities*. – While the vultures generally foraged by hunting, parasitism, or scavenging, there were many foraging opportunities on the Ostional beach. Although sometimes vultures foraged by searching for solitary hatchlings crawling toward the sea, or battling the surf, they usually searched for exposed nests or emerging hatchlings at nests, depending upon the point in the turtle nesting cycle. We identified six major types of foraging opportunities: 1) nests exposed by tidal action, 2) nests exposed by erosion of stream banks (shallow banks or vertical cliffs), 3) nests exposed by dogs digging up nests, and abandoning them before all eggs were predated (dog dug up, post-dog), 4) nests exposed on the surface, either by previous tides or winds removing sand, 5) emerging hatchlings and those crawling to the sea, and 6) eggs exposed by female ridleys digging up the eggs of previous nesters.

				<b>Nests</b>			Hatchlings

**Table 2. Foraging behavior of black vultures when feeding on nests (eggs, embryos) on olive ridley hatchlings emerging on the surface or crawling to the sea (Ostional, Costa Rica, 2012)**

Each of these opportunities attracted other vultures and other species of birds, which resulted in competition for the eggs or hatchlings. Further, these foraging opportunities were not equally available. Vulture foraged using these opportunities as follows  $(N = 858 \text{ nests})$ : tidally-exposed nests (28%), stream-exposed nests (26%), emerging hatchlings (22%), dogexposed nests (16%), surface (exposure cause unclear, 5%), digging female-exposed nests (4%). The latter was relatively low during the *arribada* because the vultures seemed unwilling to walk among the very dense nesting ridleys, seemingly because the turtles simply continued walking and would have walked over them if they didn't move, and they flew back to avoid the flinging sand when ridleys covered their nests.

*Factors Affecting Foraging Behavior and Success.* - Overall, there was an average of 12 vultures present within 5 m of an exposed nest (with eggs, hatchlings, or emerging hatchlings) being preyed upon, and half were actively feeding (e.g., able to get an egg or hatchling) within 30 sec (Table 2). In that time period, there was an average of only two vulture-vulture chases. The number of vultures eating was significantly correlated with the number of vultures within 5 m ( $r = 0.48$ , P < 0.0001), and negatively correlated with the number of dogs present or chasing vultures ( $r = -0.29$  and  $r = -0.26$ ,  $P < 0.0001$ ), number of storks present and eating ( $r = -0.24$ ,  $P < 0.0001$  for both), and number of stork chases of vultures ( $r = -0.23$ ,  $P < 0.0001$ ).

#### **Table 3. Models explaining variations in feeding behavior of black vultures feeding on eggs and hatchlings of Olive Ridley sea turtles at Ostional, Costa Rica. NS = not significant**

a. Where predation occurred.

Between 47% (number of vultures present within 5 m of an exposed nest) and 82% (number of vultures feeding) of the variation was explained mainly by feeding location (feeding opportunity), number of storks, and number of vultures present (Table 3). The number of vultures present was largely explained by the number of vultures feeding (e.g., when it appeared that most vultures were feeding, other vultures were rapidly attracted to the nest), and the number of storks present. Thus, foraging at exposed nests became frenetic when more vultures were present, and more were feeding, still more vultures arrived and attempted to feed, resulting in threat displays, chases, and actual fights. The percent of vultures feeding (of the vultures that were present) was also dependent upon the feeding location, and the number of vultures and storks that were present.

These relationships are clearer from figure 6, where the number of vultures present, the mean number of vultures feeding, and the mean percent of vultures feeding is examined by foraging opportunity. In this figure we divided nests exposed by stream erosion into two types: cliff bank and stream bank. Both types were by streams, but cliff banks were steep cuts that were nearly vertical and stream banks had a shallower incline. On the vertical cliff banks, the eggs (and embryos) that were exposed often fell directly down a couple of meters to the bottom of the bank. Thus, vultures could eat both from the nest itself (which required rapid beating of wings to maintain their position on the steep cliff), and from the eggs dropped at the bottom. Thus, the number of vultures feeding, and the percent feeding was very high. In contrast, feeding from a stream bank meant that fewer vultures had access to space where the eggs were exposed. When dogs were actively digging up nests, some dogs defended these nests, and chased any vultures that came too close. Other dogs were more tolerant. Although not enumerated, dogs typically ate  $2 - 5$  hatchlings, and then retired for several minutes before resuming their digging. Vultures would take advantage of these interludes, and although vultures are poor diggers they occasionally captured hatchlings in this manner. There were fewer vultures that stayed, and far fewer were successful in obtaining eggs when dogs were present, although once dogs left vultures could obtain some eggs or hatchlings. Dog predation was easy to identify because they made large holes that were often a half meter wide and a third of a meter deep, with dirt piles scattered on one side. Dogs were mainly able to locate nests with hatchlings (either with remaining egg yolk or ready to emerge). For example, 66% of the nests dogs located had hatchlings, and only 34% had eggs. In contrast, only 20% of nest nests exposed along stream banks, and 10% of the nests exposed by tides contained hatchlings.

The number of vultures feeding decreased significantly with depth of the nest being predated, and was lowest in the middle of the day (Figure 7). When there were few vultures feeding, there was significantly less aggression, however, when over 10 vultures were feeding, the number of chases declined with increases in the number of vultures (Figure 7).

Feeding on emerging hatchlings (compared to eggs and hatchlings still in nests) provided a different situation in that they were both place-based (some emerging from the nest), and mobile (often scattered down the beach). Thus, once a nest with emerging hatchlings was dispersed, vultures descended in groups, numbers were high, and success was high because of the spatial dispersion, and the time required to eat a hatchling (30 sec to 4 min). Solitary vultures that captured hatchlings pulled off the legs, and the head, and then swallowed the rest. Once a vulture obtained a hatchling, it walked or flew a short distance away to eat it without being disturbed, allowing other vultures to move in and capture their own hatchling at the nest.

There were several significant differences between vultures feeding at nests with intact eggs, and those feeding on hatchlings, including foraging depth, number of vultures present, number of vultures feeding, and percent of vultures foraging but not number of chases (Table 1). Partly this is a result of the scattering of the hatchlings from the nests; eggs were all in the nest, whereas nests discovered in the early morning (under low light conditions) often had hatchlings strewn down the beach as they crawled to the sea. It took many minutes for a hatched clutch of turtles to completely emerge, and the earliest would reach the sea before the last had poked their heads out of the sand. This allowed vultures to scatter down the beach, picking them off. Most nests hatching in the early morning (05:00-07:30AM) were attended by a person, either from the ADIO, the refuge, or a tourist. Unattended hatchlings were all taken by vultures, storks, or grackles, and even when two of us attended a nest to time and protect the hatchlings, bold vultures or grackles succeeded in capturing a few.

Wood storks had a negative effect on the number of vultures feeding (successfully capturing an egg from a nest or an emerging hatchling), and on the percent of vultures feeding under many foraging opportunities (Figure 6). Wood storks were generally less aggressive, and moved in less rapidly to a dense group of feeding vultures, but when they did move in, they displaced the vultures, due mainly to their longer bill and larger size (wood stork length  $= 115$  cm; black vultures  $= 65$  cm). Although the storks were less aggressive, they did chase vultures that came too close, with the effect that vultures then stayed away from them. On the other hand, storks were more wary of humans and did not make or tolerate an approach closer than about 20 m.

There were significant differences in the mean number of vultures foraging, and in the percent of vultures that were feeding for those feeding on nests at stream banks, on nests exposed by tides, and on hatchlings (Figure 6). In all cases, fewer vultures could feed when storks were present, and a significantly lower percentage of the vultures present were able to feed in the presence of storks compared to when no storks were present. The greatest difference, in both number and percent of vultures feeding, was when vultures fed on hatchlings. When no storks were present, 90% of the vultures that were present obtained a hatchling during a 30 sec observation period, but when storks were present, it dropped to 60% (Figure 6). Further, it appears that vultures moved away from foraging situations with storks because the storks dominated any nests where hatchlings were emerging. Because of their long bill, storks probed deeper to obtain eggs or hatchlings in the sand and capture hatchlings that had not reached the surface. As we approached, the storks would abandon this effort and walk away; the vultures would crowd in, but were unable to reach hatchlings due to their much shorter bills.

We also computed models to examine the number of vultures feeding on emerging and crawling hatchlings, compared to the number of vultures feeding on eggs, embryos, or subhatchlings (those nearly ready to emerge, but still below the sand surface, usually with some egg yolk attached). The former are viable offspring that had the potential to reach the sea successfully if not for vulture predation, while the latter did not (as the forces of nature had already exposed the nests, preventing their further development). Over 70% of the variation in the number of vultures feeding at nests (eggs/embryos) and on emerging hatchlings was explained by the number of storks and the number of vultures that were present, as well as feeding location, number of chases, and time of day for feeding at nests (Table 4). That is, when they fed on hatchlings that were moving away from the nest, only the number of storks

and vultures explained how many vultures were eating. In contrast, when they foraged on eggs and developing embryos at nests (place-based), feeding location, time of day, and aggression explained differences in the number of vultures that could feed.

Figure 6. The relationships between the number of vultures present and foraging opportunity at Ostional.

Figure 7. Number of Black Vulture feeding as a function of nest depth and time of day, as well as the number of chases by vultures as a function of the number of vultures present at a nest being preyed upon.

**Table 4. Models explaining variations in behavior of black vultures feeding on olive ridley hatchlings at Ostional, Costa Rica. NS = not significant**

 $NS = not significant.$ 

## **DISCUSSION**

*Vulture Populations* – At Ostional, black vultures have a variety of foraging strategies, and a range of foraging opportunities provided by environmental and social factors (Figure 8). These interact to provide continuous foraging opportunities that supported an average population of over 600 vultures foraging on the beach in the morning and late afternoon. The maximum number of vultures present was 1243 along the 1500 m section of beach that we surveyed immediately in front of and north of Ostional village. Even so, the actual local population of vultures available to exploit the turtles could have been much larger. We regularly surveyed only half of the beach that was available, and once vultures were satiated, some may have left to roost away from the beach.

Vulture populations would be expected to decrease during the vulture breeding season, when black vultures are breeding (half would be incubating at any one time). Further, vulture populations may change during migration periods when more birds move about Costa Rica, or when other food sources draw them from the beaches. Vultures in Costa Rica move to Panama in the winter (GRIN 2013).

*Foraging Methods and Strategies* - Environmental forces provided opportunities by exposing nests from stream bank erosion, tidal erosion, and wind erosion. Social factors provided opportunities because of the presence of other vultures and birds that indicated exposed or open nests, the presence of dogs that provided these opportunities, and the presence of people who exposed nests or scattered rotten eggs or developing embryos following egg harvesting. The presence of other predators provided additional opportunities for piracy, but also resulted in competition for eggs or hatchlings with vultures and other species (especially wood storks, Burger and Gochfeld, 2013, 2014a,b).

Physical forces, such as rain, wind, and tidal erosion provided the vultures with most of their foraging opportunities during the nesting cycle when hatchlings were not emerging. Stream and tidal erosion accounted for half of the total nests (whether they had eggs or

emerging hatchlings) that were destroyed by black vultures. In our study, more nests were preyed upon as a result of stream erosion than tidal erosion, but over the course of the year, tidal erosion may be a stronger driver because it occurs all year, and stream erosion occurs mainly during the heavy rainy season when large volumes of water result in the stream changing course nearly daily (and thus eroding one bank daily). Additional stream erosion occurred during our study when children played at stream bank edges, pushing the sand down to reveal nests, with the eggs falling down to the stream bed.

Figure 8. Vulture foraging opportunities provided by environmental and social factors. This is a model of Black Vulture foraging behavior, with data showing the relationships. Shown are the forces that affect the availability of foraging opportunities, the vulnerable turtle stages, methods of vulture predation, and the frequency of foraging types with the effects on the Olive Ridley sea turtles.

Tidal erosion would likewise vary during the month and the year, depending upon tide height, tidal force, and whether storms increased tide strength. Since females turtles choose where they nest, those nesting farther up the beach can decrease the chance that their nest experiences tidal erosion and decrease the likelihood that their clutch will be disturbed. However, nesting higher on the beach has costs in that hatchlings have farther to go to reach the water (which is likely not a problem for hatchlings emerging under darkness). Nesting later in the *arribada* also decreases the risk of their clutch being dug up by other females.

Most hatchling sea turtles emerge at night, and thus avoid most avian predators; Glen et al. (2006) found that 93% of green turtles (*Chelonia mydas*) emerged at night (Glen et al. 2006). The presence of emerging hatchlings provides the second greatest foraging opportunity because at the height of hatching, many emerged in the early morning after dawn (Figure 9). The number of emergences declined during the morning. During the peak of hatching the early morning hatchers were protected by people on the beach, but after 08:00AM, the beach was largely abandoned, and on hot sunny days the sand heated quickly, reaching  $50^{\circ}$ C, causing thermal stress and death to the late hatchers. Although there is nocturnal predation from mammals, owls, and yellow-crowned night herons (*Nyctassa violacea*), the risk for a hatchling at night is much lower than for those emerging in daylight. Thus, some of the offspring of those females survived to reach the sea. Except for the occasional nest dug up by a dog during the night, there was no evidence of nocturnal mammalian predation.

In other nests, however, the first hatchlings to emerge did so when there was light and most of these nests were detected by vultures, even before hatchlings had moved more than a few cm from the nest. The number of vultures that were coursing over the beach searching for nests was sufficiently high that nests were quickly noticed, vultures descended, and picked up those crawling to the sea or just emerging from the nest. Thus, hatchlings emerging in the early morning are exposed to intense vulture predation, and increasing sand temperatures. At higher temperatures, hatchlings overheat (Moran et al. 1999; Glen et al. 2006), and at Ostional, some died from the high temperatures. Hatchlings crawling to the sea over debris face additional stresses, as hatchlings can become ensnarled, increasing the time to crawl to the sea and exposing them to greater predation (Triessnig et al. 2012). Vultures at Ostional often patrolled debris piles searching for hatchlings caught there, and people seeking to help hatchlings survive, search debris piles as well. On most of the beach, debris was removed before the peak of hatchling, although those emerging in the first two days faced intense black vulture predation.

Further, hatchlings that emerged in the early morning when it was raining all made it to the sea because vultures flew from the beach to roost (often away from the beach) during heavy rains. Since it was the rainy season, on several rainy mornings many hatchlings reached the sea safely. Although predation on hatchlings, particularly where large numbers emerge at once has been noted, predation rates on nests of olive ridleys vary. In India, nest predation was as high as 83% on sporadic (solitary) nests, but it was as low as 2.6% at *arribada* nests in some years (Tripathy and Rajasekhar 2009).

*Competition and Social Parasitism.* – Any specific vulture is not feeding in isolation, but is feeding within a context of many other vultures that are foraging on the beach, as well as other birds, dogs, and humans. The presence of other vultures has both positive and negative effects. Vultures watched other vultures far down the beach, and flew to places where other vultures were feeding, hoping to obtain food (social parasitism). Arriving at a nest where a group of other vultures were already present worked to varying degrees. In general, more vultures feed when more are present, but this is partly a result of two factors: 1) vultures continue to arrive and remain if they are obtaining food, and 2) foraging success differs under different foraging opportunities. For example, at cliff banks, the vertical aspect means that a vulture or two can try to feed at the nest itself, but many more forage on the stream bed where the eggs have fallen to the ground (thus more vultures are successful), When foraging on emerging hatchlings, each vulture that has captured a hatchling has to move away and spend time eating it, allowing others to move in. Social parasitism (searching for other birds that appear to be foraging at some distance away) worked quite well for scavenging on carcasses of adult ridleys washed up on the shore. Such carcasses were large, and they often were broken in many pieces, allowing many vultures to actively feed at once.

Another advantage of foraging with other vultures, although it was less apparent at Ostional, is predator warning (Coulson 2001). If vultures had predators, they would be vulnerable while foraging on the ground. At Ostional, the only threats to foraging vultures were dogs and people that chased them. Thus, the advantages of many vultures feeding on the beach was parasitism (taking eggs or hatchlings exposed by other vultures), social parasitism (location a food source found by other vultures, and flying to that location), and piracy (actually stealing eggs or hatchlings from others). The main disadvantage is competition, and the chance that another vulture will steal your prey.

At Ostional, wood storks provided the most competition because of their larger size and longer bill, allowing them to probe deep in the sand (Coulter et al. 1999; Burger and Gochfeld, 2013) (Figure 10). Whenever wood storks came to a nest located by vultures, they moved in and displaced the vultures. The mean number of vultures able to eat, and the percent of vultures feeding, decreased significantly at the most common foraging situations (stream bank erosion, tidal erosion, hatchlings emerging, Figure 6). Further, because storks have longer and thinner bills, they were able to probe down well below the sand surface to extract eggs or hatchlings that were unavailable to the vultures. In the case of nests exposed by tides or stream erosion, but with hatchlings ready to emerge from the nest in the next night or two, the storks were obtaining viable offspring. There were far fewer storks on the beach (usual flock of about 30), and they remained in areas far from the village of Ostional, Their effect on foraging vultures, however, was far greater than their numbers suggest.

At Ostional, the behavior of humans also greatly influenced vulture foraging. During the peak of hatchling emergence (6 days, from 05:00AM to 07:30AM), the beach was extensively monitored by ADIO members that scared off all the vultures. This allowed foraging by vultures only before 05:00AM (on clear days a few vultures arrived before that) and after 07:30AM (when some hatchlings continued to emerge, particularly on rainy days. Conversely, we also observed that vultures and grackles were present in beach segments

where we were studying hatchling behavior. Vultures braved our presence to snatch hatchlings we were watching, even within 5 m, and it appeared they quickly learned to associate our presence with food. Even during the morning period when vultures were being chased by ADIO members, the vultures appeared disproportionately in our segment, to snatch hatchlings either from the nest or wave front. Hatchlings encountering their first wave were often driven tumbling back up the sand, where they are readily captured by predators.

Figure 10. Wood storks often forage on eggs in nests that are exposed by the rising tides when females dig nests that are too close to the water's edge.

Finally, the foraging observations and interactions described in this paper apply to the time we made observations – that is, during the rainy season, the period of a large *arribada*. At other times of the year, the relative important of different forces (erosion, social factors) and of different types of foraging opportunities would differ. However, the foraging behavior and competition would not, and the vultures would make use of whatever foraging opportunities were available. Moreover, avian predation pressure will be influenced by the breeding season of the relevant species.

*Effect of Vulture Foraging on Ridley Sea Turtle Success* - The overall effect of black vultures foraging on olive ridley sea turtles at Ostional is a function of: 1) total number of turtles nesting and the availability of nests, 2) the strength of the different physical drivers (wind, rain, and tides), 3) total number of vultures and other predators present and their foraging interactions, 4) the presence of other predators (wood storks, dogs, other birds or mammals), and 5) human intervention. All of these factors vary over the year, many vary over a given month, and still others vary over the day. The number of nests and emerging hatchlings varies by month, the rains and tides vary monthly and daily, and the number of predators varies monthly and daily.

Overall, vultures foraging at Ostional do so within a context of environmental and social forces making eggs, developing embryos and emerging hatchlings available on several beach locations . This allows vultures to engage in several different foraging methods, scavenging

on eggs, developing embryos, and adult carcasses, parastizing or pirating from other vulture (or other birds), and actively hunting for emerging hatchlings. The relative number of vultures present in the different situation, the number of vultures able to obtain food, and the number of turtle nests destroyed varied among the types of foraging opportunities (Figure 8).

The number of nesting ridleys at Ostional varies from over 3,000 to over 450,000 nesting females in a single *arribada*. Thus, the number of nesting ridleys is gigantic compared to the number of vultures foraging on the beach. This is thus a classic case of predator swamping (Ims 1990, Cornelius et al. 2007; Colbert et al. 2010), whereby so many nests and hatchlings are present, and hatchlings emerge synchronously over a few days, that predators can only eat so many. Further, vultures are only able to feed at nests that are exposed by other forces, and on hatchlings that are emerging or crawling to the sea in daylight. Thus, their main effect is to "clean up" the beach of all the exposed eggs and hatchlings exposed by other forces, or that have died while crawling to the sea. This is a positive benefit as it reduces the chances of increased bacterial and fungal diseases (Trullas and Paladino 2007), thereby decreasing density-dependent mortality (Cornelius et al., 2007; Valverde et al. 2012). Although egg loss and hatching failure are no doubt major constraints for the turtle population, vultures do not contribute to this loss, but "clean up" exposed eggs and sub-mature hatchlings. Vultures do have an impact on mature and viable hatchlings, but only during daylight hours.

Despite all the foraging opportunities, the only viable offspring the vultures take are emerging hatchlings. All the others are eggs and developing embryos (albeit some nearly ready to emerge) that are not viable because they are exposed to the elements (heat, tides) by other forces, and would not develop further. Except on rainy mornings, the vultures (and other birds were able to take almost all of the hatchlings that emerged because so many vultures courses over the beach searching for hatchlings. However, at Ostional, members of ADIO patrolled the beaches and scared away all vultures during the peak egg-laying period. Thus, a high percentage of the hatchlings that emerged in the early morning (and few that emerged much after that time because of the high temperatures) survived. It was only those emerging in the days before and after peak hatching, and after about 07:30AM that were vulnerable to vulture predation.

#### **ACKNOWLEDGMENTS**

We thank the following people for provision of timing data and logistical support while in Costa Rica: Laura Brenes, Pablo Baltodono (Director of the *Area de Conservacion Tempisque*), Celnan Molina (ADIO), Ojilbeith Rojas (University of Costa Rica), and Claire Wallis. We thank the Minister (El Ministerio del Ambiente, Energia Y Telecommunicaciones) in Costa Rica for permits to work at Ostional. We also thank C. Jeitner and T. Pittfield for logistical and analytical help throughout the project, and P. and C. Williams for taking care of our house and Tiko during hurricane Sandy. Partial funding for this study was from Rutgers University, and the Tiko Fund.

## **ABSTRACT**

Incidental catch is the major threat to the survival of loggerhead turtles (*Caretta caretta*) in the Mediterranean. In this basin more than 100,000 turtles are estimated to be caught annually due to fishing practices. The mortality due to fishing capture (10-50% depending on fishing gear) can be considered as the main reason for sea turtle decline in this basin. Nevertheless, present knowledge about the interaction of sea turtles with fishing gears and the possible mitigation measures are still insufficiently studied. Successful strategies for sea turtles conservation mainly involve the knowledge of species biology and ecology, the identification of possible areas of interaction between turtles and fishing activities and finally the introduction of mitigation measures, such as gear modification through Bycatch Reducer Devices (BRDs). In this chapter two options adopted in the Adriatic Sea (central Mediterranean Sea) for sea turtle conservation have been described.

The first is a theoretical approach based on developing models that can predict the identification of areas and periods at high risk of trawl-turtle interaction.

Two set of data represented by telemetry data from tagged sea turtles and bottom trawl track from vessel monitoring systems (VMSs) were combined to provide an interaction index enabling prediction of potential trawl-turtle interaction hotspots and periods. The risk-analysis methodology here developed provides key information to design and implement management strategies, and it might have a worldwide application, considering that Vessel Monitoring System is actually in force in several countries.

Once the areas and periods of possible trawl-turtle interaction have been identified, the effect of a flexible Turtle Excluder Device (TED) on the catching efficiency and performance of a commercial bottom trawl was tested in a gear comparison study in a Mediterranean coastal multispecies bottom trawl fishery.

Considering fishermen reticence to change the gear traditionally used, determining the optimal gear configuration to minimise the loss of commercial catch and avoid turtle captures, was the main issue of the study. Experimental sea cruises showed that the device affected neither technical performances of the gear (horizontal and vertical net opening and door spread) nor fuel consumption during fishing activities. Sorting of the catch into commercial, discard and debris (e.g. rocks, timber, marine litter) fractions demonstrated that TED use did not affect catch efficiency, since the catch of the major commercial species did not exhibit appreciable differences, whereas debris was strongly reduced when the TED was in use. Underwater video camera recordings documented that fish caught in the net swam through the grid and easily reached the codend, missing the TED escape opening. Easy storage and improved catch retention compared with previous devices tested in this area make the flexible TED a practical and valuable solution to reduce turtle bycatch in the coastal Mediterranean demersal fisheries. In conclusion, the synergy of the two approaches described, can be considered as a reliable mitigation strategy in Mediterranean sea turtle conservation.

**Keywords**: loggerhead turtle, sea turtle bycatch, trawl-turtle interaction, Interaction Index (I.I.), mitigation measures, flexible Turtle Excluder Device (TED), Mediterranean Sea

### **INTRODUCTION**

The loggerhead sea turtle (*Caretta caretta*) is the most abundant turtle species in the Mediterranean Sea. Environmental characteristics (e.g. bathymetry, preys availability, sea water temperature, etc.) determine the distribution and abundance of *C. caretta* in this basin (Casale et al. 2012). Three main ecological phases characterize the life of this turtle: the pelagic phase, when loggerheads feed on pelagic preys; the demersal phase, when they swim close to the bottom to eat benthic species; and finally an intermediate neritic phase, when loggerheads shift from pelagic-oceanic to benthic-neritic foraging habitats (Tomas et al. 2001). Loggerhead turtles exhibit high fidelity to migratory routes, foraging areas and wintering sites. Nesting areas are concentrated especially on the eastern basin (Cyprus, Egypt, Greece, Israel, Italy, Lebanon, Libya, Syria, Turkey and Tunisia) and more than 3000 nests per season are estimated (Margaritoulis et al. 2003).

Nevertheless, recent studies suggest a decline over decadal scales of Mediterranean turtle populations. The main identified threats to sea turtles are degradation of reproductive habitats (Casale and Margaritoulis 2010), intentional killing (Tomás et al. 2008; Casale et al. 2010; Casale 2011), collision with boats, and incidental catch due to professional fishing (Casale and Margaritoulis 2010; Casale 2008, 2011; Casale et al. 2015; Lucchetti and Sala 2010; Lucchetti et al. 2016). Impact of fishing activities is of paramount importance among anthropogenic mortality factors, since the Mediterranean fleets share the same routes of turtles. In particular, fishing fleets of 21 countries regularly fish in this basin and an undefined number of small boats are active in non-EU countries. This results in more than 100,000 sea turtles incidentally caught each year by a variety of fishing gears: 70,000 by longlines, 40,000 by bottom trawls, and 23,000 by bottom-set nets (Casale 2008, 2011; Lucchetti and Sala 2010) - with a mortality rate from 10 to 50% depending on gear. Thus, different types of fishing gears (towed or passive, on the bottom or in the water column) produce different captures and mortality rates (Gerosa and Casale 1999) and affect different ecological phases of turtle life-cycle. Moreover, bycatch figures are probably underestimated, since catch data are rarely reported by fishermen and information from North African countries is often poor.

The northern Adriatic Sea, the coastal waters of Tunisia and Libya, the areas south of Turkey and the Mediterranean coast of Egypt, where the continental shelf is large and turtles in the demersal phase are commonly found also in winter, are considered as the areas most impacted by bottom trawling (Casale et al. 2012). The northern Adriatic Sea (FAO Geographical Sub-Area 17, GSA 17; Figure 1), with its shallow waters and rich benthic communities, is a major feeding habitat for turtles in the demersal stage, especially for the populations nesting in Greece (Lazar et al. 2004). On the other side, its shallow depth and flat seabed are also considered an ideal fishing ground for bottom-towed gears. More than 1000 bottom trawlers, mainly from Italy and Croatia and to a lesser extent from Slovenia, Montenegro and Albania, usually operate in this area (Lucchetti and Sala 2012). The high density of bottom trawlers and sea turtles suggests that more than 10,000 annual capture events may take place in this area (Casale et al. 2004; Lazar et al. 2004; Lucchetti and Sala 2010). Mortality due to trawling is mainly caused by forced apnoea during towing activity, making towing time a critical factor affecting turtle mortality rates (Henwood and Stuntz 1987).

Present knowledge about the current level of threat affecting the Mediterranean loggerhead populations, its interaction with fishing activities and the use of possible mitigation measures are rispectively unclear and insufficiently studied. Common successful strategies for sea turtles conservation mainly involve the knowledge of species biology and ecology, the identification of possible areas of interaction between turtles and fishing activities and finally the introduction of mitigation measures, such as gear modification through Bycatch Reducer Devices (BRDs). Thanks to reseach activities carried out in TartaLife project (LIFE12 NAT/IT/000937) for sea turtle conservation in Mediterranean, finanched through the LIFE instrument of the European Community, two strategies adopted in the Adriatic Sea (Central Mediterranean Sea) for the reduction of sea turtle bycatch have been described in this chapter. The first is a theoretical approach based on developing models that can predict the identification of areas and periods at high risk of trawl-turtle interaction. In this study two set of data were analysed and combined. One dataset is represented by telemetry data; seven turtles, incidentally caught and subsequently rehabilitated in special rescue centres, were implanted satellite transmitters before their release. The other dataset results from Satellite-based Vessel Monitoring Systems (VMSs), worldwide used by management authorities as a surveillance and enforcement tool (Lee et al. 2010; Russo et al. 2011a; 2013; 2014). In European waters, all the fishing vessels with a Length Overall (LOA)  $\geq$  12 meter has to be equipped with VMSs, as requested by the European Regulation (European Commission 2009). VMS system enables to collect spatial information about fishing activity without any interference from fishermen notifications (Bertrand et al. 2007; Deng et al. 2005). Thanks to VMS data, it was possible to characterize the behaviour of Italian bottom trawl fleet, accounting for about 50% of trawlers exploiting this area. Even though other fishing activities also take place in the area of study, they do not seem to involve

a high risk of turtle bycatch (Lucchetti and Sala 2010). Telemetry data and bottom trawl track from VMSs were combined to provide an interaction index (I.I.) enabling prediction of potential trawl-turtle interaction hotspots and periods.

Once the areas and periods of possible trawl-turtle interaction have been identified, the effect of a new prototype of Turtle Excluder Device (TED) on the catching efficiency and performance of a commercial bottom trawl was tested in a gear comparison study. A TED is a grid-like device that diverts large objects (including turtles) towards an exit positioned before the codend (Mitchell et a1. 1995; Epperly 2003), with the aim of reducing turtle submergence and mortality. Some authors report that the TEDs tested until now are probably not a realistic solution for reducing turtle bycatch in the Mediterranean because they are designed for the shrimp trawl fishery and would exclude larger commercial fish (Laurent and Lescure 1994; Laurent et al. 1996; Casale et a1. 2004). However, Atabey and Taskavak (2001) and Sala et al. 2011 found promising results adopting the typical aluminium *Supershooter* grid since TEDs reduced anthropogenic debris and discards, consequently, sorting operations on board. However, the main trouble derived from the rigid structure of the TED, which often leaded to breaking the TED and the net too. In TartaLife project a new protype of TED, flexible, more lightweight, manageable and resistant, called FLEXGRID, has been experimented in coastal multispecies bottom trawl fishery. Thuis new TED was sufficiently flexible for safe winding around a standard net winch and stiff enough to maintain a rigid configuration during towing. Considering fishermen reticence to change the gear traditionally used, determining the optimal gear configuration to minimise the loss of commercial catch and avoid turtle captures, was the main issue of the study.

### **METHODS**

#### **Study Area**

The study area was represented by Central - Northern Adriatic Sea (FAO GSA 17; Figure 1), whose shallow waters (< 100 m) and rich benthic communities are held to provide a major feeding habitat for adult loggerhead turtles.

Figure 1. Mediterranean GSAs: in grey, Central - Northern Adriatic Sea (FAO GSA 17) which represented the study area.

Source: Adriatic Sea Turtles Database (2015).

Figure 2. Data on turtles stranded-caught-rescued in the Adriatic Sea in 2013.

Annual turtle bycatch in this area, which mainly involves Italian and Croatian bottom trawlers, has been estimated at more than 6,500 specimens (Casale et al. 2004; Lazar et Tvrtkovic 1995). However, data regarding only stranded-caught-rescued individuals in the Adriatic (Figure 2; Adriatic Sea Turtle Database 2015) reflect a high abundance of turtles in the area, suggesting that bycatch figures may actually be higher.

#### **Assessment of Turtle-Trawl Interaction**

#### *Telemetry Data*

Seven loggerhead turtles, incidentally caught by bottom trawl in the study area, were tagged with satellite transmitters and released, after rehabilitation in special rescue centres. Telemetry data provided information of the turtle positions and movements from 2006 to 2012. In detail, geographical (latitude and longitude based on the World Geodetic System [WGS-84]) and time (day and hour) coordinates, and location classes (LCs) representing values grading signal accuracy (Royer and Lutcavage 2008; Casale et al. 2012) were recorded for each individual.

The dataset was analysed by year and season. Seasonal positions were translated into trajectories assuming that movement takes place along the direction that joins two consecutive points. A cell grid of the study area was constructed. To increase space use information, either cells with evidence of turtle presence and those intersected by trajectories were considered as "exploited" cells. Space use intensity was thus assessed (by season) and stratified in space using 5x5 min grid cells by counting the number of detections in each cell. Presence (in percentage) of the turtles monitored by satellite tags in each sub-area for each season. Finally, "presences" were ranked and classified according to a score from one to three: 1 if presence in percentage ranged between 0 and 0.33, 2 if varied between 0.33 and 0.66, 3 between 0.66 and 1.00.

#### *VMS Data*

The satellite-based VMS information was available for the whole northern and central Adriatic (FAO GSA 17), but only data for the western (Italian) side were analysed, to prevent that the lack of VMS data for the Croatian trawlers would affect the Interaction Index (I.I.) reliability. The VMS dataset, obtained from the Italian Ministry for Agricultural, Food and Forestry Policies, provided location (latitude and longitude in the WGS-84), course and speed data (km h−1) of Italian commercial fishing vessels at 2 h intervals.

Fishing data were analysed using R-platform VMSbase freeware [\(www.vmsbase.org\)](http://www.vmsbase.org/). An exhaustive description of VMS data collection and processing is reported in Russo et al. 2011b; 2013; 2014. A fully processed database for each year was thus obtained and the fishing effort was estimated by computing the number of "fishing" points - each representing 10 min of fishing - in each cell at the same spatial and temporal resolution of that used for turtle movement. For each season (*t*) the fishing effort detected in a cell was computed as the mean number of hours estimated over the whole period of time (*T*) and referred to the cell surface:

$$
E_{i,t} = \frac{\left[\frac{\sum_{i=1}^{T} E_{i,t}}{T}\right]}{A_i}
$$

where  $E_{i,t}$  is the effort in cell *i* in season *t*, and *T* is the total number of years. Thus  $\left[\frac{\sum_{i=1}^{T} E_{i,t}}{\tau}\right]$  is the mean effort detected in cell *i* in all years  $(T)$ , and  $A_i$  is the area of cell *i*. Finally, the percent seasonal effort was calculated for each cell.

#### *Interaction Index*

Satellite data from the tagged turtles were combined with the VMS data of bottom trawlers. The model developed combined spatial and temporal information on the intensity of space use by turtles and on the fishing effort of the Italian trawler fleet in each season. The model was applied to predict the areas where trawl-turtle interactions are more frequent and the risk of bycatch was expressed as an I.I. The data of turtle density on a seasonal base (number of detections per cell) were converted into relative interaction probabilities by calculating the likelihood that a turtle will occupy i-th cell relative to all cells  $n$ , using equations modified from Roe *et al.* (2014):

P (turtles)<sub>i,t</sub> = 
$$
x_{i,t}/n
$$
 ( $\sum_{i}^{n} x_{i,t}$ )

where,  $x_{i,t}$  is turtle density in cell *i* in season *t*, and *n* is the total number of cells in the grid.

Similarly, the probability of the fishing effort being carried out in grid cell *i* in *t*-th season relative to all cells *n* is calculated as.

$$
P\left(effort\right)_{i,t} = E_{i,t}/n\left(\sum_{i}^{n}E_{i,t}\right)
$$

Finally, the I.I. in cell *i* during the *t*-th season relative to all cells *n* was computed using the equation:

$$
P_{(interaction)_{i,t}} = P_{(turtle)_{i,t}} P_{(effort)_{i,t}} / (\sum P_{(turtle)_{t}} P_{(effort)_{t}})
$$

where  $P_{(turtle)_r}$  is the sum of detections in the *t*-th season and  $P_{(effort)_r}$  is the total amount of effort in the *t*-th season.

#### **Flexible Turtle Excluder Device (TED)**

In parallel with the prediction of trawl-turtle interaction hot-spots, a study on the performance and catching efficiency of a flexible TED (FLEXGRID) was carried out. This was the first study in the Mediterranean comparing a typical bottom trawl and a trawl equipped with a flexible TED. The choice of this new prototype has been driven by the fact that the models of TEDs tested previously (Sala et al. 2011) have shown some problems relating to the hauling operation logistics and resistance of the aluminium TED.

#### *Trawl Gear and TED Specifications*

The gear comparison study was carried out comparing the performance and cacth efficiency of a traditional bottom trawl gear with the same gear rigged with the FLEXGRID. Bottom trawl trials were conducted aboard the Italian Research Vessel "G. Dallaporta" (LOA, 35.30 m; gross tonnage, 285 GT; engine power, 810 kW).

The gear was a typical Italian commercial trawl commonly used in the central Adriatic, made entirely of knotless polyamide (PA) netting (Figure 3A). A 40 mm square mesh codend complying with European Council Regulation 1967/2006 was used in all hauls. Rigging components and trawling speed were those of typical central Adriatic trawl fisheries.

FLEXGRID was made of flexible plastic material and was able to keep a stiff configuration during trawling without hampering hauling operations. The grid was designed according to the technical specifications suggested by Mitchell et al., 1995: height 1130 mm; width 845 mm; circumference 3110 mm; bar diameter 20 mm; space between bars 96 mm (Figure 3B). The grid was mounted on a tubular netting section (Figure 3C) in front of the codend.

Figure 3. A) Detail of TED functioning and positioning in the trawl. B) Design of TED flexible TED used in the study. Details and size (in mm); C) Technical drawing of TED rigging (lateral view). GF, Guiding Funnel. AB and AN, types of net cuttings (figures indicate number of meshes). The average grid angle recorded during sampling is also reported.

The escape opening was cut on the upper portion of the net, just before the TED and it was covered by a netting panel functioning as an escape hatch both for larger objects (i.e. marine debris) and turtles. In addition, an accelerator funnel installed before the TED, drove the fish down and away from the exit panel and through the TED bars, towards the codend.

#### *Study of Gear and TED Performance*

Trawl performance was expressed in horizontal and vertical net opening [HNO and VNO, respectively] and door spread [DS]). To assess the grid's effects on net behaviour the SIMRAD PI50 system (Norway), represented by a PC laptop, hydrophone and acoustic sensors, has been used. To assess grid influence on the net drag and fuel consumption towing force has been measured by 2 TEKKAL (Germany) electronic load cells. Post processing data methodology is reported in detail in Prat et al., 2008 and Sala and Lucchetti, 2011.

The TED angle is a key factor influencing TED efficiency and preventing loss of commercial species during the tow (Mitchell et al., 1995; Eayrs, 2007). An optimal angle is estimated between 40° and 55°; in this regard, the TED angle was continuously monitored by an angle sensor (Star-Oddi DST pitch and roll, Iceland) that collected pitch and roll angle data.

Underwater cameras GoPro *Mod. Black Hero 3* (US) were additionally used to monitor grid position during the haul, grid behaviour with the commercial catch, fish reaction to the TED and fish behaviour inside the net, and grid effectiveness in ejecting debris.

#### *Catch Analysis*

The gear comparison study was performed by adopting alternate haul method.

Basically, the net rigged with the TED was the experimental gear and the traditional net was used as "control". Since experimental hauls were carried in close succession over limited time periods and the fish population in this area was not expected to vary considerably between hauls, no attached netting bag to the escape opening (to monitor the catch deflected by TED, see Sala et al. 2011) was used. This strategy was chosen to not influence TED behaviour during towing.

Catch was sorted into commercial, discard, and debris (i.e. rocks, timber and marine litter) fractions. Commercial and discard species were classified to the lowest possible taxonomic level, and their biomass was standardized as mean catch per hour ( $g \times h^{-1}$ ). Because the mean of the original (non-transformed) data could be oversensitive to extreme values, and confidence intervals were large, catch rates were transformed using a natural logarithm (Cochran 1977).

One way analysis of variance (ANOVA) was applied to highlight significant differences among categories (commercial, discard, debris and total catch). In case of significant differences, a multivariate multiple permutations test (SIMPER Similarity Percentage analysis, described by Clarke 1993) was used to determine which species were responsible for the differences between the two nets. The analysis was applied to the biomass data and performed using PRIMER (Plymouth Routines in Multivariate Ecological Research) software.

At the end of each haul, the size frequency distributions of the main commercial species were calculated to the nearest 0.5 cm: total length (TL) for fish; mantle length (ML) for cephalopods; and carapace length (CL) for crustaceans.

Random subsamples were taken in case of abundant catches. The length frequency distributions of the main commercial species caught with and without the TED were compared by two samples Kolmogorov-Smirnov test (Sokal and Rohlf 1995), to evidence any possible TED influence on the sizes of fish caught.

## **RESULTS**

#### **Identification of Turtle-Trawl Interaction**

Data obtained from satellite tracking were clearly in line with the data available from literature (Lazar et al. 2003; Lazar and Tvrtkovic 1995; 2003; Casale et al. 2004; Casale and Margaritoulis 2010; Vallini et al. 2006), suggesting that the monitored turtles were representative of the Adriatic population.

Telemetry data documented a broad variety of movements, but a seasonal pattern could however be recognised (Figure 4). Turtles seem to winter in the central Adriatic Sea and mainly along the eastern coast, in spring they move from the south Adriatic towards the Po delta, in summer they concentrate to the north of this basin and begin to migrate southward, and in autumn they are scattered throughout the Adriatic with a concentration in the coastal area south of the River Po delta (Figure 4).

Bottom trawl activities were roughly homogenous throughout the year, operating both inshore and offshore (Figure 5). Fishing effort varied according to the seasonality of the main target species. According to VMS data, a high concentration of fishing activities was observed inshore (within 10 miles from the coast) in autumn (Figure 5), after the seasonal fishing ban (i.e. August-September).

The I.I. resulting from the spatio-temporal combination of the two set of data varied within the year depending on seasons and fishing areas (Figure 6). In summer and, more clearly in winter, the I.I. showed a moderate-to-high bycatch risk in some areas, mainly in fishing grounds south of the River Po delta, and a low bycatch risk in the northernmost Adriatic areas. In spring, moderate risk of bycatch was predicted only for fishing grounds in front of the River Po delta. In autumn, a moderate bycatch risk was estimated in the fishing grounds south of the River Po delta; in this case the I.I. demonstrated a very broad area of potential impact, considering the high concentration of vessels inshore. Mean monthly data on stranded turtles, collected between 2003 and 2013 in the coastal area south of the River Po delta (Adriatic Sea Turtle Database 2015), confirmed a high risk of fishery-turtle interactions with a peak in autumn-early winter.

The variability of the I.I. can be explained by taking into account the seasonal migration routes of both turtles and main fisheries target species.

Figure 4. Index of intensity predicting the probability that loggerhead turtles will be swimming in 5x5 min grid cells (central and northern Adriatic). 1, 2 and 3 indicate the intensity of detections in each cell (sum of detections).

In spring the risk of trawling-turtle interaction in the north Adriatic is high due to the nutrient inputs from the River Po (the primary source of freshwater and nutrients in this basin; Degobbis and Gilmartin 1990) and their effect in terms of increased phytoplankton concentrations (Böhm et al. 2003; Spillman 2007) which result in ideal foraging conditions for turtles due to prey abundance.

Considering that, the main large-scale surface circulation pattern in the Adriatic is cyclonic (Orlic et al. 1992; Artegiani et al. 1997; Poulain 2001), in spring and summer nutrients follow counter-clockwise currents and are more densely concentrated in coastal areas south of the River Po delta, which is a nursery area for most of commercial species targeted by trawlers. In late summer-autumn most commercial species migrate from inshore growing areas to offshore recruitment areas.

Concurrently, in this period, in Italy a one-month fishing ban is established. When fishing resumes, target species have returned to the coastal areas, resulting in a high concentration inshore of fishing effort. A high density of both turtles and trawlers thus occurs in this area in autumn, explaining the high I.I. and risk of bycatch.

Figure 6. Relative interaction indices of loggerhead turtles and bottom trawlers in 5x5 min cells (central and northern Adriatic). Values derived from the interaction index equation represent the relative bycatch risk for each season and grid cell combination.

This is also confirmed by the records concerning stranded turtles in this area. In winter the main driving factor affecting sea turtle movements is due to sea temperature. The warmer Levantine sea current from the east Mediterranean contribute to increase water temperature in the central and east Adriatic (12-14°C; Russo et al. 2012), offering a warmer wintering habitat compared to the rest of the central-northern Adriatic, where cold winter winds (Bora) sometimes reduce the sea surface temperature to 5-6°C.

This is the reason for the high occurrence of turtles detected by satellite in Croatia in winter. Even though the lack of VMS data for Croatian vessels did not allow calculation of the I.I. for the east side of the northern-central Adriatic, the likelihood of bycatch might be nonetheless high, especially in the northern Adriatic. Neverthless, this area is less accessible to trawling due to huge number of small islands, and other gears are used in coastal waters (i.e. passive nets and longlines). A high risk of capture also applies to the turtles remaining in the central part of the basin in winter, due to the intense fishing effort, as demonstrated by the high number of turtle stranded in the central Adriatic-west coast in this period.

#### **Flexible Turtle Excluder Device (TED) Performance**

During sea trials 25 hauls were performed with TED and 30 with traditional trawl. The main results of the gear comparison study on gear performance and catch efficiency are reported in [Table 1.](#page-830-0)

#### *Gear Behaviour*

The technical parameter of the two gears monitored did not show any statistical difference [\(Table 1\)](#page-830-0) confirming that the TED did not affect bottom trawl behaviour.

In detail, the mean values of the geometric parameters monitored with the acoustic sensors were for traditional gear and TED equipped gear rispectively: HNO =  $15.1 \pm 0.4$  m and  $15.4 \pm 0.3$  m, HVO =  $1.2 \pm 0.1$  m and  $1.1 \pm 0.1$  m, DS =  $56.6 \pm 1.6$  m and  $58.8 \pm 1.2$  m, and TF = 3009  $\pm$  56.7 kgF and 3070  $\pm$  47.2 kgF. The mean TED angle recorded during towing was appreciable  $(46.5^{\circ} \pm 1.1)$  and in line with Mitchell et al., 1995 guidelines.

Moreover, the flexible TED did not affect routine onboard procedures or the time required for shooting, confirming its easy use and manageability.

## <span id="page-830-0"></span>**Table 1. Standardized catch (kg∙h-1) and gear performance measured in each haul: TED, net equipped with a TED; Tradit, net in a traditional configuration (without TED). Total catch and catch are divided by categories: COM, Commercial; DIS, Discard; DEB, Debris. Gear technical parameters: HNO, Horizontal Net Opening; VNO, Vertical Net Opening; DS, Door Spread; TF, Towing Force**

#### *Catch Efficiency*

Commercial catch accounted on average for 42% and 55% of total weight for traditional gear and TED equipped gear respectively (Figure 7). Furthermore, debris was reduced by TED from 29% to 13%, whereas the discard fraction showed similar values (29% without TED and 32% with).

Analysis of dissimilarity [\(Table 2\)](#page-831-0) showed that most of the catch difference between the two nets was due to horse mackerel (*Trachurus spp*), a gregarious pelagic species whose presence in the fishing grounds varied randomly from one haul to another.

Figure 7. Percentage of the three categories found in the trawl with and without the TED: a) COM, Commercial; DIS, Discard; DEB, Debris; TED, trawl equipped with TED; Tradit, trawl without TED. b) The scenario obtained after exclusion of Trachurus spp from the analysis is also shown.

<span id="page-831-0"></span>

Average dissimilarity = 55.37

Its removal from the data analysis showed a similar catching efficiency for the two configurations (Figure 7), respectively 43% and 39% with and without the TED (ca. 18 kg/h in either net), and that only debris was significantly reduced (from 31% to 16%;  $p = 0.015$ ).

Figure 8. Size frequency distributions of the major commercial species and total length (fish); mantle length (cephalopods); and carapace length (crustaceans). Dotted lines indicate the MCRS (Minimum Conservation Reference Sizes). Spec, specimens. K-S: Kolmogorov-Smirnov test.

Figure 9. Underwater images of fish behaviour in the TED equipped net: a) fish swam upstream (towards the mouth of the net) during towing, whereas at the end of the haul b), when the vessel speed reduced, they turned towards the codend, swam through the TED bars, and reached the codend, missing the escape opening.

The size frequency distributions of the major commercial species caught by the two nets (Figure 8) showed a significant difference (Kolmogorov-Smirnov test) only for horse mackerel and common sole (*Solea solea*), while the modal class was similar for all species.

The trawl rigged with the TED generally caught commercial species with a greater mean length excepting the cuttlefish (*S. officinalis*). The capture of European hake (*M. merluccius*) and common sole specimens below the Minimum Conservation Reference Sizes (MCRS) were common in both nets. This is manly due to to the low selectivity of Mediterranean trawling.

Finally, the underwater video-recordings allowed to understand the fish behaviour in the TED equipped net. In particular, fish swam upstream (towards the mouth of the net) during towing (Figure 9A), whereas at the end of the haul, when the vessel speed reduced, they turned towards the codend, swam through the TED bars, and reached the codend, missing the escape opening (Figure 9B). Moreover, it was possibile to demonstrate that a large amount of marine litter was deflected by the grid (Figure 10), thus enhancing the quality of fish caught in the codend.

Figure 10. Underwater images of marine litter (in this case a plastic can): a) capture and b) following ejection through the escape opening (TED equipped net).

Video-recordings also enabled to immortalize the capture of three individuals of *C. caretta* (Figure 11): two turtles were released from the net with TED, while one turtle was found in the codend of the traditional gear.

However, the low number of encountered turtles prevented any statistical evaluation of the TED efficacy, but the preliminary results are promising. The exclusion of considerable amounts of marine litter strongly suggests that the flexible TED can be equally effective with turtles, which moreover can actively swim out of the net.

Figure 11. *C. caretta* caught during trawl by TED equipped net. The turtle was successively ejected through the escape opening.

### **CONCLUSION**

According to telemetry data, the seven *C. caretta* individuals resided and spent the whole year in the Adriatic. This result, which is supported by the increased number of turtles stranded in the Adriatic in the last few years, is probably due to the higher sea temperature. A broad variety of movements have been recorded during the year demonstrating seasonal patterns (Casale et al. 2012; Lucchetti et al. 2016).

The analysis of trawl-turtle interactions in the Northern Adriatic (FAO GSA 17) presented herein allowed identification of the areas at highest potential risk of sea turtle bycatch in each season. Even though satellite data were available for seven turtles and detailed VMS data on trawler activity were available only for Italian trawlers, the methodological approach can be further tested in other areas and integrated with new data. Recently, Slovenia and Croatia have also joined the EU and will be required to monitor their vessels by VMS. The additional data will hopefully contribute to draw a more exhaustive picture of turtle movement and distribution patterns in the Adriatic. The present pilot study can be considered as a risk-analysis approach directed at identifying the areas and times of

possible trawl-turtle interactions. By identifying the areas at highest risk of turtle bycatch, the I.I. has the potential to provide key information to design and implement mitigation strategies. The I.I. enabled to predict a high risk of trawl-turtle interaction in coastal areas. In this regard, a new prototype of Bycatch Reduction Device was tested to deal with this problem. Experimental sea cruises showed effective improvements by using the new flexible grid, compared with TEDs developed in previous studies (Lucchetti et al. 2008; Sala et al. 2011). FLEXGRID was able to maintain a rigid configuration during towing and was sufficiently flexible for safe winding around a standard net winch. Therefore, it did not require changes to onboard procedures and did not waste fishermen's time during hauling. Moreover, this device affected neither technical performances of the gear (horizontal and vertical net opening and door spread) nor fuel consumption during fishing activities. Sorting of the catch into commercial, discard and debris (e.g. rocks, timber, marine litter) fractions demonstrated that TED use did not affect catch efficiency, since the catch of the major commercial species did not exhibit appreciable differences, whereas debris was strongly reduced when the TED was in use. Underwater video camera recordings documented that fish caught in the net swam through the grid and easily reached the codend, missing the TED escape opening. Easy storage and improved catch retention compared with previous devices tested in this area make the flexible TED a practical and valuable solution to reduce turtle bycatch in the coastal Mediterranean demersal fisheries. In conclusion, the synergy of the two approaches herein described, can be considered as a reliable mitigation strategy in Mediterranean sea turtle conservation. More in general, identification of bycatch hotspots, coupeld with BRDs implementation and spatio-temporal closure of some areas may contribute to a more effective management of fisheries and to the conservation of endangered species at a global scale.

#### **ACKNOWLEDGMENTS**

This study was conducted with the contribution of the LIFE financial instrument of the European Community, project TartaLife - Reduction of sea turtle mortality in professional fishing (LIFE12 NAT/IT/000937). It does not necessarily reflect the European Commission's views and in no way anticipates future policy. This support is gratefully acknowledged. We are indebted to CNR-ISMAR, Ancona personnel, and to the crew of R/V Dallaporta for their huge effort in the fieldwork.

## **ABSTRACT**

Spatial-temporal distribution of sea turtle nests is a main factor for hatching success. Beaches with good access to the sea, fine sands, adequate humidity and temperature are indicators to carry out oviposition. Many nesting beaches have been modified mainly by human activities and high impact natural phenomena such as hurricanes, causing many sites to show unfavorable conditions for egg laying during the nesting season. This study was performed in Tuxpan, Veracruz, during 2010 and 2011 nesting seasons. This site was chosen because it is one of the few beaches in the State where two sea turtle species nest: Kemp's Ridley Turtles (*Lepidochelys kempii*) and Green Sea Turtles (*Chelonia mydas*). The aim was to determine spatial-temporal conditions for the nesting of the two sea turtle species. We determined the months and sites of highest nesting, monthly number of eggs and distribution of nests in the beach area. The results showed spatial-temporal differences in nesting. There were more Kemp's Ridley Sea Turtle nests on the northern and center portions of the beach, and more Green sea turtle nests in center and southern areas of the beach. Kemp's Ridley Sea Turtle nesting season occurs from April through July, while Green Sea Turtle nesting occurs from May through August. The peak number

<sup>\*</sup> Corresponding Author's Emails: jmmavil@gmail.com; jormorales@uv.mx; Fax: (228) 8418919.

of Kemp's Ridley Turtle nests was in June, and the Green Turtle peak was in the month of July. Both species nest mainly in the zone of the beach that is the nearest place to the vegetation or even inside of it. It is essential to perform long term monitoring of sea turtle nesting populations on center and northern beaches of the Veracruz State, with the purpose of obtaining more information in a regional context.

**Keywords:** Chelonian, sea turtles, nesting, distribution, abundance, Kemp's Ridley turtles, *Lepidochelys kempii*, Green sea turtles, *Chelonia mydas*

## **INTRODUCTION**

Selection of the nesting site is one of the meaningful stages for oviparous species. In species that do not provide parental care, adequate site selection is vital for embryonic development, and for subsequent hatching success. In sea turtles, the nesting stage is a vulnerable for the deposited eggs and for the female (Márquez-M 2004). The selection of the oviposition site is generally carried out by the female, based on diverse biotic and abiotic factors. Turtles commonly choose sites based on temperature, humidity, access to the sea, and sand grain among others (Bolongaro et al. 2010, Zavaleta-Lizárraga & Morales-Mávil 2013).

Unfortunately, high human activity in beaches due to tourism development, fishing and engineering, amongst other indirect causes, have destroyed or modified the turtles' habitats and their nesting sites (Arias & Vernet 2006, 2007, Ferrer et al. 2007, González & Ugas 2007, Balladares & Mora 2008). This problem is more complex because females come back to spawn to the same place each nesting season. Moreover, once hatchlings mature they may also use the beaches where they hatched (Eckert & Grobois 2001).

For the State of Veracruz, Mexico, nesting beaches have been extremely altered by human activity therefore; there are few beaches with favorable conditions for the spawning of more than one turtle species per nesting season (Montes & Licona 1996). Our study was performed on a beach in the northern area of the State of Veracruz, where at least two different species of turtles nest. We aimed to describe the spatial-temporal condition of the nesting of two turtle species [Kemp's Ridley Turtle (*Lepidochelys kempii*) and Green Turtle (*Chelonia mydas*)], identifying and describing their interaction period.

## **METHODS**
