## **ABSTRACT**

In the Black Sea copepod species from marine and coastal areas (including Ponto-Caspian and boreal relicts, old Mediterranean immigrants and recent Atlantic and Indo-Pacific invaders), the salinity tolerance ranges and osmotic responses to salinity changes were estimated. Also, the effect of temperature and dissolved oxygen concentration on respiration rate, feeding, growth and locomotion activity was studied in these copepods. In comparison with native marine species, conspecific alien copepods possessed wider salinity tolerance ranges and were able to osmoregulate. Moreover, the Ponto-Caspian relict *Calanipeda aquaedulcis*, capable to survive as in fresh as in hypersaline water, was found to be an exceptional osmoconformer over the salinity range of 0.2 to 40 psu. A population strategy of overwintering (unknown for cyclopoid copepods) was first reported for the warm-water Indo-Pacific cyclopoid *Oithona davisae*. The unique specific adaptation to local temperature and oxygen regimes was shown in *Calanus helgolandicus* (dominating species in the open zone of the Black Sea). Due to diel vertical migrations from surface warm oxygenated layers to deep cold hypoxic zones, the late developmental stages of this species can decrease their energy requirements and increase the duration and efficiency of lipid accumulation in the form of wax esters. Therefore, the values of definitive body size, lipid amount and productivity in the Black Sea *C. helgolandicus* are as high as those in *Calanus* species from the more productive North Atlantic seas. ## **1.INTRODUCTION**

The Black Sea is nowadays the world's largest brackish and anoxic semi-isolated basin. Mean salinity of the sea upper layers amounts to about 18 psu (nearly half than that of the surface layers of the World Ocean). As a rule, water salinity decreases near the river creeks down to 15 psu and increases up to 22 psu at the depths bordering upon the hydrogen sulfide zone. In the coastal areas, the temperature varies from  $0^{\circ}$ C in winter to  $28 - 29^{\circ}$ C at maximum summer insolation. However, even in summer the upper layer temperature of the Black Sea may change sharply by  $15 - 20^{\circ}$ C due to the winds (Zaitsev, 2006). In the deep-sea regions, the cold intermediate layer (CIL) with the temperature of  $6 - 8^{\circ}$ C is located permanently under the upper quasi-homogeneous zone at the depth of 30 – 100 m. Below the CIL, temperature and salinity increase slightly whilst oxygen concentration decreases dramatically down to zero at a depth of 100–200 m, where a permanent halocline separates oxygenated waters from the sulfide-rich deep waters (Sorokin, 1983).

Copepods constituting the major Black Sea mesozooplankton fraction play the key role in transferring the primary production to higher trophic levels. Modern taxonomic composition of the Black Sea copepods (Gubanova *et al.*, 2014) reflects the general geological processes and modern trends of ecosystem formation (Mordukhay-Boltovskoy, 1960; Zaitsev and Alexandrov, 1998; Zaitsev and Oztiirk, 2001). According to the origins of the species, copepods inhabiting open and coastal Black Sea regions can be divided into six groups:

- 1) Mediterranean-Ponto-Caspian relict *Calanipeda aquaedulcis* (Grindley, 1969 and 1984). The most ancient inhabitant and primitive form is found in the waters with low salinity.
- 2) Palaearctic halophylic species like *Arctodiaptomus salinus* (Boxshall and Defaye, 2008) living in salty and brackish inland lakes, common in the mouths of rivers, discharge areas and estuaries of the Black Sea (Mordukhay-Boltovskoy, 1972) and also in the hypersaline lakes of Crimea (Belmonte *et al.*, 2012).
- 3) Boreal-Atlantic immigrants: *Calanus helgolandicus* (*euxinus*)\**, Pseudocalanus elongatus* and *Oithona similis*, because in the Black Sea these three species form the united deep-sea complex of cold-water copepods (Nikitin, 1929). Probably, in the period of melting of glaciers, the cold waters brought by rivers from the northern seas filled the ancient Black Sea (Polischuk, 1984; Zaitsev, 2006). This fact is in agreement with the results of Unal *et al.* (2006) reporting the absence of substantial genetic differentiation between the Black Sea *C. helgolandicus* and *P. elongatus* and the same species from the English Channel. According to Papadopoulos *et al.* (2005), the divergences between the Mediterranean and the Black Sea populations of *C. helgolandicus* are much older than the estimated dates of colonization of the Black Sea. Perhaps, the last connection between the North and Black Seas could have been

about 2800 - 2700 BP in the Late Holocene (Polischuk, 1984). Nowadays, *C. helgolandicus, P. elongatus* and *O. similis* constituted more than 90% of the Black Sea mesozooplankton inhabiting open zones of the sea.

- 4) Mediterranean immigrants like *Paracalanus parvus*, *Centropages ponticus*, *Acartia clausi*, *Pontella mediterranea*, *Anomalocera patersoni* that have invaded and ultimately adapted to local environmental conditions after the connection of the Mediterranean and Black Seas. These species form up to 90% of the total mesozooplankton in the Black Sea coastal area. Most of them prefer warm upper layers of the sea. This group also includes *Acartia margalefi*, *Paracartia latisetosa* and *Oithona nana*, recently they have disappeared from the Black Sea (Gubanova *et al.*, 2014).
- 5) Freshwater species: mainly calanoid copepods of the family Diaptomidae (Samchyshyna, 2011) and Cyclopoida introduced by river discharges, which usually occur in the sea water during the maximum river run-off.
- 6) Alien species *Acartia tonsa* and *Oithona davisae* introduced by ship ballast waters from the countries where these species are distributed. *A. tonsa* was transferred to the Black Sea via Baltic-Black sea connection (Belmonte *et al.*, 2011) probably starting from the North American Atlantic coastal regions which are considered to be a native area of this species (McAlice, 1981). *O. davisae* is a representative of the Indo-West Pacific Oithonidae (Ferrari and Orsi, 1984) which are distributed widely all over the world after the synanthropic introduction, probably from Japanese coastal waters.

Since the Mediterranean Sea (which connects the Black Sea with the Atlantic Ocean) is a highly saline and oxygenated water body with moderate temperature regime, one could suggest that the cold, brackish and hypoxic Black Sea was inhabited by the eurybiotic species. This hypothesis may be tested by studying the adaptive potential of the Black Sea copepods and mechanisms of their physiological adaptation to salinity, temperature and oxygen changes.

		Habitual conditions		Experimental conditions

**Table 1. Capture location and sampling and experimental conditions of studied species**

Nikitin (1926) was the first to determine the temperature preferences of mass copepod species of the Black Sea. Nikitin and Malm (1932) studied their tolerance to oxygen, hydrogen ions and carbon dioxide concentrations. Kovalev (1966) investigated the effect of salinity on survival of the mass Black Sea copepods. The influence of temperature on growth and development of copepods was investigated by Sazhina (1987). Svetlichny (1989) analyzed the locomotor activity of *C. helgolandicus* under different temperatures.

This review aims to synthesize the understanding of the processes of behavioral and physiological adaptation of the key copepod species to the highly diversified Black Sea environment. In particular, the impact of changing salinity, temperature and oxygen concentration on survival, respiration rate, moving behavior, egg formation and lipid accumulation will be discussed for native and introduced species. This work is based on laboratory and field studies carried out by the Department of Animal Physiology and Biochemistry, Institute of Biology of the Southern Seas (IBSS) from 1984 to 2014.The list of the studied species and experimental conditions used are given in Table 1.

# **2. SALINITY TOLERANCE OF THE BLACK SEA SPECIES AND THEIR CONGENERIC POPULATIONS FROM THE MARMARA AND IONIAN SEAS**

Salinity tolerance was studied in females of all the species listed in Table 1 (except *Pseudocalanus elongatus*). The experiments were carried out on board of research vessels "Professor Vodyanitsky," "Bilim" and "Knorr" during the cruises and in the laboratories of the Institute of Biology of the Southern Seas (Sevastopol), Istanbul University (Turkey) and Marine Biological Station, University of Salento (Italy).

To study the effect of salinity on the survival of copepods, we placed 20-30 (for species with the body length greater or equal to 1 mm) or 40-50 (for species with the body length of about 0.5 mm) active females of every species (in 3-5 treatments) into transparent 100 mL beakers filled with filtered seawater and exposed (at natural habitat temperature) to a gradual decrease or increase in salinity over the periods ranging from 2 to 10 h at a rate of 2–3 psu h<sup>-1</sup> (Hubareva *et al.*, 2008; Svetlichny *et al.*, 2012a and b; Hubareva and Svetlichny, 2016). The range of salinity changes was determined according to the results of preliminary experiments (Kovalev, 1966; Svetlichny *et al.*, 2006a). The salinity tolerance range of copepods was estimated basing on the values of the median lethal salinity  $(LS_{50})$ . To access the ability of copepods to shift the salinity tolerance range, in some experiments the females which had survived at the  $LS_{50}$  were exposed to a slow uniform increase in salinity due to natural evaporation of seawater. Salinity tolerance of *Calanus helgolandicus* was estimated taking into account behavioral and physiological response of separate individuals to salinity change.

## **2.1. Salinity Tolerance in** *Calanipeda aquaedulcis* **and** *Arctodiaptomus salinus*

*Calanipeda aquaedulcis* and *Arctodiaptomus salinus* are representatives of two taxonomically and ecologically close families: Pseudodiaptomidae and Diaptomidae. According to Grindley (1984), "Pseudodiaptomidae have arisen from the sea and represent an intermediate stage in adaptation to the freshwater environment" while "Diaptomidae appear

equally well adapted to the fresh-water environment." Although *C. aquaedulcis* and *A. salinus* are not strictly marine copepods, these two species have been considered for comparison with the marine ones.

Figure 1. Salinity tolerance of *Calanipeda aquaedulcis* (A) and *Arctodiaptomus salinus* (B) reared at 0.2 psu ( $\circ$ ) and 18 psu ( $\bullet$ ) in 5–10 d after gradual salinity acclimation. The salinity tolerance range in females and males of both species was between 0.1 psu; the horizontal long-dashed line denotes 50% mortality (from Svetlichny *et al.*, 2012a with changes).

According to our results, *C. aquaedulcis* and *A. salinus* are able to develop successfully as in fresh water, as in the Black Sea brackish water. These species have been kept for 4 years in the laboratory at a room temperature and salinity of 18 psu, and two months prior the experiment half of the culture was transferred to fresh water. For fresh water copepod generations, the salinity tolerance ranges were within 0.2 to 17 psu in *A. salinus* and 0.2 to 35 psu in *C. aquaedulcis*. For individuals of both species acclimated to 18 psu (Black Sea water) the borders of salinity ranges were shifted to 35-40 psu (*A. salinus*) and 50 psu (*C. aquaedulcis*) (Figure 1). In our experiments 50% of population of *C. aquaedulcis* could survive gradual salinity changes during 8 - 10 h up to 30 psu, whereas that of *A. salinus*  tolerated only salinity alterations limited to a range of about 20 psu.

## **2.2. Salinity Tolerance of Native** *Acartia clausi* **and Alien** *Acartia tonsa*

Copepods of the genus *Acartia* inhabit many coastal and offshore environments where they are usually among the most abundant zooplankton species. *Acartia tonsa* possesses a wide range of tolerance to salinity whilst *Acartia clausi* is considered to be a more stenohaline species (Stalder and Marcus, 1997; Calliary *et al.*, 2006 and 2008). *A. tonsa* adapted to high food concentration (Paffenhöfer and Stearns, 1988) usually is more abundant in the near-shore environments and estuaries. Similar trend in the distribution of these species is observed in the Black Sea. After the introduction of *A. tonsa* in the Black Sea presumably in 1976, both species can coexist (Gubanova, 2000); however, *A. clausi* dominates in the open zone of coastal areas, while *A. tonsa* occurs in semi-closed bays (Delpy and Pagano, this volume; Marques *et al.*, this volume; Villate *et al.*, this volume).

Salinity tolerance ranges for females of *A. clausi* and *A. tonsa* collected at 18 psu in Sevastopol Bay (Black Sea) were estimated as 10-35 and 3–30 psu, respectively (Figure 2). However, after 1 week of acclimation to 30 psu the salinity tolerance ranges were extended up to 50 psu in *A. tonsa*. Therefore, in comparison with *A. clausi, A. tonsa* introduced in the Black Sea possessed the salinity tolerance range shifted to lower salinity (up to 3 psu) and, at the same time, this species was able to acclimate to high- saline water (50 psu).

Salinity, psu

Figure 2. Mortality of *Acartia clausi* (A, ●) and *Acartia tonsa* (B, ♦) in 3 days after gradual salinity change of the individuals acclimated to 18–20 psu. ◊ - Effect of salinity on mortality of *A. tonsa* acclimated during one week to 30 psu. (Figure 2B from Svetlichny and Hubareva, 2014a with changes).

Consequently indigenous *A. clausi*, living at the quasi-permanent salinity of 18 psu in natural environment but demonstrating the ability to survive in the high-saline water, showed the "genetic memory" about the conditions of its oceanic origin. Salinity tolerance range of *A*. *tonsa* inhabiting the Black Sea was close to that of the same species from Øresund kept for several generations at *ca.* 33 psu in the laboratory (Calliari *et al.*, 2006), also being capable to sustain the decrease in the salinity down to 2 psu. Thus, *A*. *tonsa* may be considered as an extremely euryhaline species widely distributed in the eutrophic regions of the World Ocean.

#### **2.3. Salinity Tolerance of the Copepods from the Genus** *Oithona*

The effect of salinity on mortality of Oithonidae was studied (Figure 3) at 20 °C for warm-water *Oithona davisae* and *Oithona nana* (Svetlichny and Hubareva, 2014a) and at 8- 10 ºС for cold-water *Oithona similis* (Hubareva and Svetlichny, 2016). Salinity tolerance range (5–45 psu) of the Black Sea invader *O. davisae* (Ferrari and Orsi, 1984) in 3 days after the gradual salinity acclimation at a rate of 2-3 psu h $^{-1}$  was significantly wider than that of indigenous copepods *O. similis* (10–30 psu) and especially *O. nana* (15–28 psu). Narrow salinity tolerance range of *O. nana* was known from the studies of Kovalev (1966) and, probably, may be one of the reasons of the elimination of this species from the Black Sea as the most vulnerable component of the zooplankton community which underwent dramatic changes during last decades (Gubanova *et al.*, 2014).

Figure 3. Salinity tolerance of *Oithona davisae* (1), *Oithona similis* (2) and *Oithona nana* (3) (from Isinibilir *et al.*, 2016).

On the contrary, high salinity tolerance of *O. davisae* seemed to facilitate the expansion of this species from Eastern Asia waters to the European and American seas.

An extraordinary sustainability of *O. davisae* was confirmed by our experiments (unpublished data) when  $63.8 \pm 20.5\%$  of females were alive during 3 days after the transfer from 18 to 35 psu and  $86.9 \pm 9.7\%$  of individuals survived after the transfer from 35 to 18 psu during the same period. After sharp increase in salinity the bodies of copepods shrunk and flattened. Such individuals descended to the bottom of the aquaria and kept the immobility for several hours. After that, their bodies reshaped and the copepods began to swim in the water again.

#### **2.4. Salinity Tolerance of** *Calanus helgolandicus*

*Calanus helgolandicus* is widely distributed in the North Atlantic seas. *Calanus euxinus* in the Black Sea is considered to be a phenotypic variation of *C. helgolandicus* (Papadopoulos *et al.*, 2005; Unal *et al.*, 2006; Yebra *et al.*, 2011). To evaluate the adaptive potential of this species, we studied the effect of gradual salinity changes on survival, locomotion and feeding (as mostly sensitive indicator of animal health) of *C. helgolandicus* living at the quasi-homogeneous salinity of about 38 and 18 psu in the Ionian and Black Seas, respectively, and in the Marmara Sea with a two-layer salinity structure (about 20 and 38 psu in the upper and lower layers, respectively).

In 0.5 L aquaria, the individuals of this species usually aggregate near the bottom whilst after salinity changes these copepods ascend to the surface and swim there. In *C. helgolandicus* collected in the Black Sea at 18 psu, a gradual decrease and increase in salinity at a rate of 2 psu h-1 within the range of 10-40 psu resulted in an increase in locomotion activity up to maximum values at 14 and 31 psu, and dramatic decrease at the following salinity change (Figure 4A). Although after salinity increase up to 40 psu the copepods remained alive, the muscles of these individuals became opaque indicating irreversible tissue changes (Svetlichny *et al.*, 2010b). More than 50% of studied copepods died in  $3 - 5$  days after gradual salinity increase higher than 30 psu (Figure 4B).

Figure 4. Time spent routing swimming (A) in the Black Sea *Calanus helgolandicus* as a response to gradual salinity changes and survival (B) of *C*. *helgolandicus* from the Black (black circle) and Ionian (open circle) Seas after 72 and 24 h of salinity changes, respectively (data on *C*. *helgolandicus* from the Ionian Sea from Isinibilir *et al.*, 2011).

In the feeding experiments (see details in Svetlichny *et al.*, 2010b) a gradual salinity increase from 17 to 25 psu during 1.5 h did not affect dinoflagellate *Prorocentrum minimum* consumption rate in females from the Black Sea. The anterior part of the gut was constantly full of algae in all individuals. During the following salinity increase, every change in the salinity (by 2–3 psu) brought to rapid gut evacuation and renewed feeding during the period of acclimation to new salinity. The duration of salinity acclimation period changed from 15- 40 min at 17–25 psu to 80–120 min at 28-30 psu. When the salinity exceeded 31 psu, copepods completely stopped consuming algae. However, after the acclimation to 27 psu during about 3 days *C. helgolandicus* kept the ability to feed.

In *C. helgolandicus* inhabiting the Ionian Sea, the gradual salinity transition from 39 to 26 psu did not affect the survival of preadults and adults; however, after further reduction of the salinity down to 18 psu all animals died within 24 h (Figure 4B) (Isinibilir *et al.*, 2011). According to the  $LS_{50}$  criteria, the critical salinity for survival of population in the Ionian Sea was equal to 22 psu. Therefore, without the pre-adaptation the salinity tolerance range in *C. helgolandicus* living at constantly high salinity amounted to 22-40 psu whilst that for this species from the brackish Black Sea was about 15-30 psu (Svetlichny *et al.*, 2010b).

In the Marmara Sea with two types of water masses (brackish Black Sea and high-saline Mediterranean water), *C. helgolandicus* inhabit the whole water column performing diel vertical migrations (Svetlichny *et al.*, 2010b). From this perspective, the Marmara Sea can be considered as the zone of natural wide amplitude acclimation. In *C. helgolandicus* females sampled in deep high-saline layers of the Marmara Sea near the Prince Islands, moving activity did not change significantly after gradual (during 4 h) salinity increase from 22 to 40 psu and only at 40-50 psu we observed a pronounced depression of locomotion (Svetlichny *et al.*, 2010b). We found no regular trends in changing of locomotor activity of females kept for several days at 38.5 psu and then exposed to a short-term (2.5 h) gradual salinity decrease down to 22 psu. During gradual increase and further decrease in salinity within the range of 22–38.5 psu the copepods did not stop consuming food. The copepods were alive even after the acute transfer from 22 to 39 psu (Svetlichny *et al.*, 2010b).

#### **2.5. Types of Osmotic Response in the Black Sea Copepods**

According to Mauchline (1998), most marine copepod species are osmoconformers with the internal osmolality following the molality of the surrounding water. In this case, the mass body density of these animals should be proportional to the surrounding water density. It is advantageous for floating in the water because the buoyancy and sinking speed are constant, and energy losses to keep the body in the water are independent of the salinity. In the benthic copepod *Tigriopus brevicornis* mass density (determined in the formalin preserved individuals with the density test medium) linearly increased from 1.036 to 1.085 g  $cm^{-3}$ (McAllen *et al.*, 1998) with a salinity increase from 5 to 100 psu (Figure 5A). The authors considered this species to be a euryhaline osmoconformer. In the Black Sea, marine indigenous *A. clausi*, coastal *C. aquaedulcis* and *A. salinus* inhabiting the Crimean coastal hypersaline lakes the body mass density (measured in accordance with sinking speed of anesthetized individuals) varied in the range of 18–40, 0.2–43 and 0.2-40, respectively. This was directly in accordance with the theoretical expectation suggesting that copepod body volume is constant and that water content is iso-osmotic to the surrounding water (Figure 5A). In males, non-ovigerous and ovigerous females of *Eurytemora affinis* from Seine estuary (Seuront, 2006), sinking speeds did not change significantly within the salinity range from 0 to 35 psu, indicating that this estuarine species is also as strong osmoconformer, as the above mentioned Black Sea species. Therefore, an osmoconformic response to salinity changes can be attributed not only to marine copepods, but also to the eurybiotic species, such as *C. aquaedulcis* and *A. salinus*.

Nevertheless, some copepods may possess homeostatic mechanisms which permit physiological compensatory osmoregulation. The ability to regulate the inorganic ion content of hemolymph was found in the benthic copepod *Tisbe reticulata* (Battaglia and Bryan, 1964) and pelagic copepods *Calanoides acutus* and *Rhincalanus gigas* (Sartoris *et al.*, 2010). Osmoregulatory responses to salinity alterations in organic osmolyte content were reported for the marine copepod *E. affinis* (Roddie *et al.*, 1984) and estuarine copepods *T. californicus* (Goolish and Burton, 1989) and *Temora longicornis* (Tang *et al.*, 2000). The ability to keep a body fluid homeostasis allows species-osmoregulators to overcome abrupt salinity changes at rain, evaporation, river flow and tides. Jeffries (1962) suggested that estuarine *A. tonsa* had developed an efficient osmoregulatory mechanism. Nevertheless, Lance (1965) found no

clear evidence that *A. tonsa* could effectively control its water balance although in laboratory experiments the body fluid of this species was hyper-osmotic to the external medium salinities ranging from 90% to 15% sea water for 12 h.

Figure 5. A: Effect of salinity on body mass density of females of *Arctodiaptomus salinus* (shaded diamonds) and *Calanipeda aquaedulcis* (shaded circles) reared at 18 psu for 4 years (from Svetlichny *et al.*, 2012a with additions and changes) and *Acartia clausi* (open circles) collected at 17.5 psu (unpublished data). Short-dashed line: theoretical change in body mass density in the case of ideal osmoconformity of copepods with a water content of 76% of the body volume. The long-dashed line shows the relationship between body mass density and salinity in *Tigriopus brevicornis* (McAllen *et al.*, 1998). B: Effect of salinity on body mass density of *Acartia tonsa* acclimated to 18 ( $\Diamond$ , open diamonds) and 3 psu (♦, shaded diamonds), and *Oithona davisae* acclimated to 18 (○, open circles) and 41 psu (●, shaded circles). Short-dashed line shows the isometric changes of body mass density (from Svetlichny and Hubareva, 2014a with changes).

Our results (Svetlichny and Hubareva, 2014a) demonstrated the clear evidence of osmoregulation in *A. tonsa* from the Black Sea within the salinity tolerance range of 2–30 psu (Figure 5B). Females of *A. tonsa* collected at 18 psu and acclimated to 3 psu for 2 weeks, kept quasi-constant body density of 1.064 g cm<sup>-3</sup>, however, responded hyper-osmotically at the salinity increase from 30 to 50 psu. It is worth noting that hyper-osmotic increase in body mass density of *A. tonsa* after the salinity increase from 30 to 50 psu in our experiments is not in accordance with the data on hypo-osmotic changes in free amino acid pool (Farmer and Reeve, 1978) and hemolymph Na (Farmer, 1980) in *A. tonsa* after the increase in external

salinity from 34 to 39 psu. Probably, the results of these authors may reflect not only the osmoregulation processes but also an inadequate metabolic response of the organisms under the extreme salinities because such experimental artifacts as starvation may affect *A. tonsa*  body composition.

In *O. davisae* within the range 3–60 psu, three types of reaction to salinity changes were found: a) hypo-osmotic response: abrupt decrease in body mass density due to pronounced swelling and watering of the body after salinity changes from 6 to 3 psu; b) homeostatic regulation: maintenance of constant body mass density at salinity increase from 18.4 to 35.1 psu in females collected in the sea at 18 psu, and at salinity decrease from 41 to 25.7 psu in females acclimated for one week to 41 psu. This phenomenon may be due to low permeability of *O. davisae* integuments, providing an osmotic isolation from the external medium as a mechanism of physiological regulation of ion exchange in stressful habitats (Lee *et al.*, 2012); c) iso-osmotic response: body mass density changes equiproportionally to surrounding water salinity decrease from 18 to 6 psu and increase from 40 to 60 psu in the copepods collected in the sea at 18 psu.

Wide salinity range and osmoregulation ability in *A. tonsa* and *O. davisae* seem to be the features that facilitate the formation of self-reproducing populations of only these two species in the Black Sea (Gubanova *et al.*, 2014), despite the fact that a great number of copepods was brought with ship ballast waters from adjacent and distant seas (Selifonova, 2011).

#### **2.6. Copepod Egg Salinity Tolerance**

Despite the fact that females of some marine copepods (for example, *A. tonsa*) possess the ability to osmoregulate, the volume of their eggs immediately follows the salinity changes as a perfect osmometer (Calliari *et al.*, 2006; Hansen *et al.*, 2012), and the egg density alters as well (Miller and Marcus, 1994). At the decrease in salinity from 31 to 15 psu, mass density of eggs in *A. tonsa* from the Gulf of Mexico reduced from 1.087 to 1.066 g cm<sup>-3</sup> (Miller and Marcus, 1994). In the Black Sea *A. salinus* acclimated to fresh water, a salinity increase from 0.2 to 18 psu resulted in an increase in the mass density of both resting and subitaneous eggs (Figure 6).

As a whole, in marine copepods hatching success of subitaneous eggs is in accordance with the parental salinity tolerance. Egg hatching success of widely euryhaline *A. tonsa* remained high as at extremely low salinity of 2 psu, as at high salinity of 39 psu (Calliari *et al.*, 2006; Svetlichny *et al.*, 2010a).

For copepods with narrower salinity tolerance range, egg hatching success is due to a parental shift in salinity acclimation. In *A. clausi* from the Black Sea almost all eggs died after the gradual salinity increase from 18 to 39 psu (Figure 7A); however, up to 50% of eggs of this species living in the Marmara Sea at changing salinity (22-39 psu) kept the ability to develop into nauplii at 39 psu (Svetlichny *et al.*, 2010a). On the contrary, egg hatching success in *A. clausi* maintained for several generations at a salinity of *ca.* 33 psu decreased dramatically at salinity lower than 20 psu (Calliari *et al.*, 2006).

Eggs laid by the Black Sea *C. helgolandicus* females at 17–18.7 psu died at salinities >30 psu, in contrast to  $47 \pm 11\%$  of eggs laid by the Marmara Sea females which produced nauplii successfully after the salinity increase from 22 to 39 psu (Figure 7B).

Hansen *et al.* (2012) proposed that the embryo of *A. tonsa* can be protected from the salinity stress by its plasma membrane and that water exchange driven by osmosis was restricted to the perivitelline space of the egg. However, under extreme hypo-saline (0 psu) or hyper-saline (76 psu) conditions the eggs swelled or compressed, respectively, due to passive osmosis and killed the embryo.

Figure 6. Effect of salinity on mass density of subitaneous (open circles) and resting eggs of *Arctodiaptomus salinus* (shaded circles) (data from Table 2 of Svetlichny *et al.*, 2012a) and subitaneous eggs of *Acartia tonsa* (open diamonds) (from Miller and Marcus, 1994).

Figure 7. Hatching success of egg in *Acartia clausi* females from the Marmara (□) and Black (■) Seas (A) and *Calanus helgolandicus* females from the Marmara (◊) and Black (●) Seas (B) at different salinity (from Svetlichny *et al.*, 2010a with changes).

We observed similar effect of salinity on the eggs of *C. helgolandicus* from the Marmara Sea living at changing salinity. The eggs laid at 22 psu became wrinkled during gradual salinity up to 38.5 psu (Svetlichny *et al.*, 2010a) due to the loss of water (Figure 8). However, at long-term (1-2 days) keeping at this salinity the shape of survived eggs recovered and nauplii hatched successfully from these eggs.

Figure 8. Eggs of *Calanus helgolandicus* from the Marmara Sea after salinity increase from 22 to 38 psu.

However, our results showed that copepod eggs are more sensitive to extremal salinities than the adults. Anufriieva (2014) found adults of *A. salinus* in hyper-saline lakes of Crimea at the salinity of about 300 psu. In our experiments, some *A. salinus* specimens survived for more than 14 d at the salinities of about 70 psu, and up to 15% of *C. aquaedulcis* females were alive for 10 d at 60 psu. However, we did not observe hatching of nauplii from the ovisacs of *A. salinus* and *C. aquaedulcis* females at salinities higher than 50 psu. Probably, this phenomenon was due to osmotic effects during hatching**.** According to Marshall and Orr (1972) and Davis (1959), nauplii burst out from eggs after cracking the outer membrane due to a sharp increase of pressure inside the inner case. The pressure increase seems to be caused by active absorption of water through the inner membrane. This suggestion may be confirmed by the increase in respiration rate of eggs at the hatching time (Nielsen *et al.*, 2007). According to Rokneddine and Chentoufi (2004), the reproductive potential of *A. salinus* from the Zima salt marsh in Morocco decreased 5-fold with an increase in salinity to the upper boundary of its tolerance range. In other estuarine copepods, the critical salinity for survival of their juvenile stages was also found to be lower than in adults of *E. affinis* (Ishikawa *et al.*, 1999; Lee *et al.*, 2007) and *P. annandalei* (Chen and Suzuki, 2006).

#### **2.7. Effect of Salinity on Copepod Respiration Rate**

Variations in respiration rate of copepods at the salinity changes are considered to be connected with additional energy losses for osmotic regulation (Gyllenberg and Lundqvist, 1978; McAllen and Taylor, 2001). Theoretically, the minimum osmotic work for ion transport constitutes only from 1 to 5% of the total metabolic energy requirements in brackish and freshwater animals (Potts, 1954). However, Goolish and Burton (1989) showed that the daily energy required for adjusting metabolism to hyperosmotic stress in *T. californicus* acclimated to constant salinity amounted to 11.6% of the total energy respired. In copepods metabolic rates of active individuals can exceed the basal metabolism by 6-fold (Buskey, 1998; Svetlichny and Hubareva, 2005); therefore, the energy of muscular activity associated with typical copepods avoidance response to unfavorable conditions may mask the losses for

osmoregulation. Probably, therefore, the results of numerous studies concerning the effect of salinity on respiration rates of copepods are very contradictory and are highly dependent on the functional mobility of the species.

For example, an increase in respiration rate of *A. clausi* and *A. tonsa* (Calliari *et al.*, 2006) and *Calanus finmarchicus* (Anraku, 1964; Marshall and Orr, 1972) followed to the increase in water salinity, while in *T. brevicornis* (McAllen and Taylor, 2001) an increase in salinity caused a decrease in oxygen consumption rate and activity as well. There was no evidence of salinity-associated respiratory distress in respiration experiments with *E. affinis* in the range of 0-40 psu (Roddie *et al.*, 1984). The respiration rate of *Pseudodiaptomus hessei* females also showed no differences within the salinity range of 3-31 psu (Isla and Perissinotto, 2004). According to Newrkla (1978), respiration rate and moving activity of *Arctodiaptomus spinosus* did not vary within the salinity range of 3–66 psu. In *C. helgolandicus* collected from the deep layers (38.5 psu, 15ºC) of the Marmara Sea and kept under laboratory conditions (20 $^{\circ}$ C) at a salinity of 38.5 psu during 6 d and 22 psu over 13 d, weight-specific respiration rates did not differ significantly amounting to  $1.62 \pm 0.05$  and  $1.76$  $\pm$  0.2  $\mu$ g O<sub>2</sub> mg<sup>-1</sup> h<sup>-1</sup>, respectively (Svetlichny *et al.*, 2010b). In the Black Sea for osmoconformers *A. salinus*, *C. aquaedulcis*, *A. clausi* and for osmoregulators *A. tonsa* and *O. davisae* there was also no significant difference in weight-specific respiration rates within the salinity tolerance ranges (Hubareva *et al.*, 2008; Svetlichny and Hubareva 2014a; Svetlichny *et al.*, 2012b).

#### **3. EFFECT OF TEMPERATURE**

#### **3.1. Effect of Temperature on Respiration Rate**

Respiration rates of ectothermic animals are known to be affected by temperature with the Van't Hoff coefficient  $(Q_{10})$  varying within the range of 2.0-2.5 (Prosser, 1973). According to Winberg, (1983), a mean  $Q_{10}$  value of 2.25 can be applied to the majority of hydrobionts within the range of tolerable temperatures. After the analyses of literature and own data on temperature dependence of respiration rate in planktonic copepods, Lee *et al.* (2001) concluded that most of them fitted well to Van't Hoff rule, however, the exceptions were found which may be interpreted as a dissimilarity of eurythermic and stenothermic responses in copepods (Conover, 1956).

Copepods inhabiting permanently the coastal zone of the Black Sea undergo mainly seasonal gradual changes in temperature (up to  $30^{\circ}$ C), whilst species from the open sea regions experience diel temperature variations during the warm season because nearly all these animals are able to migrate from warm  $(17 - 25^{\circ}C)$  surface layers to cold  $(6.8^{\circ}C)$  mixed strata. At the winter-spring homothermia, the temperature dependence of respiration rate for both copepod groups may be similar. In our study for cold-water *Calanus helgolandicus* and *Pseudocalanus elongatus* and overwintering (warm-water) *Oithona davisae,* respiration rate followed the Van't Hoff exponential rule (Figure 9) with the  $Q_{10}$  of 2.07 (Svetlichny *et al.*, 2009), 2.08 (unpublished data) and 2.06 (Svetlichny *et al.*, 2016), respectively. In the Marmara Sea *C. helgolandicus* the  $Q_{10}$  varied near 2 for all development stages from nauplii to adults (Svetlichny *et al.*, 2010b). The Q<sup>10</sup> varying from 1.93 to 2.25 was found in *Acartia*

*clausi* for the range of 10 - 20 $^{\circ}$ C (Gaudy *et al.*, 2000). Similar  $Q_{10}$  values of about 2 were obtained for *Pseudocalanus newmani* (Lee *et al.*, 2001), *Calanus pacificus* (Vidal, 1980b) and other copepod groups (Ikeda *et al.*, 2001). However, in the experiments of some authors the temperature dependence of respiration rate in copepods was not found (*A. clausi*, see Anraku, 1964), or the Q<sup>10</sup> was extraordinary high (about 6 in *Pseudocalanus* sp., see Isla *et al.*, 2008). Since the energy cost of swimming constitutes the main part of metabolism, these data discrepancies may be due to the specific behavioral response to temperature. Nevertheless, Hirche (1987) reported that in Arctic copepods respiration rates increased with temperature following the Arrhenius equation being independent of the activity. One should take into account that the trends in the temperature dependence of respiration rate of copepods may be affected by the combinations of methodical errors due to several factors including duration of experiment, capture and starvation stress (see review of Ikeda *et al.*, 2000).

Figure 9. Effect of temperature on respiration rate of *Calanus helgolandicus*, *Pseudocalanus elongatus* and *Oithona davisae* (regression lines are constructed based on the tabular data from Svetlichny *et al.*, 2009 and 2016).

#### **3.2. Effect of Temperature on Moving Activity**

In calanoid copepods active swimming is realized by two principally different modes: uniform locomotion using the mouthparts limbs and unsteady jerk locomotion using mainly the thoracic limbs.

The effect of temperature on the parameters of swimming in copepods may be due to the temperature dependence of muscle contraction and neurogenic rhythm controlling muscle action (see a review of Lenz *et al.*, 2005). For example, the contractile rates of vertebrate skeletal muscle were temperature-dependent with the Van't Hoff temperature coefficients  $Q_{10}$ of 1.95 – 2.42 (Bennett, 1985), and a pyloric rhythm in the intact crab increased significantly with the  $Q_{10} = 2-2.5$  (Tang *et al.*, 2012).

Nevertheless, the  $Q_{10}$  values of locomotor parameters are predominantly lower than those mentioned above.

Figure 10. Effect of temperature on force production (A), beat frequency ( $\bullet$ ) and mechanic power ( $\Diamond$ ) of mouth limbs at routing swimming (B) and the period of circadian rhythm of activity (C) in *Calanus helgolandicus* (from Svetlichny, 1989).

Figure 11. Effect of temperature on kick frequency  $(\bullet)$  and maximum power  $(\Diamond)$  of stroke phase of kicks during escape swimming of *Calanus helgolandicus* (from Svetlichny, 1989).

The frequency of locomotor patterns shows a strong effect of temperature on locomotor activity and behavior both in free swimming (Hirche, 1987) and tethered copepods (Lenz *et al.*, 2005; Gill and Crisp, 1985). In *Temora longicornis* frequency of beats by mouthpart limbs within the temperature range of  $5{\text -}20^{\circ}\text{C}$  increased from 11.5 -15.4 to  $23.8 - 30.2$  Hz (Gill and Crisp, 1985) (our calculated  $Q_{10} = 1.66 \pm 0.2$ ). In the experiments of Larsen *et al.* (2008) the swimming velocity of *Acartia tonsa* in the temperature range of  $\sim 6$  - 20°C changed from 0.17 to 0.45 cm s<sup>-1</sup> ( $Q_{10} = 1.7$ , calculated according to their equation in Figure 1). In behavior experiments of Lenz *et al.* (2005) with *Calanus finmarchicus* tethered to a force transducer, force transients produced by swimming legs and kick frequency during escape reaction increased with temperature with a  $Q_{10}$  value ranging from 1.23 to 1.86 and from 1.28 to 1.86, respectively.

In the Black Sea *C. helgolandicus*, force production and beat frequency of mouthpart limbs at routing swimming increased with the  $Q_{10}$  of 1.34 and 1.57 under strictly exponential law while the changes of power occurred in accordance with a power equation (Figure 10A, B). The period of the circadian rhythm of locomotor activity in copepod attached to a semiconductor force sensor in darkness was inversely related to the temperature described by the exponential equation (Figure 10C). It should be noted that the daily rhythm of 24 h was observed at a temperature of about  $6^{\circ}$ C, which is close to the temperature of the cold mixed layer of the Black Sea where in total darkness *Calanus* spend the daytime during the warm season.

Parameters of quick and short-term escape reaction were also temperature-dependent with the Van't Hoff temperature coefficients  $Q_{10}$  of 1.65 for the maximum jump frequency and 3.75 for mechanical power (Figure 11). Stronger temperature dependence of mechanical power both for routine and escape locomotion (Figure 10B and Figure 11) in comparison with the  $Q_{10}$  of respiration rate (about 2) seems to be due to the auxotonic type of muscle contraction during swimming when force, power and energy efficiency of muscles increase following the increase of their contraction. Therefore, one can suggest that maximum swimming speed should correlate with the temperature optimum for copepods.

## **3.3. Temperature Impact on the Life Cycle and Respiration Rate of the Black Sea Native and Alien Species**

Due to lack of low-temperature tolerance in subitaneous eggs (capable to descend to the cold layers during development period) and nauplii (Svetlichny *et al.*, 2010a), *A. tonsa* population in the Black Sea inhabits shallow zones (mainly the bays) in summer and autumn, while in winter it endures cold period in the stage of resting eggs.

*O. davisae* is a perennial species. No records on production of diapausing eggs by cyclopoids are known (Alekseev and Starobogatov, 1996), and no evidence of any diapause stage exists for copepods from Oithonidae family (Marcus, 1996). Therefore, population of *O. davisae* cannot be temporarily intermittent but depends on year-round recruitment of mated females, and its abundance significantly depends on seasonal temperature alterations (Uye and Sano, 1995; Altukhov *et al.*, 2014; Svetlichny *et al.*, 2016). Our field observation and laboratory experiments (Svetlichny *et al.*, 2016) indicate that *O. davisae* population in the Black Sea can survive winter low temperature of about 8°C in the stage of pre-fertilized females similarly to *Cyclops strenuus* (Nsess and Nilssen, 1991). In our experiments, overwintering females transferred from the Black Sea to the laboratory began to lay viable eggs progressively to temperature higher than 10°C. The share of ovigerous females in *O. davisae* population increased in proportion to temperature reaching 100% at 24°C (Figure 12A).

In another experiment (Svetlichny *et al.*, 2016) with long-term exposures for *O. davisae* females (without males) fed *ad libitum* by heterotrophic dinoflagellates *Oxyrrhis* sp. during 34, 56 and 71 days at 8ºC, copepods began to lay eggs on the day 2 - 3 after the increase of temperature from 8 to 20ºC, and the viable nauplii hatched on day 5. The maximum number of ovigerous females was observed after 56 days of exposition at 8ºC (Figure 12B). The number of eggs in the ovisacs varied from 1 to 9 (mean value of 4.1  $\pm$  1.5) and was independent of the exposition at 8ºC.

Figure 12. Effect of temperature on the reproductive activity of freshly collected overwintering females (А) (from Hubareva and Svetlichny, 2013) and egg production rate (B) of *Oithona davisae* females at 20ºC after the incubation during 34, 56 and 71 days at 8°C. All females used in the experiments were collected at the beginning of March.

Consequently, the maintenance of *O. davisae* population in the Black Sea during the cold period depends on the ability of females to keep the sperm in a spermatheca until the spring increase in temperature. However, in spite of high share of overwintering females which are capable to lay eggs, their clutch size was small, both in freshly collected from the sea and experimental *O. davisae*. The most probable explication to this phenomenon was the age of females affecting greatly the productivity of *O. davisae* (Ceballos and Kjorboe, 2011). On the contrary, in females developed in Sevastopol Bay in summer-autumn natural populations, the clutch size reached up to  $19.4 \pm 5.5$  eggs female<sup>-1</sup>.

Weight-specific respiration rate of active and anesthetized overwintering *O. davisae* females collected in spring at 8°C and acclimated to 20°C were significantly (about 1.5 times) lower than those of summer females at the 20°C (Figure 13). Probably, due to the temperature-induced shift in metabolic rates, *O. davisae* females can overcome the winterspring decrease in number of small flagellates typical for the Black Sea (Uchima, 1988).

Figure 13. Weight-specific respiration rate of active and anesthetized *Oithona davisae* females collected during spring and summer. Values are presented as mean  $\pm$  SD (constructed based on the data from Table 1 in Svetlichny *et al.*, 2016).

Figure 14. *Calanus helgolandicus.* Weight-specific respiration rate at 20°C of active (■) and anesthetized  $(\Box)$  females from the Black (BS), Marmara (MS), Ionian (IS) Seas and the Black Sea females reared in the laboratory at 18°C (BSC) (calculated from the data in Table 2 in Svetlichny *et al.*, 2010b).

Similar temperature shift was found in *C. helgolandicus* from the seas with different temperature regimes (Figure 14). In the Black Sea at the permanent temperature of daytime habitat (6 – 8°C), weight-specific respiration rate of *C. helgolandicus* females (1.2  $\pm$  0.36 µg  $O_2$  mg<sup>-1</sup> h<sup>-1</sup>) was 1.6-fold and 1.34-fold lower than those in the Marmara and Ionian Seas, respectively, where this species developed at 13-15°С. This value was also 1.5-fold lower than weight-specific respiration rate of the Black Sea females cultivated from eggs at 18°С.

Probably, this is due to the same patterns of changes in the basal metabolism when females inhabiting the seas with different temperature regimes have close metabolic energy losses for activity varying between 0.74 and 1.12  $\mu$ g O<sub>2</sub> mg<sup>-1</sup> h<sup>-1</sup>.

However, it is necessary to take into consideration a higher salinity of the Marmara and Ionian Seas, which can accelerate the metabolism of copepods as well (Svetlichny *et al.*, 2010b).

## **4. TOLERANCE OF THE BLACK SEA COPEPODS TO OXYGEN DEFICIENCY STRESS**

In the entire Black Sea below a depth of about 150 m, the oxygenated layers are replaced by hydrogen sulfide anoxic zone (probably, the largest one on the planet). The North-Western shelf of this basin and some shallow coastal areas are affected by seasonal hypoxia caused by the enrichment of seawater by nutrients from rivers.

Nikitin and Malm (1932) first estimated the lower habitat border for copepods in the Black Sea as  $0.1 - 0.3$  mL  $O_2$  L<sup>-1</sup> where *Calanus helgolandicus* aggregate during daytime. These authors reported that under conditions of experimental hypoxia the individuals of this species died at the close oxygen concentrations of 0.2-0.3 mL  $O_2$  L<sup>-1</sup>. Further studies (Flint, 1989; Vinogradov *et al.*, 1992; Arashkevich, 1996) showed that in summer-autumn season the daytime aggregation of *C. helgolandicus* had а two-layer structure. The lower layer

formed by diapausing CV  $(CV_d)$  was located where the oxygen concentration was near 0.2 mg  $O_2 L^{-1}$ . The upper layer consisting of migrating CV (CV<sub>m</sub>) and adults was located at the oxygen concentration of about 0.8 mg  $O_2 L^{-1}$ .

Vinogradov *et al.* (1992) reported that the respiration rate of  $CV_d$  decreased about 3-fold from 0.13 to 0.043  $\mu$ L O<sub>2</sub> mg<sup>-1</sup> h<sup>-1</sup> at the oxygen concentrations changing from 9.2 to 0.2 mg  $L^{-1}$ . They also found that CV<sub>d</sub> were able to survive for some days under oxygen deficiency (up to 0.08 mg  $O_2 L^{-1}$ ), however, the oxygen concentration of 0.06 mg  $L^{-1}$  was pointed as the lethal one.

## **4.1. Effect of Oxygen Concentration on Energy Metabolism of the Migrating and Diapausing** *Calanus helgolandicus*

More detailed studies of the effect of dissolved oxygen on respiration rate and ammonia excretion in active and anesthetized (both diapausing and migrating copepods) *C. helgolandicus* were conducted in shipboard experiments (Svetlichny *et al.*, 1998, 2000 and 2002) with the individuals collected in offshore regions of the Black Sea.

In CV and adult females of *C. helgolandicus* performing daily vertical migrations, specific values of the total and basal metabolic rates*,* as well as the ammonium excretion rates as an indicator of protein catabolism, did not differ significantly. Therefore, the data obtained on migrating  $CV<sub>m</sub>$  and females were joined and represented as one environmental group (CM).

It was shown that when the oxygen concentration decreased from 9 to 0.8 mg  $L^{-1}$ , in the CM collected at night in the sub-surface layers the weight-specific metabolic rate at 8○C reduced 2.7-fold from 7.0 to 2.6 J mg<sup>-1</sup> h<sup>-1</sup> (Figure 15A). At the same temperature, the energy of the protein catabolism was independent of the oxygen concentration varying randomly within the range from 3.1 to 4.6 J mg<sup>-1</sup> h<sup>-1</sup>. Constituting about 60% of total energy metabolism under the normoxia, protein catabolism exceeded the respired energy by 50% at the oxygen concentration of 0.8 mg  $L^{-1}$ . These data point to the great contribution of the anaerobic protein catabolism to the total energy metabolism in CM during daytime aggregation in the hypoxic layers.

In the anesthetized individuals from the CM group, both respired energy and the protein catabolism significantly decreased proportionally to the oxygen concentration. Due to this reason, in the individuals from the CM group, when the oxygen concentration reduced, the ratio between total metabolic energy of active and anesthetized CM increased from 2.5 under normoxia to 4.5 at 0.8-0.9 mg  $O_2 L^{-1}$  indicating a high cost of activity in CM under hypoxic conditions.

In  $CV<sub>d</sub>$  collected at night in the hypoxic layers, the total energy metabolism also depended upon the oxygen concentration (Figure 15B). Higher metabolic rate of untreated  $CV<sub>d</sub>$  in comparison with anesthetized individuals indicated that during diapause  $C$ . *helgolandicus* were able to show locomotor activity necessary for controlling the habitat depth near the hydroxide sulfide zone border. At the oxygen concentrations of  $0.6 - 0.8$  mg  $O_2$  L<sup>-1</sup> (minimum values for CM), the total energy metabolism in untreated CV<sub>d</sub> was on average 2.3-fold lower than that in active СM, whilst the metabolic rates in anesthetized СM and  $CV<sub>d</sub>$  were close. However, the ability of  $CV<sub>d</sub>$  to live at the lower oxygen concentration

(about 0.3 mg  $O_2 L^{-1}$ ) allows them to reduce 4-fold their metabolism in comparison with the possible minimum metabolism of active and anesthetized СM. As a result, the metabolism of  $CV<sub>d</sub>$  aggregating in the active state in the hypoxic layers was 7-fold lower in comparison with the metabolic rate of active СM living at normoxia, whilst there was 28-fold difference between the metabolic rates of active CM and torpid  $CV<sub>d</sub>$  under normoxic and hypoxic conditions, respectively. This difference was significantly higher than that between the specific metabolic rates in active CV and overwintering torpid CV<sub>d</sub> of *C. finmarchicus* and *C. helgolandicus* (about 7 times) from the Norwegian fjords (Hirche, 1983), and *Calanoides carinatus* (factor of 11) from the Antarctic region of the Southern Ocean (Drits *et al.*, 1994) where the hypoxic zones are absent.

Figure 15. Energy equivalents  $(J mg^{-1} h^{-1})$  of weight-specific respiration and ammonia excretion rates in CM (A) and diapausing  $CV_d$  (B) of *Calanus helgolandicus* at different oxygen concentrations and constant temperature of 8 $\degree$ C. A: respiratory energy of active ( $\bullet$ ) and anesthetized ( $\bullet$ ) CM and ammonia excretion rate of active ( $\circ$ ) and anesthetized ( $\circ$ ) CM; B: energy of total metabolism ( $\bullet$ ) and catabolized protein ( $\circ$ ) of active diapausing CV<sub>d</sub> and energy of basal metabolism in anesthetized CV<sub>d</sub> ( $\bullet$ ) (From Svetlichny *et al.*, 2002 with changes).

Figure 16. C*alanus helgolandicus.* Effect of oxygen concentration on locomotor parameters at 8ºC. A: time spent swimming (% of total time) and B: beat frequency (Hz) of mouthparts in CM ( $\bullet$ ) and  $CV_d$  ( $\circ$ ), and C: active metabolism (J mg<sup>-1</sup> h<sup>-1</sup>) of CM ( $\bullet$ ) and CV<sub>d</sub> ( $\circ$ ) and mechanical power (J mg<sup>-1</sup> h<sup>-1</sup>) of CM ( $\bullet$ ) and CV<sub>d</sub> ( $\Diamond$ ) (From Svetlichny *et al.*, 2002 with changes).

The effect of the oxygen concentration on the parameters of locomotion activity was examined in the individuals attached to a semiconductor force sensor. In the experiments with CM, the oxygen concentration was decreased by bubbling the water with gaseous nitrogen during 2-3 hours imitating oxygen concentration changes during diel vertical migrations (Svetlichny *et al.*, 2000; Mutlu, 2003). In our study the individuals of  $CV_d$  collected at the depth by the plankton net experienced gradual oxygen concentration decrease in the similar mode. At every value of oxygen concentration, copepods were kept about 10 min when force production by mouth and swimming limbs, their beat frequency and duration of main behavioral acts were recorded.

Under experimental conditions, the decrease in oxygen concentration brought to an increase in the regularity of routine swimming of CM using mouth appendages (Figure 16A), until at about 1 mg  $O_2$   $L^{-1}$  the activity of copepods became nearly persistent. Such type of behavior in CM seems to be due to the necessity to control the habitat depth in the hypoxic layers located above the anoxic zone. These experimental results were confirmed by the numerous field acoustic studies of vertical migrations of *C. helgolandicus* in the Black Sea conducted by Mutlu (2003 and 2007). However, an increase in the regularity of swimming was followed by the decrease in beat frequency of mouthparts (Figure 16B) reflecting the speed of limb strokes. As a result of such adverse hypoxic effect, active metabolism of CM estimated from the difference in the energetic equivalents of active and anesthetized individuals insignificantly depended on the oxygen concentration, whilst the mechanical power of locomotion calculated from the force production by mouth and thoracic limbs and their circular speed (Svetlichny *et al.*, 1998) weakly decreased. Consequently, the total efficiency of the transformation of mechanical energy to biological one also reduced following the decrease in the oxygen concentration from 13 to 7% (Figure 16С).

The parameters of activity in  $CV_d$  showed similar trends of oxygen concentration dependence while their absolute values were significantly lower, especially the locomotion efficiency constituting only 3-4%. One should take into consideration that the absence of complete torpidity in  $CV_d$  may be due to the increase in their activity resulting from capture and maintenance in the oxygenated seawater.

#### **4.2. Effect of Oxygen Concentration on Respiration Rate of** *Calanipeda aquaedulcis* **and** *Arctodiaptomus salinus*

In contrast to *C. helgolandicus*, in *Calanipeda aquaedulcis* and *Arctodiaptomus salinus* females a significant response of respiration rate to oxygen concentration changes over the range of  $1 - 8$  mg  $O_2 L^{-1}$  was not found. However, when oxygen concentration decreased from 0.7 mg  $O_2$  L<sup>-1</sup> to sublethal values (about 0.2 mg L<sup>-1</sup> in *C. aquaedulcis* and 0.4 mg L<sup>-1</sup> in *A*. *salinus*), which experimental copepods can tolerate only for 1 - 2 h, respiration rates fell dramatically (about 5 times) in both species (Figure 17).

Consequently, according to our results, the Black Sea deep-water *C. helgolandicus* and coastal *C. aquaedulcis* and *A. salinus* perform two types of reaction to oxygen concentration changes (see Prosser, 1973): oxyconformic response, when animals steadily reduce their energy metabolism with decreasing ambient oxygen concentration; and oxyregulation response, when animals keep nearly constant respiration rate up to critical value of oxygen concentration, after which oxygen consumption declines. In *C. aquaedulcis* and *A. salinus* a

critical oxygen concentration of  $0.7 - 0.8$  mg  $O_2$  L<sup>-1</sup> (or  $0.5 - 0.6$  mL  $O_2$  L<sup>-1</sup>) was found, lower than  $1-2$  mL  $O_2$  L<sup>-1</sup> which is the shift value for hypoxic and normoxic sea conditions (Middelburg and Levin, 2009). Nevertheless, these species may be considered as the oxyphilic copepods similar to *Acartia tonsa*, which experienced sub-lethal effects of hypoxia below the oxygen partial pressure of 3.1 mg  $L^{-1}$  (2.3 mL  $L^{-1}$ ) (Elliott *et al.*, 2013) and died at the oxygen concentration of 0.7 mL L -1 (Marcus *et al.*, 2004).

Figure 17. Effect of the oxygen concentration on respiration rate of *Arctodiaptomus salinus* (●) and *Calanipeda aquaedulcis* ( $\Diamond$ ) (Recalculated from Svetlichny et al., 2012b).

## **4.3. Energy Benefits of the Development of** *Calanus helgolandicus* **in the Black Sea Environment**

*C. helgolandicus* is widely distributed in the North Atlantic seas. Fleminger and Hulsemann (1987) were the first who put attention to the fact that the definitive body size of females from the Black Sea exceeds greatly that of females of *C. helgolandicus* from the West, Mid-North, East–North Atlantic and Mediterranean Sea. Only in the Celtic Sea (Williams and Robins, 1982) and North Sea (Hirche, 1983), the body length of *C. helgolandicus* approximates to that of the Black Sea individuals. CVs and adults from the Black Sea population are able to accumulate large amount of lipids, mainly wax esters (Yuneva *et al.*, 1997 and 1999) reaching up to 30% of body volume (Svetlichny *et al.*, 1998) which is close to lipid content of *C. helgolandicus* from the North-East Atlantic regions (Miller *et al.*, 2000). However, in the North-East Atlantic the development of *C. helgolandicus* population is timed with algae bloom at very high chlorophyll *a* (Chl *a*) concentration up to 7.6  $\mu$ g L<sup>-1</sup> (Ceballos *et al.*, 2004), while the Black Sea population develops at low algae concentrations (0.29–0.68 μg Chl *a* L<sup>-1</sup>) (Yuneva *et al.*, 1997). We suggest that diel descending of *C. helgolandicus* from upper layers to cold hypoxic zone of the Black Sea facilitates the utilization of the energy of consumed food for growth and lipid accumulation. The ability to decrease energy expenditure is of great importance especially during summer season, when chlorophyll *a* concentration reduces to 0.22  $\mu$ g L<sup>-1</sup> (Yunev *et al.*, 2005).

To test this hypothesis, we conducted comparative studies of ontogenetic changes of size, lipid content, molting patterns and respiration rate of *C. helgolandicus* collected in the Black Sea (BS), Marmara Sea (MS) and Ionian (IS) Sea. The phases of molting cycle were determined in CV basing on changes in the mandibular gnathobase during tooth formation (Miller *et al.*, 1991; Arashkevich *et al.*, 2004; Svetlichny *et al.*, 2006b).

In all studied areas, the modal intervals of the egg diameter varied in the same range of 172–180 µm, which also was close to the egg diameter of this species in the English Channel (Marshall *et al.*, 1953, Guisande and Harris, 1995, Poulet *et al.*, 1995).

In *C. helgolandicus* from the BS, MS and IS the body sizes of nauplii and early copepodites were close as well. However, starting from CIII, the divergence of prosome length began to increase, and resulted in 20 - 25% excess of prosome length in CV and adults from the BS in comparison with the MS and IS (Figure 18A). In *C. helgolandicus* from the MS and IS, lipid accumulation in the oil sac occurred almost uniformly and reached maximum values in females (similar to the populations of this species in the North Sea, see Rey-Rassat *et al.*, 2002). By contrast, in the Black Sea *C. helgolandicus* CVs showed the maximum rate of lipid storage, which was spent then by females and males in the reproductive process (Figure 18B). In our opinion, the following reasons can determine the lipid accumulation in the Black Sea *C. helgolandicus*:

In our opinion, the following factors may contribute to a more efficient accumulation of lipids in the Black Sea *С. helgolandicus*: 1) an adaptation to periodic hypoxia during diel vertical migrations from subsurface to cold, hypoxic layers shifts the total energy metabolism of CVs to a lower level, as compared to non-migratory individuals (Figure 18C), due to lower level of the basal energy metabolism (Figure 14); 2) a decrease in temperature and oxygen concentration during vertical migration reduces the metabolic rates of CVs to the level of the basal metabolism due to the inhibition of their motor activity; both these factors lead to an increase in efficiency of use of food consumed for the formation of lipid reserves; 3) under hypoxic conditions during the daytime, the catabolism of lipids is depressed whilst the synthesis of fatty alcohols from non-lipid components in the oil sac may be facilitated (Sargent and McIntosh, 1974); 4) the development rate at the reduced metabolic level is decreased and CVs molted from CIVs have a longer period to accumulate lipids.

This phenomenon may be confirmed by the fact that, in contrast to CVs from MS and IS, in the BS CVs group during all seasons predominantly consisted of the postmolts (Figure 19A). In April 2003, during the cruise of the R/V "Knor," the postmolts with soft integument, low lipid content and small gonads and also the postmolts, intermolts and premolts with high lipid content and increased gonads were found simultaneously at night in the upper layers of the Main Rim Current of the BS (Figure 19B), whilst in the hypoxic layers diapausing postmolts without gonads and with high lipid content aggregated. Consequently, the population of *C. helgolandicus* concurrently included lipid-poor migrating CVs postmolts (just after molting), migrating CVs postmolts with medium lipid content and lipid-rich diapausing CVs postmolts (Svetlichny *et al.*, 2009). One can suggest that the main pool of reserved lipids is accumulated in the Black Sea *C. helgolandicus* in the phase of the postmolts of CVs. In any case, in the Black Sea the postmolts of CVs possessed 8-fold higher lipid content than CIVs (Figure 18B) collected during numerous cruises in 1996-2010 (Svetlichny *et al.*, 1998, 2006b, 2009; Svetlichny and Hubareva, 2014b).

Figure 18. Ontogenetic changes of size (diameter of eggs, total length of nauplii and prosome length of copepodites) (A) in *Calanus helgolandicus* populations from the BS ( $\bullet$ ), MS ( $\lozenge$ ) and IS ( $\blacktriangle$ ), oil sac volume (B) in populations from the BS ( $\blacksquare$ ), MS ( $\Box$ ) and IS ( $\ddot{\odot}$ ) and weight-specific respiration rate (C) of the BS and MS *C. helgolandicus* from nauplii to adults during winter-spring period (Recalculated and combined data from Isinibilir *et al.*, 2009; Svetlichny *et al.*, 2010b; Svetlichny and Hubareva, 2013).

To estimate the duration of the development stages and lipid accumulation in the Black Sea *C. helgolandicus*, a reconstruction of their age dynamics was made basing on the field studies (April 2003) of molt increments of the body weight, lipids content and specific growth rate as a function of stage specific metabolic rates and growth efficiency at 8°C (Svetlichny *et al.*, 2009). According to our estimates, the period of intensive lipid reserve formation from late premolts of CIVs to late postmolts of CVs took approximately 20 d while total duration of CVs is about 30 d. This is significantly higher than median development time (9.6 to 12.1 d) of CV in *Calanus* elsewhere at ~8°C (Vidal, 1980a; Thompson, 1982; Corkett *et al.*, 1986; Campbell *et al.*, 2001). Therefore, total development time from eggs to adults lasted about 66 d, which is in accordance with the development time only in subarctic *C. finmarchicus* (Miller and Tande, 1993; Jensen *et al.*, 2006).

Figure 19. Frequency distribution of molting cycle phases (A) in CVs of *Calanus helgolandicus* from the BS ( $\bullet$ ), MS ( $\Box$ ) and IS ( $\circled{3}$ ) and mean oil sac volume of the Black Sea *C. helgolandicus* CVs molting groups (B) just after molting from CIVs ( $\blacksquare$ ), diapausing postmolts ( $\Box$ ) and migrating ( $\blacksquare$ ) postmolts (P), late postmolts (LP), intermolts (IN), early premolts (Epr) and late premolts (LPr) (Recalculated from Isinibilir *et al.*, 2009, and Svetlichny and Hubareva, 2014b).

Due to such characteristics of growth and development, the maximum daily production of 132 mg C m-2 day-1 (Svetlichny and Hubareva, 2011) for *C. helgolandicus* in the Black Sea was slightly lower than those for this species in the phytoplankton-rich North Sea (140 mg C m<sup>-2</sup> day<sup>-1</sup>) (Hay, 1995) and for *Calanus algulhensis* in the South Atlantic (164.4 mg C m<sup>-2</sup> day-1 ) (Hutchings *et al.*, 1995), and significantly lower in comparison with that for the North Sea *C. finmarchicus* (910 mg C m<sup>-2</sup> day<sup>-1</sup>) (Williams and Lindley, 1980).

## **CONCLUSION**

In summary, when comparing the adaptive potentials of the Black Sea copepods, one should note the extraordinary euryhaline abilities in the Pontian relict *Calanipeda aquaedulcis* and Palaearctic *Acartodiaptomus salinus* when 50% of specimens of these species underwent salinity changes in the range of  $0.2 - 50$  and  $0.2 - 35$  psu, respectively. Both species collected in salt lakes of Crimea were able to be cultivated in the brackish and fresh water. Such osmotic relations of organisms with their environment characterize euryhaline amphiosmotic osmoregulators that originated from freshwater environments (Khlebovich and Aladin, 2010) although, according to our results, both studied species are osmoconformers as most marine copepods. It is important to emphasize that these abilities are genetically determined in both species as they were maintained at constant salinity of 18 psu for about 4 yr before the experiments. According to our results, up to 15% of *C. aquaedulcis* specimens survived at 60 psu during 10 d, and some individuals of *A. salinus* were alive for

more than 14 d at salinities up to 70 psu (Svetlichny *et al.*, 2012a). This fact may be considered as extraordinary because even the intertidal harpacticoid copepod *Tigriopus japonicus*, active in a salinity range of 0 to 60 psu, became dormant at salinities above 80 psu (Finney, 1979). Similar to harpacticoids, *C. aquaedulcis* and *A. salinus* are not sensible to Artenminimum barrier (5 to 8 psu) of Remane (1934), 'critical salinity' postulated by Khlebovich (1969), or 'the horohalinicum' (Kinne, 1971) dividing marine and freshwater species.

At the same laboratory conditions *C. aquaedulcis* (whose specific name means 'fresh water') withstood higher increase in salinity than *A. salinus* (whose specific name means 'salty'). In the Aral Sea *A. salinus* was a dominating species at low salinity (< 13 psu), however after the salinity increase up to 20 psu the invader *C. aquaedulcis* completely substituted for *A. salinus*. The effect of substitution can be related to the trophic factor, nevertheless when *C. aquaedulcis* disappeared from the Aral Sea after the increase in salinity up to 50 psu, *A. salinus* did not return to the sea from the adjacent lakes (Aladin *et al.*, 2004).

Widely euryhaline *C. aquaedulcis* is also an eurythermic species capable to develop within the temperature range from 3 tо 30℃ (Bledzki and Rybak, 2016), whilst the lower temperature border for *A. salinus* was near 13°C (Anufrieva and Shadrin, 2014), which is significantly higher than the winter temperature of the Black Sea. *A. salinus* survive cold season in the stage of diapausing eggs.

According to the response to oxygen concentration changes, both relict species are oxyphylic copepods.

A wide adaptive plasticity was found also in the alien species *Acartia tonsa* and *Oithona davisae* which was limited by critical salinity from 2 - 3 to 40 - 50 psu. According to Deaton and Greenberg (1986), the most pronounced changes in ionic composition of diluted seawater are attributed to the salinities lower than this value, therefore the salinity of  $2 - 3$  psu to a greater extent may be considered to be a physico-chemical barrier for brackish animals than "critical salinity" reported by Khlebovich (1969). Both of these marine species were able to osmoregulate in the salinity tolerance ranges.

Thermophylic *A. tonsa* and *O. davisae* used two different strategies of surviving at the low temperature during the assimilation in the Black Sea. Due to the absence of lowtemperature tolerance, *A. tonsa* in the Black Sea survive winter in the stage of resting eggs, while population of *O. davisae* can overcome late winter to mid-spring period in the state of mating females.

Salinity tolerance range of the Mediterranean immigrants, the eurythermic *Acartia clausi* and the cold-water stenothermic *Oithona similis*, obtained in our experiments were typical for marine species. *A. clausi* collected in the Black Sea at 18 psu withstood gradual salinity changes from 10 to 35 psu, whilst the individuals collected in the Marmara Sea at 22 psu were not sensitive to salinity about 40 psu. Within that salinity range *A. clausi* performed the isoosmotic response. For *O. similis* a salinity tolerance range turned out to be narrower  $(10 - 30)$ psu), however this fact may be due to the difficulties of keeping this species under laboratory conditions. According to Nikitin and Malm (1932), both species are able to survive at the oxygen concentration decrease to  $0.17$  mL  $L^{-1}$ , while only *O. similis* can descend to the hypoxic layers of the Black Sea.

The most abundant inhabitant of the open zone of the Black Sea, *Calanus helgolandicus* is well adapted to low temperature, oxygen concentration and salinity, although this species can tolerate a salinity about 40 psu after gradual salinity acclimation (Svetlichny *et al.*,

2010b). All these abiotic factors which decrease the metabolism, especially hypoxia, determine the successful development of *C. helgolandicus* in the Black Sea. The North Atlantic *C. helgolandicus* was considered to be transferred into the Black Sea after flooding of the Black Sea with Mediterranean waters and to form there a phenotypic isolated population which was recognized as a distinct species by Fleminger and Hulsemann (1987) with the name of *Calanus euxinus* (Hulsemann, 1991). However, the genetic divergences between the North Atlantic, Mediterranean and Black Sea populations are much lower than congeneric interspecific divergences in calanoid copepods (Papadopoulos *et al.*, 2005; Unal *et al.*, 2006). In addition, within the limits of revealed genetic variations in local populations in Swedish and Norwegian Fjords, Oceanic Inflow, North-East Atlantic, Adriatic Sea, Mljet Island, Aegean Sea and Black Sea the lowest level of genetic difference was obtained between the Fjords and Black Sea populations (Yebra *et al.*, 2011). Fjords, as a land-enclosed water bodies, have a long residence time, little water exchange and often exhibit temperature and oxygen depletion in deeper waters. Therefore, if the hypothesis of Polischuk (1984) about the penetration of of boreal species into the Black Sea directly from the northern seas is right, one can suggest that this species has been already pre-adapted for living in its highly stratified environment. In the Black Sea, *C. helgolandicus* is the most abundant copepod of the Main Rim Current system which is slightly sensitive to the global ecological trends. Therefore, the population of *C. helgolandicus* seems not to be affected by warming events so profoundly as the coastal copepod populations.

During several decades, coastal copepod species as *Paracartia latisetosa*, *Acartia margalefi* and *Oithona nana* were eliminated from the zooplankton community of the Black Sea. The ecological niches of *A. latisetosa* and *A. margalefi* were occupied by the invader *A. tonsa* (Gubanova, 2000), while since 2001 a new species *O. davisae* (Gubanova *et al.*, 2014) identified first as *Oithona brevicornis* (Zagorodnyaya, 2002) appeared instead of *O. nana* in the Black Sea.

Among our studied species, *O. nana* has extremely narrow salinity range (15 – 28 psu) indicating a narrow ecological specialization of this species, nevertheless this copepod is widely distributed in the high-saline and even hyper-saline Adriatic Sea (Razouls *et al.*, 2005 - 2017). At the beginning of the 1990s *O. nana* was eliminated from the Black Sea after the invasion of *Mnemiopsis leidyi*. According to Kovalev (2007), an inhabitant of the surface layers, broadcasting *O. nana* was subjected to the most severe elimination because females of this species were eaten by *M. leidyi* together with the brood. This copepod species survives until now in the brackish upper layers of the adjacent Marmara Sea (Isinibilir *et al.*, 2011) and Golden Horn Estuary (Dorak and Temel, 2015), probably due to lower abundance of *M. leidy*i in these regions. However, *O. nana* did not return to the Black Sea after the trophic balance restore in the late 1990s as a result of the appearance of another predator, the ctenophore *Beroe ovata* feeding on *M. leidyi*. The Bosphorus Strait as an ecological barrier may be one reason for this situation (Öztürk and Öztürk, 1996; Svetlichny *et al.*, 2006a; Oğuz and Öztürk, 2011). In order to return to the Black Sea, *O. nana* needs to use the Bosphorus bottom counter current with the salinity of about 38 psu which is harmful to this species. Another factor of its failure in the Black Sea may be the fact that its ecological niche from the early 2000s was occupied by the more competitive *O. davisae*.

#### **ACKNOWLEDGMENTS**

The present study was partly supported by TUBITAK (Turkish Scientific Technical Research Council) - NASU (National Academy of the Ukraine) joint projects №104Y208 and №107Y001, NATO Linkage Grants №971818 and №983036, the Research Fund of the Istanbul University (IRP-49165) and project PERSEUS (FP7-287600). We appreciate the cooperation and help of the staff at the R/V "Professor Vodyanitsky," "Bilim" and "Knorr" during the cruises.

The authors express heartfelt appreciation to Prof. G. Belmonte and Dr. S. Zervoudaki for their suggestions and constructive comments on the manuscript.

# **THE BIOLOGY OF MYELIN IN CALANOID COPEPODS**

# *Petra H. Lenz\* and Daniel K. Hartline*

Békésy Laboratory of Neurobiology, Pacific Biosciences Research Center, University of Hawaiʻi at Mānoa, Honolulu, Hawaii, US

#### **ABSTRACT**

Myelin is an evolutionary innovation by the nervous system that greatly speeds nerve impulse conduction, thus reducing communication delays within an organism and enhancing its information processing capabilities. The discovery of myelin in approximately half of calanoid copepod taxa came as a surprise. The evolution of myelin is usually associated with large organism size and/or complex nervous systems, not small organisms with simplified nervous systems. Myelinate and amyelinate species occur in similar numbers, with both groups being highly abundant and key members of marine planktonic communities. Myelinates and amyelinates have similar size distributions, similar antennule to prosome length ratios, overlapping maximum escape speeds scaled to copepod length, and similar sensory and motor system organization. Nevertheless, the biogeographic distributions and functional ecological groups of myelinate and amyelinate taxa differ markedly, suggesting niche separation based on nervous system architecture. Behavioral differences between the amyelinate and myelinate forms are apparent: not only are myelinate copepodites quicker than amyelinates in responding to a sudden hydromechanical stimulus but they are also better at localizing and escaping away from its source. The enhanced performances conferred by nervous system myelination in calanoids in combination with biogeographic observations supports the conclusion that myelination provides extra protection in habitats characterized by high risk from visual predators. In contrast, amyelinate calanoids may depend on strategies that reduce encounter rates with predators, such as diel vertical migration, dormant eggs and reduced activity levels.

## **1.INTRODUCTION**

A fundamental paradigm shift in ecological theory came with the realization that major interactions such as the impact of predators on prey, competition for limiting resources, habitat use, and the nature of food webs could not be understood without incorporating behavior (Schmitz *et al*., 2008; Valdovinos *et al*., 2010; Sih *et al*., 2012). In turn, animal behavior is determined by the nervous system: information is acquired through sensory systems, which is transmitted for central processing prior to generating a behavioral output. The nervous system is critical to an organism's behavioral repertoire, and sets constraints on its niche. Thus, any major change to the nervous system in a group of organisms not only affects their behavior directly, but it has significant impacts on ecological patterns. The evolution of myelin in half of calanoid copepods is a prime example of such a change (Davis *et al*., 1999). Myelin is a radical innovation of the nervous system that increases the speed of nerve impulse conduction by an order of magnitude (Ritchie, 1984). This potentially endows a myelinate species with a multitude of advantages over similar amyelinate species, including greater success in escape from predators, greater success in predatory attacks, improved coordination in muscle contraction, greater compactness of nervous systems, more rapid processing of complex information, maintenance of timely communication over greater body distances (*e.g.*, whales and dinosaurs) and enhanced precision in event timing (Hartline and Colman, 2007; Hartline, 2008). Thus, the observed split of the calanoids into either amyelinate or myelinate taxa is of major significance not only to the animal's behavioral performance but also to its ecology.

How has the evolution of myelin affected calanoid copepods and planktonic communities in general? While it is unlikely that this question can be answered directly, behavioral studies in combination with analyses of plankton community structure and trophic cascades, placed against an understanding of the properties of myelinated nerves (Hartline and Colman, 2007; Rosenbluth, 1999), can provide insights into niche separation between myelinate and amyelinate taxa. Here, we review the biology of myelin in calanoids with two major goals: 1) to describe the current knowledge of the structure and function of myelin including its development; and 2) to discuss the significance of myelination to behavior and its potential role in the ecology of zooplankton communities. We propose that myelin plays an important role in the effectiveness of a copepod's escape response, which is key to niche separation between myelinate and amyelinate taxa.

## **2. STRUCTURE AND FUNCTION OF COPEPOD MYELIN**

#### **2.1. Copepod Myelin is an Axonal Sheath Composed of Multiple Concentric Layers of Membrane**

Detailed anatomical studies of *Calanus finmarchicus* (myelinate) and *Epilabidocera amphritites* (amyelinate) show that the two species are similar in the overall organization of their central and peripheral nervous systems (Lowe, 1935; Park, 1966). The number and type of sensory setae on the antennules are similar in myelinate and amyelinate copepods (Huys
and Boxshall, 1991; Ohtsuka and Huys, 2001). Myelin stands out as the major difference between the nervous systems of myelinate and amyelinate calanoids.

The difference between a myelinated and an unmyelinated copepod axon is dramatic, as illustrated by the electron micrographs in Figure 1 (A, B). The unmyelinated axon consists of a single simple cell membrane surrounding microtubule-containing cytoplasm (termed "axoplasm"; Figure 1A). The myelinated axon is ensheathed in many concentric layers of membrane compacted together along one face (Figure 1B). The layers in the copepod are unusual in being without any gaps or seams, forming in mature myelin, concentric tubes surrounding the length of the axon and interrupted only in places by myelin-free patches termed "nodes" (Davis *et al*., 1999; Weatherby *et al*., 2000).

### **2.2. Copepod Myelin is Produced by Nerve Cells, Not Glia**

Myelination of the nervous system is gradual and occurs throughout development. In the paracalanid *Bestiolina similis*, the first nauplius stage (NI) has been found to lack myelin completely (Wilson and Hartline, 2011a). Wilson and Hartline (2011a) were able to follow reidentifiable axons from one stage to the next and demonstrate how "naked" axons transition into myelinated axons through several intermediary stages as the copepod develops first through the six naupliar and then six copepodite stages. The first sign of myelin occurs in the second nauplius (NII) with the appearance of "partial" myelin in a single axon of the protoventral nerve cord. Two more axons commence myelination in the NIII stage. These three reidentifiable pairs of myelinated naupliar axons are likely involved in relaying sensory information from posterior mechanoreceptors to anterior centers involved in escape behavior. "Partial" myelin originates as a single internal cisterna adhering to a portion of the inner surface of the axon membrane (Figure 1C) (Wilson and Hartline, 2011a and b). As development progresses, additional cisternae are added internally against the layer previously laid down to form a stack. As the myelin develops further, the stack expands around the inside of the axon (Figure 1D) to eventually envelop it completely in a seamless multilamellar sheath of myelin (Figure 1B) (Wilson and Hartline, 2011a and b). The number of myelin layers surrounding individual axons is greater in larger fibers, as is the case with vertebrate myelin. The formation of myelin internally to the axon is a radical departure from all other known cases of myelin formation, in which it is derived from the surrounding glial cells (Raine, 1984). "Copepods break all the rules" (T.M. Weatherby, personal communication).

Large changes in form, including a reorganization of the nervous system, occur between the nauplius and the copepodite stages (Mauchline, 1998). The transition is characterized by the loss of the three pairs of large myelinated naupliar axons (Wilson and Hartline, 2011a). Myelination of the central nervous system and the antennular nerves is still at an early stage in the first copepodite, with just a few axons so ensheathed. The first axons to become myelinated in the early copepodite are the giant axons in the ventral nerve cord, which presumably are involved in escape responses (Lowe, 1935). Increases in both the number of myelinated axons and the number of layers are observed throughout the copepodite stages. Myelination is not complete until the final molt into the adult (Wilson and Hartline, 2011a). The overall pattern of myelin formation includes an anterior to posterior progression, large axons myelinating first, as happens also in vertebrates, and myelin developing earlier in the

Figure 1. Ultrastructure of calanoid copepod myelin. A. Cross section through the antennular nerve of an amyelinate, *Candacia aethiopica*. Axons (ax) have at most a simple single-layer glial sheath (gc); other abbreviations: muscle (mu); mitochondria (mi). Note the large size of one mechanosensory axon presumed to mediate rapid responses to hydrodynamic disturbances. B. Cross section through a myelinated axon from the central nervous system of *Bestiolina similis*. Note the multiple continuous concentric layers of membrane tightly apposed along one face to neighboring membrane. Glial cells (gc) are not involved in forming the myelin. C. Cross section through an early stage in the development of a myelinated axon. A single internal cisterna (solid arrow) is apposed to the inner surface of the axon. The investment is incomplete, leaving a portion of the axonal membrane exposed on both intracellular and extracellular faces (open arrow). D. Cross section through an axon showing a somewhat later stage of myelin development: four cisternae are stacked together against the inner surface of the axon. Scale bars: A: 1 μm; B: 200 nm; C, D: 50 nm. A: from [www.pbrc.hawaii.edu/~petra/copepod.html,](http://www.pbrc.hawaii.edu/~petra/copepod.html) with permission. modified from image by A. Davis, B-D: Modified from Wilson and Hartline (2011b), with permission.

These studies show that myelination, and by inference the conduction speed enhancement it provides, increases continuously throughout development. In adult calanoids, nearly all axons are myelinated, even very small, presumed chemosensory axons of the first antenna (Weatherby *et al*., 2000). The advantages accruing to the organism from the faster conduction speed are expected to increase in parallel.

### **2.3. Myelin Functions by Electrically Insulating Axons**

Myelin speeds nerve impulses by providing an insulating sheath around an axon that prevents leakage of electrical current needed to regenerate and propagate the impulses (Ritchie, 1984). Direct measurements of conduction speed have not been made in copepods owing to their small size. Nevertheless, the same principles are expected to govern its properties as for all other cases of myelin (Hartline, 2008). Consistent with properties of other myelinated nerve, extracellularly-recorded impulses in myelinate copepods are shorter in duration and smaller in amplitude than those in amyelinates (Lenz *et al*., 2000).

The better the insulation the faster the conduction. A nerve impulse is initiated when current through an axonal patch raises the trans-membrane voltage above a threshold level. Thereupon, voltage-gated sodium channels open sufficiently to cause regenerative entry of sodium ions that sustain the impulse. In unmyelinated fibers, the electrical current thereby produced expends itself charging near-by regions ahead of the travelling impulse to bring them to threshold. When those near-by regions are electrically insulated with myelin, the current passes unimpeded farther down the axon to the next uninsulated channel-bearing membrane (typically a node), where rapid charging to threshold results in a faster conduction speed. The seamless concentric leak-free construction of the copepod myelin along with the small-amplitude impulses observed suggests that the insulating properties may be better than those of other myelin sheaths.

# **3. COPEPOD MYELIN IS CONFINED TO MORE RECENTLY EVOLVED SUPERFAMILIES**

Calanoid diversity is characterized by a nearly 50:50 split between amyelinate and myelinate taxa (Lenz, 2012; Lenz *et al*., 2000). The Calanoida have been organized into 10 super-families (Park, 1986). While this organization into super-families is generally supported by more detailed morphological analysis and molecular-based phylogenetic tree, it is likely to be an oversimplification of the evolution of the taxon (Blanco-Bercial *et al*., 2011; Bradford-Grieve *et al*., 2010). Nevertheless, the super-families provide a well-supported framework for the absence/presence of myelin (Davis *et al*., 1999; Lenz *et al*., 2000). Myelin has only been found in calanoids, where it is absent in taxa belonging to basal superfamilies, but is present in the more recently evolved ones (Figure 2). Amyelinates surveyed included representatives from the families Metridinidae in the Augaptiloidea, and Acartiidae, Candaciidae, Centropagidae, Pontellidae, Temoridae and Tortanidae (added since) in the Centropagoidea. Myelinate species were members of the families Calanidae, Megacalanidae (added since) and Paracalanidae in the Megacalanoidea; Eucalanidae in the Eucalanoidea, and Aetideidae, Clausocalanidae, and Euchaetidae in the Clausocalanoidea. Thus, myelinate taxa are largely absent from freshwater systems, which have been colonized primarily by centropagoidean (amyelinate) taxa (Boxshall and Jaume, 2000). So far no members of the superfamilies Bathypontioidea or Spinocalanoidea have been surveyed, but based on their phylogenetic placement, both are likely to be myelinate.

The identification of myelin (or lack thereof) requires examination of nerve tracts using transmission electron microscopy (Figure 1B-D), since myelin is poorly resolved at lower

magnification. Copepods that have been checked for myelin using TEM have either shown no evidence of myelin, or they have a fully myelinated nervous system with nearly all, if not all axons enveloped by myelin (Figure 2). For example, a detailed study of the antennule of *Euchaeta rimana*, a member of the Clausocalanoidea, has shown that motor, mechanosensory and chemosensory axons are all enveloped by myelin sheaths ranging from just a few layers to *ca*. 50 layers (Weatherby *et al*., 2000). Ultrastructural studies of harpacticoids, cyclopoids and siphonostomatoids have not found myelinated axons in these copepod orders (Fahrenbach, 1962 and 1964; Gresty *et al*., 1993). Thus, myelin appears to have evolved a single time in the Copepoda - in the Calanoida, most of which are free-living and planktonic. Some evidence suggests evolutionary trends within the different myelinate groups, for example a greater tendency for more complete membrane condensation in the Clausocalanoidea (*E. rimana*). No examples of copepods representing intermediate stages in myelin evolution have been found, nor any examples of myelin loss. However, the number of species that have been investigated is small, and additional studies are needed to either confirm or refute these generalizations.

Figure 2. Phylogenetic tree of the Copepoda showing the hypothesized relationships between amyelinate (medium grey) and myelinate (black) taxa. Myelin appears only in the more recentlyevolved superfamilies of the Calanoida. Light grey indicates unknown. Phylogeny of the order Copepoda from Huys and Boxshall (1991); that of the Calanoida from Park (1986).

## **4. BODY SIZE DOES NOT CORRELATE WITH MYELINATION**

Since one major benefit of myelin is a ten-fold increase in nerve impulse conduction speed, it has been suggested that the emergence of myelin in the vertebrates was an important contributor to the evolution of larger size (Castelfranco and Hartline, 2016; Salzer and Zalc, 2016; Zalc, 2016). By analogy, one might predict that myelin would lead to the evolution of larger copepods. An analysis of total length of myelinate and amyelinate taxa does not support this prediction (Figure 3A, B). The mean lengths of myelinate and amyelinate species in a broad selection of calanoids from the North Pacific figured in a plankton atlas (Yamaji, 1976) were 2.4 mm (n = 36) and 2.3 mm (n = 57), respectively (Student's t-test; *p* = 0.74). A similar analysis based on data from copepods in the Mediterranean Sea (Benedetti *et al*., 2016) confirmed no difference in size between the two groups (myelinate taxa: average length  $= 2.2$  mm, n = 68; amyelinate taxa: average length  $= 2.2$  mm, n = 54; Student's t-test,  $p =$ 

0.86). However, calanoid copepods were significantly larger than non-calanoid copepods (cyclopoids, poecilostomatoids and mormonilloids: average length =  $1.4$  mm, n =  $69$ ; Student's t-test,  $p = 1 \times 10^{-4}$ ; data from Benedetti *et al.*, 2016). While the calanoid body is quite compact, the antennules are long, typically as long or longer than the prosome length. Longer sensor-bearing antennules provide a copepod with greater sensitivity to water-borne disturbances that signal potential predatory threats (Kiørboe and Visser, 1999), but at the expense of a longer delay in the arrival of that information in the central nervous system (CNS) where it must be acted upon to produce a behavioral response. Faster conduction of this sensory information would alleviate the disadvantage of long antennules. Thus, it might be predicted that antennular length is greater in myelinate than in amyelinate species. The data do not support this prediction (Figure 3C, D) – the median ratio of antennule length to prosome lengths is 1.3 ( $n = 38$ ) and 1.2 ( $n = 58$ ) in myelinate and amyelinate species, respectively (Wilcoxon-Mann-Whitney Rank Sum Test;  $p = 0.50$ ). Thus, the general predictions of myelin leading to the evolution of larger bodies and longer communication distances between remote regions in calanoids are not supported.

Figure 3. Histogram distributions of calanoid lengths (A, B) and antennular (A1) to prosome length ratios (C, D) of adult females in myelinates (black) and amyelinates (grey). Data were obtained from Yamaji (1976). Prosome and antennular lengths were measured from illustrations using ImageJ software. Calanoid lengths were obtained from descriptions, when a range of lengths were given a median value was used for the histogram. Calanoids were categorized into myelinate/amyelinate according to Lenz *et al*. (2000). Total number of observations – A: 36; B: 57; C: 38; D: 58.

# **5. MYELINATE COPEPODS HAVE SHORTER REACTION TIMES THAN AMYELINATES**

While expanding body size does not appear to be a factor in copepod myelination, reaction times are a different matter. Two studies compared response latencies in amyelinate and myelinate species, with somewhat different results. Lenz *et al*. (2000) used brief controlled displacements of a small plastic sphere to produce a calibrated near-field dipole flow stimulus triggering escapes in copepods tethered to a force transducer, so that the time between the onset of the stimulus and that of the force transient of the escape was measured with sub-millisecond accuracy. In two myelinate (*Neocalanus robustior* and *Undinula vulgaris*) and two amyelinate (*Labidocera madurae* and *Pleuromamma xiphias*) species tested (> 2 mm in prosome length), minimum response latencies of myelinate taxa were significantly shorter than those of the amyelinate ones (Figure 4A). A study using an acoustic stimulus and high-speed video to record escapes in free-swimming copepods (myelinate: *Paracalanus parvus*, *Mesocalanus tenuicornis*, *Subeucalanus pileatus*; amyelinate: *Acartia spinata*, *Centropages typicus*, *Pontella marplatensis*, *Pontella* sp., *Pontellopsis brevis*, *Temora turbinata*) failed to find a similar pattern (Waggett and Buskey, 2008). Most of the measured average response latencies ranged between 2 and 4 ms irrespective of the state of myelination or copepod size (prosome length:  $0.6 - 2.3$  mm). However, the experimental setup may not have been optimized for this type of analysis given the ambiguous nature of the acoustic stimulus, the temporal resolution (1 ms) and synchronization between the stimulus and the camera  $(\pm 0.5 \text{ ms})$ . The predicted difference in response latency would be less than 1 ms in the small species tested and requires sub-millisecond resolution to determine reliably. In addition, the two outliers, one myelinate (*S. pileatus*) and one amyelinate (*T. turbinata*) species, responded with longer delays, suggesting that these escapes were mediated by a slower escape circuit, possibly an alternative to the giant fiber circuit (Park, 1966; Lowe, 1935). While not much studied in copepods, arthropods including crustaceans possess multiple neuronal escape circuits having different response latencies (Herberholz and Marquart, 2012). Additional measurements of minimum response latencies to precisely controlled stimuli with high temporal resolution are needed to resolve differences in reaction times among these small organisms.

# **6. MYELINATES LOCALIZE SUDDEN HYDRODYNAMIC DISTURBANCES BETTER THAN AMYELINATES**

Another, more recent study examined the question of whether the presence of myelin might affect escape responses other than through response latencies (Buskey *et al*., 2017; Figure 4). This study, motivated by the presence of exceptionally small myelinate calanoid copepods  $(< 1$  mm total length) compared the directionality of the escape response between myelinate and amyelinate species (Figure 4B, C). Using a precisely controlled abrupt movement of a small plastic sphere to produce a rapidly rising deformation in the surrounding water, Buskey *et al*. (2017) discovered that myelinate copepodites and adults are better at localizing the stimulus and redirecting their escape away from it than amyelinates (Figure 4B, C). This difference was pronounced in copepodites that were initially oriented towards the

stimulus (Figure 4C), while those oriented away directed their escape away regardless of state of myelination (Figure 4B). While the difference in the ability to locate the stimulus was highly significant in copepodite stages (CI-CVI), it was not observed in the nauplii (Buskey *et al*., 2017). The absence of the long antennules and the early stage of myelination of the naupliar forms likely explain this difference.

Figure 4. Calanoid copepod responses to a mechanosensory stimulus. A. Latencies to an abrupt stimulus. Cumulative distribution of the percent of responses within 10 ms after the stimulus was triggered. Black: myelinate species (*Undinula vulgaris* [circles, solid line; n = 77], *Neocalanus robustior* [squares, dashed line; n = 7]; grey: amyelinate species (*Labidocera madurae* [circles, solid] line; n = 13], *Pleuromamma xiphias* [squares dashed line; n=12]). Response latencies measured for individuals tethered to a force transducer. Data redrawn from Lenz *et al*. (2000; Figure 5). Number of responses with delays greater than 10 ms of the stimulus trigger: *U. vulgaris* (n = 0), *N. robustior*  $(n = 0)$ , *L. madurae*  $(n = 3)$ , *P. xiphias*  $(n = 14)$ . B & C. Direction of escape swims of myelinate and amyelinate free-swimming copepods oriented away from (B) or towards (C) the stimulus. Direction of escape response of copepodites (CI-CIII, and CVI) triggered by an abrupt stimulus located at the top of the observation chamber. Species tested: myelinate species - a: *Bestiolina similis*, b: *Parvocalanus crassirostris* (black bars); amyelinate species - c: *Acartia tonsa*; d: *Eurytemora affinis*; e: *Centropages hamatus* (grey bars). Data presented as percentages; number of observations for panel B - a: 14; b: 19; c: 12; d: 37; e: 4, number of observations for panel  $C - a$ : 73; b: 67; c: 54; d: 117; e: 35. ## **7. DO MILLISECONDS MATTER?**

How might the speed advantages of myelin play out in a predatory attack on a copepod? A number of behavioral studies have quantified various aspects of the copepod escape response including outcomes of interactions between copepod prey and fish predators (Bradley *et al*., 2013; Burdick *et al*., 2007; Buskey *et al*., 2002 and 2012; Clarke *et al*., 2005; Coughlin and Strickler, 1990; Coughlin *et al*., 1992; Gemmell and Buskey, 2011 and this volume; Gemmell *et al*., 2012; Jackson and Lenz, 2016; Waggett and Buskey, 2007). While these studies do not answer the question directly, they provide data that can be applied to hypothetical situations to estimate how differences in response time might affect the outcome of a predator-prey interaction. A copepod's peak escape speed matches that of a fish 10 to 30 times its body length (Lenz *et al*., 2004). Thus, a copepod 1 mm in body length can "outrun" a fish 1 to 3 cm in length. Pelagic fish larvae are in this size category and they are major predators of planktonic copepods (Sampey *et al*., 2007). If it takes 1 ms for a 1-mm copepod accelerating at a rate of 200 m  $s^2$  (Buskey *et al.*, 2002) to exceed the peak ram speed of  $\sim$ 200 mm s<sup>-1</sup> of a 1-cm fish larva ( $v_{(mm/s)} = 45 \times BL_{mm}^{0.68}$ ) (Lenz *et al.*, 2004), the copepod can travel 0.1 mm in this time ( $s = 0.5$  at<sup>2</sup>;  $s =$  distance; a = acceleration; t = time). However, there is an expected response-time delay of some 2 ms between detection and the initiation of the escape behavior by amyelinate copepods of this size (*Acartia*: Buskey *et al.*, 2002). The fish would thus have at least a 3-ms head start on the copepod in which time it can cover a distance of 0.9 mm if it is capable of the same acceleration. Thus, the copepod can out-distance the fish if the strike distance is  $> 1$  mm, which is comparable to reported strike distances (China and Holzman, 2014; Coughlin, 1994). Nerve fibers in  $\sim$ 1 mm calanoid escape circuits are  $\sim$ 3  $\mu$ m in diameter (Figure 1A; Wilson and Hartline, 2011a) and are expected to conduct at around 1.7 m  $s^{-1}$  if unmyelinated and around 8 m  $s^{-1}$  if myelinated (Bullock and Horridge, 1965). A myelinate calanoid of this size can thus shave ~1.2 ms off its conduction time along a 2.25 mm pathway (antennule + ventral nerve cord; see also Lenz *et al.* 2004). So the fish would have to reduce its strike distance to 0.2 mm for a successful capture (absent suction) – less easily achieved without alerting the copepod to the fish's approach.

Another important component of the escape is its direction. On a purely random distribution of escapes relative to the direction to the predator, half of escapes would be toward it and half away. While some of the escapes toward the predator might be sufficiently off the line of attack to elude capture (absent strong suction), those directed away are on average more likely to be successful. Thus, an effective escape often involves a reorientation by the prey (Figure 4B, C), but this adds an additional delay to the escape swim. *Acartia tonsa*, for example, takes 1 ms or more to turn 100° (Buskey *et al*., 2002). For a strike from a distance of 0.9 mm, a 1.2 ms faster reaction would allow a myelinate copepod to reorient by up to 120º without exceeding the time needed to achieve a successful escape speed. While the discussion here is speculative, it provides specific hypotheses that might be tested experimentally using high-speed videography to quantitatively compare predatory lunges with escape behavior of copepod prey.

## **8. ECOLOGY OF MYELIN**

## **8.1. Myelinates Dominate over Amyelinates in Marine Environments with High Visibility**

Anti-predator strategies can be divided into adaptations that either 1) lower encounter rates with predators, or 2) allow the prey to escape from a predator once an encounter has occurred (Langerhans, 2007). While calanoids possess numerous adaptations that decrease encounter rates with predators such as transparent and small bodies, diel vertical migration, "sit-and-wait" strategies, and dormancy (Bollens and Frost, 1991; Pasternak *et al*., 2006; Thuesen *et al*., 1998; Strickler *et al*., 2005), the behavioral studies described above support the conclusion that myelin is an adaptation that enhances escape performance, and that it might be a factor in niche partitioning. Since myelinate and amyelinate taxa are widespread and co-occur in all marine environments, this raises the question how this difference in escape performance affects ecological success, measured either by diversity or abundance. A biogeographic study of the distribution of myelinate and amyelinate taxa in oceanic and estuarine environments addressed this question, and concluded that myelinate taxa are more abundant and diverse in environments where a better escape response may effectively decrease risk from visual predators (Lenz, 2012).

Figure 5. Vertical distribution of 10 abundant calanoids of the North Pacific gyre. Bars represent the range over which the indicated species are found. Myelinates (left set of short bars - black) show little diel vertical migration, hence their bars are short. Amyelinates (long, grey bars on the right) are found deeper and many undergo extensive diel vertical migration, so they are found at different depths at different times of the day, greatly expanding their vertical range. Data from Ambler and Miller (1987).

Epipelagic oceanic environments are characterized by high water transparency, low standing stocks of phytoplankton and an abundance of vertebrate and invertebrate predators. Resident calanoid copepods in the upper 100 m are typically dominated by myelinate taxa (Lenz, 2012; Fernández de Puelles *et al*., this volume). While amyelinates are important members of these communities, most of them are predominately diel vertical migrators, which enter the upper water layers primarily at night, thus avoiding day-time encounters with visual predators (Lenz, 2012). Thus, an analysis of the vertical distribution of amyelinate and myelinate taxa in the North Pacific gyre shows a pattern of narrow vertical distributions for the dominant myelinate species, and broad distributions extending into mesopelagic depths for the amyelinates (Figure 5; data from Ambler and Miller, 1987).

Near-shore coral-reef-associated habitats, which are characterized by high transparency and low seasonality, have a predominance of myelinate taxa (Lenz, 2012). These habitats harbor diverse communities of planktivorous fishes, and hence present high risk from visual predators. This is in contrast to most estuarine environments, which are typically dominated by amyelinate calanoid copepods. Many of the latter environments are characterized by high turbidity, which reduces visual predation. Temperate estuaries also experience strong seasonality, so amyelinate calanoids in these environments produce overwintering eggs, a strategy that enhances survival during unfavorable environmental conditions including periods of high predation risk (Marcus, 1984 and 1996; Castro-Longoria and Williams, 1999).

## **8.2. Myelin is Correlated with Niche Separation between Co-Occurring Myelinate and Amyelinate Species**

Niche separation between myelinate and amyelinate species within a zooplankton community is supported by a re-analysis of a study characterizing copepods by their ecological role in the Mediterranean Sea (Benedetti *et al*., 2016). The study found evidence for six distinct ecological niche groupings  $(=$  "functional groups") after clustering 191 copepod species by similarity using data on vertical distribution/migration, swimming behavior, feeding habits/trophic position and morphology. The analysis included 122 calanoids (68 myelinate and 54 amyelinate taxa), 61 cyclopoids/poecilostomatoids, six harpacticoids and two mormonilloids. While five of the six functional groups had a significant number of calanoid species, myelinate and amyelinate taxa did not contribute to these groups proportionally ( $p \le 0.001$ ; Chi-square test; Figure 6). Nearly half (49%) of myelinate taxa belonged to a single functional group (group 4), which consists of species that are mostly herbivorous, oceanic and contribute significantly to carbon flux. Of the remaining myelinate taxa 34% were assigned to functional group 6, which includes a large number of detritivores and small cruising herbivores. Amyelinate taxa were over-represented in three functional groups (70%, groups 1, 2 and 3), which include the large and small carnivores (groups 1 and 2, respectively) and mostly neritic species (group 3).

Metabolic studies of deep-living copepods provide additional evidence for niche separation based on the presence/absence of myelin. Calanoid taxa that occur in mesopelagic  $(200 - 1000 \text{ m}$  depth) and bathypelagic habitats  $(1000 - 4000 \text{ m}$  depth) include suspension feeders, detritivores and carnivores from both amyelinate and myelinate taxa. While in general deep-living calanoids have lower metabolic rates than epipelagic ones (Ikeda, 2008), adjusted metabolic rates (AMR), protein, energy content and condition factor index (CFI = dry weight/prosome length<sup>3</sup>) were all significantly higher in myelinate calanoids compared with amyelinates (Ikeda *et al*., 2006a, 2006b and 2007). These indicators suggest that myelinates in these deep environments are more active than amyelinates.

Figure 6. Distribution of myelinate vs amyelinate copepod species of the Mediterranean Sea among 6 functional groups defined by Benedetti *et al*. (2016). Myelinates dominate in groups 4 and 6; amyelinates in groups 1-3. Total number of species: myelinate, 68; amyelinate 54.

Figure 7. Relationship between citrate synthase activity and lactate dehydrogenase activity in copepods collected from depths between 200 and 2000 m. Black circles: myelinate taxa (*Onchocalanus magnus*; *Landrumius gigas*, *Gaetanus* spp., *Megacalanus* spp., *Bathycalanus* spp., Euchaetidae); grey squares: amyelinate taxa (*Metridia princeps*, *Pleuromamma abdominalis*, *Gaussia princeps*, *Arietellus plumifer*; Heterorhabdidae, Augaptilidae, Lucicutiidae). Giants: *Megacalanus* spp., *Bathycalanus* spp., *Gaussia princeps* (males, females). Data redrawn from Thuesen *et al*. (1998; Figure 8). Calanoids were categorized into myelinate/amyelinate according to Lenz *et al*. (2000). Error bars: standard errors.

Deep-living calanoids differ in their ATP metabolism and this difference correlates with myelin. Eukaryotes have two pathways for producing ATP: an aerobic one for which the activity level of citrate synthase is an indicator, and an anaerobic one, characterized by activity of lactate dehydrogenase (LDH). The anaerobic pathway is important when oxygen supply is insufficient to sustain high muscle activity. Using these two indicators, Thuesen *et al*. (1998) examined the relative importance of these pathways in calanoids. In general, they found that LDH activity levels are high in mesopelagic and bathypelagic calanoids compared with surface dwelling ones, while citrate synthase activity is low. Thus, they concluded that the deep-living calanoids have a higher dependence on anaerobic metabolism, which is

presumably important for episodic energy demands such as burst swimming. A re-analysis of Thuesen *et al*.'s (1998) data suggests that myelinates and amyelinates differ in LDH activity levels (Figure 7). With the exception of the giant calanoids, LDH activity was lower in myelinate calanoids than in amyelinates. Thus, deep-living myelinate calanoids, which are metabolically more active than amyelinate ones (Ikeda *et al*., 2006a), have a much less pronounced difference in the relative importance of aerobic and anaerobic energy production. By eliminating the need to restore sodium concentrations along the inactive insulated stretches of axons after an impulse, myelin is thought to greatly reduce demand on metabolic energy sources supporting neural activity. These phenotypic differences between myelinate and amyelinate calanoids may thus be indicators of differences in life history strategies related to optimizing survival. Reduction of activity level is one strategy to decrease encounter with and/or detection by potential predators (Langerhans, 2007). While this may be an important strategy for all mesopelagic and bathypelagic calanoids, it may be even more important for amyelinate taxa.

# **9. INVASION OF THE PELAGIC ENVIRONMENT AND EVOLUTION OF MYELIN**

While copepods inhabit a variety of environments and niches that include interstitial, benthic, troglodytic and even terrestrial ecosystems, their importance as key members of pelagic communities in marine and freshwater habitats stands out. It has been proposed that planktonic taxa have evolved from benthic forms (Huys and Boxshall, 1991). The invasion of the pelagic may have occurred during a period of high turbidity during the Devonian (~400 million year ago [Mya], "Age of Fish"), which made the benthos a less favorable environment due to low light, decreasing food resources and low oxygen availability (Marcotte, 1999). High-speed miniaturization assured the success of many taxa including copepods, since it allowed them to selectively feed on small food particles (phytoplankton) mixed with inert ones (Marcotte, 1999). However, high turbidity also meant limited visibility, providing an opportunity for benthic forms to invade the water column during a period of relatively low risk from visual predators. The pelagic Arietelloidea (= Augaptiloidea) and Diaptomoidea (= Centropagoidea) may have evolved during this early period (Bradford-Grieve, 2002). High turbidity was followed by a period of high transparency during the Permian  $(\sim 275 \text{ Mya})$ . Based on the fossil record, diversity in pelagic species decreased dramatically, while there was an increase in benthic crustaceans, *i.e.* decapods (Marcotte, 1999). Increased predation risk from visual predators due to high transparency might have been a driving selective force. Thus, Bradford-Grieve (2002) hypothesized that the evolution of more-recent super-families such as the Calanoidea (Megacalanoidea) and Clausocalanoidea along with myelin occurred during this time.

### **CONCLUSION**

The unexpected discovery of myelin in half of all calanoid copepods has raised questions regarding the advantages of this innovation in small organisms with simple nervous systems. Ted Bullock (1996), a comparative neuroscientist and founding father of neuroethology, concluded that there was an inherent paradox in adaptations that increase conduction speeds in small organisms, since conduction delays are essentially negligible. The existence of taxa with and without myelin in the calanoids provides a unique opportunity to address the paradox and quantify the benefits of this innovation in small organisms. We have reviewed studies comparing escape reactions and predator-prey ecology between myelinate and amyelinate copepods, arguing that several lines of evidence support the hypothesis that the presence of myelin confers greater resistance to predation, especially from visual predators. The fact that there are few confounding differences between myelinates and amyelinates strengthens this conclusion: they share similar body forms, size distributions, antennule to prosome length ratios, maximum scaled escape speeds, and organization of sensory and motor systems.

Lower susceptibility to visual predators has led in turn to differences in biogeographic distributions and ecological functional groups of myelinate and amyelinate taxa, suggesting niche separation based on nervous system architecture. Early-stage development of myelin is observed in calanoid nauplii, and its presence may confer some benefit to these young stages. However, the extent of myelination of axons in the central and peripheral nervous systems is much greater in the copepodite stages and progressively increases to the adult stage. It is in the copepodites that behavioral differences between the amyelinate and myelinate forms become apparent. "Negligible" conduction delays notwithstanding, response latencies are shorter in myelinate copepodites than amyelinates, and myelinates are better at localizing and escaping away from a stimulus source.

Planktonic communities are characterized by high predation pressure and both phytoplankton and zooplankton exhibit a variety of adaptations that lower predation risk. Myelin is an adaptation that is likely to increase the chances of survival once an encounter has occurred. Thus, differences in escape performance are expected to lower predation risk in environments with high encounter rates, especially with visual predators that stalk unwary prey and then attempt capture with a sudden attack. The evolution of myelin is a key innovation in the Calanoida that undoubtedly promoted radiation within several superfamilies.

### **ACKNOWLEDGMENTS**

This manuscript benefited from discussions with J. R. Strickler, and we would like to thank him for his valuable input and encouragement. We are also very grateful to two reviewers (one of whom was J. Bradford-Grieve) for their careful and constructive comments on the manuscript, which is much improved as a result. This study was partially supported by a grant from the National Science Foundation (OCE 12-35549). The views expressed herein are those of the authors and do not reflect the views of NSF or any of its sub-agencies. This is the University of Hawaiʻi at Mānoa School of Ocean and Earth Science and Technology contribution Number 10111.

### **ABSTRACT**

Copepods are a key link in marine food webs and are consumed by a wide range of predators. As a result, copepods have evolved numerous adaptations for avoiding predation. The escape response of calanoid copepods is arguably one of the most important adaptations as it is well-developed in most species and developmental stages and functions against a variety of predatory modes. Copepods have evolved sensitive mechanoreceptors in the antennae to detect the presence of predators, and respond with powerful swimming strokes which can produce speeds in excess of 500 body lengths per second. Copepods also respond with one of the shortest response latencies of all aquatic organisms, and can react to a hydrodynamic disturbance in as little as 2 milliseconds. Yet many predators are capable of capturing copepods with high success. However, success in capturing copepods varies with predatory mode and developmental stages of the copepod. The great abundance of copepods within the marine environment and number of species that rely on them as food indicate the importance of understanding these interactions. Here we discuss the interactions between predators and their copepod prey, the ability of copepods to evade predators, and several of the mechanisms predators employ to capture copepods.

# **1.INTRODUCTION**

Copepods are an evolutionarily successful group, as they are among the most numerous multicellular animals on earth (Humes, 1994). On a global scale copepods are estimated to

 $\overline{a}$ 

<sup>\*</sup> Corresponding Author's Email: ed.buskey@utexas.edu.

process 7.5-10.5 gigatons of carbon per year (Calbet and Saiz, 2005). Therefore, this group of animals plays a key role in marine food webs which makes their behavioral adaptations to predation important to understand. Copepods in the order Calanoida are considered to be the most ecologically significant group, in part, because they often exceed other copepod groups within the neritic and pelagic zones in terms of abundance or biomass (Dagg and Turner, 1982). Calanoid copepods are important grazers on microplankton in marine food webs (Banse, 1995) and are, in turn, preyed upon by a wide range of predators with diverse feeding adaptations. In addition to their ecological roles, copepods are known to be a superior food source when compared to traditional feeds used in aquaculture such as enriched *Artemia* sp. (Shields *et al.*, 1999). Thus, understandings of copepod-predator interactions have both direct ecological and economic implications.

In nature, planktonic copepods are subject to predation from a wide array of different taxonomic groups. As such, they require a variety of adaptations that aid in minimizing detection, capture and ingestion from a host of different predation strategies. In this chapter many of these different predation modes will be explored with respect to a copepod's ability to detect, respond and ultimately survive encounters. Non-visual predators are the most taxonomically diverse and consist of cnidarian medusae, ctenophores, chaetognaths and even other copepods. There are also a host of benthic invertebrate predators that feed on copepods which include: bivalve molluscs (*e.g*.*,* mussels), crustaceans (*e.g.,* barnacles), cnidarians (*e.g.,* corals). Visual predators consist primarily of fish but also include cephalopods, large mammals (*e.g.,* baleen whales) and occasionally some bird species. Since fishes themselves are a highly diverse group, there is a variety of predation adaptations which result in high variation in predation success on copepods.

In order to survive in an ocean teeming with predators, copepods possess an array of adaptations to prevent detection, capture and ingestion (Figure 1). At each of these steps predators and prey are involved in an evolutionary arms race. Predator adaptions are aimed at increasing encounter, capture and ingestion rates while copepods possess adaptions that aid in minimizing these. The primary focus of this chapter will be on the factors that determine the outcome of post encounter interactions with predators. However it is worth identifying some of the other important factors that allow copepods to avoid succumbing to predators both preencounter and post capture.

Figure 1. Potential outcomes of copepod interactions with a predator. The primary focus of the chapter will be on the factors that influence results of post-encounter situations that determine whether a copepod escapes or is captured.

The result of any predator-prey encounter will depend upon many factors. One central factor that emerges from the behavioral ecology of copepods is that there is no place to hide from a diverse assemblage of predators in open water. In order to limit encounters with predators, nearly transparent tissues help copepods lower their conspicuousness to visual predators. However this has implications for feeding because ingesting pigmented food during daylight hours can partially mitigate this effect (Giguere and Northcote, 1987). A common behavioral mechanism to minimize encounters with predators is diel vertical migration. Copepods migrate downwards to depths with reduced light intensity during daylight hours to avoid the suite of visual predators that rely on light for prey detection (Bollens and Frost, 1989). In cases where non-visual invertebrate predators dominate and follow a similar migration pattern as copepods, a reverse diel vertical migration can occur where copepods move into surface waters during the day to minimize encounters with the dominate predator (Frost and Bollens, 1992). Another behavioral adaptation copepods can employ to minimize encounters is modifying their swimming patterns. Swimming kinematics that generate low hydrodynamic disturbance are likely to minimize encounters with rheotactic predators relying on the detection of flows created by moving prey (Titelman and Kiørboe, 2003; Tiselius *et al.*, 1997; Ohman, 1988).

If a copepod fails to avoid detection by a predator, it can still survive the encounter if it can promote rejection by the predator. Some copepods possess spines, which are known to cause rejection by small fish feeding on planktonic crustaceans (Barnhisel, 1991). Certain species of copepods can physiologically produce bioluminescence (Latz *et al.*, 1987; Herring, 1988) in response to a physical disturbance simulating the approach of a predator (Hartline *et al.*, 1999), and flashes of bioluminescence can trigger a startle response (Buskey and Swift, 1985) or potentially distract potential predators (Herring, 1988). However, the escape response which rapidly propels the animal away from a potential predator is arguably the most important mechanism in avoiding predation once an encounter has occurred.

# **2. DETECTION OF PREDATORS**

In order to respond to a potential threat, there must be reliable mechanisms in place to detect the predator. Calanoid copepods have three sensory modalities by which they can potentially sense an approaching predator prior to executing an escape: photosensory, chemosensory and mechanosensory receptors. The visual system of copepods often consists of three pigment cups that combine to form a naupliar eye (Ong, 1970). This eye is not capable of forming images, only responding to rapid changes in light intensity such as flashes of light or shadows (Buskey *et al.*, 1986). Copepods can detect and respond to rapid changes in light with an escape response which may be an adaptive response to the presence of a diurnal predator overhead (casting a shadow) or to a bioluminescent predator such as a ctenophore (Buskey *et al.*, 1986). It therefore makes sense for both types of photic stimulation to elicit an escape response in copepods. Although copepods can detect sudden changes in light intensity, they appear unable to distinguish between sources. This is supported by observations that bioluminescent dinoflagellates, which are a food source of copepods, can elicit escape responses from copepods by producing their own bioluminescence (Buskey and Swift, 1983; Buskey *et al.*, 1986). Because these flashes of light from the dinoflagellate appear indistinguishable from those of a potential predator, the dinoflagellates may use this as a defense to disrupt the normal feeding behavior of the copepod.

Chemical stimuli can be detected via chemosensory cells located on the first antenna (Boxshall and Huys, 1998) but do not appear important in generating an escape response (Fields and Yen, 1997) or triggering vertical migration in the water column (Bollens *et al.*,

1994). Instead the chemosensory cells found in copepods likely function in prey and mate detection (Weissburg *et al.*, 1998; Yen *et al.*, 1998; Langhoff *et al.*, this volume). The first antennae is also lined with setae (or sensilla), which are small structures that are innervated by sensory cells (Figure 2; Strickler and Bal, 1973; Yen and Nicoll, 1990). Mechanical disturbances are detected from the deformations of fluid movement (Yen *et al.*, 1992). Depolarization causes the transmission of an action potential to a motor neuron which stimulates muscles and generates the escape response. The mechanosensory systems of pelagic adult copepods are well developed. The first antennae (antennules; A1) mechanoreceptors of the adults are highly sensitive (Hartline *et al.*, 1996) and have many microtubules (500 to 3000) which fill the distal dendrites of the mechanosensory neurons (Weatherby *et al.*, 1994). Each pair of dendrites is surrounded by a well-developed scolopale and by two sheath cells, one of which is firmly attached to the cuticle via microfilaments (Weatherby and Lenz, 2000). These characteristics make the system particularly rigid and thus contribute to its high mechanosensitivity (Hartline *et al.*, 1996).

Figure 2. Photograph of the copepod *Acartia tonsa*. This species exhibits very short response latencies and high swimming velocities in response to hydrodynamic disturbances created by predators, which are detected using the large setae on the prominent antennule.

In order for a copepod to survive an attack from a predator, it must be able to detect the approach of a predator and perform an appropriate escape response. However, the strength of detection and escape vary depending on the developmental stage (Buskey, 1994). This is likely due to the fact that the setae on the distal tip of the antennae are primarily responsible for the detection of predators (Lenz and Yen, 1993), but the distal portion of the antennae does not fully resemble the adult until developmental stage N6 (Boxshall and Huys, 1998). This suggests that predator detection ability increases throughout each molt during the nauplii stages. During the transition from nauplii (N6) to copepodite (C1), the predator detection capabilities also increase (Buskey, 1994). This trend continues through each copepodite stage as the number of segments and setae proximal to the tip increase with subsequent molts (Boxshall and Huys, 1998), which provides a plausible mechanism for the continued improvement in sensitivity with each molt. Although the distal tip resembles that of the adult at the N6 stage, sensitivity may also still improve at the distal tip due to continued development of the sensory neurons involved in detecting hydrodynamic disturbances, but little is known about the internal structures of antennae during development.

### **3. GENERATION OF AN ESCAPE JUMP**

Rapid escape swimming may be the most important anti-predator adaptation copepods possess once encountered (Figure 3). During the peak of a typical escape, copepods exceed speeds of 100 body lengths per second (bl  $s^{-1}$ ) and some species can achieve instantaneous speeds in excess of 500 bl  $s^{-1}$  (Trager *et al.*, 1994; Buskey *et al.*, 2002; Lenz *et al.*, 2004). Due to their small size, copepods perform rapid escape swimming under low/transitional Reynolds numbers (Re) from less than 100 (van Duren and Videler, 2003) to roughly 500 (calculated from Buskey *et al.*, 2002). In order to achieve such speeds, copepods must produce a large amount of force. Escaping copepods are capable of producing more than 100 dynes per jump (Lenz and Hartline, 1999) which is more energy per gram of body weight than almost any other animal. While achieving high relative swimming speeds through powerful swimming muscles is a clear advantage for surviving encounters with predators, the ability to react quickly to a perceived threat could be equally important. Copepods have one of the shortest reaction latencies known for aquatic organisms and can respond in as little as 2 ms to a hydrodynamic disturbance (Lenz and Hartline, 1999; Buskey *et al.*, 2002; Waggett and Buskey, 2007a).

Generally, there are six naupliar stages (N1-6) and five copepodite stages (C1-5) before a copepod molts into an adult (Lawson and Grice, 1970), and the escape response is present in all stages of copepod development (Buskey, 1994; Titelman, 2001; Green *et al.*, 2003). The escape response is produced by a different set of appendages in the youngest (naupliar) stages compared to the adult and copepodite stages (Gauld, 1959). In addition, many of the mechanoreceptors for hydrodynamic sensing of an approaching predator are missing in the youngest stages (Weatherby and Lenz, 2000). Interestingly, escape speed in terms of body lengths per second is similar for both nauplii and copepodites (Buskey *et al.*, 2002; Bradley *et al.*, 2012).

In the adult and copepodite stages, copepods are primarily propelled forward by anteriorto-posterior metachronal strokes of the thoracic pereiopods (Strickler, 1975). During the initial stages of the escape when the animal achieves maximal acceleration, the use of the telson as a thrust generating appendage is also very important (Figure 4). The sweeping motion of the telson creates a large jet directed posteriorly to the animal such that both pereiopods and telson motion contribute to forward thrust. Using these appendages, copepods accelerate within milliseconds to speeds up to 800 bl  $s<sup>-1</sup>$  (Lenz *et al.*, 2005). However, the mechanism used for generating thrust for escapes is considerably different in the naupliar and copepodite stages. Nauplii lack pereiopods so in order to generate a rapid escape they beat the 1<sup>st</sup> antennae, 2<sup>nd</sup> antennae and mandibular palps sequentially (Gauld, 1959). In comparison, the  $1<sup>st</sup>$  and  $2<sup>nd</sup>$  antennae contribute very little to the propulsive forces that are generated during an escape for adults and copepodites as the antennae become folded against the body making the copepod more streamlined (Lenz *et al.*, 2004). The emergence of pereiopods in copepodites results in an escape that is stronger and therefore allows the animals to propel themselves a greater distance from a potential predator (Landry, 1978). With each subsequent molt from C1 to C5, a new pair of pereiopods emerges and older ones become larger and presumably more powerful.

Figure 3. The copepod *Acartia tonsa* responding to the approach of a juvenile pinfish (*Lagodon rhomboids*) with rapid escape swimming.

Figure 4. *Acartia tonsa* responding to a hydrodynamic disturbance. The left image is time zero, before initiation of the escape jump. In the center image, 4.5 ms later, the antennae is used to generate thrust and provide the initial reorientation away from the disturbance (a) and the telson is pulled back perpendicular to the prosome. In the right image at 11 ms, completion of the sequential movement of the pereiopods results in a jet of fluid ejected behind the copepod (b). However, the sweeping movement of the telson appears to generate most of thrust during the initial acceleration as evidenced by the much larger jet it produces (c).

Adult copepods are also able to change orientation of escape in response to an approaching predator (Buskey *et al.*, 2002). Escapes responses for adult *Acartia tonsa* usually begin with a rapid, random reorientation from the source of the stimulation which causes the escape, and the animals do this by turning at a rate of approximately 30° ms-1 (Buskey *et al.*, 2002). Adults reorient either by the asymmetrical sweep of the A1, or through a backward summersault produced by a combination of pereiopod and urosome movement. Directional capabilities are therefore likely to depend on differences in stimulus strength at the two A1

tips, as well as timing in the sensory neurons (Buskey *et al.*, 2017). The ability to produce a powerful escape with directionality is important, but another key to surviving an attack from a predator is being able to respond rapidly. Some species within the order Calanoida also possess myelination around neurons which, as in vertebrates, allows faster transmission of the action potential and thus faster responses to stimuli (Davis *et al.*, 1999). The reaction times of myelinated species can be 2 to 5 times faster than some non-myelinated species (Lenz *et al.*, 2000). This may provide an advantage by which myelinated species can respond more quickly to a hydrodynamic signal from a predator. However, non-myelinated species can also exhibit short response latencies, and some small non-myelinated copepods can exhibit minimum response latencies comparable to those of myelinated species (Waggett and Buskey, 2008). It was also observed that myelination did not result in increased survivorship when exposed to a visually hunting fish predator (Waggett and Buskey, 2007a). Because of this, it has been suggested that perhaps myelin functions more as an energy saving mechanism due to more efficient transfer of action potential which provides a likely advantage in low food oceanic habitats where myelinated species are most prevalent (Waggett and Buskey, 2008), or for more accurate detection of the direction of approach of a predator (Buskey *et al.*, 2017). This topic is discussed in more detail in the chapter by Lenz and Hartline (this volume).

The dominance of planktonic copepods within the mesozooplankton results in part from their highly developed detection and anti-capture adaptations. As with many species, predation risk is not uniform with age or developmental stage, and in copepods predation is greatest on the younger developing stages compared to the adults (Sell *et al.*, 2001). One reason is likely that younger stages are less capable of detecting a potential predator (Buskey, 1994), and even when an approaching predator is detected in time to generate an escape response, the escape of a young copepod is often much less effective than an adult's (Sell *et*  al., 2001; Titelman, 2001). However, with respect to relative escape speeds  $(i.e., bl s<sup>-1</sup>)$ copepods outperform fish by an order of magnitude, suggesting that an escaping copepod can keep ahead of a pursuing fish up to 30 times longer than the copepod itself (estimated from Lenz *et al.*, 2004). The changes in the escape system from nauplius (stages N1 to N6) to copepodite (C1 to C5) to adult in response to hydrodynamic and bioluminescent stimuli are substantial, but poorly understood. Most focus has been on research involving external changes to appendages, but behavioral studies are required to determine the significance in relation to interactions with predators which will have adaptive and evolutionary significance on both predator and prey.

# **4. NON-VISUAL PREDATORS**

Predators of copepods can be classified into two main groups; visual and non-visual predators. The non-visual class includes a wide variety of organisms from entangling predators, such as medusae and ctenophores, to suspension feeders, such as bivalve mollusks and even other copepods. Chaetognaths (arrow worms) are raptorial predators on copepods and locate prey using the hydrodynamic disturbances created by copepod swimming (Feigenbaum and Reeve, 1977). Corals (Sebens *et al.*, 1996), barnacles (Trager *et al.*, 1994) and even larger copepods (Landry, 1980) are known to prey on smaller copepods. For

avoiding non-visual predators, mechanisms such as transparency are not effective; instead, reducing hydrodynamic signals to limit detections and exhibiting high sensitivity to hydrodynamic disturbance created by predators is vital.

Some cnidarian medusae create fluid motion during swimming to entrain prey and bring them in contact with tentacles (Costello and Colin, 1994) which contain immobilizing nematocysts. This flow over the bell creates a hydrodynamic regime different from surrounding water, and this shear stress potentially provides a signal for detection by copepods. The strength of the flow field is a function of medusa bell diameter. Medusae with bell diameters less than 7 cm produce weaker flow fields, and therefore highly evasive prey such as adult copepods will be negatively selected for, while prey which exhibit low escape velocities will be captured frequently (Costello and Colin, 1994). Thus, adult copepods should only be captured at high rates by larger medusae which can create high flow velocities which could exceed escape velocities of copepods. Suchman and Sullivan (2000) found that when *Acartia hudsonica* encountered the scyphomedusae *Aurelia aurita* and *Cyanea* sp*., less than 1% of encounters resulted in ingestion suggesting that copepods could successfully detect and escape from these predators. This result is interesting as* several studies have concluded that gelatinous predators such as medusae can exert top-down control on copepod populations (Lindahl and Hernroth, 1983; Matsakis and Conover, 1991; Behrends and Schneider, 1995; Omori *et al.*, 1995). Perhaps turbulence in nature may increase encounter rates or mask the hydrodynamic signals available for copepods to detect a potential predator. Also, the impact on copepod populations may not be occurring strongly at the adult stage but instead on developing ones, which are known to have lower sensitivity to hydrodynamic disturbances (Buskey, 1994). Indeed developing copepods were found to be captured at a higher rate than adults (Suchman and Sullivan, 2000), which may explain the results suggesting an ability of medusae to exert top-down control of copepod populations under certain conditions.

Ctenophores have been found to be more effective predators on copepods than most cnidarian medusae, with clearance rates 1.2 times greater by volume and 3 times greater by carbon biomass (Purcell and Decker, 2005). The feeding mode of lobate ctenophores such as *Mnemiopsis* sp. is different than that of medusae, and appears specialized to capture evasive prey such as copepods. Studies by Waggett and Costello (1999) revealed two major routes by which prey are encountered and captured. The first is through feeding currents generated by the auricular cilia. This is the predominant mechanism producing encounters with smaller prey such as copepod nauplii (Waggett and Costello, 1999). The second mechanism is by entrapment on the broad oral lobes which is most effective with the larger, rapidly swimming prey such as adult *Acartia tonsa*. Entrainment through the tentillae selects for prey whose swimming speeds are less than the flow field velocities generated by the auricular cilia (Waggett and Costello, 1999). Nauplii rarely attempt to escape while being carried by the auricular flow towards the auricles and tentillae. Therefore the nauplii are thought to often fail to detect the predator's presence. This is supported by experiments by Fields and Yen (1997) which find that *A. tonsa* nauplii are much less sensitive to shear in flows than older stages and escape much less frequently in a suction flow. In contrast, adult *A. tonsa* are more active and stronger swimmers (Buskey, 1994) and, if entrained, should respond as shear rates increase near the tentillae and auricles. However, the use of cilia by lobate ctenophores creates a mechanism capable of processing large volumes of water but creating virtually no hydrodynamic signal (Colin *et al.*, 2010). This mechanism is likely responsible for

ctenophores being able to consume large quantities of copepods, as they can successfully avoid triggering escape response.

Bivalve mollusks such as clams and mussels are generally considered herbivorous suspension feeders consuming mainly phytoplankton, and are known to occur in high densities in the benthos (Meadows *et al.*, 1998). Because many bivalves can process large volumes of water (Davenport and Woolmington, 1982), they are known to substantially affect the overlying planktonic community in shallow water and can be important in determining not only phytoplankton dynamics (Cloern, 1982 and 1991; Møhlenberg, 1995; Dolmer, 2000), but also zooplankton communities (Green *et al.*, 2003; Davenport *et al.*, 2000; Maar *et al.*, 2008). Adult copepods and copepodites are occasionally captured by bivalves but nauplii are captured more frequently (Zeldis *et al.*, 2004). However, even nauplii often responded to the fluid deformation created by the feeding current of the bivalve siphon (Green *et al.*, 2003). N1 nauplii of *Temora longicornis* are captured more often than those of *A. tonsa*, which reflect their sensitivity to shear, and both species are captured more frequently when they are located furthest away from exhalent siphon where the fluid deformation rate is lowest. In this region nauplii are assumed to be unable to detect the hydrodynamic disturbance in time to escape (Green *et al.*, 2003).

Chaetognaths are small planktonic predators which often remain motionless suspended in the water column. Among the mesozooplankton, they are often second only to copepods in abundance and biomass (Froneman and Pakhomov, 1998; Fernández de Puelles *et al.*, this volume). Chaetognaths are one of the main sources of predation on the copepod community and have a substantial influence on the population structure of lower trophic levels (Pearre, 1980; Feigenbaum and Maris, 1984). Because chaetognaths are small, travel with ambient flow and do not actively swim while hunting, copepods are unlikely to detect the presence of a chaetognath unless an attack occurs. Copepods produce hydrodynamic disturbances when they swim or feed and these stimuli are detected by chaetognaths through sensory hairs (Feigenbaum and Reeve, 1977). Chaetognaths lie motionless in the water column until a copepod comes to within range of 1-3 mm (Horridge and Boulton, 1967). The rapid strike of a chaetognath provides only a brief time period in which to react before grasping spines are used to secure prey. Therefore, in order to escape from these non-visual predators, a short response latency is likely to be the most important adaptation and perhaps species exhibiting myelinated nerves may have a slight advantage for surviving these encounters.

Some copepod species exhibit carnivory and will readily feed on other copepods (Greene, 1988). This is a rather interesting scenario from the perspective of the copepods escape since the sensory and motility structures used to avoid predators are the same ones being used to detect and pursue them. While the structures (antennae and pleopods) may be present on both predator and prey, it has been argued that prey perception depends on the absolute magnitude of the fluid velocity generated by the moving prey, while predator perception depends on the magnitude of one or several of the components of the fluid velocity gradients (deformation rate, vorticity, acceleration) generated by the predator (Kiørboe and Visser, 1999).

To successfully avoid detection by carnivorous copepods, the prey species must minimize the hydrodynamic disturbance generated (Kiørboe and Visser, 1999; Kiørboe *et al.*, 2014). One strategy for doing this is to decouple feeding and swimming (Tiselius *et al.*, 1997). Species in which feeding and swimming are separate processes are able to generate hydrodynamic disturbances with a much faster dissipation rate and are able to display 'quiet' propulsion (Kiørboe *et al.*, 2014). If detected, prey copepods must have a very short response

latency and/or be capable of generating very high swimming speeds. Since speed is often proportional to body size, it is not surprising that predatory copepods capture higher proportions of small-bodied copepods (Yen, 1983) and nauplii (Lonsdale *et al.*, 1979). Cannibalism is also prevalent among copepods and occurs primarily on naupliar stages, even when sufficient phytoplankton is present (Hada and Uye, 1991). For omnivorous species, cannibalism makes up less than 10% of the minimum daily food requirement but can still result substantial mortality of naupliar stages (Hada and Uye, 1991).

# **5. VISUAL PREDATORS**

Predators that hunt visually upon copepods are most commonly fish (Confer *et al.*, 1978) although other visually hunting species also consume copepods. Some species of birds are known to consume copepods (Hunt and Harrison, 1990). Birds have been documented feeding on large copepods which accumulate at oceanographic fronts (Hunt and Harrison, 1990), but no information exists on the success rates of birds feeding on copepods. Investigations into the interactions between these visual predators and copepods are needed to determine potential ecological effects and trophic interactions. The fact that copepods are known to react with escape jumps to shadows (Buskey and Hartline, 2003) suggest that perhaps this may be effective in limiting predation from birds feeding from above, but further investigation is necessary.

Larval squid also consume copepods which can make up a significant portion of their diet, and predation success rate increases as larval squid age and learn about capture of evasive prey (Chen *et al.*, 1996). Copepods are also used in aquaculture to raise *Loligo* sp. (Yang *et al.*, 1983). Some predatory zooplankton species such as mysids may use vision to assist with prey capture but are probably unable to capture evasive copepods (Viitasalo *et al.*, 1998). Whales (baleen) and some large sharks (basking, whale), although visual animals well known to consume large quantities of zooplankton including copepods (Lowry *et al.*, 2004), are not considered visual zooplanktivors due to the fact that they filter their food in massive volumes and do not visually track and locate individual copepods.

Teleost fishes are the most well-known visual predators on copepods (Confer *et al.*, 1978). They possess many sophisticated sensory systems including vision, chemoreception, hearing, and a lateral line. Because most fish are visual hunters, the color, size, and motion of prey should significantly affect the prey's chance of survival. Transparency, which is ineffective against non-visual hunters, acts to reduce contrast and reduce visual conspicuousness to visually hunting predators (Aksnes and Giske, 1993; Buskey, 1994). However, susceptibility can increase in species which bear highly visible clutches of eggs, as females have the highest encounter rates with fish and the egg-clutch is a major determinant of their susceptibility, while males are least successful in escaping once encountered (Svensson, 1992). It was hypothesized that this difference in escape reaction may have evolved because of sex-specific requirements in mate encounter and mate location, with male copepods using hydrodynamic disturbances to locate mates possibly leading to higher signal thresholds for initiation of escape behavior (Svensson, 1992). Another important aspect to consider when transparency is used to avoid visual predators is that feeding can increase visual conspicuousness by concentrating pigmented food in the gut (Giguere and Northcote,

1987). Copepods have been shown to exhibit a nocturnal feeding pattern (Stearns, 1986) which may be an adaptive strategy to limit conspicuousness during daylight hours. Brightly colored parasitic copepods visible through the cuticle of their amphipod secondary host can also alter visual conspicuousness and lead to more encounters with visual predators, including their primary fish host (Bakker *et al.*, 1997).

Diel vertical migration, where copepods move into deeper waters during daylight hours and back into surface water during darkness, is a mechanism to avoid visually hunting fish predators (Zaret and Suffern, 1976; Pearre, 1979; Bollens and Frost, 1989). Some copepods do not vertically migrate and remain in the brightly lit surface waters during the day. Pontellid copepods are one family containing several species that reside in the neustonic environment. These animals are often highly pigmented to reduce the effects of damaging UV radiation (Byron, 1982; Hansson *et al.*, 2007), and are larger in comparison with many other copepod species. This large size, combined with pigmentation, makes these copepods more visually conspicuous, and thus should be preferred by visual fish predators (Brooks and Dodson, 1965; Morgan and Christy, 1996). This would appear to put these copepods at a significant disadvantage, but at least two species, *Anomalocera ornata* and *Labidocera aestiva,* have been shown to make aerial escapes, whereby the animals break the surface tension of the water and travel many body lengths through the air, reentering the water beyond the perceptive field of the fish predator (Gemmell *et al.*, 2012) (Figure 5). The energetic cost of breaking the surface tension is high (copepods lose up to 88% of their kinetic energy), but the vastly lower density of air allows them to travel many times further from a predator than they could underwater.

Fish create a fluid disturbance when feeding, and copepods can receive a signal to alert them to the presence of a predator. To counter this, many fish exhibit adaptive morphology and behavior of their own. Many planktivorous fish feed by suction (Coughlin and Strickler, 1990; Coughlin, 1994; Holzman and Wainwright, 2009). In order to capture copepods in this manner, a fish must get sufficiently close to their prey to allow the suction flow to overwhelm the prey and draw it into the mouth. Both swimming towards the prey and suction flow create a hydrodynamic disturbance, which can elicit an escape response by the copepod. To overcome the bow wave created by swimming towards a copepod, the fish rapidly opens its mouth creating suction, thereby reversing fluid deformation (Holzman and Wainwright, 2009). Therefore, during a strike many fish can be detected only by its suction-induced disturbance, rather than the disturbance from the bow wave. These fish are able to produce a more subtle disturbance than expected based on their flow speeds and mouth size alone. Jaw protrusion and the rapid opening of the mouth during the strike both help to minimize the signal available to the prey (Holzman and Wainwright, 2009). It is likely that the jaw protrusion observed in many planktivorous fish is an adaptation to minimize the initiation of copepod escape responses.

Fish can also limit their hydrodynamic conspicuousness prior to the strike, during the approach phase. It is crucial for fish to get close to evasive copepods prior to initiating a feeding strike, given that suction-based feeding produces flows that are exceptionally short lived, lasting only 10–50 ms, and are restricted to an area very close to the mouth (Ferry-Graham *et al.*, 2003; Van Wassenbergh and Aerts, 2009; Day *et al.*, 2005). To avoid detection by copepods prior to a feeding strike, fish can mask their hydrodynamic signatures by utilizing either morphology or behavior. Seahorses are an example of fish that can overcome a copepod's sensory defense through morphology as the narrow, elongated snout, separated from the blunt head is associated with minimal fluid deformation, which allows these fish to approach evasive copepods to within 1 mm (Gemmell *et al.*, 2013b). Other fish appear to behaviorally minimize the fluid deformation profile in front of the mouth by creating minor suction to offset the water being pushed forward (Gemmell *et al.*, 2014). Both of these strategies reduce the fluid deformation in the strike zone of the fish to levels just below detection limits of copepods, and illustrates the evolutionary "arms race" occurring and this important trophic link.

In the absence of modifications to minimize fluid disturbances, high strike speeds can also be successfully employed by some planktivorous fish. Small reef dwelling fish (blennies, *Acanthemblemaria* sp.) that live within small holes on coral reefs, wait for potential meals to swim or drift by in the current. Once a copepod is located visually the blenny attacks its prey by lunging forward, mouth agape to ingest its prey. The speed of attack is  $\approx$ 230 mm s<sup>-1</sup> (Waggett and Buskey, 2007a). Although rapid, this strike velocity is lower than the maximum escape velocity of *Acartia tonsa* ( $\approx$ 500 mm s<sup>-1</sup>). This results in most copepods being able to sense and escape successfully from blennies under still water conditions (Clarke *et al.*, 2005). It is only under moderate turbulence that the reduced ability to hydrodynamically sense a predator results in higher capture success by the fish (Clarke *et al.*, 2009).

Copepods exhibit both continuous to intermittent modes of swimming. Species that maintain a relatively smooth swimming pattern and nearly constant frontward motion are termed 'continuous cruisers.' Species that only swim intermittently are known as either 'hopand-sink' swimmers, where brief forward jumps are followed by a short period of sinking when appendage motion ceases, or 'cruise-and-sink' swimmers, which exhibit longer periods of forward swimming followed by short periods of sinking (Bainbridge, 1952). The pauses during intermittent swimming are believed to increase the perceptual abilities of the copepod by reducing any self-generated hydrodynamic noise (Bundy and Paffenhöfer, 1996; Yen, 2000; Kramer and McLaughlin, 2001). However, an intermittent swimming pattern can act to increase conspicuousness to a visual predator (Peterson and Ausubel, 1984; Buskey *et al.*, 1993). Even within a species, male and females can have different swimming patterns and this can translate into higher capture rates of males (Saito and Kiørboe, 2001). Alteration of swimming patterns behavior can also be used by fish such as herring to increase their encounters with prey. At low copepod densities, fish will increase speeds by approximately 100% compared to speeds at high copepod densities (Munk and Kiørboe, 1985). It is also noteworthy that fish, like copepods, appear to have increased perceptive abilities when not actively swimming. In cod larvae 94% of copepod prey are perceived during glide events where the fish are not actively swimming (Hunt von Herbing and Gallager, 2000). This has important implications for determining realistic encounter rates.

Due to their smaller size, nauplii should be less visually conspicuous and therefore be less vulnerable than larger stages to visual predators such as fish (Eiane *et al.*, 2002). This is in contrast to most findings on encounters with non-visual predators, where nauplii are often captured at significantly higher rates than later developmental stages (Costello and Colin, 1994; Waggett and Costello, 1999; Suchman and Sullivan, 2000). As copepods molt and become larger, this should make them more conspicuous to a visual predator which may translate into increased frequency and distance of attacks from a predator. However later stages have greater sensory abilities and greater escape responses (Buskey, 1994) which may act to offset the increase in visual conspicuousness.

Figure 5. Aerial escape behavior of the pontellid copepod *Labidocera aestiva*. This is one of only a few species known to break the surface tension of the water during an escape and travel many times their own body length through air before re-entering the water.

# **6. EFFECT OF WATER MOTION**

The escape response involves rapid acceleration which is energetically costly, using over 400 times the normal energetic expenditure (Strickler, 1975; Alcaraz and Strickler, 1988). Therefore copepods must maintain a balance between being able to successfully avoid predators and conserving energy. In order to conserve energy, copepods of all developmental stages display escape behaviors only when a stimulus is detected above a certain threshold. This prevents a copepod from performing energetically costly escape responses when they are not necessary. However, when copepods are constantly stimulated above the threshold for escape, for instance in a turbulent environment, they have the ability to habituate to these stimuli which may reduce their ability to detect an approaching predator and result in a greater likelihood of capture (Costello *et al.*, 1990; Hwang *et al.*, 1994).

Most behavioral studies with marine copepods have been done under still water conditions, but turbulence has been shown to play an important role in determining how predator-prey interactions involving copepods operate in more realistic conditions (Clarke *et al.*, 2005 and 2009; Robinson *et al.*, 2007; Finelli *et al.*, 2009). Turbulence was originally thought of as a mechanism that simply increased encounter rates between predators and copepods (Rothschild and Osborn, 1988), but turbulence can impact capture and escape success of both predator and prey (Clarke *et al.*, 2009). The exact impact turbulence has on capture success is often difficult to predict because it has two opposing effects. Turbulence can create erratic movement patterns of prey particles making a fish (predator) more likely to miss during an attack or abort a pursuit completely (MacKenzie and Kiørboe, 2000).

Turbulent water motion can also mask the signals that copepods use to avoid capture making their reaction distances to stimuli shorter (Robinson *et al.*, 2007), which will increase the predation risk for evading a visual predator (Clarke *et al.*, 2009). The escape response and capture rates of the copepod *Acartia tonsa* were examined in laboratory flumes that created both unidirectional and oscillatory flow conditions. The reactive distance to a siphon remained the same as still water in low-flow conditions, but was reduced by 25% at elevated flow speeds, indicating a decline in the copepods' ability to detect velocity gradients formed

by the siphon (Robinson *et al.*, 2007). Turbulence appears to make it more difficult for a copepod to respond to a potential threat and may also affect the strength of the response. Escape speed of copepods can be slower under turbulent conditions (Lee *et al.*, 2010) but may not impact the total escape distance (Waggett and Buskey, 2007b). Copepod developmental stage and predator species are also important to consider in the context of water motion. Some planktivorous fish exhibit similar capture success rates under both calm and flow conditions, whereas other fish species display strong differences both within and across copepod developmental stages. For example the dwarf seahorse, *Hippocampus zosterae*, captures both copepodites and nauplii with very high success (>90%) under calm conditions compared to the blenny, *Acanthemblemaria paula*, which captures nauplii at a significantly higher rate than copepodites (Gemmell and Buskey, 2011). Under flow conditions however the blenny is able to maintain similar capture rates on both nauplii and copepodites but the seahorse success rate plummets to nearly zero.

# **7. EFFECT OF TEMPERATURE AND VISCOSITY**

In addition to turbulence, physical characteristics of water such as viscosity and temperature can affect escape performance in copepods. As water becomes cooler, it also becomes denser and more viscous. For example, a decrease of temperature from 20°C to 10°C increases viscosity from 0.0109 Pa s to 0.0139 Pa s (**Bolton and Havenhand, 2005**). Therefore, the change in temperature alters not just the metabolic rate of organisms but also the physical characteristics of the ambient fluid, which in turn affects the ability of very small organisms to feed, move or escape within the water column. These effects of temperature are very important at hydrodynamic scales where viscous forces dominate motion (Re < 1) because low Re has a marked influence on the drag that operates against the feeding and swimming structures of small aquatic ectotherms such as copepods (Koehl and Strickler, 1981; Lagergren and Stenson, 2000).

This inverse relationship of water temperature and viscosity has particular importance for copepods living in temperate and sub-tropical coastal environments, where they are subject to large fluctuations in water temperature throughout the course of a year (from  $5-30^{\circ}$ C). Here, the escape response will be subject to water temperature variations from local weather (*e.g.,* cold fronts), seasonal variations, and large-scale global patterns (*e.g.,* climate change). Because viscosity fluctuates inversely with temperature, the impact of high viscous drag on small organisms' routine locomotion has substantial effects on swimming speeds (Bolton and Havenhand, 1997; Podolsky and Emlet, 1993; Fuiman and Batty, 1997; Muller *et al.*, 2000; Larsen *et al.*, 2008). However, the effect on escape behavior is unknown because non-escape (routine) locomotion occurs at  $Re = 0.1$  (for copepod nauplii) based on body length and cruising speed, and escaping nauplii exhibit unsteady motion and their flow environment can rapidly transit to Re = 6 (Gemmell *et al.*, 2013a).

Although altering viscosity will undoubtedly influence locomotion, the effect on predator and prey will not be equal. This is because larger bodies operate at a higher Re and exhibit less viscous drag than smaller ones. Because predators (*e.g*.*,* fish larvae) are often much larger (an order of magnitude or more) than the nauplii themselves, the predator will be less affected by viscosity (Herbing, 2002) and should capture nauplii more effectively when viscosity

increases. Small organisms should escape less effectively at colder temperatures (Fuiman, 1986). However, field studies on copepod nauplii predation have shown no evidence that nauplii are captured more successfully at colder temperatures (Paul, 1983; MichaudI *et al.*, 1996) suggesting an ability of nauplii to compensate for viscosity disadvantages at reduced temperature. Gemmell *et al.*, (2013a) showed that the early nauplii of *Acartia tonsa* can indeed compensate to a certain degree and maximize the effectiveness of escape swimming at both ends of their natural thermal range. This is accomplished by a shift in timing of appendage motion which creates an increase in power stroke duration relative to recovery stroke duration at low temperatures. The shift in power stroke duration relative to recovery stroke duration is found to be regulated by the temperature dependence of swimming appendage muscle groups (Lenz *et al.*, 2005; Gemmell *et al.*, 2013a), not a dynamic response to viscosity change. While some copepod nauplii have natural adaptive mechanisms to compensate for viscosity variations with temperature, it would not appear to function in situations in which viscosity varies independent of temperature, such as in some phytoplankton blooms (Seuront *et al.*, 2006).

### **CONCLUSION**

A copepod's success in escaping from predators depends on its ability to detect the predator's approach and to respond quickly and effectively, and the result of any predatorprey encounter will depend upon many factors. There is no place for copepods to hide from a diverse assemblage of predators in the pelagic ocean, and they have evolved escape performances matched by few other organisms, vertebrate or invertebrate.

Copepods provide model organisms to investigate the kinematics of escape in the aquatic environment, correlate it with physiological and morphological changes through development, and compare these results to measurements of predator susceptibility and changing environmental conditions. Previous studies have examined the changes in copepod vulnerability to predators through developmental stages, although changes in escape kinematics with development were not considered. By studying the developing stages of calanoid copepods, their ability to avoid predation at various stages of development and how environment affects these interactions, we can begin to understand which stages of copepods are most susceptible to different types of predators. Through the use of emerging techniques such as micro-Particle Image Velocimetry (µPIV) (Gemmell *et al.*, 2014) and 3D methods (Gemmell *et al.*, 2013a and 2014; Malkiel *et al.*, 2003) we are beginning to understand the role that the physical fluid environment plays in mediating these interactions. Eventually this may help to understand the factors that control plankton community structures, localized abundances or deficiencies of both predator and prey in the marine food webs, and predict the robustness of species to seasonal and long-term changes in climate.

## **ABSTRACT**

Male copepods of the species *Temora longicornis* are able to follow a pheromone trail laid out by a female. Moreover, the male is able to change the direction of its movement if it initially follows the trail in the wrong direction. Previously, we proposed that the female pheromone may be blend of multiple compounds with different chemical properties and that the male senses their ratio rather than an absolute concentration. This allows for a better method to decide in which direction to move. Here we implement a simple, yet efficient design for the olfactory apparatus using the Leaky Integrate-and-Fire neuronal model. We implement a Simulated Annealing algorithm for the selection of optimal synaptic weights and show that the circuit enables ratio detection over a wide array of input signals. Our results encourage further research on similarities of brain organization in copepods and airborne arthropods in which ratio detection plays an important role.

**Keywords**: chemosensation, ratio detection, *Temora longicornis*, neuronal model

## **1.INTRODUCTION**

At a population density of about one individual per liter of water in the world ocean, copepods are the most abundant class and the greatest reservoir of organic carbon among all animals. They constitute a key link between autotrophic phytoplankton and higher trophic levels in freshwater and marine food webs. Thus their ecology has tremendous implications on other life forms, all the way to land and air based animals. Current challenges to their wellbeing include anthropogenic acidification and chemical pollution of their natural habitats. It is imperative to understand their ecology, in particular their mating behavior, to predict whether and how these challenges may be met by the world's copepods.

Copepods are sexual animals and their mating behavior has been a fascinating research topic for two centuries. Katona (1973) proposed that copepods use chemical signaling mechanisms to find each other in the dark and three-dimensional water column. This view was substantiated in a series of works at the turn of the 21st century (Bagøien and Kiørboe, 2005; Doall *et al.*, 1998; Seuront, 2013; Tsuda and Miller, 1998; Weissburg *et al.*, 1998; Yen *et al.*, 2004). Males often display swimming adaptations aimed at increasing the encounter success with conspecific females (Nihongi *et al.*, 2004; Uttieri *et al.*, 2007; Yen and Lasley, 2011). A key observation by Doall *et al.* (1998) was that when a male *Temora longicornis* finds the trail laid by a female, but begins the pursuit in the wrong direction, he is able to turn around and to continue until he has reached the female. This happens within a remarkably short time, after only 1-2 s of pursuit in the wrong direction (Figure 1). The observations of Doall *et al.* (1998) do not indicate that the males know the direction of the female at the moment of finding the trail.

In earlier work (Hinow *et al.*, 2017) we presented a simple mathematical description of how the directional information can be encoded in the pheromone trail left behind by the female. Even in quiet and undisturbed water, any compound emitted by the female is subject to diffusion and chemical decay reactions. In the fixed frame of the moving female, the concentrations of the compound(s) form an idealized one-dimensional trail of concentrations that decrease with the distance from the female. A searching agent (the male) can be equipped in one of two ways. On the one hand, it can attempt to detect a change in the absolute concentration of a single compound. If the concentration is increasing in the direction of the motion, it should continue in that direction; if the concentration is decreasing in the direction of the motion, it should turn around. On the other hand, the female can emit two compounds at roughly the same rate that differ however in their decay or diffusion rates. At a distance from the female, the male will encounter these compounds in a ratio that differs from 1. The direction of the motion should be maintained if the ratio approaches 1 and it should be reversed otherwise. Using mathematical modeling and simulation we found evidence that an

agent able to detect a ratio outperforms an agent that is dependent on the gradient of a single compound (Hinow *et al.*, 2017). Indeed, if the initial direction of motion is opposite to the direction of the moving female, it is possible to enter the trail further away from the female and still make the turn. Moreover, the threshold in the signal change required for turning can be chosen bigger.

Extracting directional information from chemical cues is an important task for a large number of animal species though the precise mechanisms often remain only partially understood. A well-known example are dogs (*Canis familiaris*) with special breeds for tracking purposes (Hepper and Wells, 2005; Gadbois and Reeve, 2014; Wells and Hepper, 2003). Ratio detection of chemicals has been investigated in a number of species (Clifford and Riffell, 2013; Wyatt, 2010), most notably in moths and other lepidopterans (Belmabrouk *et al.*, 2011; deBruyne and Baker, 2008; Zavada *et al.*, 2011). In various moth species where the chemical components of the pheromone blends have been identified, sympatric sister species use identical components of the mixture, albeit in different ratios. Zavada *et al.* (2011) proposed a simple competition-based neuronal model that is capable to compare the strengths of two signals and to lead a search towards a region where the signals are in the desired ratio. Their model is composed of sets of Olfactory Receptor Neurons (ORNs) that excite Local Neurons (LNs) of different types. The local neurons, in turn, are connected by inhibitory synapses. The presence of multiple compounds in the moth pheromone blend indicates that species-specific information is also conveyed. This can help to maintain species integrity, provided that the ratios of the components remain stable in the plume. Hinow *et al.* (2017) postulated that the ratio of components needs to change over time so that the trail can point toward the animal that laid it.

The goal of this chapter is to revisit the observations of Doall *et al.* (1998) in light of newer insights gained from chemically modulated mating behavior in airborne insects. We begin by reviewing in part the Schlieren optical technique pioneered by Töpler (1866) and its application to the capture of small translucent animals in water in Section 2. In Section 3 we consider a simplified version of the neuronal model proposed in Zavada *et al.* (2011). Instead of modeling the neurons by sophisticated models such as the one by Hodgkin and Huxley (1952), we use the Leaky Integrate-and-Fire (LIF) model (Gerstner *et al.*, 2014). This model can be traced back to Louis Lapicque (1907) from a time long before mechanisms generating neuronal action potentials were known (Abbott, 1999; Brunel and van Rossum, 2007). The LIF model is widely used today. Its main advantage, the computational simplicity, allows a focus on questions of design of circuitry. In Section 4 we implement the Simulated Annealing (SA) (Press *et al.*, 2007) algorithm to optimize the synaptic weights of the network. We find that a simple network model consisting of LIF neurons with conductance-based synaptic weights can implement a ratio detection mechanism. The optimal synaptic weights for the model indicate a strong mutual inhibition of the specialist and generalist local neurons. The relative simplicity of the network topology lends credibility to the thesis that ratio detection evolved early on in the ancestry of today's marine copepods.

## **2. OBSERVATIONS OF** *TEMORA LONGICORNIS*

Most if not all photographs taken by the public at large are of "amplitude objects". In such an object, spatial differences in color values make it visible on the image. To image a clear wine glass submerged in clear water is one of the biggest challenges in photography. Special lighting at special angles may reflect from the surfaces to show parts of the glass. What has not been used in this case is the fact that the glass has a different refractive index than water. In such an environment, the glass should be looked at as a "phase object", and the optical techniques of making phase objects visible would render a distinct image of the glass. Phase objects with their refractive index slow down the light, creating a difference between light passing through the object and light from the background. Schlieren and shadowgraph techniques (Settles, 2001) render images based on differences in refractive indices. To employ these optical techniques became easier with the advent of single-line lasers and optics that allow collimated light beams carrying the information of an object for a long distance. For example, in our case, copepods swimming in a 1.5 L volume of water  $(10\times10\times15$  cm) were imaged by a camera 2.16 m away with a resolution of 0.1 mm (Doall *et al.*, 1998; Strickler, 1977 and 1998; Strickler and Hwang, 1999).

Using collimated laser beams emitting laser light at one wavelength adds another component that can be used to observe particles of different sizes in 3D and suspended in volumes of water. Schlieren optical pathways were employed using white spectrum point sources, as well as laser in the visible and near-infrared emission range (Strickler, 1977; Strickler and Balázsi, 2007; Strickler and Hwang, 1999). Doall *et al.* (1998) used the advantage of the long distance between the object and the image to split the original collimated laser beam in two beams crossing each other perpendicularly in the vessel of the animals. The subsequent combination of the two beams in one gave us a beam that carried the information of the front and side view of each phase object swimming around in the vessel. The result was then a dark-field picture of the vessel with white to light grey images of the objects. A single video camera was used to register the events. The task to evaluate the videos in the late 20th century was to click on the object frame-by-frame, giving us the 3D coordinates at 60 Hz.

Figure 1 shows the time before a mating event as observed by Doall *et al.* (1998). The female starts at position *a'* and the male a little later at position *a*. The male meets the track of the female at position *b*, takes a turn and follows the track of the female. However, the male follows the track in the wrong direction. After 1.2 s it turns and back-tracks to catch up with the female at position *c*. In 27 of 67 pursuit observations (40%) the male started in the wrong direction, which does not suggest a good method to determine the direction at the moment of finding the trail. In 22 out of 27 observations when the initial swimming direction was incorrect the male turned around (81%). Thus, in a total of 92% of cases, the male eventually followed the female in the correct direction, a remarkable achievement for any member of the animal kingdom. Back tracking with similar time components was also observed in presence of trails simulating tracks from swimming zooplankters (Yen *et al.*, 2004).

Figure 1. Trails of a female and a male from Doall *et al.* (1998). The fat and thin trails are that of the female and the male, respectively, while colors indicate swimming speeds. The male encounters the female's trail at position *b* and proceeds for the next  $\approx$ 1.2 s in the wrong direction before turning around and finally capturing the female at position *c*. The grid unit is 1 cm. Reprinted from (Doall *et al.*, 1998) with permission from the Royal Society.

# **3. THE SPIKING NEURON MODEL FOR RATIO DETECTION**

Simple phenomenological spiking neuron models are very useful for investigation of neural coding, memory and other functions, as they are easier to analyze than detailed electrophysiological neuron models; see Gerstner *et al.* (2014) for a thorough introduction to both classes. The simplest form of the LIF model for a single neuron is given by the following differential equation for the membrane potential *v*

$$
\tau \frac{dv}{dt} = -v(t) + RI(t) \,, \tag{1}
$$

where  $\tau$  is the membrane time constant, *R* is the resistance of the membrane and *I* is an external current, if present. Spikes are generated whenever the membrane potential reaches a threshold  $\vartheta$ . Then the membrane potential is reset to the resting potential  $v_r$ ,

if 
$$
v(t-) = \vartheta
$$
, then  $v(t+) = v_r$ ,

which also defines *t* as the spiking time of the LIF neuron. A schematic output of a LIF neuron with a single excitatory input is shown in Figure 2. For simplicity, a spike of the presynaptic neuron causes an immediate increase in the membrane potential.

Figure 2. The membrane potential *v* of a LIF neuron governed by Equation (1) with  $I = 0$  that receives a single excitatory input ("a.u." = auxiliary unit). At each incoming spike,  $\nu$  is increased by 0.2. The spiking times of the neuron are indicated by red dots.

To model the synaptic connections between neurons we use the conductance-based model as described by Vogels and Abbott (2005). The sub-threshold membrane potential *V* and the excitatory, respectively inhibitory conductances *gex* and *ginh* are governed by

$$
\tau \frac{dV}{dt} = (V_r - V) + g_{ex}(E_{ex} - V) + g_{inh}(E_{inh} - V) ,
$$
 (2)

$$
\tau_{ex} \frac{dg_{ex}}{dt} = -g_{ex},\tag{3}
$$

$$
\tau_{inh} \frac{dg_{inh}}{dt} = -g_{inh},\tag{4}
$$

as long as no spiking takes place. We choose the resting potential  $V<sub>r</sub>=-60$  mV, the relaxation time constant for the membrane  $\tau=20$  ms and the synaptic time constants  $\tau_{ex}=5$  ms and  $\tau_{inh}=10$ ms, respectively (Vogels and Abbott, 2005). The key difference in the influence of the excitatory and inhibitory conductances is that the two reversal potentials are chosen to be  $E_{ex}=0$  mV and  $E_{inh}=80$  mV, respectively. Once the membrane potential reaches the threshold of  $\theta$ =-50 mV, the time is recorded as a spiking time and *V* is reset to *V<sub>r</sub>*. Upon spiking of a presynaptic neuron at time *t*, all postsynaptic neurons have their excitatory respectively inhibitory conductances changed by a certain amount, depending on the nature of the synapse. If the synapse is excitatory, the excitatory conductance of the postsynaptic neuron is increased,

$$
g_{ex}(t+) = g_{ex}(t-) + w_{ex},
$$
\n(5)

if the synapse is inhibitory, the inhibitory conductance of the postsynaptic neuron is increased,

$$
g_{inh}(t+) = g_{inh}(t-) + w_{inh}.
$$
 (6)

The amounts of increase in the respective conductances of the postsynaptic neuron are called the weights of the synapse. Their selection will be discussed in greater detail in Section 4. Note that these weights are non-negative in both cases and that only one of them characterizes a synapse.

A network topology for a ratio detection mechanism was proposed by Zavada *et al.* (2011). ORNs of types *a* and *b* are excited upon binding of their respective ligand. These are modeled as Poisson sources with firing rates *r<sup>a</sup>* and *rb*, respectively. Precisely, the probability that there are *k* spikes in a time interval *Δt* is

$$
P{k \text{ spikes during } \Delta t} = \frac{e^{-r\Delta t} (r\Delta t)^{k}}{k!}.
$$

Each ORN's firing rate grows linearly with respect to the logarithm of the ligand concentration *u*. This has been shown to hold for several orders of magnitude in the moth *Antheraea polyphemus* (Kaissling, 1996; Zack, 1979). For lack of better resources, we use the relationship

$$
r=48\lambda+400
$$

where  $\lambda$  is the logarithm of the concentration of the compound, see Figure 3 in Kaissling (1996), ranging from -8 to -2, and *r* is the firing rate in Hz. This is the hypothetical response curve for both components of the mixture.

The ORNs are connected to two types of LNs by excitatory synapses. Each ORN of type *a*, respectively *b*, is connected to a specialist LN of the same type and these receive excitatory input only from the corresponding ORNs. Simultaneously, the ORNs also are connected to a generalist LN, that receives excitatory input from both types of ORNs. In both cases, there is a convergence ratio of N ORNs feeding a single LN. For simplicity, we choose this convergence ratio to be the same for all excitatory connections. The LNs of all three types are connected by inhibitory synapses. We pick the smallest number possible, namely just one  $LN<sub>a</sub>$ , one  $LN<sub>b</sub>$  and one  $LN<sub>gen</sub>$ . The synaptic connections are characterized by five weights where we make the following symmetry assumptions for the target ratio 1:1

- 1. the connections ORN<sub>x</sub>  $\rightarrow$  LN<sub>x</sub> have the same weights for *x*=*a* and *x*=*b*,
- 2. the connections ORN<sub>x</sub>  $\rightarrow$  LN<sub>gen</sub> have the same weights for *x*=*a* and *x*=*b*,
- 3. the mutual inhibition between  $LN_a$  and  $LN_b$  is symmetric,
- 4.  $LN_{a/b}$  act the same way on  $LN_{gen}$ , and
- 5. LN<sub>gen</sub> acts the same way on LN<sub>a/b</sub>.

The network is depicted schematically in Figure 3. The output of the network is the firing rate of  $LN<sub>gen</sub>$ . Note that by Dale's principle this output is necessarily inhibitory, as  $LN<sub>gen</sub>$ already inhibits  $LN_a$  and  $LN_b$ . This signal is processed by further local intermediate neurons and projection neurons that we do not include in our model.

Figure 3. The topology of the ratio detection mechanism adapted from Zavada *et al.* (2011). Ligands of type *a* and *b* bind to the respective ORNs. The convergence from ORNs to LNs is indicated only once for clarity. Pointed and blunt arrows indicate excitatory respectively inhibitory relationships; labels indicate the independent weights.

The output of the generalist neuron LNgen, *i.e.* its firing rate *rgen* is the output of the mechanism, as a function of the firing rates  $r_a$  and  $r_b$ . If the mixture components *a* and *b* are present at the ratio 1:1, both  $LN_a$  and  $LN_b$  inhibit each other. Thus the ORNs excite directly  $LN<sub>gen</sub>$ . If, however, component *a* is present at a much higher concentration than component *b*, then  $LN_a$  will silence both  $LN_b$  and  $LN_{gen}$ , similarly if *b* is present at a much higher concentration than component *a*.

# **4. SYNAPTIC WEIGHT SELECTION**

The spiking neuron model in Equations (2)-(6) is almost complete except for the choice of the synaptic weights. Recall that the weights are non-negative numbers associated with each synapse. Thus the problem of choosing weights can be viewed as an optimization problem, where we optimize the network's behavior with respect to the desired output as a function of the five numerical weights. For each such weight vector we simulate the network behavior for selected ratios of *ra:rb*. Specifically, we use rates

$$
r_a^i = r_0 \cdot 1.3^i, \ r_b^j = r_0 \cdot 1.3^j,
$$
 (7)

for *i, j*=0,..., 9 and  $r_0$ =10 Hz. This corresponds to logarithmic concentrations ranging from 10<sup>-</sup> <sup>8</sup> to 10<sup>-6</sup>. While the ORN firing rates span a much larger range, we chose this range to demonstrate ratio detection at very low concentrations. The firing rate of  $LN<sub>gen</sub>$  is recorded for each such simulation in a  $10\times10$  response matrix **R**. The numerical cost for each weight vector is defined to be the negative of the Frobenius inner product of the response matrix **R** with a convolution kernel **T** as in Figure 4,

$$
C_T(w) = -\sum_{i,j=0}^{9} R_{i,j} T_{i,j} .
$$
 (8)

Note that for example negative off-diagonal entries in **T** strongly penalize against positive entries in the corresponding positions in **R**.

Figure 4. The convolution kernel **T** to determine the "cost" of the response matrix **R** used in Equation (8). The indices *i* and *j* are those from Equation (7).

We have implemented a SA algorithm (Press *et al.*, 2007, Section 10.12) to optimize the weights using the cost function in Equation (8). The PYTHON code is available from the github repository (Langhoff, 2017). The SA algorithm is built on an analogy from thermodynamics, namely the freezing and crystallization of liquids. Provided that the liquid cools sufficiently slowly, the constituents are able to align and to form ordered structures many orders of magnitude larger than the typical particle size. This amounts to a global minimization of the energy, as opposed to a rapid cooling that results only in a "quenched" or "amorphous" state corresponding to a local minimum. In practice, if a location x has been found, a random perturbation  $\Delta x$  is added. If  $\Delta f = f(x + \Delta x) - f(x) < 0$ , then  $x + \Delta x$  is chosen as the next point of the iteration. If  $\Delta f = f(x + \Delta x) - f(x) > 0$ , then  $x + \Delta x$  is chosen with a certain

probability that is proportional to I J  $\left(-\frac{\Delta f}{\pi}\right)$ L  $\left(-\frac{\Delta f}{T}\right)$  $\exp\left(-\frac{\Delta f}{T}\right)$ , where *T* is the quantity analogous to temperature. Thus any improvement in the cost function is taken, while a worsening is sometimes accepted, but less and less likely as the temperature decreases. The main choices to be specified are the generator for the random perturbations  $\Delta x$  and the method for decreasing *T*, called the "annealing schedule". Here we select Δx from a uniform distribution and enforce the constraint that all synaptic weights are non-negative. The temperature is multiplied by 0.85 every fifth iteration.

## **5. RESULTS**

We choose the convergence ratio of  $N=100$  ORNs feeding onto a single LN, for all possible ORN  $\rightarrow$  LN connections. The optimal synapse weights are listed in Table 1.

Figure 5. Optimal output of the networkm defined as the  $LN_{gen}$  firing frequency. The  $(i, j)$ -entry corresponds to ORN firing frequencies of 10∙1.3<sup>i</sup> Hz and 10∙1.3<sup>j</sup> Hz respectively.

We note that the excitatory connections from the ORNs to the specialist LNs are stronger than to the generalist LN. Moreover, the mutual inhibition relations between the local neurons are roughly of similar strength. The model is somewhat limited in its discriminatory power at the lower end of the concentration ranges which may be caused by its strong simplification. In

future work one may increase the number of LNs in the mutually inhibitory groups in the triangle in Figure 3 and include the subsequent intermediate LNs and projection neurons.

### **CONCLUSION**

It is difficult for us humans to imagine how challenging pelagic copepod life must be. They live at low Reynolds number, at low population densities, and in the dark and three dimensional ocean. With the adult males of some species even lacking functional mouthparts, finding mates can absolutely not be left to chance. It is therefore natural for the males to respond to specific chemical signals (Yen and Lasley, 2011). To the best of our knowledge it is still an open question whether the copepod sex pheromones are specifically produced by the female or whether they are incidental byproducts of naturally occurring metabolism as, say, would be  $CO<sub>2</sub>$ . Another important open question is how the well defined trails that were observed in water at rest are deformed and perhaps torn in the actual oceanic habitat of *Temora longicornis*.

We have shown that even a minimalistic, simplified neuronal model is capable of ratio detection. This represents a significant simplification from the previous model (Zavada *et al.*, 2011), where a full Hodgkins-Huxley model in addition to a rate-based Hodgkins-Huxley model of the neuron were used. Phenomenological models like the LIF model considered here do not explicitly model the individual ion channels in a neuron and treat spikes as formal events (Abbott, 1999). By omitting some of the biological details, we can gain insight into the behavior we seek to understand. The simplification is of course more relevant for much more complex networks, containing for example  $10<sup>5</sup>$  neurons. In our case we see the relative weight of the neural pathways used for ratio detection. In reality, the ratio detection network will consist of more than just three LNs. At present little is known about the neuroanatomy of copepod brains and peripheral nervous systems, but there is evidence from the species *Tigriopus californicus* that it is endowed with a complex brain (Andrew *et al.*, 2011). In the future it will be valuable to investigate and to model the "spatial structure" that arises from the presence of ORNs on both antennas of the copepod sending signals to a pair of LN structures. We anticipate that further impulses for research will come from comparison with airborne arthropods due to the high level of conservation of neural circuitry in the pancrustaceans (the clade comprising crustaceans and hexapods).

So far only few semiochemicals used by copepods have been identified. One example is isophorone which is used by the parasitic sea louse *Lepeophtheirus salmonis* to locate its host, the Atlantic salmon (*Salmo salar*) (Ingvarsdóttir *et al.*, 2002); see Figure 6. It has a molar mass of 138.21 g/mol and is used by airborne arthropods as semiochemical as well (El-Sayed, 2017). Very recently Selander *et al.* (2015) identified so-called "copepodamides" that signal to phytoplankton the presence of their zooplankton predators and thereby induce the production of toxins as a defense. Identification of such chemicals in seawater can be done by coupled liquid chromatography and mass spectrometry (LC-MS), and an electroantennographic detector (EAD) to confirm the response of the animal's antenna at precisely the moment that the chemical is detected. If there are candidates for the pheromone components, behavioral assays such as the Y-tube assay (Ingvarsdóttir *et al.*, 2002) can be used. Selander *et al.* (2016) present a list of 87 exudates from male and female *T. longicornis*.

Their list contains nine compounds that are produced mainly or even exclusively by the females. These compounds did not initiate the pursuit reaction in the male, but this can be because there were other volatile compounds that were not retained. Future research is needed to investigate the decay and diffusion rates of the compounds and to locate potential differences. The number of compounds, their relatively large molecular masses (300-700 g/mol) and their likely complicated chemical structures indicate that a host of information should be available from their combined presence for the trained "observer".

Figure 6. Isophorone is a kairomone used by the parasitic sea louse *Lepeophtheirus salmonis* to locate its host (Ingvarsdóttir *et al.*, 2002). Structural formula from Wikipedia (2017).

All marine fauna are currently challenged by increasing chemical pollution and decreasing oceanic pH values, both of human origin. Changes in the background chemical landscape have harmful effects on olfactory-mediated behaviors in fish and crustaceans (Olsén, 2011). Due to their critical linking position in the marine food web, it is of high value to identify the chemical components of copepod sex pheromones and how their mating behavior is affected in the presence of pollutants.

#### **ACKNOWLEDGMENTS**

We thank Dr. Marco Uttieri for the kind invitation to contribute to this volume. We thank him, Dr. Rachel Lasley-Rasher and Dr. Andrei Zavada for valuable comments that improved the manuscript considerably. PH acknowledges partial support from the Simons Foundation grant "Collaboration on Mathematical Biology" during a visit to the Georgia Institute of Technology. JRS's research was made possible by a grant from The Gulf of Mexico Research Initiative. Data are publicly available through the Gulf of Mexico Research Initiative Information & Data Cooperative (GRIIDC) at https://data.gulfresearchinitiative.org.

## **ABSTRACT**

Since the very first DNA fragment was sequenced in early 70s and the 1980s Nobel Prize was awarded to Sanger and Gilbert "for their contributions concerning the determination of base sequences in nucleic acids," both biology and medicine have taken great steps forward. In particular, marine biologists have taken advantage of technical development and are increasingly applying molecular techniques to address biological and ecological questions. Recently, the growing interest in marine and freshwater organisms expressed by private companies involved in pharmaceuticals, nutriceutics, and bioproduction have boosted interest and applications of genomics, transcriptomics, proteomics and metabolomics. In parallel, molecular techniques like genetic transformation, genome modification, and gene silencing have been developed for nonmodel species. This improvement of molecular biology-related approach has enhanced academic research in biology, ecology and physiology of a plethora of metazoan nonmodel species. Copepods are the most species-rich class among the marine arthropods, are globally distributed and inhabit every environment from coastal to oceanic waters, where they represent the dominant group of zooplankton, and can also live as symbionts or parasites. This diverse array of life strategies and environments make copepods highly interesting as target species for genomic and transcriptomic studies. In the present contribution, we provide an overview of the state of the art about 'omics' studies in calanoid copepods, focusing on marine free-living species. Finally, we will suggest some future perspectives for possible applications of functional genomics studies in copepods.

**Keywords**: calanoid copepods, transcriptomics, metabolomics, proteomics

## **1.INTRODUCTION**

The phylum Arthropoda is one of the most successful among animals on our planet, with more than one million species (Telford *et al.*, 2008) inhabiting every environment. Among Arthropoda, copepods belong to the class Maxillopoda (Sub-phylum Crustacea, sub-class Copepoda), which is thought to have arisen during the Paleozoic, between the Cambrian and the middle Devonian (Regier *et al.*, 2005).

Copepods represent the most abundant group of multicellular animals, and more than 14,000 species have been described to date (Humes, 1994). Their adaptive radiation is astonishing: they colonised literally every subaqueous, subaerial and subterranean environment (Huys and Boxshall, 1991; Boxshall and Halsey, 2004). The same authors suggested that all orders of copepods are derived from ancestral marine epibenthic forms, and that the invasion of the pelagic environment was accompanied by strong morphological specializations. Besides their free-living life-style, copepods have evolved symbiosis and parasitism as well (Ho, 2001). It has been hypothesised that during evolution, copepods have left the free-living habitus on at least 11 independent occasions (*e.g.*, Bayly and Boxshall, 2009). Because of their species richness and incredibly high biomass, copepods have been dubbed the 'insects of the sea' (Huys and Boxshall, 1991). In a review paper, Schminke (2007) has even emphasised this assumption, in saying that insects should be called 'the terrestrial copepods', due to the evidence that Crustacea and Insecta may form a monophyletic group called Tetraconata or Pancrustacea (Schminke, 2007). The relationship between these two sister groups has been recently validated by molecular and morphological phylogeny (Legg *et al.*, 2013). However, unlike insects, the studies on genetics and genomics of copepods is in its infancy. Here we will focus on free-living marine calanoid copepods because the ecological role they play in marine ecosystems as primary consumers is crucial for the whole food-web. Bron *et al.* (2011) have already presented the state of the art in copepod genomics in a very elegant and omni-comprehensive review. In particular, genomic resources have been used to address issues related to species identification (*e.g.*, Bucklin *et al.*, 2009; Sabia *et al.*, 2017; Di Capua *et al.*, 2017), biogeography (*e.g.*, Rubao *et al.*, 2012), cryptic species detection (*e.g.*, Schoville *et al.*, 2012; Cornils and Held, 2014), symbiosis and parasitism (*e.g.*, Fallang *et al.*, 2005; Fast *et al.*, 2007), and acute and sub-lethal responses to environmental stressors (*e.g.*, Raisuddin *et al.*, 2007; Hansen *et al.*, 2011). In this chapter, we aim to update the state of the art, paying particular attention to the techniques developed since 2011. We will emphasise recent gene expression studies on free-living keystone copepod species, and then will give a more thorough description of 'omics' studies (transcriptomics, proteomics and metabolomics), addressing specific questions in copepod biology and ecology. Finally, we will give some future perspectives for functional genomics studies in copepods.

## **2. TECHNIQUES**

In the present section, the molecular biology techniques that will be discussed in the following sections are described.

#### **2.1. RT-qPCR**

The acronym RT-qPCR stands for Real-Time quantitative Polymerase Chain Reaction. This technique is an improvement of the conventional end-point PCR and takes advantage of fluorophores. Such fluorophores are used in two different ways: 1) they can directly bind in a stochiometric way to double stranded DNA so they emit photons when incorporated into the amplicon or 2) they are linked to a probe binding to the region which contains the DNA fragment to be amplified. The probe is linked to both the fluorophore and to a quencher which hampers fluorescence if it is in the vicinity of the fluorophore. Polymerase binds to the region to be amplified and unwinds it. Because the probe is bound the one portion of this region, polymerase removes the probe, the quencher and the fluorophore are separated, and fluorescence is released. In both cases, photons are released and detected at each PCR cycle.

The main goal of RT-qPCR is to quantify the amount of template DNA present in the sample. In the present chapter, studies based on RT-qPCR have been used to determine gene expression levels under two experimental conditions. This is achievable by amplifying complementary DNA (cDNA) samples obtained by reverse transcribing RNA from specimens under a given experimental condition. RNA is not amplifiable by PCR so it is necessary to synthesise cDNA first. To do so, a viral enzyme, the RNA-dependent DNA polymerase, colloquially called reverse transcriptase is used. This enzyme synthesizes DNA from RNA templates. When RT-qPCR is used to determine gene expression levels, the relative quantity of the template cDNA from a gene of interest (GoI) is measured in comparison to the relative quantity of a series of reference genes (RG). This procedure is needed to normalise cDNA quantity used for the reaction mix. RG's are usually house-keeping genes whose expression does not change over a broad range of experimental conditions. In order to define the suitable RG's among a set of candidates, different algorithms are used. To be valid, RT-qPCR-based works should rely on at least 3 RG's. For a wide review of RT-qPCR we suggest Valasek and Repa (2005) and Bustin *et al.* (2009).

#### **2.2. Microarray**

Microarrays, or the DNA chip technique, is based on the principle of nucleotide hybridisation. Oligomer probes (short DNA fragments) are spotted on a glass microscope slide. Oligomers can be fragments of genes or transcripts. The slide is then put in contact with nucleic acid extracts (DNA or cDNA) from two samples: one control and the other from the experimental condition. If cDNAs are hybridised to the microarray, the outcome is the gene expression level in the experimental vs the control condition. In order to obtain such a comparison, RNA samples are reverse transcribed and labelled with fluorescent dyes of a different colour. Individual fragments in template cDNAs, complementary to the probes spotted onto the chip, will anneal. The chip scanner reads the relative intensity of each dye and gives relative quantification of a given template fragment in one sample compared to the other. In the case of microarrays internal or external controls are needed to normalise the expression levels (Lippa *et al.*, 2010). In order to rule out any bias due to differential efficiency in the reverse transcription and labelling, a dye swap (*e.g.*, Hori *et al.*, 2015) is carried out. This procedure is performed by hybridising twice the chip with the same sample pair, but with the samples labelled alternately with the two different fluorescent dyes. This constitutes a technical replicate, with cDNA that is reverse transcribed separately from the same RNA sample to label with different dyes the first cDNA strand. In addition, it is also a methodological control, possibly reducing the occurrence of false positives due to the bias of fluorescent dyes (Mary-Huard *et al.*, 2008). Microarrays can be used to measure the expression of thousands of genes simultaneously, but lack the ability to detect transcripts whose sequence is unknown. This makes such technology unsuitable to work on non-model organisms, where little or no genomic and transcriptomic information is available. Microarrays are currently applied mostly in molecular diagnostics because protocols have been standardised and validated for health and clinical investigations (*e.g.*, Yoo *et al.*, 2009; Govindarajan *et al.*, 2012).

## **2.3. EST and SSH**

Expressed Sequence Tag libraries (EST) are sets of sequenced cDNAs from specific conditions or tissues and are used primarily for gene discovery or tissue-specific gene expression analyses (Adams *et al.*, 1991). cDNA synthesised under specific conditions or from tissues are inserted into vectors like plasmids, cosmids or fosmids and then transformed into competent bacterial cells. This procedure enables sequencing of unknown mRNA transcripts or random genomic DNA fragments. ESTs have been very useful in the field of molecular ecology to understand the population structure, and the genetic basis of phenotypic variation and adaptation of species. Through the discovery of new molecular markers, ESTs may provide a means for investigating gene family and genome evolution (Bouck and Vision, 2007).

If the problem to address is to identify genes differentially expressed between an experimental condition and that of the control (or in one tissue compared to another), one of the ways to enhance the yield of differentially expressed genes is to produce subtraction libraries by means of suppressive subtraction hybridization (SSH) (Diatchenko *et al.*, 1996). This technique enriches the library from the sample of those transcripts that are differentially expressed compared to the control. The basis of such an enrichment is the elimination of those transcripts that are present in both samples. For an extensive and exhaustive description of the method we suggest Rebrikov *et al.* (2004).

#### **2.4. RNA-Seq and** *De Novo* **Assembly of Transcriptomes**

In the studies reviewed in the present chapter, RNA sequencing (RNA-seq) for transcriptome production have been mainly performed using Illumina or 454 sequencing platforms. These sequencing techniques differ from the Sanger sequencing in many aspects, most importantly in that Sanger sequencing relies on capillary electrophoresis of a population of ddNTP-terminated dye labelled products that are separated by molecular weight and the dye detected. Each colour corresponds to one of the four nucleotides. Sanger sequencing is based on DNA synthesis. Illumina and 454 sequencing are based on solid-phase bridge PCR amplification, and emulsion PCR amplification, respectively. The 454 method produces longer reads compared to Illumina sequencing and with its newly released version of the platform (454 GS FLX+) can equal Sanger sequencing in read length. Although softwares

exist to assemble short reads with a very high degree of effectiveness, longer reads can help with scaffold assembly in *de novo* assemblies. Sequencing technology advances very rapidly and a complete overview of all the techniques presently available is beyond the aims of the present section. Here we will briefly describe only the two major sequencing techniques currently used in marine copepod transcriptomics analyses. The most up-to-date sequencing method is the nanopore sequencing technology (Feng *et al.*, 2015). Single molecules electrophoretically pass through a pore that separates two reservoirs, called the *cis* and the *trans* reservoirs. When the analyte passes through the pore, the voltage through it is blocked and by statistically analysing the amplitude and the time of such blockage, the nature of the molecule can be identified. This technology needs still improvements (Feng *et al.*, 2015) but will reduce costs and manipulation of samples (*e.g.*, Quick *et al.*, 2017). For a detailed description of all the Next Generation Sequencing (NGS) technologies we suggest the following papers: Branton *et al.*, 2008; Shendure and Ji, 2008; Quail *et al.*, 2012; Rhoads and Au, 2015; Wang *et al.*, 2015; Feng *et al.*, 2015; Yuan *et al.*, 2016.

Briefly, RNA-seq is based on the great technological advancement of NGS that allow obtaining billions of base pairs (Gb) and millions of short reads between 30-400 bp long per run without any cloning steps. As discussed in the above-cited papers, together with the augmentation of sequence power, the costs have dramatically decreased, enabling obtaining transcriptomes to be more widely available. An RNA-seq experiment has to be thoroughly planned beforehand with the proper questions to address. The amount of data generated by a single RNA-seq experiment is enormous and the bioinformatics analyses required are quite demanding. A transcriptome is usually produced for two main reasons; 1) to identify new genes specifically expressed in a given condition or tissue; 2) to pinpoint differentially expressed genes in different conditions or tissues or even different developmental stages. In addition to these scenarios, the only limitation to the technique is the researcher imagination. Consider the case 2. Total RNA is extracted from specimens under the experimental and control conditions. The control can be arbitrarily chosen. cDNA is synthesised as described above and libraries are constructed. The library construction depends on the sequencing technology of choice (*e.g.*, Pease and Sooknanan, 2012; Baran-Gale *et al.*, 2015). In order to be statistically robust, *i.e.*, to obtain sound results with the lowest false positive rate possible, replicates are required. Usually triplicates are accepted (Conesa *et al.*, 2016) although it has been recently demonstrated that at least six biological replicates are needed in order to be able to statistically identify differentially expressed genes (Schurch *et al.*, 2016). The output of sequencing is a variable number of variably long sequences (depending on the technique) called reads. Reads are quality filtered *in silico* in order to obtain mainly sequences from messenger RNAs, *i.e.*, expressed genes, and other RNA types like micro RNAs (miRNA), long non-coding RNA (lncRNA), etc. The assembly of short reads into full length genes is a complex bioinformatic process. Assembly can either rely on a reference genome, if available, which is usually the case for model organisms; or can be done *de novo*. In the former case, a series of algorithms (pipelines) align the reads to the reference genome sequence; in the latter, reads have to be assembled without a guide (*e.g.*, Haas *et al.*, 2013). Once the reads have been assembled into contiguous overlapping regions, referred to as contigs, which can eventually match with full length transcripts, annotation is performed. For a review on read assembly see Miller *et al.* (2010). Annotation is a bioinformatic procedure which assigns to contigs gene models (Yang and Kim, 2015; Conesa *et al.*, 2016) or other features like *e.g.*, retrotransposons or transposable elements (Criscione *et al.*, 2014; Jin *et al.*, 2015). With

appropriate normalization procedures, the number of reads can be quantified and the expression level of each transcript defined. Differential expression analyses can be now performed using adequate software (Conesa *et al.*, 2016). RNA-seq is devoid of problems derived from technical issues inherent to microarray probe performance such as crosshybridization, non-specific hybridization and limited detection range of individual probes. Additionally, RNA-seq technology does not require species- or transcript-specific probes (Zhao *et al.*, 2014).

A recent study by Wang *et al.* (2009) compared RNA-seq, microarray and cDNA sequencing techniques in transcriptome profiling and found that RNA-seq was superior in detecting low abundance transcripts, differentiating biologically critical isoforms, and allowing the identification of genetic variants. RNA-seq also demonstrated a broader dynamic range than microarrays, which allowed for the detection of more differentially expressed genes with higher fold-change (see Table 1 in Wang *et al.*, 2009).

# **3. THE TARGET SPECIES**

A few gene expression and transcriptomic studies have been published to date on freeliving marine copepods. The most investigated genera are the calanoid *Calanus* and the harpacticoid *Tigriopus*. Calanus has been used as model organism for studies on mechanisms inducing diapause, on the life cycle in general (Tarrant *et al.*, 2008; Lenz *et al.*, 2012), and responses to microenvironmental discontinuity (Unal *et al.*, 2013). *Tigriopus* has been used for investigating temperature tolerance of different populations, ecotoxicology and for phylogenomic purposes (Raisuddin *et al.*, 2007; Schoville *et al.*, 2012). However, as it is not a planktonic species, *Tigriopus* is not dealt with in the chapter.

Only a few transcriptome studies have been performed on *Calanus* despite the extensive knowledge on its biology and ecology. The focus of these studies has been to better understand the molecular basis of their physiological responses to intrinsic and extrinsic factors. *Calanus finmarchicus* and *Calanus helgolandicus* are two of the most widely studied *Calanus* species in terms of biology (Niehoff, 2007) and distribution (Mackas *et al.*, 2012; Maud *et al.*, 2015). *C. finmarchicus* is a very abundant copepod species possessing a subarctic distribution with a latitudinal range from 40°N to 80°N (Bryant *et al.*, 1998) and inhabiting shallow to very deep waters. Its ecological importance is linked to its abundance and subsequently to the impressive amount of energy that flows through this primary consumer in most ecosystems from the primary phytoplanktonic production to economically relevant fish larvae (Prokopchuk and Sentyabov, 2006). Similarly, *C. helgolandicus* is one of the dominant zooplankton species in European waters, living in open and coastal waters of the temperate Eastern Atlantic Ocean and the Mediterranean Sea (Northern Adriatic Sea) (Bonnet *et al.*, 2005). Recent surveys showed that both species distributions are gradually shifting northward due to the increase in water temperature, with *C. finmarchicus* moving into Arctic waters and *C. helgolandicus* expanding its area towards the North Sea (Beaugrand *et al.*, 2002). As indicators of different water masses, both species are routinely identified by the Continuous Plankton Recorder (CPR) Survey, operated by the Sir Alister Hardy Foundation for Ocean Science (SAHFOS) in Plymouth (UK) (Wootton *et al.*, this volume).

Within the *Calanus* genus, it is notable that *Calanus sinicus* is a widespread coldtemperate species that inhabits the Northwest Pacific Ocean from the Yellow Sea to the Sea of Japan and the South China Sea and Taiwan Straits (Huselmann, 1994; Hwang *et al.*, 2006). *C. sinicus* has been one of the target species of the China-GLOBEC program (Sun, 2005), because it is a strong link between the anchovy and sardine fisheries and the copepod secondary production in this area (Uye, 2000; Yang *et al.*, 2014). Because of its ecological relevance, this species has recently received much attention using RT-qPCR and RNA-Seq approaches (see section 4).

# **4. GENE EXPRESSION APPROACH**

#### **4.1. RT-qPCR-Based Works**

Gene relative expression and expression profiling can be achieved by different means, *i.e.*, RT-qPCR, DNA microarrays (section 4.2), and RNA-seq (section 4.3). The former is limited to genes already identified and for which a sequence and possibly a function are already known. This RT-qPCR approach has been extensively applied in the ecotoxicology field because stress-related genes responding to environmental stressors have been identified in copepods (*e.g.*, Hansen *et al.*, 2008 and 2013). Recently, a RT-qPCR approach was also used to explore the deleterious effects of harmful algal diets on copepod gene expression. In particular, the expression levels of genes involved in generic stress responses, defence systems and apoptosis regulation in *Calanus helgolandicus* feeding on the diatom *Skeletonema marinoi* were investigated (Lauritano *et al.*, 2011a and b). *S. marinoi* is able to produce cytotoxic metabolites called 'oxylipins' from the oxidative metabolism of fatty acids (Fontana *et al.*, 2007; Gerecht *et al.*, 2011; Di Dato *et al.*, 2017). In *C. helgolandicus*, the diatom induced the regulation of α and β tubulins, possibly revealing cellular rearrangement, and of several other genes related to stress response (heat shock protein 40), detoxification (several aldehyde dehydrogenases ALDHs) and apoptosis (cellular *apoptosis* susceptibility, CAS and inhibitor of apoptosis, IAP). These studies provided the first molecular evidence that the primary defence system that would be activated to protect copepods against toxic algae could be inhibited (Lauritano *et al.*, 2011a and b). Interestingly, this approach enabled testing for subtle differences among the responses of *C. helgolandicus* populations isolated from North Sea, Atlantic Ocean and Mediterranean Sea. Despite the only three bp difference in a 518 bp-long mitochondrial COI fragment among the three *C. helgolandicus* populations, the Mediterranean population showed stronger gene down-regulation compared to the others (Lauritano *et al.*, 2012).

Similar results were obtained with the congeneric species *Calanus sinicus* fed on *S. marinoi* for two and five days (Lauritano *et al.*, 2015). At day five, *C. sinicus* showed upregulation of several ALDHs, catalase (CAT), and glutathione-S-transferase (GSH-S), known to enzymatically reduce free radicals and reactive species (RS).

These studies provided new insights for understanding copepod population- and speciesspecific responses to toxic algae and co-evolution between toxic algae and detoxification mechanisms in copepods.

The results presented above, were partially corroborated by an in situ study carried out on wild *C. helgolandicus* specimens collected at the end of the spring diatom bloom in the Northern Adriatic Sea during an oceanographic cruise (Lauritano *et al.*, 2016). Surprisingly, detoxification genes did not revel consistent regulation. This complicates our understanding of this complex phenomenon in copepods and calls for more detailed investigations. The response to a possibly noxious diet could be different if the copepods are fed with phytoplankton other than diatoms. In fact, when *C. helgolandicus* was fed on a non-toxin producing strain of the dinoflagellate *Karenia brevis* for three, five and eight days, the results were completely different (Lauritano *et al.*, 2013). β tubulin, ALDHs, CAS and HSP40 were significantly down-regulated, but only after eight days of exposure to this food. This could be due to a different effect of unknown compounds produced by the dinoflagellate. Chemical analyses of the same strain were performed but they did not reveal any harmful compound (Turner *et al.*, 2012). Such a discrepancy suggests how intricate the copepod-prey ecotoxicological landscape can be and highlights the need to more detailed functional studies.

#### **4.2. Microarrays and EST Libraries**

Microarrays or DNA chips, suppressive subtractive hybridization (SSH), expressed sequence tag (EST) libraries and RNA-seq (section 4.3) are useful techniques that have been applied to disentangle copepod transcriptional responses to different environmental stressors and different diets or to identify genes involved in reproduction and molting.

The first *C. finmarchicus* microarray was produced by Lenz *et al.* (2012). Before the target genes to spot on to the chip were defined, <11,000 ESTs were sequenced, assembled and annotated together with the other ESTs publicly available at that time for the species. Around one thousand target genes were selected according to their function. 50mers (synthetic oligonucleotides composed of 50 bp) were spotted on the chip. The microarray was first tested with *C. finmarchicus* under food stress compared to adequately fed animals. A second test was performed comparing lipid-rich and lipid-poor animals. In both cases, several genes resulted differentially expressed. This pioneering work led to the conclusion that copepods respond to food limitation similarly to other organisms and they tend to save energy.

The '*Calanus* physiological microarray' (Lenz *et al.*, 2012) was then used in an in situ investigation by Unal *et al.* (2013) who, in 2008, compared gene expression in deep and surface *C. finmarchicus* individuals. The custom 995-gene microarray was hybridised with cDNA produced from 9-12 copepod RNA extractions. Chip hybridisations involved comparison between surface and deep females, and surface females with deep juvenile stages (copepodite V, CV). No CV were detected at the surface in that sampling occasion. The differential expression patterns displayed by surface and deep individuals presented a scenario where in deep waters individuals recently emerged from diapause were completing their developmental process ready to migrate to the surface. The individuals at the surface were metabolically more dynamic with grazing and predator escaping activities (Unal *et al.*, 2013). These observations are in accordance with the bimodal vertical distribution of the species. In spring copepodites emerge from diapause and migrate to the surface to feed and reproduce. This is corroborated by the up-regulation of genes involved in development and phototransduction, as well as of some genes involved in late embryogenesis. In deep females,

the set of differentially expressed genes suggested that diapause emergence, early embryogenesis and tissue remodeling take place. Despite the absence of dye swap, the data in Unal *et al.* (2013) were statistically robust because all the possible normalization and quality controls were performed. Moreover, the work represented a novel approach.

In 2014, the first transcriptional profiling study of a copepod exposed to a harmful algal diet (the oxylipin-producing diatom *S. marinoi*) was performed by Carotenuto *et al.* (2014) on *C. helgolandicus* using a SSH technique. *Rhodomonas baltica* was used as food for control copepods. Although this method did not provide as many sequences as the RNA-seq analysis (less than 1k), it generated two reciprocal EST libraries composed of longer sequences (on average 370 bp) compared to RNA-seq. This enabled a more robust annotation of the database, with about 62% of ESTs showing a BLAST match compared to 40% reported in Lenz *et al.* (2014), and about 81% of ESTs functionally annotated into Gene Ontology (GO, http://www.geneontology.org) categories (475 out of 583) compared to 13% (5k out of 38k) (Lenz *et al.*, 2014). The annotation statistics improved when the ESTs were eventually assembled into longer contigs (on average 420 bp, and 70% with a Blast-hits). A differential expression analysis, performed on the two reciprocal ESTs libraries using the Fisher's Exact Test with Multiple Testing Correction of False Discovery Rate (FDR < 0.01), showed that several GO terms were significantly enriched in both libraries. More specifically, in *Rhodomonas*-fed *C. helgolandicus*, macromolecule biosynthetic process, ribosome biogenesis and cell cycle processes were enriched. This suggests that animals are in an active state and that they are healthy. In *Skeletonema*-fed copepods the enriched GO-terms were biological regulation, nucleotide binding, signal transduction and protein folding. This transcriptional scenario can reveal a stressing state the organisms have to cope with. The results were validated and confirmed by RT-qPCR, and led to the conclusion that in *C. helgolandicus*, the diatom diet was inducing a generalised Cellular Stress Response mechanism, characterised by over-expression of molecular chaperones aimed at re-establishing the cellular homeostasis of the copepod.

## **4.3. RNA-Seq**

In 2013 the complete transcriptome of *C. siniucs* was sequenced using the 454 GS FLX method (Ning *et al.*, 2013). Copepodites and adult males and females were collected from the field and cDNA was obtained from total RNAs extracted from pools of CIV-CV and adult males and females. Almost  $1.5 \times 10^6$  350 bp reads were obtained in total from both libraries sequenced, 7% of which did not pass quality and size control. The transcriptome was *de novo* assembled and ca. 15k genes annotated. RNA-seq data were analysed for differential expression and ca. 2k genes resulted up- and 2k down-regulated in copepodite vs. adult library. Among these genes, some were of great interest because linked to diapause regulation. In this study, RT-qPCR validation of 7 transcripts was performed on the same cDNAs used for sequencing and all of them were significantly differentially expressed validating the RNA-seq results. This validation adds robustness to the results. In the study by Ning *et al.* (2013)  $>2\times10^5$  single nucleotide polymorphisms (SNPs) and  $>3\times10^4$ insertions/deletions (indels) were found. The sequencing was performed on a mixture of individuals so the intrapopulation level variability could be detected. SNPs can be of great

utility for phylogenomic studies as in bacteria and coral systems (*e.g.*, Bryant *et al.*, 2016; Rosser *et al.*, 2017) or population genetics (Coates *et al.*, 2011).

Later on, the transcriptome of *C. sinicus* was also sequenced by means of Illumina technology (Yang *et al.*, 2014). The results obtained from this second study corroborated and enriched that of Ning *et al.* (2013), giving a deeper coverage of the transcriptome with nearly 6×10<sup>6</sup> 100 bp reads sequenced. In Yang *et al.* (2014), GO term assignment was similar to that reported by their colleagues for 'molecular function' (30% vs 32%) and for 'biological process', being in both cases the most represented term. Given that Yang *et al.* (2014) obtained seven times more enzyme code (EC) assignments, *i.e.*, KEGG gene pathways annotations (KEGG: Kyoto Encyclopedia of Genes and Genomes, http://www.genome.jp/ kegg/) with 14K vs 2.9K transcripts compared to Ning *et al.* (2013), the most represented pathways were the same: carbohydrate, amino acid and energy metabolisms. In both studies, particular importance was paid to lipid metabolisms for its involvement in diapause. Noteworthy, most transcripts identified as diapause-related, such as a long chain fatty acid elongase (ELOV), several HSPs and ferretin, were differentially expressed between copepodites and adults (Ning *et al.*, 2013). Yang *et al.* (2014) identified stress- and immunerelated genes as well. This is of great interest for future studies focusing on the effect of different pollutants on marine ecosystems in general.

In 2014 and 2016 *C. finmarchicus* was the target species for three Illumina RNA sequencing projects. The first produced from different developmental stages (Lenz *et al.*, 2014), the second dealing mainly with molting (Tarrant *et al.*, 2014 and 2016) and the third showing the copepod response to a toxic dinoflagellate (Roncalli *et al.*, 2016). These studies were aimed at obtaining new resources on key copepod species. Lenz *et al.* (2014) produced the first complete transcriptome for *C. finmarchicus* and immediately after Tarrant *et al.* (2014) produced a second complete transcriptome on the same species. The former *de novo* assembly was carried out using reads from six cDNA libraries built on RNA extracts from different developmental stages of the target copepod, namely embryos, early and late nauplii (NI-NII and NV-NVI, respectively), early copepodites (CI-CII), pre-adults (CV) and adult females (CVI). Ribosomal sequences were filtered from the raw data ( $>4\times10^8$  100 bp-reads) and library-specific adaptors removed before transcriptome assembly. The number of unique contigs was 96k, of which ca. 38k presented a significant blast with protein-coding genes (about 40%). This number is in the same order of magnitude as the *Daphnia pulex* genome (ca. 31k reported genes; Colbourne *et al.*, 2011) but is twice as many putative genes as *Drosophila melanogaster*'s (ca. 18k genes; Hoskins *et al.*, 2015) and 2.5 times as many as Eriocheir sinensis crab's (14k genes; Song *et al.*, 2016). The second transcriptome by Tarrant *et al.* (2014) was carried out from pooled RNA of copepodites V individuals from two time points (three and 10 days growth). To this pool, *C. finmarchicus* RNA from wild CV's was added.

Without a complete genome sequenced, it is very difficult to extrapolate the number of genes composing a genome from RNA-seq data. On the other hand, this exercise has been done for a congeneric species, C. sinicus, and for Tigriopus californicus. In both instances, around 15k genes have been found to be expressed in these copepods' transcriptomes (Barreto *et al.*, 2011; Ning *et al.*, 2013). In comparison, the human genome has been estimated to be composed of around 19k protein coding genes (Ezkurdia *et al.*, 2014). The genome size of *C. finmarchicus* was indirectly estimated to be 6 Gb (http://www. genomesize.com), which is almost double the size of the human haploid genome.

In Lenz *et al.* (2014), the *C. finmarchicus* RNA-seq data were used to infer transcript differential expression among developmental stages. Usually, a differential expression analysis enables identification of genes that are specifically or preferentially expressed in one treatment compared to the condition set as control (*e.g.*, treated vs. non-treated). In their study, Lenz *et al.* (2014) carried out a differential expression analysis among the different developmental stages of a number of transcripts involved in lipid biosynthesis. The *C. finmarchicus* transcriptome provides a great amount of information for gene discovery. In this study at least one third of the transcripts are not expressed in any particular developmental stage. A few transcripts, though, showed pronounced stage-specificity: an acyl transferase expressed in adults and embryos; an ELOV and a  $\Delta$ 9 desaturase in copepodites. All these transcripts have EST support and are consistent with previous findings showing that copepodites stock fatty acids (FA) to be used in wax and the adults and embryos synthesise triacylglycerols (TAGs) suggesting a different lipid metabolism in the different developmental stages. This finding is consistent with Tarrant *et al.* (2014) as well. Voltagegated sodium channels (NaV) were also identified using D. melanogaster protein sequence. This protein is the target of saxitoxin poisoning and mutated  $\text{Nav}$  proteins can be at the basis of resistant strains. Actually, different transcripts had Na<sub>V</sub> identity. Unfortunately, in the transcriptome produced by the same group on *C. finmarchicus* fed with the toxic dinoflagellate *Alexandrium funndiense*, no Na<sup>V</sup> genes were differentially expressed (Roncalli *et al.*, 2016). Actually, the entire detoxification machinery did not show any sign of regulation. In this second study, the authors identified cellular stress and homeostatic responses at day two and five, respectively, but no striking detoxification response as expected from comparisons with other organisms exposed to toxic compounds. Overall, this work enabled investigation of the subtle physiological response of the copepods to suboptimal food conditions, namely the ingestion of a toxic alga, which did not reduce the copepod survival but could potentially lead to lower reproductive potential and population fitness.

Together with a previously produced database (~ 12k ESTs; Lenz *et al.*, 2012), gene model predictions and sequences can be used to design primers for specific genes involved in biological processes or environmental responses. Once an annotated transcriptome or genome becomes publicly available for a species (especially a non-model species), the research on it gets a kick onwards and thus ecologically, biologically and biotechnologically relevant questions are addressed. Moreover, the *C. finmarchicus* transcriptome will be used as reference for new RNA-seq studies, like it has been done in Roncalli *et al.* (2016).

In 2015, the transcriptome response to thermal stress of the temperate *C. finmarchicus* vs. the arctic *Calanus glacialis* was compared using an Ion Torrent RNA-seq experiment (Smolina *et al.*, 2015). Results, validated by RT-qPCR, suggest that *C. finmarchicus* responds to thermal stress activating HSPs, chaperons and proteins involved in ROS detoxification. The Arctic *C. glacialis*, on the contrary, did not show differential expression of transcripts due to the treatment. The conclusion was that the *C. glacialis* lacks the machinery to respond to thermal stress, like other organisms adapted to low temperatures (*e.g.*, Clark *et al.*, 2008). This finding does not indicate that *C. glacialis* is not stressed by temperature. On the contrary, at high temperatures the animals appeared to be dormant. Results suggest that this species is less resilient to temperature variations and hence is more vulnerable to higher temperatures. Global warming would thus endanger *C. glacialis*.

## **5. METABOLOMICS AND PROTEOMICS**

The analyses of either endogenous or exogenous molecules like peptides, amino acids, nucleic acids, carbohydrates, organic acids, vitamins, that are usually below 1.5 KDa is called metabolomics. Typically, these analyses are performed by Nuclear Magnetic Resonance (NMR) or Mass Spectrometry (MS) techniques, coupled with statistical tools such as principal component analysis (PCA) and partial least squares (PLS). Metabolomics is a broad and multidisciplinary field and the description of the different techniques is beyond the aims of the present chapter. A main distinction has to be made between the non-targeted unbiased analysis of large sets of low molecular weight organic metabolites, and the targetedmetabolomic approach. The former complements genomics, transcriptomics and proteomics, and represents the closest link to phenotype; the latter is aimed at measuring defined groups of chemically characterised metabolites. For a detailed description of protocols, we suggest the book by Metz *et al.* (2011) or the review paper by Zhang *et al.* (2012).

Proteomics is a term that was first introduced in the early 90s mirroring the word 'genomics', which identified the investigation of the totality of genes present in a given genome. Actually, the word proteomics identifies a plethora of different analyses like expression proteomics, which highlights differentially expressed proteins in two conditions or samples, protein-protein interactions, proteome fingerprinting, *etc*. Techniques are mainly based on gel separation like Sodium Dodecyl Sulphate - PolyAcrylamide Gel Electrophoresis (SDS-PAGE), two dimensional PAGE (2D-PAGE), or high performance liquid chromatography (HPLC) or MS.

Here we will give a short overview of recent works in targeted- and non-targeted metabolomics and proteomics on planktonic calanoids. Recently, the effect of ocean acidification (OA) and temperature variations were investigated in two planktonic calanoids, Paracalanus sp. (Garzke *et al.*, 2016) and a nearly 1:1 mixture of *Calanus helgolandicus* and *Calanus finmarchicus* (Mayor *et al.*, 2015). Targeted analysis of FA composition in adult copepods was investigated by means of Gas Chromatography, together with analysis of body size. Results suggest that in the next two centuries, warming and OA would produce a shift in copepod body size and FA composition. This would impair copepod suitability as valuable food for higher trophic levels. Changes in FA compositions in copepods would be driven by variation in the different classes of FA in phytoplankton. Remarkably, docosaexahenoic acid  $(DHA, 22:6 \omega 3)$  would dramatically diminish with increasing temperature and decreasing pH. This, together with the variation of other FAs, might impair the development of copepods as well (Garzke *et al.*, 2016). The reduced productivity and abundance of copepod food due to warming (Behrenfeld *et al.*, 2006; Boyce *et al.*, 2010) would lead to food stress in the future for copepods. This scenario, integrated into the context of global warming, was investigated by means of non-targeted metabolomics based on chromatography/MS techniques (Mayor *et al.*, 2015). Copepodites (CmV) of *Calanus* species were exposed to two temperatures and two pCO<sup>2</sup> conditions and starved for five days. The four treatment groups did not show statistically significant differences after five days of starvation, however results were different when comparing the pre-experimental to the post-experimental animals ( $t_0$  vs  $t_5$ ). Almost all polar compounds, such as amino acids, were down-regulated at t<sub>5</sub>, while saturated and monounsaturated FA were all up-regulated. Only DHA and eicosapentaenoic acid (EPA, 20:5 3) were down-regulated (Mayor *et al.*, 2015). Food-deprived animals also showed

significantly higher levels of a new class of taurine-containing lipids, which the authors speculated might act as an active transporter of substrates to a catabolic site. Similar compounds were previously identified in *C. finmarchicus* and *Centropages typicus* (termed as 'copepodamides'), where they played a role as signal molecules modulating toxin production in the dinoflagellate *Alexandrium minutum* (Selander *et al.*, 2015). In conclusion, though copepods seem to be more strongly affected by starvation than by warming and OA, both influence the copepod survival by indirectly changing the phytoplankton lipid composition and productivity (Mayor *et al.*, 2015).

Non-targeted metabolomics studies in copepods are in their infancy. The pioneering environmental toxicometabolomic works by Hansen and co-authors on *C. finmarchicus* (Hansen *et al.*, 2010 and 2017) have clearly showed a relationship between copepod metabolic responses and sub-lethal xenobiotic exposure. As with transcriptomics (section 4.3), metabolomics studies as well deserve further investigation.

The first proteomics study on a planktonic calanoid, *Eurytemora affinis*, including protein sequencing, was published by Boulangé-Lecomte *et al.* (2016). The effect of two pollutants were investigated, namely phenylureic hericide commercially known as diuron (DCMU, 3- (3,4-dichlorophenyl)-1,1-dimethylurea) and a mixture of two alkylphenols, the 4-nonylphenol (4-NP) and the nonylphenol-ethoxy-acetic-acid (NP1EC), widely used in synthetic industry. The two pollutants produced strikingly different results, with DCMU inducing the highest protein variation. DCMU exposure induced a defense mechanism against cell damage which triggered an elevated energy request, as showed by up-regulation of ATP synthase and arginine kinase genes to cope with high ATP demand. Signal transduction and immune response machineries were regulated as well. For the latter, the 14-3-3 zeta protein contributes to oocyte mis-development, as also shown in other systems. Oxidative stress response was induced as well with GSH and superoxide dismutase proteins being upregulated. In *E. affinis*, as in *C. helgolandicus* fed on a potentially toxic diatom (Lauritano *et al.*, 2011b), HSPs and protein-folding related proteins were up-regulated. Alkalylphenols produced an opposite result with most of the proteins down-regulated. This study, although suffering from the lack of a reference genome, shed light on copepod proteomic response to environmental concentrations of pollutants, but also posed the basis for further development of new biomarkers for water quality assessment.

## **6. GENOME UP-DATES**

In the last few years, two genome projects for calanoids were initiated, the 'Whole genome assembly of common copepod (*Eurytemora affinis*)' as part of the Baylor College of Medicine-Human Genome Sequencing Center (BCM-HGSC) i5k Pilot Project (Accession: PRJNA203087; ID: 203087) and 'Restriction site-Associated DNA sequencing (RAD) tag study of populations of *Centropages typicus*, a marine copepod' (Accession: PRJNA265130; ID: 265130), to detect population genetic structure and connectivity among North Atlantic populations of this species (Blanco-Bercial and Bucklin 2016).

The calanoid copepod *E. affinis* is a euryhaline epibenthic species that can live both on the sediment and in the water column and is able to adapte to wide salinity gradients. For this reason, this species can disperse quite easily from estuarine areas to inland waters. Since *E.* 

*affinis* can be a carrier of important pathogens, this ability has attracted researchers' interest to this species. In 2012 a genome sequence project of this species was started (https://www.hgsc.bcm.edu/arthropods/eurytemora-affinis-genome-project); the ~ 7K assembled contigs are available on the National Center for Biotechnology Information (NCBI) website under the ID 17731 (https://www.ncbi.nlm.nih.gov/genome/17731) where BLAST searches can be performed. A publicly accessible genome browser with automated annotation can be found at https://apollo.nal.usda.gov/euraff/jbrowse. The size of the genome was estimated to 0.6-0.7 pg DNA/cell ( $\sim$ 587-685 Mb, assembly reaches  $\sim$  500Mb) with a CG content of 35.8%.

This newly available resource has enabled a very elegant work on chemosensory-related gene families in arthropods, with particular focus on copepods (Eyun *et al.*, 2017). Most interesting was the discovery of gustatory receptors (GRs) in Pancrustacea and that in *E. affinis* (that contains 10 GR genes) they are poorly expressed like in insects. Also, it was demonstrated that Ionotropic Receptors (IRs) were differentially expressed in sexes. This finding could give an indication of their function. Moreover, it was found a gene family duplication of antenna IRs in males that would be a way to over-express these genes during mating.

# **CONCLUSION**

The abovementioned studies on large-scale gene expression profiling, genomics, metabolomics and proteomics performed on planktonic calanoids have significantly improved our understanding of the mechanistic processes underlying fundamental biological and ecological issues in copepods (reproduction, molting, diapause, xenobiotic detoxification, ocean acidificiation and global warming). In the future, it is important that these analytical techniques would be integrated to better predict the species' response to changing environmental conditions, evaluate ecosystem health and environmental risk, and improve food security and nutrition. One of the main constraints limiting the full exploitation of highthroughput copepod transcriptomic studies is the lack of routine protocols for genetic transformation of copepods. These techniques will allow a better understanding of the functions of the newly sequenced genes. Such reverse-genetic tools have been already developed for the model crustacean *Daphina magna*, where exogenous RNA was injected into ovulated eggs to achieve specific gene silencing by RNA interference (RNAi) method (Kato *et al.*, 2011). Posttranscriptional gene silencing by RNAi method have been developed in *Lepeophtheirus salmonis* for identification of molecular targets of new drugs or vaccines for management of aquaculture fish parasites (Eichner *et al.*, 2014), and in *Tigriopus californicus* for testing the role of genes putatively involved in thermal adaptation (Barreto *et al.*, 2014.). In the future, we envision this approach could be also applied to other key calanoid species (*i.e.*, *Calanus*), to better elucidate the role of specific gene functions in copepod physiology and ecology, and also to generate transgenic individuals for biotechnological applications.

In conclusion, functional genomics studies in marine free-living copepods have grown in number since 2011, but the way to go is still very long. Only two genomes are currently available for planktonic calanoids and this slows down functional approaches as well as
forward and reverse genetics for those species that are not yet sequenced. Once genomic resources become available for a wider number of copepods and different molecular tools will be routinely applied, the biological, ecological, ecotoxicological and eventually biotechnological research will take major steps further. Some species can then become models for marine invertebrates.

# **ACKNOWLEDGMENTS**

We are grateful to Marco Uttieri for inspiring discussions and comments on an early version of the present chapter. Prof. Grace Wyngaard and an anonymous Reviewer are thanked for commenting on this chapter and for allowing us to improve it in its final shape.

# **ABSTRACT**

Plant and animal derived products are the main ingredients currently used by the feed industry to produce concentrate feed. There is a need of novel feed ingredients to meet the demand of high quality products by the aquaculture, ruminant and swine production systems, together with the challenge of implementing new sustainable and environmentally friendly processes and ingredients demanded by the modern society. Macroalgae are a large and diverse group of marine organisms that are able to produce a wide range of compounds with unique biological properties. This chapter discusses the incorporation of macroalgae or macroalgal derived ingredients as a source of both macronutrients (i.e., proteins, polysaccharides and fatty acids) and micro-nutrients (i.e., minerals and pigments) for animal feed production. The biological health benefits of the macroalgal ingredients beyond basic nutrition for the development of functional feed in the aquaculture, the ruminant and the swine sectors are also discussed together with the industrial challenges of its application.

**Keywords:** macroalgae and seaweed, nutrition, feed, functional feed, aquaculture, ruminant, swine

# **1.INTRODUCTION**

The global human population is projected to grow to 9.6 billion individuals by 2050 and will continue to grow up to 12 billion by 2100 (Gerland et al., 2014). Within this scenario an increase of 70% in animal production and thus 235% more animal feed will be needed to sustain that growth (Herman  $\&$  Schmidt, 2016). The animal feed industry faces the challenge to meet the demand of high quality products by the aquaculture, ruminant and swine production systems, and implementing new sustainable and environmentally friendly processes and ingredients demanded by the modern society. There is a need to find new alternatives to traditional animal feed ingredients that could compete in the market in terms of nutritional quality (i.e., macro and micro-nutrient composition) and environmentally sustainable (Garcia-Vaquero & Hayes, 2016).

Macroalgae are a diverse group of marine organisms with more than 10,000 different species (Collins et al. 2016). Based on their pigments marine macroalgae are classified as brown (Phaeophyta), red (Rhodophyta) and green macroalgae (Chlorophyta). Marine macroalgae are able to adapt to the changing and extreme marine environmental conditions i.e., salinity, temperature, nutrients, radiation and combination of light and oxygen concentration by producing unique secondary metabolites including proteins, polysaccharides, lipids, pigments and minerals (Collins et al., 2016). Macroalgae are known for their richness in the previously described bioactive molecules with wide variety of biological properties i.e., anti-oxidant, anti-bacterial and anti-tumour amongst others (Holdt & Kraan, 2011). Thus, macroalgae represents great potential for its use in human food and animal feed or for the extraction of biologically active compounds that could be incorporated into the animal's diet.

This chapter discusses the incorporation of macroalgae or macroalgal derived ingredients as a source of both macro-nutrients (i.e., proteins, polysaccharides and polyunsaturated fatty acids) and micro-nutrients (i.e., minerals and pigments) for animal feed production. The nutritional and biological health benefits of the incorporation of macroalgal ingredients for the development of functional feed in aquaculture, ruminant and swine nutrition were discussed together with the advances and challenges for macroalgal incorporation in animal feed.

# **2. MACROALGAE AS SOURCE OF MACRO-NUTRIENTS**

Seaweeds have a highly variable composition, with large differences in the final content of both macro- and micro-nutrients depending on multiple factors such as macroalgae species, date of collection and environmental conditions including pollution, water temperature, light intensity and nutrient concentration in water (Mišurcová, 2011).

### **2.1. Macroalgal Proteins**

Macroalgae species and the season of collection are the most common factors affecting both macroalgal protein content and amino acid composition (Joël Fleurence, 1999). The

protein content described in brown macroalgae is generally low in comparison with green (10-26%) and red macroalgae species (35-47%) with protein contents comparable to proteinrich foods such as soybean, cereals, eggs and fish (Garcia-Vaquero & Hayes, 2016). Seasonal variations were appreciated in red macroalgae, with higher protein concentrations in the biomass harvested during the winter season (approximately 22%) when compared to the summer period (~ 12%) (Galland-Irmouli et al., 1999).

In addition, most seaweed species are considered a rich source of essential amino acids (Garcia-Vaquero et al., 2016) and acidic amino acids such as aspartic acid and glutamic acid (Fleurence, 2004). The macroalgae contents of amino acids such as threonine, lysine, tryptophan, cysteine, methionine and histidine in macroalgal proteins are higher than those found in terrestrial plants (Fleurence, 1999).

Together with protein, macroalgae also contains large amounts of non-protein nitrogen (i.e., nitrates), resulting in an overestimation of their protein content when analyzed by traditional laboratory methods. Nitrogen to protein conversion factors of 5.38, 4.92 and 5.13 have been proposed for brown, red and green algae respectively as alternatives to the traditional factor of 6.25 (Makkar et al., 2016).

### **Table 1. Protein contents (% dry weight) in selected macroalgae described in the literature**

Protein is regarded as the most expensive nutrient in animal feed (Rezaei et al., 2013). Thus, the high protein levels described in macroalgae (see *Table 1*) together with its amino acid profile could suggest its incorporation in animal feed as an alternative source of high quality protein

#### **2.2. Macroalgal Polysaccharides**

The total polysaccharide concentrations in macroalgae range from 4% to 76% of dry weight with the highest contents described in *Ascophyllum*, *Porphyra* and *Palmaria* spp., in comparison with green macroalgae (Holdt & Kraan, 2011). Differences in polysaccharide content and composition could be appreciated depending on the macroalgae species, parts of the macroalgae sampled and seasonal variations (Skriptsova et al., 2011; Kim, 2012; Men'shova et al., 2012).

Macroalgae contain a number of complex carbohydrates and polysaccharides in variable amounts depending on the macroalgae species. Brown algae contain alginates, sulphated fucose-containing polymers and laminarin; red macroalgae is a rich source of agars, carrageenans, xylans, sulphated galactans and porphyrans; and green algae contain xylans and sulphated galactans (Makkar et al., 2016).

Marine polysaccharides from seaweeds are an integral part of a globally thriving marinebio industry. Seaweeds are the most abundant source of polysaccharides including (1) alginate, agar, agarose and carrageenan with commercial applications in the biomedical and pharmaceutical industries (Venkatesan et al., 2015) and (2) laminarin and fucoidan with promising potential in food and animal feed. Fucoidan and laminarin, showed a wide range of biological activities such as anti-inflammatory, anti-microbial, anti-coagulant, anti-adhesive, anti-oxidant, anti-viral, anti-peptic, anti-tumour, anti-apoptosis, anti-proliferative and immunostimulatory, in both *in vitro* and *in vivo* model systems (Hahn et al, 2012; Kadam et al., 2015).

#### **2.3. Macroalgal Fatty Acids**

Brown macroalgae typically have the highest total lipid content, followed by green and red macroalgae (Gosch et al., 2012). However, there is considerable variation in total lipid between species and also season. I.e., levels of 68.9 mg/g dry weight (DW) and 57.5 mg/g DW were described in different species of green macroalgae within the Bryopsidales order (Gosch et al., 2012). Also high lipid contents were described in winter and spring in *Ulva lobate*, *Egregia menziesii* and *Chondracanthus canaliculatus* (Nelson et al., 2002).

In recent years, lipid composition in marine algae has raised considerable interest due to their high content of polyunsaturated fatty acids (PUFA). PUFA contents varied from 34% of the total fatty acids content in *Porphyra* spp. to 74% in *Undaria pinnatifida* (Dawczynski et al., 2007). Macroalgal PUFA include α-linolenic (18:3 n-3), octadecatetraenoic (18:4 n-3), arachidonic (20:4 n-6) and eicosapentaenoic acids (20:5 n-3) (Kendel et al., 2015). I.e., *Ulva* spp. is unique in comparison with plant and fish derived oils due to high levels of octadecatetraenoic acid, as well as offering essential dietary eicosapentaenoic and docosahexaenoic acids, which are generally absent in terrestrial plants (McCauley et al., 2016). PUFA are considered essential nutritional components in humans and animals, playing an important role in the prevention of cardiovascular diseases, osteoarthritis and diabetes. Additional beneficial health properties include anti-microbial, anti-viral, anti-inflammatory and anti-tumour properties (Kendel et al., 2015).

Recent studies showed the future potential of the controlled cultivation of *Ulva* spp. biomass to generate an algal-based oil for human and/or animal nutrition, as part of a biorefinery process for high value products (McCauley et al., 2016).

# **3. MACROALGAE AS SOURCE OF MICRO-NUTRIENTS**

# **3.1. Minerals**

The capacity of macroalgae to accumulate metals depends on multiple factors, but it is mainly related to the bioavailability of the metals in the surrounding water, the uptake capacity of the macroalgae (Besada et al., 2009) and the efficient adsorption of metal/organometallic species from seawater (Besada et al., 2009; Romaris-Hortas et al., 2010).

Important essential minerals for human health, such as iodine, copper, selenium and zinc were found in high proportions in macroalgae. *Laminaria* spp. are known to be the best iodine accumulators among all living systems and the accumulation of iodine can be up to 30,000 times larger than in the surrounding environment (Holdt & Kraan, 2011). Copper, selenium and zinc levels described in macroalgae in Norway showed to be safe when applied the macroalgae as food and feed, with higher levels of zinc described in red and brown macroalgae (Duinker et al., 2016). Reported accumulation of heavy metals in seaweed includes arsenic, cadmium, chromium, nickel, vanadium, mercury, lead, cesium-137, and radium-226 (van der Spiege et al., 2013). Large amounts of arsenic in its inorganic form were found in *Sargassum* spp., while the organic arsenic contents ranged from 38 to 75% (Almela et al., 2002). However, in a recent study the health risk due to the toxic elements in seaweed was estimated and the contribution to total element intake of arsenic, cadmium and lead of macroalgae does not appear to pose any threat to the consumers, although the concentrations of these heavy metals should be controlled to protect the consumers' health (Desideri et al., 2016).

# **3.2. Pigments**

There are three different groups of light harvesting and photoprotective pigments in macroalgae named chlorophylls, carotenoids and phycobiliproteins present in different proportions depending on the macroalgae species (Hallerud, 2014).

Chlorophylls are green lipid-soluble photosynthetic pigments found in all macroalgae species, terrestrial plants and cyanobacteria (Holdt & Kraan, 2011). Chlorophyll a is found in all photosynthetic macroalgae, while chlorophyll b and c are found in green and brown macroalgae respectively (Hallerud, 2014). The increasingly restrictive legislation concerning the origin of food preservatives (anti-oxidants and anti-microbials) and the growing demand for natural compounds, has renewed the interest in anti-oxidants such as chlorophylls from natural sources, instead of chemically synthesised molecules (Guedes et al., 2013).

Carotenoids include carotenes and xanthophylls with relative abundance variable depending on the macroalgae species. Green macroalgae species include β-carotene, lutein, violaxanthin, neoxanthin and zeaxanthin, red macroalgae contain mainly α-and β-carotene, lutein and zeaxanthin and brown macroalgae are a rich source of β-carotene, violaxanthin and fucoxanthin (Holdt & Kraan, 2011). Due to their potential health benefits, the incorporation of carotenoids into functional foods or dietary supplements is a major interest of both consumers and the food industry (Salvia-Trujillo et al., 2013). The beneficial effects of carotenoids are thought to be due to their role as anti-oxidants. Other activities include the pro-vitamin A ability of β-carotene (Holdt & Kraan, 2011), the protective role against eye disease showed by lutein and zeaxanthin (Johnson, 2002) and the promising anti-tumour activities of fucoxanthin (Holdt & Kraan, 2011).

Phycobiliproteins include phycoerythrin, phycocyanin, allophycocyanin, and phycoerythrocyanin. Phycoerythrin levels of 12% DW in *Palmaria palmata* and 0.5% in *Gracilaria tikvahiae* (Fleurence, 2004). Phycobiliproteins showed spontaneous fluorescence, property that is used by the biomedical industries in the development of diagnostic techniques such as fluorescent immunoassays (Harnedy  $\&$  FitzGerald, 2013). Also, phycobiliproteins showed multiple biological activities i.e., anti-oxidant, anti-inflammatory, anti-viral and antitumour (Sekar & Chandramohan, 2008) that could be used in the development of functional foods (Langellotti et al., 2013).

# **4. MACROALGAE AS FUNCTIONAL FEED**

There is an increased interest in the scientific community to discover new functional foods or functional food ingredients. Functional foods were described as foods or dietary components that may provide a health benefit beyond basic nutrition (Wildman et al., 2016). Several functional food ingredients of different chemical nature have been reported to possess anti-oxidant, anti-bacterial, anti-hypertensive, anti-inflammatory and anti-tumour activities (Wildman et al., 2016). Functional foods could help in the prevention or reduce the progression of many chronic diseases, such as cardiovascular disease, cancer and degenerative diseases (Olaiya et al., 2016).

Animal nutrition (i.e., aquaculture, ruminant and swine) has been traditionally evaluated in terms of productive parameters such as animal weight gain or feed utilization (France et al., 2000). Recently, animal nutrition has gained attention as an effective way to produce functional food ingredients with beneficial health effects that could increase the price of animal products in the market (Siró et al., 2008). In example, the use of supplements in cattle (Rey-Crespo et al., 2014; López-Alonso et al., 2016) or swine feeds (Dierick et al., 2009) to increase the contents of essential trace elements in milk or meat.

In animal nutrition, functional feed has not a clear definition to date (see *Figure 1*). Functional feed for pet animals adopt the definition previously described for functional foods, focusing on the additional health benefits that the functional ingredients could provide to the pets such as reduction of risk of obesity, osteoporosis, colon cancer and inflammatory bowel disease (http://www.petfoodindustry.com/articles/2926-advances-in-functional-petfoodingredients). However, functional feed in production animals such as aquaculture have been modify to incorporate the important economic benefits of the incorporation of the ingredients in animal production. In this sense, functional feeds were described as dietary ingredients that

provide growth, health, environmental and economic benefits beyond traditional feeds (Olmos Soto et al., 2015).

Due to the wide variety and biological properties of the compounds discovered in macroalgae, the incorporation of algal biomass or isolated molecules in functional feed formulation could represents a great opportunity in animal nutrition.

### **4.1. Aquaculture Nutrition**

Aquaculture is the fastest growing sector of the food economy, increasing by more than 10% per year and currently accounts for more than 50% of all shrimp/fish consumed (Olmos Soto et al., 2015). Feeding represents 40-60% of the total production costs in shrimp/fish farming (Olmos Soto et al., 2015) thus, the development of new ingredients or novel feed formulations that could help to reduce the production cost and improved animal health represents a promising field from both scientific and industrial points of view. The use of animal protein sources, such as fish meal in aquaculture feeds is expected to be reduced or completely eliminated as a consequence of increasing economic, environmental and sanitary regulations (Olmos Soto et al., 2015). Macroalgae species with elevated protein content and production rates could be considered as potential novel feed ingredients in aquaculture (Valente et al., 2006).

Figure 1. Scheme showing the possibilities for incorporation of macroalgae or macroalgal derived ingredients for the development of functional feeds for animals.

The partial substitution or inclusion of different percentages of macroalgae into the diet of fish showed promising results improving productive parameters in fish (i.e., growth rates), enhancing animal health (i.e., metabolic rates or response to stress) and increasing certain beneficial compounds in derived animal products (i.e., pigmentation or iodine concentration). *Eucheuma denticulatum* can be efficiently utilized by Japanese flounder juvenile (*Paralichthys olivaceus*) and promote best growth and feed utilization at a level of 3% (Ragaza et al., 2015). The addition of 5% of *Ascophyllum nodosum*, *Porphyra yezoensis* or *Ulva pertusa* to the feed of fingerling red sea bream (*Pagrus major*) increased body weight, feed utilization and muscle protein deposition in comparison with the fish fed a normal diet (Mustafa et al., 1995). *Porphyra dioica* at levels of 10% in rainbow trout's feed showed no negative effects on the growth performance and increased the flesh pigmentation of the fish (Soler-Vila et al., 2009). The inclusion of 5% *Gracilaria* or *Alaria* spp. into the feed of meagre (*Argyrosomus regius*) modulated the metabolic rates and enzymatic responses during a bacterial infection without affecting the growth performance of the fish (Peixoto et al., 2016). Similarly dietary macroalgae supplementation (*Ulva*, *Gracilaria* and *Fucus* spp.) improved the immune and antioxidant responses in European seabass (*Dicentrarchus labrax*) without compromising growth performance of the fish (Peixoto et al., 2016). The inclusion of up to 5% of *Gracilaria vermiculophylla* in diets for rainbow trout (*Oncorhynchus mykiss*) did not affect the growth of the fish. The supplemented fish showed improved flesh quality traits (higher colour intensity and juiciness) and the flesh iodine content on the flesh doubled in comparison with the fish of the control diet (Valente et al., 2015).

Similarly, recent studies used macroalgae in the diet of important aquaculture production systems such as shrimps and molluscs. Commercial feed of marine shrimp (*Litopenaeus vannamei*) could be replaced up to 50% with *Ulva lactuca* as source of protein and lipids without negative effects on the growth performance of shrimps (Pallaoro et al., 2016). The co-culture of juvenile shrimp and green macroalgae *Ulva clathrata* showed increased growth rates, diminished lipids in shrimp carcass and also and higher body carotenoids content in comparison with the animals without co-cultured macroalgae (Cruz-Suárez et al., 2010). In mollusc culture, the culture of macroalgae *Hynea spinella*, *Hynea musciformis* and *Gracilaria cornea* in a biofiltration unit with fishpond waste water effluents was successfully used as feed in juvenile abalone (*Haliotis tuberculata coccinea R*.). The survival and growth rates of juvenile abalone were similar to those raised commercial conditions (Viera et al., 2005).

#### **4.2. Ruminant Nutrition**

There is growing interest and evidence of the benefits of using macroalgal biomass in livestock production systems, particularly for ruminants (Machado et al., 2015). The use of extracts from macroalgae *Ascophyllum nodosum* was extensively reported in feed-lot steers (Evans & Critchley, 2014). The potential benefits of the macroalgae extracts include improved carcass characteristics and meat quality (Braden et al., 2007), ruminal organic matter and total tract crude protein digestibility in cattle (Leupp et al., 2005) and color stability and extend beef shelf-life of meat products (Montgomery et al., 2001). Also, the inclusion of 2% of Ascophyllum nodosum extract in feedlot cattle diets showed a reduction in *Escherichia coli* in fecal samples (Braden et al., 2004)

In small ruminants the macroalgae *Laminaria digitata* and *Laminaria hyperborea* biomass could be used as an alternative feed source due to the high organic matter content, digestibility, and rumen dry matter degradability of these macroalgae species (Hansen et al., 2003). The addition of 1% of macroalgal meal to the forage of lambs had no significant

influence on relative growth of body components, but it influenced hot carcass weight (Al-Shorepy et al., 2001). Furthermore, the addition of *Ascophyllum nodosum* extract at 2% in the diet of goats improved the anti-oxidant status of the animals exposed to simulated preslaughter stress (Kannan et al., 2007).

The use of seaweed to increase mineral content in animal products is currently of interest, especially in relation to increasing the iodine content of foods (Rey-Crespo et al., 2014; López-Alonso et al., 2016). A mixture of three macroalgal species *Ulva rigida*, *Sargassum muticum* and *Sachorhiza polyschides* at 0.5% of the total daily feed intake in organic dairy cattle significantly improved the animals and milk mineral (mainly iodine and selenium) status (Rey-Crespo et al., 2014; López-Alonso et al., 2016). Similarly, the dietary inclusion of *Ascophyllum nodosum* in dairy cows led to an improvement of the iodine content in milk, and to a modification of its microbiota with a positive effect on milk hygiene and transformation (Chaves Lopez et al., 2016).

# **4.3. Swine Nutrition**

Moderate to high amounts of brown macroalgae in the diet may be detrimental to pigs (Makkar et al., 2016) i.e., the inclusion of *Ascophyllum nodosum* at 10% in pigs diets produced weight loss in the animals after several weeks (Jones et al., 1979). However, the incorporation of macroalgal derived polysaccharides, such as laminarin and fucoidan showed promising results used as prebiotics in pigs diets to modulate the microbiota in the digestive tract and immunomodulating properties in pigs (Sweeney et al., 2012; Walsh et al., 2013). *In vivo* studies incorporating laminarin from brown macroalgae in the diet of pigs showed a down-regulation of the expression of inflammatory cytokines in the colon (Sweeney et al., 2012) and mucin gene expression in the ileum and colon (Ryan et al., 2010; Smith et al., 2010). A down-regulation of pro- and anti-inflammatory cytokines was appreciated in the colon of post-weaning pigs supplemented with laminarin and a reduction in *Enterobacteriaceae* counts was appreciated in the animals supplemented with fucoidan (Walsh et al., 2013).

As in the case of ruminants, the use of macroalgae in pigs feed has been proposed to increase iodine concentration in pig meat that could be beneficial for its consumption by deficient population. The organic iodine found in *Laminaria* or *Ascophyllum* spp. is readily metabolized and stored in the muscle, unlike inorganic iodine (Banoch et al., 2010). The addition of 2% of *Ascophyllum nodosum* to the diet of pigs increased the concentration of iodine by 2.7-6.8 in different animal derived products. The consumption of these iodine enriched products could be one safe strategy to help deficient population (Dierick et al., 2009). Similarly, the inclusion of *Enteromorpha* sp. to the diet of pigs did not affect the growth and productive parameters of the animals in comparison with animals supplemented with inorganic salts of copper and zinc. The meat of the animals supplemented with macroalgae showed higher manganese (49%), but also slight increases in iron (13%), copper (12%) and zinc (4%) when compared to the meat of the piglets supplemented with inorganic salts (Michalak et al., 2015).

# **5. FUTURE PROSPECTS**

Crop cultivation induces a significantly high carbon debt and high water consumption, thus, terrestrial biomass seems not to be sustainable at present due to environmental as well as economic impacts (Jung et al., 2013). Macroalgae could be a good alternative as a novel ingredient in both human and animal feed. Overharvesting of wild macroalgae could lead to negative environmental impacts and problems in the sustainability of the supply in the market. Despite this, growth rates of marine macroalgae far exceed those of terrestrial biomass (Kraan, 2013). Also, widely marketed species such as *Ascophyllum nodosum* have shown quick re-generation and growth after being hand harvested in portion only on the top of the fronds allowing annual harvesting from the same beds (Ugarte et al., 2007).

Mariculture could provide a solution for sustainable supply of macroalgae. Cultivation systems include rope farms, tidal flat farms and floating cultivation systems that are currently used successfully in the production of *Laminaria* spp. (offshore), *Ulva* spp. (tidal flat farm) and *Sargassum* spp. (floating cultivation) (Kraan, 2013). Also, the combination of macroalgal culture with other production animals such as fish and molluscs could be a viable commercial alternative (Burg et al., 2013).

As previously commented, the incorporation of macroalgae biomass in animal feed as source of macro-nutrients (i.e., protein) in substitution of traditional ingredients or as a source of micro-nutrients (i.e., mineral or pigments) could be a viable alternative for the development of both functional animal feed and for the fortification of the derived animal products that could be used in the market of functional foods (see **Figure 1**). Also, the extraction of macroalgal compounds (i.e., polysaccharides) for their incorporation into animal feed has shown promising results as pre-biotics improving animal's health.

# **ABSTRACT**

This chapter provides a brief review of seaweed co-culture and its environmental impact on coastal fisheries. First, the current situation and problems facing the coastal fisheries, and the plans to overcome these issues, are discussed. Finally, the positive and negative effects of seaweed culture, role of seaweed co-culture, and the overall environmental impact are addressed.

Although worldwide mariculture production has increased steadily, productivity has tended to decline due to continued aquaculture activity in confined areas and natural disasters, such as, typhoons and outbreaks of red tide. In particular, the nutrient loading from unconsumed feed waste results in the deterioration of the water quality and outbreaks of diseases. To overcome these problems, integrated multi-trophic aquaculture has been suggested. In the integrated culture of seaweed and fish, seaweed plays an important role as both a  $CO<sub>2</sub>$  sink and biofilter, greatly reducing the environmental impacts on coastal fisheries. The addition of the integrated culture of lugworms to this system could also have further benefits because of its potential for waste recycling and value as bait, which is expected to contribute towards a more sustainable and productive form of aquaculture. Furthermore, the use of cultured seaweed and their waste has been expanded based on the development of useful microbes, reducing their environmental impact.

# **1. COASTAL FISHERIES**

## **1.1. Current Situation and Problems**

# *1.1.1. Global Situation*

The growth in global aquaculture has remained strong up to present day. Annual marine aquaculture production has reached 20.1 million tons, and global food fish production has grown almost twelve times in the past three decades (FAO, 2012). By 2020, fish consumption in the developing countries is predicted to increase by 57%, and that in developed countries is predicted to increase by 4% (Delgado et al., 2003). In the developing countries, this estimate is based on the changes in supply and demand for fish protein under rapid population growth, increasing affluence, and urbanization. Total aquaculture production shows an average annual increase of 6-7%, and approximately 90% of this production comes from Asia (Halwart et al., 2007). Although cages were originally used in Asia for holding and transporting fish almost two centuries ago (Pillay and Kutty, 2005), the commercial marine cage culture was pioneered in Norway in the 1970s for salmon farming (Beveridge, 2004). In Asia, the start of cage farming in brackish and inshore waters is relatively recent, and was first adopted in Japan. Cage farming is diverse with a variety of species cultured at different intensities. With no large individual operations, the farming activities form a cluster due to the limited site availability in coastal waters (Halwart et al., 2007).

Apart from traditionally farmed species, such as, amberjacks and snappers, the inshore marine cage farming of groupers and cobia has spread in Southeast Asia. Some cage farming in Asia is still dependent on hatchery stock obtained from wild catch, especially for groupers. China is the largest finfish producer in the region, and its marine fish farming is expected to expand further in line with the rapid economic development (Halwart et al., 2007). Although the future prospects for cage farming appear relatively positive in Asia, it has been suggested that the large-scale, capital-intensive, and vertically-integrated marine cage farming seen in northern Europe and South America are unlikely to occur. Instead, clusters of small cage farming that attain a high efficacy are likely to be seen in the future. Similarly, off-shore cage farming is not expected to become widespread in Asia, due to difficulties in the availability of capital and the hydrography of the surrounding seas. Despite these limitations and constraints, cage farming in Asia will continue to contribute significantly to global aquaculture production, leading the world in total production (Halwart et al., 2007).

Because of the rapid development of aquaculture, fishmeal production cannot sustain the feed demand. In particular, lack of feedstock for fishmeal production has caused a serious problem in aquaculture. This is because the feedstock, such as, sardine, Jack mackerel, and mackerel are also used as food. Therefore, feedstock that is unused at present will have to be newly exploited to balance the demand for aquaculture feed. Due to the imbalance in supply and demand for marine products, increases in the price of marine products often occur through inflation.

#### *1.1.2. Domestic Situation*

Fisheries production in Korea has remained at 3,180-3,330 thousand tons since 2010 (Statistics Korea, 2015). Among these fisheries, the production from shallow-sea cultures has steadily increased and reached 1,662 thousand tons in 2015. However, the domestic production of fish aquaculture reached a maximum in 2009 and has decreased since then. The total number of cultured fish was approximately 353,293,000 in 2015. One of the reasons for this trend is that the increase in the production of fish, such as, flounder and rockfish, resulted in a sudden fall in fish price and, as a result, there was intervention in production at aquaculture farms.

In 2014, the total number of households managing fish aquaculture was 1,793, which was 4.0% lower than that in 2013 (Statistics Korea, 2015). This was because of the merging of low competition, small-scale fish aquaculture farms, and the shutdown of others because of red-tide damage. Recently, mass damage of fish culture farms by high water temperature has also occurred due to global climate change. Other factors causing lower production are long-term sequential culture, genetic recessiveness, and high-density culture (iPET, 2010). Particularly in cageculture farms, self-pollution resulting from feeding is unavoidable. Furthermore, most culture farm sites located in Korea are concentrated in gently-flowing bays that are vulnerable to pollution. Therefore, lower fishery production is also caused by environmental problems (Halwart et al., 2007).

The multiple uses of coastal waters restrict further development of marine fish aquaculture, and local cage-culture industries have some difficulty in maintaining the initial production levels (Halwart et al., 2007). Another issue in domestic aquaculture is the difficulty of aquaculture farm succession, as the current population of farmers and managers ages. Furthermore, security of fishmeal as aquaculture feed in Korea is mainly dependent on imports. Recently, the imbalance in the supply and demand of fishmeal has increased due to the increase in demand by latecomers, including China, into fish farming. Therefore, it is expected that there will be difficulty in securing a stable supply of fishmeal.

#### *1.1.3. Problems Facing Coastal Fisheries*

The development of marine aquaculture has caused some negative impacts, such as, the breakdown of marine habitats, introduction of non-native species, eutrophication, and disease outbreaks. The balance between the risk of marine aquaculture and its benefits has to therefore be considered (Price and Beck-Stimpert, 2014). Another potential impact on aquaculture production is the change in climate caused by global warming, which often results in environmental disasters (De Silva and Soto, 2009). Furthermore, self-pollution from marine net cages is a serious problem confronted by mariculture, clearly showing the importance of environmental management of marine aquaculture (Halwart et al., 2007). The following is a description of factors that are causing problems in coastal fisheries.

#### **1.1.3.1. Environmental Impact**

Marine cage culture operations can have an ecological impact on the marine environment and, therefore, on sensitive habitats and biodiversity. Typically, nutrients (mainly C, N, and P) are discharged as excess feed remains or as fish waste, resulting in a series of chemical and biological reactions. In nature, organic waste settling on the ocean floor is consumed by bottom feeding animals or degraded by microbes. Organisms in the sediment take up the

nutrients, and promote the diversity of plants and animals. However, if the accumulation of organic waste becomes excessive, the chemical and biological reactions shift to an anaerobic state with little or no available oxygen. Once this phenomenon occurs, it can lead to a decrease in the diversity of the benthic community. Appropriate farm operations in wellflushed areas can help minimize nutrient accumulation, causing the least impact on the benthic community (Price and Beck-Stimpert, 2014). As a result, understanding potential sitespecific ecological impacts is necessary prior to initiating farm operations.

#### **1.1.3.2. Diseases**

The continued intensification of culture practices has caused an increase in disease outbreaks in marine cage farming (Bondad-Reantaso et al., 2002). Diseases are caused principally by environmental and management effects, nutritional issues, and viral, bacterial, parasitic, and fungal pathogens (Arthur and Ogawa, 1996). The associated viruses include nodavirus, iridoviruses, lymphocystis virus, herpes virus, astro-like virus, and reovirus (Bondad-Reantaso et al., 2002). There is much concern about the increase in the intensification and clustering of marine cage farming in restricted areas. These types of culture practices may lead to outbreaks of major epizootics. In addition, there is a high possibility of trans-boundary movement of broodstock, fry, and fingerlings across cagefarming regions, especially in Asia. However, little attention has been paid to this problem. When such movement occurs, exotic diseases, pests, and invasive alien species can be spread extensively with potential impacts on biodiversity (Halwart et al., 2007).

### **1.1.3.3. Fish Production**

The production of some fish species in cage-farming systems is dependent on the capture of wild juveniles because of the limited availability of hatchery-produced fry and fingerlings of target fish species (Halwart et al., 2007). If sufficient seed fish under high-level hatching skill is secured, this can lead to overproduction exceeding the demand (FAO, 2006; Merican, 2006; Ottolenghi et al., 2004; Rimmer, 2006). Another negative effects on cage farming are the continuous increase in working expenses, such as, feed, oil, and seed, and concerns about the hesitation of fish consumption according to an advance in fish price. The dependency of cage farming systems on feed has increased because feedstock, such as, fishmeal, fish oil, and low-value 'trash fish' species, are not sufficiently available as feed (Halwart et al., 2007). If fish feed is not sufficient, it leads to low production that cannot meet the consumer demands. As a substitute for raw fish feed, formulated feed mixture has been developed to provide a stable supply.

## **1.1.3.4. Social Concerns**

Community concerns about the use of shared coastal water bodies for cage farming systems may increase due to problems relating to pollution and the possible displacement by other uses, resulting in the need for consultation with all stakeholders (FAO, 2006). Furthermore, the long-term environmental and ecological sustainability of rearing fish in cage-based farming systems is also of public concern (Goodland, 1997). Therefore, there is an increased need for governmental control of the development of the farming sector under environmental monitoring and implementation of good on-farm management practice (Alston et al., 2006; Boyd, 2005; FAO, 2006).

#### **1.1.3.5. Geographical Effects**

The size and strength of cages, and how they respond under in-situ conditions have an effect on fish production in cage-based farming systems (Halwart et al., 2007). For example, when large and robust cages, such as those of Norwegian design, were introduced in Langkawi Island, Malaysia, they were less successful because they were unable to function at full capacity due to the lack of support facilities for such large cages. The regions that have seasonal severe typhoons are not geographically appropriate for cage-farming. Locations, such as the South China Sea, are relatively shallow, and have strong surface and bottom currents but less wave height. Under these geographical features, open-ocean cages must be built to reduce drag rather than to withstand the wave height (Halwart et al., 2007).

#### **1.2. Development Schemes**

#### *1.2.1. Existing Schemes*

#### **1.2.1.1. Environmental Monitoring**

Sediment monitoring protocols should include the early detection of excessive nutrient loads, anoxia, and heavy metals, making the implementation of adaptive management possible. Prior to restocking, site planning should be established that includes cage rotation in the event that there is a measurable impact on the sediment. This practice usually takes less than two years, and can provide chemical and biological recovery (Price and Beck-Stimpert, 2014). A way to reduce metabolic waste is the use of formulated feed under good feed management practice. Today some farms install underwater cameras to reduce nutrient discharge to the water column by monitoring feeding and fish activity (Price and Beck-Stimpert, 2014).

#### **1.2.1.2. Feed Management**

The use of formulated feed under good feed management practice can help reduce the amount of excess feed discharge. This results in a reduction in the release of heavy metals into the environment because they are less soluble in water compared with fish feed (Price and Beck-Stimpert, 2014). To date, raw fish feed has been used more. In Asian aquaculture, the total amount of trash fish used as feed for marine cage farming was estimated at approximately 53,301 kilotons in 2010 (FAO, 2014). The main reasons for the continued use of trash fish as feed for cage farming are: the farmer's perception of better performance by trash fish, low price of trash fish compared with formulated feed, the ease of availability, the shortage of suitable formulated feed for all life cycle stages of culture species, and social restraints with the existing livelihood strategies of many coastal fish farmers compared with more organized lot farming (Halwart et al., 2007). However, farmers should be encouraged to use formulated feed to remove the stress of negative environmental impacts by the use of raw fish feed. To reduce the nutrient load on the sediment, high energy feeds with high digestibility should be formulated and used (Halwart et al., 2007).

#### **1.2.1.3. Limitations**

Marine cage farms must be placed away from sensitive ecosystems including corals, seagrass, and mangrove habitats (Price and Beck-Stimpert, 2014). In some countries, liquid fisheries waste is disposed of through the municipal sewage system or discharged directly into a waterbody. The receiving waterbody must be able to degrade the biological and chemical constituents present in the waste to have no detrimental effect on the aquatic fauna and flora (Naidoo and Olaniran, 2014; UNICEF and WHO, 2012). Furthermore, the damage on submerged habitats by farm installation must be considered, because they may be sensitive to shading from net pens, cages, and other moored structures. In some cases, many surrounding species of marine organisms can be influenced by the slow leaching of toxicants from copper-based antifoulant coating on nets or cages. Furthermore, the use of chemicals to remove fouling should be avoided. Instead, mechanical scrubbing by divers, or lifting cages or nets out of the water to desiccate fouling organisms is recommended (Price and Beck-Stimpert, 2014). Onsite cleaning may cause an increase in the organic load on the benthos.

#### **1.2.1.4. Farming Site Management**

Reducing waste and debris can contribute to the maintenance of water quality at cage farming sites. The timely removal of dead fish will avoid fouling of the water column, impede proliferation of predators, and prevent the spread of disease. During harvest and slaughter, waste can be reduced through careful treatment (Price and Beck-Stimpert, 2014). To prevent disease outbreak, enhanced means for disease resistance or vaccines must be developed (Halwart et al., 2007).

# *1.2.2. Integrated Multitrophic Aquaculture*

The use of integrated multitrophic aquaculture (IMTA) can reduce the impact of nutrient loading on water quality. IMTA is the integrated culture of low-level trophic organisms (shellfish and seaweed) and high-level trophic organisms (fish and prawn). For example, it is common practice in finfish culture to combine production with shellfish (mussels and oysters) and seaweed that filter waste particulates. Lobsters and sea urchins have also been used with some success (Price and Beck-Stimpert, 2014). Therefore, this approach has some potential to mitigate environmental impacts and it simultaneously expands the economic base of the farming operation. As a result, IMTA is an experimentally sustainable marine aquaculture, and in some cases can obtain social acceptance (Price and Beck-Stimpert, 2014). In Figure 1, the simple IMTA model is shown where fish, as the high-level trophic organism, and seaweed, as low-level trophic organism, are cultured together.

#### *1.2.3. Use of Lugworm*

Global legal controls exist to protect the marine environment, and this consecutive effort has made aquaculture farms environmentally-friendly. Polychaete worms have the potential to mitigate environmental impact (Brown et al., 2011). The *Nereis* species can efficiently use solid waste (unconsumed feed and fecal material) collected from a marine recirculating system, and is an excellent candidate for integrated aquaculture and waste recycling (Bischoff et al., 2009; García-Alonso et al., 2008; Honda and Kikuchi, 2002). The use of aquatic worms also has great potential in bioremediation of waste deposited on net pens or in fish ponds (Kinoshita et al., 2008; Riise and Roos, 1997). Therefore, their role in the decomposition and

mineralization of organics can be critical for recovery in impacted coastal aquaculture sites (Heilskov et al., 2006). Furthermore, their availability at these sites can be used as an indicator of the level of environmental impact by coastal aquaculture operations (Tomasseti and Porrello, 2005).

Lugworm is an important marine resource because of its role in water purification and simultaneous commercial value, mainly as bait (Cho, 2011). The market price of lugworm is twice as much as the prime cost from its culture (Jung, 2014). Therefore, the benefits of lugworm can be applied to maximize the potential of IMTA in terms of productivity and to reduce the level of nutrient loading release into the marine environment. The IMTA models primarily represent co-culture of fish with invertebrates, such as, sea cucumbers and sea urchins. This IMTA model can be modified by considering the main parameters to simulate the growth and nutrient uptake of different species under various environments. Lugworms settle beneath the farm site and perform effectively in recycling the larger organic particles that are produced from the other (feed or non-feed) components in the IMTA system (Aquaculture in Canada, 2013).

# **2. SEAWEEDS**

# **2.1. Diversity**

Seaweeds are a group of photosynthetic plant-like organisms, or macroalgae, that are macroscopic and multicellular. They are classified into three major groups based on their dominant pigmentation: red (*Rhodophyta*), brown (*Phaeophyta*), and green (*Chlorophyta*). Seaweeds have been traditionally used as food in East Asia. For this reason, about 33 genera of seaweed, mainly red and brown, are commercially harvested and cultivated (McHugh, 2003). Furthermore, close to 500 species in about 100 genera are used locally (Mouritsen, 2013).

Figure 1. Simple IMTA model showing co-culture of fish and seaweed.

The representative red seaweed include *Porphyra tenera*, *Gelidium amansii*, and *Gracilaria verrucosa*, and their carbohydrate content based on dry weight ranges between 40- 75% (Suo et al., 1986). Brown seaweed, including *Undaria pinnatifida*, *Laminaria japonica*, *Sargassum fulvellum*, and *Hizikia fusiforme*, contain about 36-60% carbohydrate, while green seaweed, including *Enteromorpha compressa*, *Ulva lactuca*, *Monostroma nitidum*, *Codium fragile*, and *Capsosiphon fulvescens*, contain about 41-53% carbohydrate. The main carbohydrates contained in each seaweed are different: agar, carrageenan, cellulose, mannan and xylan in red seaweed; alginate, laminaran, fucoidan, cellulose, and mannitol in brown seaweed; and cellulose, mannose, xylan, and starch in green seaweed. The content based on dry weight of proteins and lipids are 2-39% and 0-2% (red seaweed), 6-20% and 1-3% (brown seaweed), and 17-23% and 0-1% (green seaweed), respectively.

#### *2.1.1. Current State in Korea*

Brown and red seaweed are a good match for the oceanic climate of Korea. The seaweed culture sites in Korea are mainly located on the western side of the south coast, accounting for almost 90% of total seaweed cultivation. The total production of seaweed in 2015 was 1,105,498 metric tons at a value of USD 421,754,469 (Ministry of Oceans and Fisheries, 2015). More specifically, the production of *Pyropia*/*Porphyra*, *Saccharina*/*Laminaria*, *Undaria*, and others were 419,024; 372,311; 283,714; and 30,449 metric tons at a value of USD 269,447,654; USD 67,515,494; USD 58,614,306; and USD 25,177,014, respectively. The production of *Pyropia*/*Porphyra* has increased since the 1980s due to artificial seeding, development of the float culture system, transplantation of new species, and expansion of the culture sites. Its high market price is the result of continuous consumer demand for highquality products (NOAA, 2015).

#### *2.1.2. Domestic Uses*

Koreans have traditionally used raw or dried seaweed for food, and industries have manufactured diverse seaweed products since the 1980s. Recently, fast food-type and diversely packed products have also been developed. Dried laver is the most valuable marine product obtained from a single fishery. Another important product of processed seaweed is salted *Undaria* that is manufactured mainly on the southwest coast of Korea. The annual production of *Undaria* has increased steadily due to the increase in the demand for healthy food (NOAA, 2015). At present, about 80% of the total seaweed production is directly consumed by humans. The remaining 20% is used as a source of the phycocolloids used in food, industrial, cosmetic, and medical industries (Browdy et al., 2012; Critchley et al., 2006; Lahaye, 2001; McHugh, 2003; Mouritsen, 2013; Ohno and Critchley, 1993), and as an animal feed additive, fertilizer, water purifier, and probiotic in aquaculture (Abreu et al., 2011; Chopin, 2012; Chopin et al, 2001; Chopin et al, 2012; Fleurence et al., 2012; Kim et al., 2014; Neori et al., 2004; Pereira and Yarish, 2008; Pereira and Yarish, 2010; Rose et al., 2010).

# **2.2. Seaweed Culture**

Seaweed culture is practiced using various culture methods and each method interacts in some way with the environment (Phillips, 1990). Therefore, the nature of the interaction and

environmental impact are dependent on the culture method, surface area of the farm, and farming site. Seaweed culture is significantly influenced by environmental factors, including, turbidity, levels of organics and heavy metals, phytoplankton blooms, and temperature and salinity fluctuations (Trono, 1986).

#### *2.2.1. Positive Effects*

#### **2.2.1.1. Physical Aspects**

There is some potential for large-scale seaweed farms to increase sedimentation of organic matter and to influence coastal water movement, demonstrated by the large areas covered by the *Laminaria japonica* culture in China (Phillips, 1990). Seaweed farms can protect coastal areas from erosion. The large-scale seaweed farms may also provide shelter for other sensitive culture species and systems. For example, mussel or scallop culture species and systems have been protected under *Laminaria japonica* culture zones in China. Furthermore, facilities installed in seaweed culture, such as, rafts, ropes, and anchors, may enhance the production of other marine organisms due to an increase in the substrate surface area. Seaweed culture may also be effectively used to rehabilitate degraded coastal areas.

#### **2.2.1.2. Ecological Aspects**

Seaweed culture is an extensive system that depends mainly on a natural nutrient supply. Therefore, seaweed culture has the potential to deplete nutrients present in coastal waters. Lower nutrient levels have been detected in *Laminaria japonica* culture areas (UNDP/FAO, 1989), implying a good correlation between nutrient concentrations and seaweed production (Chung, 1986). The use of supplementary feed in intensive aquaculture systems causes an increase in nutrient levels, and it has a positive effect on seaweed production (NCC, 1989). In some areas placed in a nutrient-depleted state, fertilization is needed for seaweed growth (UNDP/FAO, 1989). The benthic area under seaweed cultures has been used for production of other aquatic animals, such as, abalone and sea cucumber, therefore making the best use of the allotted area (Phillips, 1990). Facilities for seaweed culture also have a significant influence on the productivity of coastal invertebrate and vertebrate populations due to the increased availability of shelter and food (Suo et al., 1986). Furthermore, seaweed culture has been grown in abandoned shrimp ponds, thus making use of wasted resources (Phillips, 1990).

#### *2.2.2. Negative Effects*

#### **2.2.2.1. Physical Aspects**

The main physical impact of seaweed culture systems is likely the large surface area required. Other factors include site preparation, routine management, and culture facilities. For some species, site preparation involves the removal of rocks or other obstructions, including competitive grasses and predators (Juanich, 1988). Such operations may cause some damage to coastal ecosystems, and in some cases, the loss of species of conservation interest, such as, seagrasses (Pullin, 1989). The routine management of seaweed culture in shallow waters may also cause damage through trampling and accidents. Some areas of seaweed culture are shaded by the culture facilities, and this physical shading may result in

changes to the benthic communities and primary production in the water column. Although the influence of seaweed culture on benthic communities has not been studied extensively, a shading problem in large-scale seaweed farming can potentially reduce benthic productivity, especially in shallow inshore areas.

#### **2.2.2.2. Ecological Aspects**

Extensive aquaculture as a result of overstocking causes an eventual decrease in aquaculture production because the 'carrying capacity' of the environment has been exceeded (Beveridge, 1984). In some locations, over-production has resulted in outbreaks of disease (ICES, 1989), which may be linked to nutrient decline (UNDP/FAO, 1989). To overcome these problems, the balance between the ecological requirements for seaweed culture and the carrying capacity of the environment must be carefully considered. Another concern that has arisen in intensive and semi-intensive aquaculture is the potential impact of chemicals used for the control of disease, predators, and fouling organisms (Santelices and Doty, 1989; North, 1987). Furthermore, the attractive characteristics of seaweed can foster prey-predator interaction between the seaweed, invertebrates, and finfish (North, 1987).

## **2.3. Seaweed Co-Culture**

Seaweed production accounts for approximately 35% of the global mariculture production, but its harvest value represents only 7% of the total value (FAO, 2010). To increase space efficiency and yields, co-culture with alternative or valuable aquaculture species in existing seaweed-culture areas may be necessary. Therefore, co-culture is more efficient than monoculture, especially in limited coastal areas (Beltran-Gutierrez, 2016). Fish cage culture relies on external food supplies, which results in a negative impact on water quality (Fang et al., 2016). Conversely, seaweed culture can reduce nutrient loading from fish aquaculture. Therefore, co-culture of seaweed with other species could provide more profit, and concurrently have ecological benefits (Fang et al., 2016).

#### *2.3.1. Role of IMTA*

The implementation of IMTA can be beneficial to an ecosystem. Fish cage culture always produces unconsumed feed waste. This causes nutrient loading on the seabed and results in the release of  $CO<sub>2</sub>$  as a greenhouse gas. In this situation, co-culture of seaweed with fish can turn the system into a  $CO<sub>2</sub>$  sink through photosynthesis by uptake of nutrients (Tang et al., 2011). In some IMTA systems, co-culture of seaweed with abalones, clams, and sea cucumbers is possible (Tang et al., 2013): seaweeds and phytoplankton proliferate by the uptake of  $CO<sub>2</sub>$  and NH<sub>4</sub> from the nutrients present in water. Abalones and clams then grow feeding on the seaweed and phytoplankton, respectively, and produce some detritus. Sea cucumbers finally consume these detritus for their growth. These co-cultured organisms at different levels of the food chain simulate the functioning of natural ecosystems, and this type of a balanced system with recycling nutrients would ultimately provide healthier waters (Aquaculture in Canada, 2013).

Seaweed, including kelp, is able to extract dissolved inorganic nutrients, such as, nitrogen and phosphorus, helping reduce levels of dissolved inorganic nutrients generated in the IMTA
system. Therefore, seaweed plays an important role as a bio-filter (Hayash et al., 2008; Neori et al., 2007). To date, *Sacchaarina japonica*, *Gelidium amansii*, and *Codium fragile* can effectively use the nutrients in an IMTA system (Kim et al., 2014). Co-culture of seaweed *Ulva* sp. with Atlantic salmon (*Salmo salar*) and sea urchin (*Paracentrotus lividus*) has also been shown in another IMTA model that considered the environmental conditions on the west coast of Scotland (Lamprianidou et al., 2015). The model simulated the growth, uptake, and release of nitrogen by these organisms to study the nitrogen bioremediation potential of lowlevel trophic organisms (Lamprianidou et al., 2015). Overall, seaweeds as primary coastal producers can provide nurseries, habitats, and food for aquatic fauna (Ohno, 1993; Watanuki and Yamamoto, 1990).

#### *2.3.2. Association with Lugworm*

As a candidate for integrated aquaculture and waste recycling, lugworms can be affiliated with the IMTA system (Bischoff et al., 2009; García-Alonso et al., 2008; Honda and Kikuchi, 2002). They settle beneath the farm site and play an important role to effectively reduce the amount of organic particles produced from the other components in the IMTA system (Aquaculture in Canada, 2013). Therefore, their role is important to remedy impacted coastal aquaculture sites (Heilskov et al., 2006). As a result, they contribute towards a more sustainable and productive form of aquaculture (Aquaculture in Canada, 2013).

For the practical use of lugworms in the IMTA system, at least 2-month old, grown, juvenile lugworms must be used because of high mortality during the larval stage. The normal feed for worms is decaying organic material, such as, seaweed, microalgae, dead animals, and some bacteria (Alyakrinskaya, 2003). In lugworm culture, the early larval stage was fed with marine *Chlorella* and green laver powders, and then feed for adult breeding was fed after the juvenile stage in which the grown larvae infiltrated into sediment (Choi, 2006). Seaweed can then be used as a supplementary feed for lugworms (Harris, 2010). The lugworm species, *Tubifex*, was cultured using a biofloc system to enhance their survival and growth, because the biofloc system could provide good water-quality by the decomposition of waste loading, including ammonia (Wahyuni et al., 2016).

#### **2.4. Schemes for Diverse Uses**

Seaweed is cultivated on the waste resulting from fish culture in IMTA systems, while they are used as ingredients for fish feed, such as, immune-stimulating, feces-binding, and fishmeal-replacing additives (Palstra et al., 2015). The reuse of the seaweed waste generated during their processing has recently gained interest, as the number of people seeking seaweed as a health food increases. Therefore, the security of useful microorganisms for the reuse of seaweed waste is important to reduce the environmental impact of the waste.

#### *2.4.1. Acquisition of Useful Microbes from the Lugworm viscera*

Benthos inhabiting in intertidal zones have been used in the removal of organics and in water purification (Campos et al., 2002; Davidson et al., 2008; Palacios and Timmons, 2001; Vigneswaran et al., 1999). In particular, lugworms, including the Perinereis sp., have been used in shrimp culture farms (Fujioka et al., 2007). Suspension feeders, including lugworms, have been studied extensively to understand the nutritional function of suspended bacteria (Gili and Coma, 1998; Orejas et al., 2000; Prieur et al., 1990). Lugworm Sabella spallanzanii was able to efficiently accumulate and enrich bacteria from the surroundings (Stabili et al., 2006). This is because the lugworm's viscera can provide an optimum environment for microbial growth (Kathrin et al., 1997). In earthworm viscera, Brevibacillus agri, Bacillus cereus, Bacillus licheniformis, Bacillus licheniformis, and Brevibacillus parabrevis were found to be indigenous microbes showing proteolytic and lipolytic activities (Kim et al., 2010). The Bacillus species found in lugworm viscera have also synthesized various enzymes, including protease, amylase, and cellulase to degrade diverse organics (Ziaei-Nejad et al., 2006; Verschuere et al., 2000; Ghosh et al., 2002). Furthermore, some strains isolated from lugworms showed antimicrobial activity, indicating that they could be used as a potential source to research bioactive molecules, drugs, and antifouling compounds (Shankar et al., 2015). Among the bacteria, Bacillus species found in the marine environment are used as probiotics, because they are able to stimulate the alimentary and immune systems (Gatesoupe, 1999; Ziaei-Nejad et al., 2006). B. subtilis is used as live feed by many organisms (Ziaei-Nejad et al., 2006; Verschuere et al., 2000), and some Bacillus species have been suggested as alternative antibiotics in shrimp culture farms (Phillips, 1990). In addition, B. subtilis (Vaseeharan and Ramasamy, 2003), B. licheniformis (Arena et al., 2006), and B. pumilus (Ghosh et al., 2002; Sugita et al., 1998) are able to produce antibiotics, antiviralagent, and digestion-related enzymes, respectively.

#### *2.4.2. Biodegradation of Seaweeds*

As a favorite food, various types of seaweed products are sold in Asian countries, in particular. The increase in seaweed consumption results in large generation of seaweed waste. Seaweed waste is composed of carbohydrates, proteins, and lipids (NFRDI, 2009). Through biodegradation, these components can be converted to useful compounds, such as, bioactive substances. To date, many studies have been performed on diverse microbial strains: cellulolytic *Acremonium strictum* (Goldbeck et al., 2013), alginate- and laminarin-degrading *Microbacterium oxydans* (Kim et al., 2013), agar- and carrageen-degrading *Bacillus alcalophilus* (Kang and Kim, 2014), proteolytic *Bacillus pseudofirmus* (Raval et al., 2014), and lipolytic *Aneurinibacillus thermoaerophilus* HZ (Masomian et al., 2013). The biodegraded seaweed waste can also be reused as liquid fertilizer by mixed microbes (Kim et al., 2007; Kim et al, 2010). As useful resources, they can often be applied as fertilizer, fungicides, herbicides, and phycocolloids, such as, alginate, carrageenan, and agar.

#### *2.4.3. Others*

Seaweed can be a sink for anthropogenic  $CO<sub>2</sub>$  emissions via photosynthesis in the coastal waters of some countries. Therefore,  $CO<sub>2</sub>$  removal belts formed by the seaweed culture in coastal waters are expected to be developed together with sustainable seafood production. Furthermore, seaweed is a good resource for the production of reducing sugars, and studies on the use of the produced biomass for biofuel are currently in progress. Seaweed culture can therefore contribute, to some extent, in meeting the global food, feed, and pharmaceutical requirements (Israel et al., 2010).

### **CONCLUSION**

The development of marine aquaculture has caused some negative impacts, such as, the breakdown of marine habitats, self-pollution, disease outbreaks, and environmental disasters, clearly requiring environmental management. To reduce the water-quality impact of nutrient loads sinking to the seabed, an IMTA system has been suggested. Seaweed culture is considered to be an indispensable component of this system because of its role as both  $CO<sub>2</sub>$ sink and biofilter. In addition, the introduction of lugworm culture into the established IMTA system is expected to result in more sustainable and productive form of aquaculture. To reduce the environmental impact caused by the seaweed waste, the diversity of microbes associated with lugworms has been studied. This effort for the development of useful microbes has resulted in diverse uses of cultured seaweed and their waste.

# **SUSTAINABLE PRODUCTION OF SEAWEED IN MALAYSIA: A REVIEW OF POLICIES AND FUTURE PROSPECTS**

*Velan Kunjuraman\* and Rosazman Hussin, PhD*

Ethnography and Development Research Unit, Faculty of Humanities, Arts and Heritage, Universiti Malaysia Sabah, Kota Kinabalu, Sabah, Malaysia

# **ABSTRACT**

Malaysia has the potential to be a key seaweed production player in the region if proper management and possible interventions take place. The seaweed industry in Malaysia has its own historical background as the first seaweed cultivation activity took place in 1978 in Sabah, East Malaysia. The importance of the seaweed industry has been realised when seaweed was found as an important commodity to be exported to various countries. This brings economic benefits to the country and the development of human resource in this sector. The rural people play an important role in the human resource aspect that produce and cultivate the seaweed within their respective areas. In Malaysia, Sabah is the main state for seaweed cultivation activity because of its natural abundance resources and good climate. Department of Fisheries (DOF) Sabah indicated that seaweed production in Sabah has been increased every year amounting to 32 percent from 2008- 2012. This is a good opportunity for seaweed production in Sabah where it has the potential to be developed on a bigger scale. The government of Malaysia has introduced seaweed transformation initiatives through Mini Estate System (MES) and Cluster System (CS) in year 2012 in order to enhance the seaweed industry in adhering to the scientific approach and management. These capacity building programmes' objective is to transform the conventional seaweed cultivation techniques to modern seaweed cultivation techniques by applying scientific approach. In terms of community livelihood activity, the MES and CS systems provide the seaweed cultivators with knowledge and skills in order to transform their conventional seaweed cultivation techniques to new technological approach. This MES and CS systems are still new in terms of practical

 $\overline{a}$ 

<sup>\*</sup> Corresponding Author's Email: velan1199@gmail.com.

implications. Therefore, a study to identify the effectiveness of these programmes is needed. Thus, this study is only focused on the development of both programmes by using available secondary data sources and most importantly through the documentation of these programmes. It will benefit the future researchers that are interested in this seaweed studies in Malaysia as well as in other developing countries.

**Keywords:** seaweed industry, government-led programmes, development, Sabah

## **1.INTRODUCTION**

It is evident that seaweed industry has brought significant economic revenues to the country as well as improves the standard of living of the coastal communities, for instance, the case of Zanzibar (Msuya, 2006). Seaweed has been considered as important commodity which brings economic benefits to the developing countries that produce seaweed on a large scale such as Indonesia, Malaysia and Philippines. In Malaysia, seaweed industry has been paid attention by the government with intention that it could be able to increase the country revenue through exports. Despite focus on economic benefit alone, seaweed cultivation also has potential to provide side incomes to the fishers those reside in coastal areas of Sabah, Malaysia (Hussin, Yasir, Kunjuraman & Hossin, 2015). Realising on the potential of seaweed industry, the government of Malaysia has been introduced with some possible interventions to scaling up the seaweed industry to ensure the benefits to be shared by all stakeholders. Sabah is the only state in Malaysia that is commercially producing seaweed with focus in four districts on large scale such as Semporna, Lahad Datu, Kudat and Kunak. The coral triangle are of Philippines, Indonesia and Brunei are the best locations and most appropriate for seaweed farming. With this speciality, seaweed cultivation activities are mainly being focused in Sabah and few small scale in west Malaysia.

However, the seaweed industry in Malaysia needs a transformation in terms of scientific management approach in order to achieve the country's aim. The transformation we meant was the conventional cultivation approach to scientific cultivation approach which considered reliable and efficient for this new era. Since 1970s when seaweed was introduced in Sabah, the conventional approach played a role in its growth and being practised by coastal communities in Sabah. Since then, there were no any initiatives and good methods introduced by any parties in Malaysia. Therefore, this is the right time to consider a new scientific approach in seaweed cultivation activities. There was an argument claimed by Yasir and Ali@Ally (2012) that conventional seaweed cultivation activities brought less productivity and low quality as well as over-reliant towards labour intensive based industry. Thus, the authors urged that new scientific approach in seaweed cultivation is vital in order to boost the growth and production of seaweed which could benefit the country as well as local community. Therefore, several questions arise. First, what is the new scientific approach which could be considered good for seaweed cultivation compared to the conventional methods? Who are the parties involved in developing new scientific approach? Is this new scientific approach fix into people or local community visions despite in fully focus on economic benefits? Is this scientific approach will be proven to increase the seaweed production compared to previous experience? What are the implications of introducing new scientific approach in seaweed cultivation? In the light of the above, the paper proposes that

future researchers who are interested in seaweed and development studies would consider the insights of this paper as the main reference for them to carry out the related studies of seaweed in near future.

#### **1.1. Seaweed Cultivation in Malaysia: An Overview**

Seaweed cultivation was introduced in Malaysia since year 1978 and cultivated in the island of Semporna called *Karindingan* Island (Yasir & Ali@Ally, 2012). It was a first cultivation farm in Sabah and has been spread to the other island of Semporna as well as few states in west Malaysia. For seaweed cultivation, the East Coast Sabah waters have been identified as an Aquaculture Seaweed Industry Zone due to its resources. What is seaweed? Seaweed refers to a kind of floating vegetables on top of the sea and cultivated mainly by the coastal communities especially local ethnic groups called 'Bajau'. In native language, seaweed has been called as '*sayur hijau'* or green vegetables. Mohamad, Ahmad, Noh & Saari, (2013) described seaweed as macro-algae which is growing near to the sea and has been classified into three major groups based on its pigmentation of brown (*Phaeophyceae*), red (*Rhodophycea*) or green (*Chloropphyceae*). In year 1989, seaweed species like *Kappaphycus alvarezii* has been commercialised in Sabah after Philippines (1973) and Indonesia (1986). As mentioned earlier, seaweed cultivation activities have been concentrated in four places of Sabah such as Semporna, Kudat, Kunak and Lahad Datu. This is because such areas are suitable for seaweed farm and climate as well as sufficient manpower for cultivation activities. In Asian Pacific region especially in Sabah, seaweed species such as *Euchema Cottonii* and *Kappayachus Alvarezii* are farming as a natural flora. These types of seaweeds grow along the Seaside of Sulu until Celebes Sea, which is located between of Semporna until Zamboanga Island in Philippines (Yasir, 2012). Yasir & Ali@Ally, (2012) stated that Malaysia has became a significant contributor in producing red seaweed species namely *Euchema Cottonii* and *Kappayachus Alvarezii* amounting to 20,000 metric ton of dried seaweed. The revenue are MYR60 million in year 2010. In addition, through this activity, the local community who resides in coastal areas of Sabah enjoyed the economic benefits and 9,000 hectares of seaweed farm is allocated for farming. Other than that, seaweed cultivation activities are mostly being carried out in Kerindingan Island with 15,000 hectares, Bum Bum Island with 3,500 hectares, Sebangkat Island with 7,000 hectares, Sibuan Island with 5,000 hectares and 10,000 hectares in Omadal Island. Due to these characteristics, Malaysia has the potential to be a major seaweed manufacturer and exporter in the region in terms of infrastructure development, manpower, product quality, transfer of technology, industrial support and marketing issues (Kaur & Ang, 2009).

# **2. THE INTERVENTIONS OF MALAYSIAN GOVERNMENT AGENCIES IN SEAWEED PRODUCTION**

Realising the seaweed industry has a potential to boost country's economy, the Malaysian government has proactively introduced a few of intervention programmes to enhance the country's seaweed production at par with other producing countries. In Malaysia, seaweed has been considered as one of the new sources of aquaculture commodity since 2006. A government agency called Ministry of Agriculture and Agro-Based Industry of Malaysia have been given the responsibility to deal with seaweed related issues. Seaweed was introduced as important commodity in the Malaysian National Agro-Food Policy (2011-2020) (NAP4) and assumed it could be gain economic benefits to the country. In addition, under the abovementioned policy, seaweed was identified as one of the high-value commodities under the program of Entry Point Project 3 or EPP3 (Venturing into Commercial Scale Seaweed Farming in Sabah) which was linked with the themes of 'Capitalizing on Malaysia's Competitive Advantage' (Safari, 2015). To ensure the future sustainability of the seaweed industry in Malaysia, the government has introduced various action plans such as establishing Malaysian Seaweed Industrial Development Committee, Strategic Reform Initiatives for establishing quality and standard protocol as well as enhancing research and development activities. Such government-led interventions indicate that seaweed has a big potential to be promoted nationwide as well as considered an important commodity for export purposes. Since seaweed has a potential to boost the country's economic value, the government has realised that without the partnership from the private sectors, the mission could not be achieved. Under the current policy, the government has initiated the partnership from the private sectors in order to increase the productivity of the seaweed industry. Seaweed industrial zone namely Semporna, Kudat, Kunak and Lahad Datu have been targeted to improve the current productivity of seaweed yields and enhance the coordination of quality production of seaweed. For this reason, the private companies have been given the responsible for this matter. On the other hand, these private companies also responsible to monitor and coordinate the seaweed cultivation, improve the quality of seaweeds, manpower arrangement, marketing of seaweeds and the processing of seaweeds into the high-value commodity to be exported. These stakeholders' participation in the seaweed industry in Malaysia could be beneficial for the parties who involved directly as well as the local community who produces or cultivates the seaweeds. In addition, the quality of seaweeds always be an important issue to be tackled by the government. Thus, Research and Development (R&D) is a most important element that should be included in the seaweed related interventions in order to increase the productivity of the seaweeds and safe for consumption. A few public universities also included to undertake the research on related projects of seaweed cultivation and the suitable methods for cultivation activities. Under the EPP's project, the public universities such as Universiti Malaysia Sabah (UMS), Universiti Kebangsaan Malaysia (UKM), and Universiti Sains Malaysia (USM) are in the midst of commercialising eight seaweed products which developed based on R&D initiative. In fact, Partnership with government and research institutions has been carried out to develop a Standard Operating Procedure (SOP) for the seaweed cultivation practises (Safari, 2015). Partnership with the multiple organisations are welcomed in seaweed industry and to ensure the sustainability of the industry in the long run. Safari (2015), shared that at present the seaweed production has achieved one metric ton per day and its mission to produce 10 metric tons per day by 2020. Moreover, in order to equip such big amount of seaweed production, Sabah State Government has planned to gazette another 3,000 ha of land for seaweed production. The government mission seems ambitious but with the systematic approach played by the relevant parties are important to achieve this mission.

Figure 1. Partners of seaweed in Malaysia.

# **2.1. Mini Estate System (MES) and Cluster System (CS) as a New Approach in Seaweed Cultivation in Sabah, East Malaysia**

Realising the potential of seaweed as one of the important commodity which could generate economy of the country, the Malaysian government has initiated and introduced new transformation programme called as Seaweed Mini Estate Development. Under the Economic Transformation Programme (ETP), the Malaysian government has identified seaweed as one of the National Key Economic Areas (NKEA). It was placed in one of the 16 Entry Point Project (EPP). Such initiatives have been acknowledged that seaweed was the most important commodity exported by the country. A total of 46 million was allocated to boost the seaweed industry in Malaysia by the government in 2011 (Utusan Borneo, 2011). The seaweed industry in Malaysia especially in Sabah had gained the transformation status (EPP3) when Mini Estate System (MES) has been introduced with the aim to transform the conventional seaweed cultivation to a new scientific approach. The conventional seaweed cultivation refers to those old practices such as tie seaweed with nylon string, and over exposure of seaweed drying under sunlight made the seaweed not healthy and less productive. Such conventional methods of seaweed cultivation need a transformation with the new scientific knowledge like MES. In order to manage the MES programme systematically, Universiti Malaysia Sabah (UMS), a local public university in Sabah has been given the responsibility. Since 2010, the MES programme managed by the UMS and Dr Suhaimi Md. Yasir was the director and leader of this project. The two phases of MES started in 2010 and run concurrently by the UMS. The first phase (2011-2010) focused on the initial development of MES infrastructure as well as appointment of leading companies who have the stake in seaweed cultivation. On the other hand, identification of seaweed cultivation farms also being focused in this phase.

Semporna district was identified as suitable place for seaweed production. The second phase (2013-2020) focused on the product development based on seaweeds and marketing issues. It was aimed that MES programme could increase the productivity of seaweed and could produce 150, 000 metric tons of high quality processed seaweeds worth to MYR1.45 billion by the year 2020 (New Strait Times, 2013).

Fully funded by the government, MES using the approach of 'community-based, commercial approach'. MES is a fine concept which is implemented in the seaweed cultivation programme in Semporna, Sabah. There are a few characteristics and definitions of MES. A manual book entitled '*Sistem Mini Estet Industri Rumpai Laut Negara'* was published by the Department of Fisheries Malaysia clearly mentioned about the background of MES and its significance to the seaweed industry in Malaysia. According to the manual book, MES refers to a better and new approach to the seaweed cultivation. There have been a few important factors considered in the early process of seaweed cultivation activity, namely (1) Holistic management transformation-'poor-man industry to lucrative industry', (2) Science and Technology based mechanism, (3) Reduce labour intensive production, (4) Friendly and sustainable environmental management, (5) seaweed as a new commodity, (6) 'community based, commercial approach', and (7) High quality yields and seaweed related products. There are elements in the MES that could provide the local community and industry manufacturers with the new knowledge and skills in order to embark on the new seaweed cultivation production in Malaysia.

Through the MES, an important part of the seaweed cultivation process is the availability of platform facilities. The platform facilities and accommodation for the seaweed cultivators would enable them to be involved seriously. Previously, a high level of poverty among the fishermen in both islands (Selakan and Bum Bum Islands) has led and forced them to carry out seaweed cultivation activities in a conventional way. Hence, the new technological-based approach have been introduced to assist these people to adapt themselves with the new process of seaweed cultivation. It is hoping for them to enhance their livelihoods. In MES, other facilities that have been introduced including: (1) holistic transformation (an enhancement of physically socio-economic image), (2) management system (previously 80% work on the sea and 20% on seaweed platform, but now 80% work on seaweed platform and 20% on the sea), (3) an integrative management complex, (4) estate management, (5) block management, and (6) a model of entrepreneur development (Yasir, 2012). As a result, the MES has transformed the conventional seaweed cultivation to a new and modern seaweed cultivation management.

According to Yasir (2012), the MES has its own speciality where it had many improvements over the conventional seaweed cultivation methods. For instance, the MES eliminates the use of nylon string to tie seaweeds which has been practised for decades and replaced with the UMS designed eco-friendly Tie-Tie, which is seaweed-based rope. In addition, the MES also introduced organic seaweed fertilizers for high yields and seedling pin tables or commonly known as Casino Tables as well as anchor for systematic and hygiene seaweed cultivation management.

The CS was implemented after the MES. It is considered as a branch of MES because it also focused on the production of a commercial basis rather than the domestic used. However, CS are managed by the Sabah Fisheries Department. Under the CS programme, the community that already engaged in seaweed cultivation activities are considered as

participant. The areas selected for cultivation are Bum-Bum Island, Silungan Island and Merotai Island located in the district of Semporna, Sabah, Malaysia.

# **3. SEAWEED SOCIO-ECONOMIC BENEFITS TO MALAYSIA'S DEVELOPMENT**

In Malaysia, the seaweed production has taken place in Semporna, Sabah in year 1978 and continuously growing until to date. In the initial phases of seaweed cultivation, the seaweed primarily used for coastal communities' daily meals. For coastal communities of Semporna, seaweed cultivation has been the secondary livelihood activity after the fishing activity. Since then, the seaweed cultivation became one of the significant economic activity for the coastal communities in Sabah. In terms of economic benefits, the production of seaweed has been growing gradually after 1989. The seaweed cultivation then started to grow with big scales and spread to the other potential areas of Sabah. According to the Sabah Annual Fisheries Statistic in 2013 showed that the total production of dried seaweed recorded were gradually increased from 1989 to 2001. This is an initial phase of production where it always needs some period of time to increase the efficiency of seaweed cultivation production since year 2001. In year 2002 and 2003, there were a drastic decline in seaweed production. This situation has raised attention for relevant parties to take the necessary actions. After the declination of seaweed production in year 2002 and 2003, the production of seaweed has steadily increased since 2004 until 2013 (refer Figure 2). In terms of value, in 2013, the seaweed production from Sabah amounted to 28 per cent by volume (33, 210 mt) and 3 per cent (MYR198.93 million). This value is based on the total marine aquaculture production. In fact, the seaweed production from Sabah has been recorded to be increased slightly by volume in 2013 to 110.0 metric tons compared to 2012 (Safari, 2015). This is a good revenue where the seaweed production from Sabah has high potential to be developed if serious proactive measures and interventions are taken to enhance this industry run systematically.

Figure 3 shows the statistics of Malaysian exports and imports of dried seaweeds from 2009 to 2012. The total amount of Malaysian dried seaweeds exported in the past four years were recorded a slight fluctuation with the volume increasing from 236.94 metric tons in 2009 to 656.63 metric tons in 2010. This shows a steady increasing of quantity of seaweeds exported to other countries. Table 2 also depicts that in 2011, there was a further increment of exported seaweeds amounting to 1,320.70 metric tons with revenue of 3,101,858 US dollars. However, in 2012 the amount of exported seaweeds has dropped to 502.45 metric tons. Obviously, this trend has reflected the value of seaweeds exportation showed in the parallel trend. Table 2 also indicates the statistics of dried seaweeds imported from 2009 to 2012. The amount of dried seaweeds imported have been decreased from 1,058.8 metric tons in 2009 to 668.9 metric tons in 2012. However, the value of imports where it fluctuated with a comparable average of 25 per cent from US\$ 5.4 million in 2009 increasing to US\$ 6.0 million in 2010 and US\$ 7.9 million in 2011 (Safari, 2015). This trend significantly reflected that seaweed industry in Malaysia is fragile in terms of export and import. This trend could be sustained if the stakeholders aware about the marketing strategy and increment of seaweed production. The usage of seaweed for commercial products has raised economic benefits to the country where an element of carrageenan extraction plays an important role for the

production. Thus, carrageenan from the seaweeds is valuable and potentially sustained for the seaweed industry in near future.

# **4. THE POTENTIAL USAGE OF SEAWEED IN BUSINESS VENTURES OR COMMERCIALISATION**

At present, the world demand for seaweed production especially the carrageenan. The demand was started during the Second World War where it could be the substitute for animal fat, the most popular colloid for food processing. Generally, the carrageenan was extracted from red seaweeds. In addition, the usage of seaweed specifically the carrageenan was applied in multiple commercial products such as in the food processing, pharmaceutical, animal feed, fertilizers and cosmetic industries (Phang, 2006; Valderrama, Cai, Hishamunda & Ridler, 2013). There are two types of seaweeds in Sabah such as *Euchema Cottonii* and *Kappayachus Alvarezii* were the major sources of carrageenan. Currently, there are three types of carrageenan extraction available for production of materials such as Highly-Refined Carrageenan, Refined Carrageenan and Semi-Refined Carrageenan (Safari, 2015). Such categorisation of carrageenan is widely used by manufacturers to produce products that have commercial value (see Figure 4). In order to produce semi-refined carrageenan, there are two major factories located in Sabah since year 2000 such as Tacara in Morotai, Tawau and Omi-Gel in *Jalan Kemiri* (Kemiri Road), Semporna (Phang, Yeong, Lim, Nor & Gan, 2010).

Source: Adapted from Cai, Hishamunda & Ridler, 2013: 20.

Figure 4. Summary of products based on carrageenan extraction.

For the past decades, coastal communities of Sabah used seaweed as daily meals whether as raw or blanched as salads (Phang, 2006). The seaweeds rich with vitamins such as A, C and E and good for health. In addition, it has been also considered as side dish for most of the coastal communities around the Semporna that cultivated seaweed as their full-time or parttime employment. The use of seaweeds as food are well-documented in the literature. There are different types of seaweeds have been used. Types of seaweeds used for food namely Rhodophytes *Gracilaria changii*, *Gracilaria tenuispitata*, *Eucheuma* species, Chlorophytes *Caulerpa lentillifera* and *Caulerpa racemose* are popular (Phang, 2006). Seaweeds are popular among the Chinese communities in Malaysia where they perceived it has traditional medicine value and healthy for consumption. Since seaweeds are largely cultivated in Sabah, the local community especially *Sabahans* are favour for seaweeds to include in their meals. Such popularity of seaweeds as food could sustain the seaweed industry in Sabah. Furthermore, it could become an alternative mechanism for people who prefer healthy lifestyles when it comes to food consumption. Seaweeds are not only famous among the local Malaysian but also among Japanese people. Restaurants and street food courts are now serving seaweeds as food and cook seaweeds in different methods. Among the popular species of seaweeds used in Japanese and Chinese restaurants are the temperate species of *Porphyra* (nori), *Undaria* (wakame), *Laminaria* (kombu) and *Nostoc* (fa' tsoi). In terms of daily food consumption, people can buy dried *Sargassum* and *Turbinaria* in most Chinese medicine shops in Malaysia (Phang, 2006).

# **5. PROSPECT OF SEAWEED INDUSTRY AND WAY FORWARD**

Carrageenan powder is the most important source for used in many commercial products. Therefore, it can boost the country's economy where more innovative products could be developed if the carrageenan production is sustained. The demand of carrageenan was estimated value of 40, 000 metric tons in 2006. It is projected to increase at a rate of 10-15 per cent per annum with an estimated value of US\$3.3 billion. With regards to Malaysian development perspectives, the Malaysia's Ministry of Agriculture and Agro-Based Industry targeted for wet seaweed production is expected to grow by 19.7 per cent from 365, 000 metric tons in 2015, tripling to about 900, 000 metric tons in 2020 (Safari, 2015). With this projection, the production of carrageenan are also expected to increase in line with this target. The importance of carrageenan production can be realised through government's interventions. The present government's interventions are seriously focus on the sustainability of the seaweed industry as well as the carrageenan production. It also assumed that the export value of seaweed could be tripled by 2020, from MYR376 million in 2015 to MYR1.4 billion in 2020. In context of food and pharmaceutical industries, the uses of carrageenan are important for the development of various commercial products of related industries. In Malaysia, it is hoped that the production of carrageenan could be enough to supply and fulfil the current demands. In fact, it was estimated that the world population of 8 billion in 2030, thus the overall food consumption is definitely going to increase. In line with this fact, the total production of carrageenan is also expected to increase in near future.

### **CONCLUSION**

Based on the review of Malaysian government policies related to seaweed industry, the study found that the Malaysian government is seriously committed in introducing new interventions in seaweed cultivation in order to enhance the seaweed industry in the country. This is reflected in the form of policy where seaweed production and commercialisation has become an important industry in Malaysia. The government has highlighted seaweed as one of the high-value commodity under the Malaysian National Agro Policy for the year 2011- 2020. This is proven that Malaysian seaweed industry has high potential to be developed. It is also could bring economic benefits for the country as well as socio-economic development. Kaur and Ang (2006) believed that Malaysia has the potential to be a major seaweed manufacturer in Southeast Asia region. This vision however, could not be achieved if the proper management and systematic approach take place by the relevant stakeholders. To some extent, such interventions are already in place. But it is too ambitious to claim that the seaweed industry will grow faster and sustain in near future. This is because the seaweed industry is consider as a 'fragile industry' and unpredictable in terms of its implications. Therefore, continuous monitoring efforts from stakeholders are always needed where future proactive measures are still relevant to consider. The sustainability of the seaweed industry is rely on the people hands (in this context is the local people who cultivating seaweed) and industry manufacturers in order to stabilize the production value and the volume of seaweed production. Thus, more efforts especially R&D, prevalent technologies and scientific approach are needed to boost the seaweed industry in the future in Malaysia.

*Chapter 75*

# **THE IDENTIFICATION OF MACROALGAE AND THE ASSESSMENT OF INTERTIDAL ROCKY SHORES' ECOLOGICAL STATUSES IN THE CENTRAL WESTERN COAST OF CONTINENTAL PORTUGAL**

# *Ana Lucinda Lima<sup>1</sup> , Rui Gaspar<sup>1</sup> , João M. Neto1,2 and Leonel Pereira1,2,*

<sup>1</sup>MARE (Marine and Environmental Sciences Centre), Faculty of Sciences and Technology, University of Coimbra, Coimbra, Portugal 2 IMAR (Institute of Marine Research), Department of Life Sciences, Faculty of Sciences and Technology, University of Coimbra, Coimbra, Portugal

# **ABSTRACT**

This work studied the marine macroalgae thriving at intertidal rocky shores on the west coast of Portugal (Peniche, Central Portugal). Four seashores (Baleal-Norte, Gamboa, Portinho da Areia do Norte and Consolação) located near the borderline between two adjacent types of the Portuguese coast were surveyed, the first 3 inside the northern exposed coast (type A5) and the last shore from the moderately exposed coast at the southwest coast of continental Portugal (type A6).

The aim of the study was to contribute to improve knowledge on the marine macroalgal flora of this transition zone, where the combined influence of cold waters (from North Atlantic Ocean) and warmer waters (from subtropical Atlantic Ocean and the Mediterranean Sea) may favour the development of unique macroalgal communities (different arrangement of species). The collected material was housed at herbaria and photographed (records inserted in MACOI – Portuguese Seaweeds Website), and data were compared with historical information, aiming to update the local taxonomic list of marine macroalgae, and to infer about the species evolution along a 50 years' period. Data were also used to assess the ecological quality status of the four sampled sites by applying the methodology MarMAT (Marine Macroalgae Assessment Tool).

A total of 87 macroalgal species were identified in the four localities, from which 16% have been not registered 50 years ago in local surveys. Meanwhile, more *taxa* were

 $\overline{a}$

identified after the initial campaign so no new species were recorded in the present study. Taxonomic composition showed similarities for all sites but sufficient differences were still present and Consolação (A6 typology) appeared separate from the northern shores in the MDS analysis. From the application of MarMAT to present registers and old data, resulted a similar ecological quality status. Although all sites assessed in this study resulted on High quality, MarMAT reported equally high Ecological Quality Ratio for old and some recent data, indicating that sites preserved their excellent quality along the last decades.

### **INTRODUCTION**

The first phycological studies of the Portuguese coast were published by Vandelli in 1788 [in 1] and Correa da Serra in 1796 [2]. In the following years, other studies were carried out by Welwitsch [3], Hauck [4], Palminha [5-8], Mesquita Rodrigues [9, 10], Póvoa dos Reis [11]. However, the most complete study on the Portuguese phycological flora was carried out by Ardré [12-14]. Actually, according to Sousa-Pinto [15], the Portuguese phycological flora did not suffer a significant change in terms of the number of species registered since the study made by Ardré in 1970 [13] in the late sixties, of the last century. Ardré [13] studied, identified and described 404 macroalgae species, from which 246 were Rhodophyta (red algae), 98 Ochrophyta (brown algae) and 60 Chlorophyta (green algae). In 2009, Araújo et al. [16] based on literature references, new records and herbarium data, obtained an updated checklist of the benthic marine algae of the northern coast of Portugal. This checklist includes 346 species, namely 200 Rhodophyta, 70 Ochrophyta, 50 Chlorophyta, and 26 Cyanobacteria. Of these, 33 species were recorded for the first time in this region and 21 were new records for the Portuguese coast. These new records were probably mainly related to the sampling effort, undertaken recently across more localities than in previous works, with a consequent increase of diversity on the habitats surveyed [16]. Recent new floristic records and taxonomic data were published meanwhile by other authors [17-24].

The Portuguese coast is located in a transition region, between the cold waters of the North Atlantic Ocean and warmer waters of subtropical Atlantic Ocean and the Mediterranean Sea, favourable to the development of a unique combination of species that compose the Portuguese macroalgal communities [16, 17]. Southwards there is an increasing number of Rhodophyta species and a simultaneous decrease in Ochrophyta, which enables the division into two groups: algae of the northern zone (between the mouth of the Minho river and the mouth of the Tagus river) and algae of the southern zone (between the mouth of the Tagus river and the Algarve) [25, 26]. Although the intertidal macroalgae in northern Portugal tend to be more similar to those of the central European coast, Brittany and South of British Isles, and the macroalgae of southern Portugal to get included several Mediterranean and African species [15], the global composition of macroalgal communities represents well this transition situation. This is evident when Feldmann [27] and Cheney [28] ratios are compared by geographical region, varying from 2.53 in Britain and Ireland to 3.71 in Moroccan coast, with a higher value registered for the Iberian coasts (3.57 to north Portugal, 4.09 to Basque Country) [16].

Located in the central region of the country, the Baleal-Norte, Gamboa, Portinho da Areia do Norte and Consolação coastal areas also have a great diversity in terms of phycological flora in their mediolittoral rocky shores. The first phycological records of the Baleal-Norte rocky shore were made in 1961 and 1970 by Ardré [12, 13]. Later, inserted in the project MACOI-Portuguese Seaweeds Website [29] (1998 to present), new *taxa* were identified and added to the previously described by Ardré. From a total of 131 species recorded, 20 were Chlorophyta, 29 Ochrophyta and 82 Rhodophyta. The first inventory of Gamboa beach was done by Ardré in 1966 [30] and later in 1970 [13] recording a total of 148 species (21 Chlorophyta, 33 Ochrophyta and 94 Rhodophyta). In Portinho da Areia do Norte and Consolação sites the first records appeared with the project MACOI-Portuguese Seaweeds Website [29], accounting 71 species for the first location (9 Chlorophyta, 18 Ochrophyta and 44 Rhodophyta) and 24 species for the second (5 Chlorophyta, 5 Ochrophyta and 14 Rhodophyta) [12, 13, 29, 30].

Taxonomic composition of macroalgae is important for the structure and functions characterizing marine coastal communities and, consequently, it has influence on the dynamics and changes occurred in coastal environments [31, 32]. Conversely, it is also known that species richness, taxonomic composition and the abundance of certain macroalgal species at intertidal rocky shore communities (proportion of opportunists' coverage in relation to total coverage) may reflect changes resulting from alterations in the water quality. These characteristics allowed the Water Framework Directive (WFD, 2000/60/EC), an European environmental legislation piece, to require the use of marine macroalgae as one of the biological quality elements (BQE) integrated in evaluation schemes developed by European Member States (MS) [31] to detect any significant ecological degradation resulting from anthropogenic activities. The implementation of the international environmental legislation's court forced to a concerted effort between the administration of various MS, regarding the development of environmental and ecological indicators [33]. From this need it was developed in Portugal the Marine Macroalgae Assessment Tool (MarMAT), a methodology created to evaluate the quality of coastal waters based on data collected from intertidal macroalgae communities [34].

Mostly, assessment methods require either a correct identification of macroalgal species present and a deep knowledge of taxonomic lists naturally characterizing the coastal zone under evaluation (i.e., type specific reference conditions) [34, 35]. These aspects are eventually more important in transition zones of the coast, such as the study area here presented, where assessment methods may experience changes in boundary values or in the reference conditions they have to use to compare with but where the availability of data is also low. Due to this, the increase on quality and quantity of information from those sites earns extreme importance for a robust assessment of ecological conditions of rocky shores. In this sense, the present chapter aims to improve the knowhow about the behaviour of intertidal macroalgal communities from a coastal transition zone, namely: (1) to register and update the intertidal phycological flora of four rocky shores from the western coast of Portugal (diversity and photographic records); (2) to analyse the macroalgal community structure, its similarity between study sites, and to compare historical and present taxonomic data; and (3) to assess the Ecological Quality Status (EQS) of coastal water bodies for present and first sampling situations, at the same time that MarMAT robustness is validated for sites located at the borderline of transition zones.

# **SEASHORES OF THE WESTERN COAST OF PORTUGAL (PENICHE)**

Located in the North-East Atlantic (NEA) region of the European coast, the four study sites belong to typology NEA 1/26 of EU coastal waters' category [36]. In terms of national classification, the sites (Baleal-Norte, Gamboa, Portinho da Areia do Norte and Consolação) are displaced on the borderline between two adjacent coastal water types, which are type A5 (exposed coasts, includes the first three sites) and type A6 (moderately exposed coasts, includes the last shore). The classification of Portuguese categories includes also for open coastal waters the sheltered type (A7) on the south part of the country (Algarve), and types A1 to A4 representing transition waters (estuaries) and sheltered coastal waters (coastal lagoons) along all territory [37]. The coast is influenced by a semidiurnal tide, mesotidal (2-4 m amplitude) with prevailing winds from the North/Northwest in the summer months. The sea surface temperature varies between 15 °C and 17 °C and the air between 18 °C and 25 °C during the summer season [38-40].

Inserted on the central region of the west coast of Portugal, the Baleal-Norte, Gamboa, Portinho da Areia do Norte and Consolação shores have characteristics in common, including the fact that they possess mixed substrates, more or less extensive, composed by thin, gold sands and rocky outcrops (Figure 1). However, every location presents a particular physical feature of the coast, given by the arrangement and interactions between the water and these substrates or platforms. Resulting from distinctive abiotic and biotic characteristics, the side by side presence of exposed coasts (A5 coastal waters Portuguese typology: Baleal-Norte, Gamboa and Portinho da Areia do Norte) and moderately exposed ones (A6 coastal waters Portuguese typology: Consolação), promotes the emergence of many species of macroalgae and the consequent enhancement of general diversity in the area.

Figure 1. Location of the studied areas on the Portuguese coast: A) Baleal-Norte (39°22'24.21''N -920'11.36''W); B) Gamboa (3921'51.19''N - 922'19.55''W); C) Portinho da Areia do Norte (3922'7.46''N - 922'42.28''W); D) Consolação (3919'30.57''N - 921'37.86''W).

## **SURVEY OF THE PHYCOLOGICAL FLORA**

Seaweed samples were collected between July 2012 and June 2013; maximum possible information was obtained from several visits to sites. The methodology used for harvesting macroalgae in the intertidal level was equal to all sites. The collection of specimens began before the low tide hour (information found at the Hydrographic Institute website) [41] and lasted until after that, making possible the visualization of the lower zone of the intertidal level. The macroalgal species richness was assessed through a random path in the rocks and tide pools area, from the lowest tide level to the highest level in the intertidal. All species found along this course were photographed in place, harvested and stored in labelled plastic bags. In this study was chosen a destructive method, proceeding to the collection of specimens through the uprooting in the case of larger algae and in the case of smaller algae by scraping the surface of the rocks.

The collected material was separated into two groups, the larger algae were conserved in herbarium and the small sized species were transferred into labelled vials and preserved in a solution of formaldehyde at 4% in seawater. The largest specimens were identified into the main taxonomy groups of red, brown and green algae in the laboratory, except when the accurate identification was possible in the field (Cyanobacteria were not included in this study). The screening of small sized algae was done in the laboratory under a Stereo Microscope (Lan binocular optics with digital camera, DCMC 130, 1.3M pixels) and a Light Microscope (Motic BA 310 with camera incorporated) (see Annex I). All collected species were identified and data inserted into MACOI - Portuguese Seaweeds Website [26, 29].

# **MACROALGAL DIVERSITY AND COMMUNITY STRUCTURE**

Along the four intertidal areas were identified in total 87 species of macroalgae. Of these 87 species, 10 belonged to Chlorophyta, 20 to Ochrophyta and 57 to Rhodophyta. Carrier of the highest species richness, the Baleal-Norte beach contained 55 species, than the beaches of Consolação with 53, Portinho da Areia do Norte with 50 and Gamboa with 36 species of macroalgae (Table 1). Of the 55 species of macroalgae referring to the Baleal-Norte beach, 7 belong to Chlorophyta, 12 to Ochrophyta and 36 to Rhodophyta. Of the 53 species from the Consolação beach, 7 belong to Chlorophyta, 13 to Ochrophyta and 33 to Rhodophyta. Of the 50 species from the Portinho da Areia do Norte beach, 7 belong to Chlorophyta, 10 to Ochrophyta and 33 to Rhodophyta. And of the 36 species of Gamboa beach, 5 belonged to Chlorophyta, 14 to Ochrophyta and 17 to Rhodophyta.

In all shores, the number of species belonging to Rhodophyta was the highest, followed by Ochrophyta and Chlorophyta, which permanently had the lowest number of species. Regarding the number of Orders, it was noted that in all sites, the Bryopsidales and Ulvales had the highest number of species from Chlorophyta. On Ochrophyta the Orders that stood out on the Baleal-Norte shore were Dictyotales and Fucales, on Gamboa and Portinho da Areia do Norte were Dictyotales, Fucales and Sphacelariales, and from Consolação were Fucales, Ectocarpales and Sphacelariales. In Rhodophyta, Ceramiales was more abundant in all sites, followed by Corallinales. Apart from these two Orders, on the Portinho da Areia do Norte and Consolação also Gigartinales showed a significantly high number of species. In

contrast it was found that Nemaliales, Peyssonneliales, Plocamiales and Rhodymeniales had only a single species each. Similarly, to what was verified individually for seashores, also throughout the species registered on sites was found that Bryopsidales and Ulvales Orders were the most representative of Chlorophyta with 3 and 5 species, respectively. On Ochrophyta, Dictyotales, Ectocarpales and Fucales were the most evident with 5 species each. In Rhodophyta, Ceramiales was the most expressive with 36 species, followed by Gigartinales with 7 species (Figure 2 and 3).

## **Table 1. List of species identified for the study sites and indication of photograph number**

#### **Table 1. (Continued)**

ESG - ecological status groups (I - perennial species; II - annual species); Opport. – opportunistic species; X - species recorded; RTL - different entries in the reduced taxa list (RTL).

The numbers indicate different entry present in the reduced list of species (RTL), since there are several species grouped in some single entry. Thus, the following entries consider more than one possible taxa in RTL (1) *Codium* spp.; (2) *Cladophora* spp.; (3) *Ulva* spp. 'tubular-type'/*Blidingia* spp.; (4) *Ulva* spp. 'sheet-type'/*Ulvaria obscura*/*Prasiola stipitata*; (5) *Dictyota* spp.; (7) *Colpomenia* spp./*Leathesia marina*; (8) filamentous Phaeophyceae; (10) *Cystoseira* spp.; (11) *Fucus* spp.; (12) *Laminaria* spp.; (14) *Halopteris filicina*/*Halopteris scoparia*; (16) *Asparagopsis armata*/ *Falkenbergia rufolanosa*; (17) *Acrosorium ciliolatum*/*Callophyllis laciniata*/*Cryptopleura ramosa*; (18) other filamentous Rhodophyta; (19) *Apoglossum ruscifolium*/*Hypoglossum hypoglossoides*; (20) *Bornetia* spp./*Griffithsia* spp.; (21) *Chondria* spp.; (23) *Laurencia* spp./*Osmundea* spp.; (26) erect calcareous species; (27) encrusting calcareous species; (28) Gelidiales; (29) *Ahnfeltiopsis* spp./*Gymnogongrus* spp.; (30) *Catenella caespitosa*/ *Caulacanthus ustulatus*; (33) *Dilsea carnosa*/*Schizymenia dubyi*; (35) *Plocamium cartilagineum*/ *Sphaerococcus coronopifolius*; (36) *Peyssonnelia* spp.; (37) Champiaceae.

\*Exotic species (non-native).

From the above mentioned distribution of taxa was possible to estimate the Cheney ratio -  $(R + C)/P$  [28] for all sites. The highest values were achieved by Portinho da Areia do Norte with 4.0, Baleal-Norte was next with 3.58, Consolação follow it with 3.08, and Gamboa was the last with 1.57. Except for the last site, all the others fall inside the ranged by other studies for the European coast [16], which varied from 2.53 to Britain and Ireland, 4.09 to the Basque Coast, 3.57 to North Coast of Portugal, and 3.71 to the Atlantic Coast of Morocco. Concerning the Feldmann ratio - R/P [27], a similar situation was observed, with the highest values registered for Portinho da Areia do Norte with 3.3, next was Baleal-Norte with 3.0, Consolação achieved 2.54, and Gamboa was 1.21. The tendency here (except for Gamboa site) was to be next the values obtained in other studies for the European coasts [16], which varied from 1.87 to Britain and Ireland, 3.31 to the Basque Coast, 2.86 to North Coast of Portugal, and 2.93 to the Atlantic Coast of Morocco.

Figure 2. Total number of species per order on each beach: Baleal-Norte; Gamboa; Portinho da Areia do Norte; and Consolação.

Figure 3. Total number of species per order in the four beaches of the municipality of Peniche.

Despite the geographical proximity of study sites, the macroalgal communities were relatively diverse along the sampled space. This was pretty much evident when the community was analysed based on the taxonomic composition present at different sites. Macroalgae presence/absence data were analysed through a non-metric Multidimensional Scaling (n-MDS), with Bray Curtis index as similarity measure (PRIMER 6 + PERMANOVA<sup> $\circ$ </sup> software) [42, 43], and produced an ordination of sites through a virtual space where larger distances meant also more differences between pairs of shores. Ordination results showed that, independently of the variation found between the different taxonomic groups, the taxonomic composition present was more similar between Gamboa, Portinho da Areia do Norte and Baleal-Norte, then in comparison to Consolação (Figure 4). The last site was not grouped together with the other three due to the slightly lower affinity of the fourth site existing on taxonomic compositions. Although the number of species registered on Gamboa site was considerably lower, 36 against more than 50 for the other sites, this was not sufficient to displace it from the northern shores' group. Consolação presented the second highest diversity but its list of species may be on the basis of the separation from the rest, with 8 species present in all other three sites except here (*Derbesia tenuissima*, *Dictyopteris polypodioides*, *Padina pavonica*, *Taonia atomaria*, *Sargassum vulgare*, *Acrosorium ciliolatum*, *Laurencia pyramidalis*, *Sphaerococcus coronopifolius*) and, in the opposite, 13 taxa being exclusive from this site (*Ulvaria obscura*, *Hincksia granulosa*, *H. hincksiae*, *Fucus spiralis*, *Laminaria ochroleuca*, *Aglaothamnion pseudobyssoides*, *Callithamnion tetragonum*, *Gayliella flacida*, *Cryptopleura ramosa*, *Osmundea pinnatifida*, *Pleonosporium borreri*, *Dilsea carnosa*, *Gigartina pistillata*).

From taxa absent from Consolação, 3 species (*Dictyopteris polypodioides*, *Laurencia pyramidalis*, *Sphaerococcus coronopifolius*) may be considered as Northern-cold species [16] or were not registered in southern locations during the first surveys [12, 13, 30], and from taxa exclusive form this site, eight species (*Ulvaria obscura*, *Fucus spiralis*, *Laminaria ochroleuca*, *Callithamnion tetragonum*, *Cryptopleura ramosa*, *Gigartina pistillata*, *Osmundea pinnatifida*, *Pleonosporium borreri*) are considered Southern-warm species [16] or were not registered for Portuguese northern coast in the first surveys made on the area [12, 13, 30].

Figure 4. Plot of the four studied rocky shores. Non-metric Multidimensional Scaling (n-MDS), with Bray Curtis index as similarity measure, based on macroalgae presence/absence data.

Comparing the current data, collected in the present survey, with those historically reported in the literature it was found that 84% of the species recorded (73 species) have been already identified 50 years ago by Ardré [12, 13, 16, 30]. The species not identified at that time constitute mainly new species, described more recently, or small sized species that could be easily not seen in the field. These were 14 species (16%) distributed between Ochrophyta and Rhodophyta, respectively with 3 and 11 species. All species from Chlorophyta have been indicated before as present at the surveyed area. From those 14 species, 3 have been registered for northern and southern areas by the Ardré at that time. From the 14 species not present in historical records, 3 species (*Dictyota spiralis, Padina pavonica, Erythroglossum laciniatum*) have been observed by Ardré only at southern sites from the study area, and one species (*Aglaothamnion sepositum*) for northern areas. Additionally, from the 14 species not detected by Ardré but registered in the present survey, these have been meanwhile reported for the local flora listed by recent studies [16, 44].

# **ASSESSMENT OF THE ECOLOGICAL STATUS OF COASTAL WATER BODIES**

The methodology developed in Portugal to assess the ecological quality of rocky shores fulfilling the WFD requirements is known as the Marine Macroalgae Assessment Tool (MarMAT). This tool includes seven different metrics: species richness, proportion of Chlorophyta, number of Rhodophyta, number of opportunists/ESG I (ratio), proportion of opportunists, shore description and coverage of opportunists [34]. The taxonomic composition data (presence/absence of species) registered on site is compared to a Reduced Taxa List (RTL), created for each different water typology based on macroalgae species present under different pressure levels (from naturally undisturbed to heavily impacted conditions). All MarMAT metrics, except the 'Proportion of Opportunists,' are calculated based on RTL structure.

More in detail, the first step is the *in situ* identification of *taxa* and its assignment (or not) into one of the entries in RTL. *Taxa* not assigned are not included in further calculations. Still in the field, is to do the shore description, filing in specific information into an appropriate classification table, and, at last, to calculate the percentage coverage of opportunistic macroalgae in relation to the total species coverage [34]. Species richness, proportion of Chlorophyta, number of Rhodophyta, proportion of opportunists and the ratio of the number of opportunists/Ecological State Group (ESG) I are calculated based on *taxa* in the RTL. The coverage of opportunists is usually estimated from 1-meter sq. photographed quadrats, having in mind the species considered as opportunists in the RTL [34]. The RTL considered in this study was developed by Gaspar et al. [35] for the A5 coastal waters Portuguese typology. The EQS is calculated by attributing scores to each of the MarMAT metrics (Table 2), according to the established in Neto et al. [34]. The metric 'Shore Description' functions as a correcting factor, aiming to reduce the influence of different rocky shores' morphology on the composition and abundance of macroalgae.

#### **Table 2. Quality class scores attributed to different metrics integrated in MarMAT and the translation of EQR values into Ecological Quality Status (EQS)**

a factor of 2, counts twice in the metrics sum of scores calculation.

Applying the methodology MarMAT to macroalgae data it was possible to assess the Ecological Quality Status (EQS) of the four coastal rocky shores. MarMAT was applied to data collected in the end of June 2013 and using the RTL developed for the Portuguese typology A5. In Table 1 are shown species collected in this survey and the assignments into RTL. The site with the highest species richness was Baleal-Norte with 55 species, however, for the calculation methodology (after assignment to RTL) were recorded 29 *taxa*. The following site with higher number of species registered was Consolação with 53 species and 31 RTL entries, then Portinho da Areia do Norte with 42 species and 27 entries. The Gamboa site was the one recording the lowest species richness with only 36 species and 19 RTL entries. In all monitoring events, the number of Rhodophyta species was always higher than the number of Ochrophyta and Chlorophyta species. The last registered the lowest number of species for all study sites.

In Table 3 are discriminated the results and respective scores of different MarMAT metrics, as well as the final quality assessment of studied rocky shores. For the metric shore description Baleal-Norte station presented the highest results, with 11, Portinho da Areia do Norte beach had a score of 10 and Gamboa and Consolação had 9. Regarding the coverage of opportunistic algae, Baleal-Norte showed the lowest value with 21.1%, followed by Consolação and Gamboa stations with 26.3% and 32.6%, respectively. With 45.2% the Portinho da Areia do Norte beach was the one with the highest percentage cover of opportunistic algae. The ecological quality ratios (EQR) of Baleal-Norte, Gamboa, Portinho da Areia do Norte and Consolação were 0.97, 0.81, 0.83 and 0.97, respectively. Despite the EQR differences, results rated all sites with 'High' EQS, which confirms the general elevated quality of sites. Having in mind the macroalgal species registered 50 years ago, during the first intertidal surveys, and assuming that cover of opportunistic macroalgae should have been not worst then nowadays, the calculation of the EQS for 1970 achieved also High status (EQR  $= 0.97$ ) for the area. From these results, similar to the today's best, it's possible to say that quality of the study area remained in High status since then.

Although Consolação site belongs to A6 the RTL for A5 was the one used. This was due to the geographical proximity of all sites, being also possible to validate the applicability of specific RTLs to sites located near the boundary limits but already outside the typology area.
Metrics/Beaches		<b>Baleal-Norte</b>	Gamboa	Portinho da Areia do Norte	Consolação

# **CONCLUSION**

In this survey, a total of 87 species of macroalgae were identified, from which 10 were Chlorophyta, 20 Ochrophyta and 57 Rhodophyta. The studied seashore with the greatest biodiversity was Baleal-Norte with 55macroalgal species, followed by Consolação with 53 Portinho da Areia do Norte with 50 and Gamboa with 36 species. Among the four sites, it was observed that the biodiversity in terms of taxonomic composition was not too different since a high number of repeated species was found among stations, in particular the large sized ones. Despite that, the taxonomic composition presented was sufficiently different to separate Consolação from the other three sites, which were grouped together in a compact way. The presence of *taxa* simultaneously in all sites constituting the larger group, but not in Consolação, and, by opposition, the exclusive presence of *taxa* only in Consolação, dictated the mentioned relative distribution of sites. The distribution of species through the macroalgae Phyla also places the study sites inside the expected variation for the European coast. The achieved results (except for Gamboa) were perfectly in line with results obtained from studies where the sampling effort was higher [16]. This indicates the survey was balanced and performed in a trustful way, which is important when delicate issues and conclusions are extracted from the collected data (e.g., WFD Ecological Quality Assessment).

Comparing the current data with those historically reported in the literature it is found that about 84% of the species recorded have been already identified 50 years ago by Ardré [12, 13, 16, 30], and all the remain species were meanwhile identified by other researchers so no species were added as a new register by the present survey.

The ecological quality status of Baleal-Norte, Gamboa, Portinho da Areia do Norte and Consolação reached 'High,' thus confirming MarMAT's sensitivity in the assessment of ecological quality of coastal waters. The quality assessment reporting to data collected in 1970 allowed to confirm the high quality of this coastal area, where the High status was achieved for the former survey as well as for the present one.

#### **ACKNOWLEDGMENTS**

This work had the support of Fundação para a Ciência e Tecnologia (FCT), through the strategic project UID/MAR/04292/2013 granted to MARE. This work had also the support from the European Union through EASME Blue Labs project AMALIA - Algae-to-MArket Lab IdeAs (EASME/EMFF/2016/1.2.1.4/03/SI2.750419). RG was financed by the programs POPH (Portuguese Operational Human Potential Program) and QREN (Portuguese National Strategic Reference Framework) (FSE and national funds of MEC) through a PhD grant (SFRH/BD/82014/2011). The authors also thank Ignacio Bárbara for his valuable help in the identification of some species of macroalgae and for reviewing this chapter.

Figure 6. *Codium tomentosum*: (A) A small green alga (up to 30 cm long) with a dichotomously branched, cylindrical frond; the frond is solid and spongy with a felt-like touch; (B) cross section of the thallus, showing the non-mucronate utricles (L.M. 400X).

Figure 7. *Derbesia tenuissima*: (A) Thalli bright green, 10-60 mm tall, on rock or on other plants, threadlike, sparsely branched, transverse septa absent; (B) specimens in its natural habitat.

Figure 8. *Cladophora prolifera*: (A) Unattached or basally attached coarse filaments that are usually less than 0.5 mm wide and 3-5 cm long; (B) the filaments are formed of a single row of often swollen cells; if attached then by a discoid base or by rhizoidal outgrowths (S.M.15X); (C) ramifications with rounded apexes (S.M.15X); (D) basal part with rhizoids (S.M.15X).

Figure 9. *Valonia utricularis*: (A) Thallus, translucent light- to dark-green, primarily consisting of a large (up to 5 mm thick and 20 mm long) bladder- or cluc- to hose-like "cell," branching at the base rhizoidally. Later due to outgrowths of this cell cylindrical-clavate branches, often contorted and almost gapless densely packed, thus forming intertwined erect stands [32] (L.M. 400X); (B) vesicles forming tufts (L.M. 400X).

Figure 10. *Ulva compressa*: (A-B) This species can have one of two different growth forms: the first is a flat, narrow sheet with ruffled edges; the second form (often referred to as *Enteromorpha compressa*) is a hollow tube of tissue, rounded at the top. In both forms the sheets of tissue are very thin, in fact they are exactly one cell thick; several blades or tubes arise from a common attachment point and can grow up to 200 mm long.

Figure 11. (A) General appearance of *Ulva rigida* thallus; (B) general appearance of *Ulva rigida* var. *fimbriata* thallus; (C) cross section of *U. rigida*'s thallus, in which it is possible to see the rectangular shape of the cells (L.M. 100X); (D) cross section of *U. rigida* var. *fimbriata* thallus, in which it is possible to see the conical shape of the cells (L.M. 400X).

 $(C)$  (D)

Figure 12. *Ulva clathrata*: (A) This species forms tufts, bright green, composed of branched axes, which can reach several centimeters long (20-30 cm); the main axis and branches are covered with a very characteristic (B) conical branchlets (L.M. 100X).

Figure 13. *Ulvaria obscura*: (A) Thallus widely-bladed, monostromatic (B), similar to that of laminar *Ulva*, turning brown on dying (L.M. 100X).

# **Ochrophyta (Phaeophyceae) – Brown Algae**

Figure 14. *Dictyota dichotoma*: (A) Thallus flat, homogenous yellow-brown to darker brown, with fairly regular dichotomous branches with parallel sides to 30 cm long, the tips usually bifid; branches 3 to 12 mm wide, membranous, without a mid-rib; (B) fixing disk (arrow).

Figure 15. *Dictyota spiralis*: (A) Thallus leathery, 5-15 cm high, reddish-brown, attached by decumbent stolons; branching dichotomous, often irregular; some segments cease to ramify, others grow closely by 3-4 in tuft; segments near-linear, slightly wider at nodes, basal parts often narrowed; (B) apices broad and blunt (arrow) [30].

Figure 16. *Dictyopteris polypodioides*: (A) Thallus flat and leaf-like, to 300 mm long and 20-30 mm broad; fronds olive to yellow-brown, translucent, and  $\pm$  regularly dichotomously forked with a prominent midrib extending to the apices; margins sometimes split to the midrib (B) initially with an unpleasant smell shortly after collection, and degenerating quickly [31].

Figure 17. *Padina pavonica*: (A) The frond is thin and leafy, flattish and entire when young, but often concave, or almost funnel shaped in mature specimens, with a laciniate or irregularly lobed margin; (B) the inner (or upper) surface is covered in a thin coating of slime, and the outer (or lower) surface is banded with zones of light brown, dark brown and olive green.

Figure 18. *Taonia atomaria*: (A) Thalli erect, attached by matted, branched rhizoids, up to 30 cm long, complanate, flabellate or lacerate with many elongate, cuneate branches, 0.5-6 cm broad, often tapering to the apex; (B) thallus 2 cells thick near apex increasing to 5-7 cells thick towards the thallus base, not arranged in rows in transverse section.

Figure 19. *Colpomenia peregrina* (exotic species - non-native): (A) Sometimes regularly spherical (B) or more or less irregular outline (*Colpomenia sinuosa*), yellowish-brown color, fixed to the substrate by filamentous rhizoids.

Figure 20. *Ectocarpus fasciculatus*: (A) The thallus consists of profusely branched uniseriate filaments; the cells of the main filaments are taller than broad and have tape-shaped plast (L.M. 400X); (B) lateral branches containing cylindrical plurilocular structures (L.M. 400X).

Figure 21. *Hincksia granulosa*: (A) Uniseriate filamentous thalli, erect and with opposing branches that originating several long lateral branches (L.M. 100X); (B) the cells are longer than large, with numerous discoid plasts (L.M. 400X); *Hincksia hincksiae*: (C) The main axes branch out, unilaterally, and support several plurilocular sporangia (L.M. 100X); (D) the cells have many discoid plasts (L.M. 400X).

Figure 22. *Bifurcaria bifurcata*: (A-B) Up to 30 cm in length; olive-yellow in color, but much darker when dry; holdfast expanded and knobbly; frond cylindrical, unbranched near base then branching dichotomously; elongate reproductive bodies present at ends of branches; rounded air bladders sometimes present.

Figure 23. *Cystoseira baccata*: (A) Plants usually solitary, 1 m or more in length, attached by a thick, conical attaching disk; axis simple or branched, up to 1 m in length, flattened, about 1 x 0.4 cm in transverse section; apex smooth and surrounded during periods of active growth by incurred young laterals.; lateral branch systems distichous, alternate, radially symmetrical, profusely branched in a repeatedly pinnate fashion and bearing sparse, filiform, occasionally bifurcate appendages on the branches of higher orders [32]; *Cystoseira nodicaulis:* (B) in water, the thallus has a yellowish-brown coloration.

Figure 24. *Cystoseira tamariscifolia*: (A-B) bushy seaweed, up to 60 cm in length but usually 30-45 cm; it has a cylindrical frond with irregularly branches; olive green in color, almost black when dry; when the plant is seen underwater it has a blue-green iridescence.

Figure 25. *Fucus spiralis*: (A) The fronds are usually easily recognizable by the flattened, twisted, dichotomously branched thallus, lacking bladders, and the large, oval receptacles at the frond tips, each receptacle being surrounded by a narrow rim of vegetative frond. Nevertheless, younger plants are not always so easy to identify, and even mature plants can be confused with other *Fucus* species; (B) the thallus is composed of a blade with midrib and receptacles in the apical zone.

Figure 26. *Sargassum vulgare*: (A-B) Much branched, bushy plants that grow to 50 cm tall and are attached by a discoid holdfast; thalli pseudo-parenchymatous; primary and secondary branches are cylindrical and bear lanceolate foliar branches (4 cm long, 3 mm wide) with serrate margins; bladders are formed on short pedicels [33].

Figure 27. *Laminaria ochroleuca*: (A-B) Young specimen; glossy, yellow-brown kelp that is prevalent along the intertidal zones; this kelp is quite conspicuous as it grows quite large under the right conditions; the maximum length recorded is 4 m long, but this length is rarely attained and occurs only in specific areas; under normal conditions *L. ochroleuca* is more likely to reach a maximum length of about 2 m; *L. ochroleuca* has a large heavy holdfast made up of thick haptera or rhizoids (up to 18 cm in diam.) that supports the plant and anchors (arrow) it to rocks.

Figure 28. *Cladostephus spongiosus*: (A-B) Fairly stiffly branched fronds growing from a crust-like discoid holdfast (arrow), covered with small branchlets arranged in whorls; maximum length usually about 15 cm.

Figure 29. *Halopteris scoparia*: (A) Dark brown algae that forms beautiful fluffy clumps in shallow rocky-bottomed water; growing only up to 15 cm in length, *H. scoparia* has a main axis with alternate plumed (B), S.M. 20X) branches which are more or less fan-shaped when flat, though when buoyed up by water they form inverted cone-shaped tufts with a very delicate appearance due to the many filamentous branches.

Figure 30. *Sphacelaria rigidula*: (A) Filamentous cushion-like tufts, also occurring as scattered filaments in mixed turf communities, 5-10 mm high, medium to dark brown; branching irregular, sparse (L.M. 40X); (B) the filaments are cylindrical and emerge laterally the propagules, which are also cylindrical and trifurcated (L.M. 100X).

Figure 31. *Saccorhiza polyschides*: (A) Species with a distinctive large warty holdfast and a flattened stipe with a frilly margin (in adult specimens); the stipe is twisted at the base and widens to form a large flat lamina, which is divided into ribbon-like sections; (B) presence of a large bulbous holdfast with warty appearance.

## **Rodophyta – Red Algae**

Figure 32. (A) Morphology of the *Falkenbergia rufolanosa* (tetrasporoporic phase of *Asparagopsis armata*) (exotic species – non-native) thallus, where it can be seen that it is composed of slightly branched filamentous axes and the filaments composed of an axial cell and three periaxial cells (L.M. 400X); (B) general appearance of the feathery thallus of *A. armata*; (C-D) spiny, harpoon-shaped (arrow) branches some cm in length.

Figure 33. *Acrosorium ciliolatum*: (A) Flattened, membranous, deep-red fronds, 30-200 mm long; frond deeply divided into linear-lanceolate, irregularly branched segments, often terminating in hooks; (B) the frond is traversed by network of microscopic veins, but macroscopic veins are absent (L.M. 100X).

Figure 34. *Aglaothamnion pseudobyssoides*: (A) Uniseriate filaments, uncropped and with alternate ramifications (L.M. 100X); (B) the apical cells of the lateral branches have the rounded ends (L.M. 400X); *Aglaothamnion sepositum*: (C) Thick, corticated, filamentous filament with alternate ramifications (L.M. 40X); (D) the apical cells of the lateral branches assume a false conical shape (L.M. 100X).

Figure 35. *Anotrichium furcellatum*: (A) Small reddish-pink filamentous tuft; (B) Thin filaments, uniseriate, erect and composed of apical cells with a conical shape (M.O. 40X).

Figure 36. *Antithamnion densum*: A) Uniseriate filamentous thallus with opposing branches (L.M. 100X); (B) the plumed clusters are mostly arranged at the same side (L.M. 100X).

Figure 37. *Apoglossum ruscifolium*: (A) Membranous, tufted, bright red fronds, to 100 mm long; (B) frond with conspicuous midrib and wavy margin, to 6 mm wide, repeatedly branched from midrib, apices blunt (S.M.20X); (C) numerous microscopic veins, at wide angle from midrib (L.M. 100X).

Figure 38. (A) Transverse section of the main axis of *Boergeseniella fruticulosa*, formed by nine periaxial cells, which are surrounded by a reduced cortical cell layer (L.M. 100X); (B) Transverse section of the main axis of *Boergeseniella thuyoides,* formed by ten periaxial cells, which are coated by several layers of cortical cells (L.M. 100X); (C) *Boergeseniella fruticulosa* is composed of thin transverse bands of cortical cells (S.M.35X); (D) *Boergeseniella thuyoides* has transverse bands of thicker cortical cells (S.M.35X).

Figure 39. *Bornetia secundiflora*: (A) Dark red in color, firm and rigid when fresh; the thallus is 5-20 cm high when erect, fan-shaped with blunt tips (apices), much branched and tufted, with branches often curved over; the plant has a jelly-like texture; branches are sparse at the base becoming denser towards the apices; (B) each filament consists of a single row of cells that are arranged end-to-end (S.M.20X).

Figure 40. *Callithamnion tetragonum*: (A) Brownish-red fronds, to 50 mm long; uniseriate filaments, corticated below, repeatedly branched with simple, alternate branches (L.M. 40X); (B) ultimate branchlets densely clothed with tufts of alternate ramuli, corymbosely, incurved, attenuate at base and apex (L.M. 100X).

Figure 41. *Ceramium ciliatum*: (A) Uniaxial, cylindrical, erect thalli, corticated in transverse bands, in a discontinuous way (S.M.45X); (B) the filaments at the base are comprised of cells wider than tall (between nodes) that are surrounded by transverse bands of cortical cells (nodes) (L.M. 100X); (C) the branches apexes are bifurcated and curved (L.M. 100X).

Figure 42. *Ceramium echionotum*: (A) Rough, densely tufted, purplish red fronds, to 150 mm long, repeatedly dichotomously branched, axils wide, apices strongly hooked inwards filaments of almost uniform diameter throughout.(S.M.45X); (B) Articulations corticated at nodes, 3-4 times as long as broad in lower parts, very short distally, with numerous, irregularly distributed, colorless, unicellular, needle-like spines on corticating bands (L.M. 100X); (C) the apexes are wrapped in fork and transverse bands of cortical cells emerge the single-celled spicules (L.M. 100X).

Figure 43. *Ceramium pallidum*: (A) Uniaxial, cylindrical, erect thalli, corticated in transverse bands, in a discontinuous way (S.M.40X); (B) the filaments have an alternating branching and are constituted by transverse bands of cortical cells that are intercalated by transparent cells (S.M.35X); (C) bifurcated and slightly curved apexes (S.M.45X).

Figure 44. *Ceramium pallidum*: (A) The filaments are composed by transparent cells which assume various shapes and sizes and which are arranged alternately, or not, between the dense transverse bands of cortical cells (L.M. 100X); (B) the branches apexes are bifurcated and curved (L.M. 100X).

Figure 45. *Ceramium tenuicorne*: (A) Uniaxial, cylindrical, erect and dark red thallus, in which the branches apexes are bifurcated and curved (L.M. 100X); (B) the filaments are composed of transverse bands of low and thick cortical cells (nodes), which are interspersed by small nodes (L.M. 400X).

Figure 46. *Ceramium virgatum*: (A) Small red seaweed growing up to 30 cm tall; it has a filamentous frond that is irregularly and dichotomously branched, (S.M.45X); (B) with the branches narrowing towards pincer-like tips (S.M.40X); these little seaweeds are often found growing epiphytically in association with *Fucus* spp., such as *Fucus vesiculosus*.

Figure 47. *Chondria coerulescens*: (A) The fronds are flexible and cartilaginous in texture, turning black when dry (S.M.30X); (B) in water this seaweed has bluish or yellowish fronds with blue iridescence.

Figure 48. *Compsothamnion thuyoides*: (A) Uniseriate thallus, erect and with alternate ramifications (L.M. 40X); (B) the lateral branches are, in turn, branched alternately giving rise to branches of higher order which are also branched (L.M. 100X).

(C)

Figure 49. *Cryptopleura ramosa*: (A) Thin, membranous, brownish red fronds, to 200 mm long; frond  $\pm$ dichotomously divided, becoming irregular in upper parts; (B) the blades have microscopic veins that bifurcate and recombine at various points (L.M. 100X); (C) surface view of cystocarp (L.M. 400X).

Figure 50. *Crouania attenuata*: (A) Small pompous tufts of reddish-pink color (L.M. 40X); (B) The tufts are constituted by protruding main axes that ramify of irregular and alternated form, giving lateral branches (L.M. 100X); (C) the lateral branches are formed by quadratic cells that are covered by curved and mucronate ramuli, vertically displaced (L.M. 400X).

Figure 51. *Erythroglossum laciniatum*: (A) Thallus a short stipe, erect, consisting of one or more blades to 16 cm long and 15 or 20 cm wide, fan-shaped and divided into lobes with pointed apices (S.M.15X); (B) veins macroscopic, also fine veins (M.O. 40X); (C) lateral view of cystocarp on blade edges (L.M. 100X).

Figure 52. *Halurus equisetifolius*: (A) Erect plants consisting of up to 7 irregularly branched main axes growing 6 to 22.5 cm high and 2 to 3 mm wide, resembling a horsetail fern (S.M.15X); (B) the main axes branch to 4 orders and are clothed (either sparsely or densely) in whorls of between 5 and 8 short incurved branchlets which divide di- to trichotomously; the branchlets are 1.4 to 2.4 mm long and consist of 4 to 7 cells of which the terminal one is mucronate (L.B. 30X).

Figure 53. *Herposiphonia tenella*: (A) Plants coarse and brownish red; thalli terete, having a branching pattern of three determinate axes followed by one lateral indeterminate (d/d/d/i pattern); prostate axes 120- 150 µm diam., segments 0.8-1.3 diam. long., 7-9 pericentral cells (L.M. 100X); (B) erect determinate axes up to 1 mm in height, 70-80 µm diam., 8-13 segments with 0.81.0 diam. long, 7-8 pericentral cells; apex blunt with an inconspicuous apical cell. Vegetative trichoblasts rudimentary, 1-3 at the tips of determinate axes in successive segments, pseudo-dichotomously divided 24 times (L.M. 400X) [34].

Figure 54. *Hypoglossum hypoglossoides*: (A) Membranous, rose-pink fronds, 20-300 mm long, arising from a discoid base; frond linear-lanceolate, with well-marked midrib and thin membranous margins, 1-8 mm wide, repeatedly branched irregularly from midrib (M.O. 40X); (B-C) fronds with pointed apices, margins without microscopic veins, monostromatic except in midribs (M.O. 400X).

Figure 55. *Laurencia pyramidalis*: (A) Globose tufts of brittle, cartilaginous, narrow, cylindrical, reddish brown to yellowish red fronds, 150 mm long, from small discoid base (S.M.15X); (B) axis simple, branches patent, often opposite, spirally arranged, shorter towards apex giving regular pyramidal outline; bifurcated tips and a central hole (S.M.15X).

Figure 56. *Leptosiphonia schousboei*: (A) Thallus composed by uniaxial axes, corticated and prostrate at the base, attached to the substrate through rhizoids (L.M. 100X); (B) secondary erect axes, polysifonate and presenting apical trichoblasts (L.M. 100X); (C) cross section of the thallus with 14 periaxial cells (L.M. 400X).

Figure 57. *Lophosiphonia reptabunda*: (A) Thallus consisting of prostrated axes, from which depart secondary axes which have a curvature up to the apex (S.M.35X); (B) cross section of the thallus with 19 periaxial cells (L.M. 100X); C) secondary axes with tricoblasts arranged helically (S.M.45X).

Figure 58. *Nitophyllum punctatum*: (A) Delicately membranous, rose-pink fronds with an elongate fan-shaped outline, margins distinctly frilly, to 40 mm or, exceptionally, to 1 m, sessile or shortly stipitate (<2 mm long); (B) frond veinless, undivided or deeply sub-dichotomously divided to the base; apices blunt or rounded, often ribbon-like; gametophyte plants form rounded spots to 5 mm in diameter whilst tetrasporphyte plants form characteristic elongated spots.

Figure 59. *Ophidocladus simpliciusculus*: (A) Branches erect simple or branched 1-2 times, with 16-23 periaxial cells (L.M. 40X); (B) from the branches arise tetrasporic secondary axes (L.M. 40X); (C) cross section of the thallus with 23 small periaxial cells surrounding a larger axial cell (M.O. 100X).

Figure 60. *Osmundea pinnatifida*: (A) Cartilaginous, usually markedly compressed, dark purple to pale yellow fronds, to 100 mm or more long, from discoid base; very variable in size and form; main axis usually simple; (B) branching alternate distichous, repeatedly pinnate; ultimate ramuli short, blunt (S.M.15X).

Figure 61. *Pleonosporium borreri*: (A) Erect thallus, filamentous, uncropped and with alternate ramifications (L.M. 40X); (B) the lateral branches also divide alternately giving rise to the cystocarps, which consists of small quadratic cells and rounded apices (L.M. 100X).

Figure 62. *Polysiphonia denudata*: (A) Small fronds reddish-brown color; (B) transverse section of the thallus with 6 periaxial cells (L.M. 100X); (C) composed thallus of cylindrical, uncrossed axes that branch in dichotomous form giving rise to secondary branches bearing cystocarps (S.M.45X).

Figure 63. *Polysiphonia fucoides*: (A) Cartilaginous, cylindrical, tufted, brownish purple fronds, to 300 mm long (more usually about 70 mm long), from branched rhizoidal holdfast; (B) branching  $\pm$ alternate, tripinnate, ramuli with terminal tufts of colorless dichotomous fibrils (L.B. 40X); (C) cross section of the thallus with 19 periaxial cells (L.M. 100X); (D) corticated only at base (S.M.45X).

Figure 64. *Xiphosiphonia ardreana* (formerly *Pterosiphonia ardreana*): (A) Sub-cylindrical thallus composed by 12 periaxial cells (L.M. 100X); (B) the branches are arranged alternately in an almost continuous way and are long and thin (S.M.20X).

Figure 65. *Pterosiphonia complanata*: (A) Thallus with prostate and erect axes, the erect ones flat-compressed and with distichous alternate pinnate branching; (B) brownish-red color, flexible and cartilaginous texture; attached by rhizoids which form discoid adhesive structures; veining visible with a magnifying glass (arrow) (S.M.25X); (C) cross section of main axis with multiple periaxial cells (L.M. 100X).

Figure 66. *Xiphosiphonia pennata* (formerly *Pterosiphonia pennata*): (A) Small brownish-red seaweed up to 8 cm high, with a rigid texture; transverse section of the main axis with 9 periaxial cells (L.M. 100X); (B) from the main axis emerge thin and long branches, which are arranged alternately (L.M. 40X).

Figure 67. *Ellisolandia elongata* (formerly *Corallina elongata*): (A) Whitish pink to reddish lilac, calcified, articulated fronds, fish-bone-like arrangement, to 50 mm high, axis compressed, repeatedly pinnate from discoid base; *Corallina officinalis*: (B) whitish-pink to lilac, calcified, articulated fronds, 60-120 mm high, axis cylindrical to compressed, repeatedly pinnate from and expanded discoid base, branching often irregular.

Figure 68. *Jania rubens*: (A) Slender, rose-pink, articulated, calcified fronds, to 50 mm high; repeatedly dichotomously branched, luxuriant specimens secondarily pinnate; fixed by small conical disc, but spreading vegetatively by developing attachment discs from branches in contact with solid substratum; (B) segments cylindrical, to 120  $\mu$ m diam., those bearing branches somewhat compressed, to 180  $\mu$ m diam (S.M.20X).

Figure 69. *Lithophyllum incrustans*: (A) Thick, dull chalky, yellowish, pink or lavender calcareous crusts forming irregular concretions, to 40 mm thick, margins ridged where crusts meet; *Lithophyllum byssoides*: (B) calcified and rigid encrusting thallus, strongly adhering to the bedrock; small hemispherical cushions 1 to 2 cm high, white to dark pink; crust covered with upright lamellae 10 mm high and 800 μm wide, anastomosed to each other.

Figure 70. *Mesophyllum lichenoides*: A) Pale to dark purple thin, brittle, leafy calcified fronds, attached at base, margins free, lobed; fronds semicircular, concentrically banded; reproduction takes place in winter and spring in small, wart-like conceptacles; B) Small specimens often epiphytic on *Ellisolandia elongata.*

Figure 71. *Gelidium corneum*: (A) Dark red, hard consistency, cartilaginous, and may reach 30 cm in length thalli; (B) branches with obtuse apex and attenuated at the base; this species typically forms dense stands of clumped fronds, often under a Kelp canopy; *Gelidium spinosum*: (C) dark red, hard consistency, cartilaginous, and may reach 30 cm in length thalli. Small alga, cartilaginous, crimson to purplish red, 20-60 mm long; *Pterocladiella capilacea:* (D) main axes distinctly flattened, often narrower at base, ultimate branches short, often opposite, spine-like or spatulate.

Figure 72. *Ahnfeltiopsis devoniensis*: (A) Small red marine alga growing to only several cm in length from a disc-like holdfast; (B) it forms a medium-sized flattened frond with regular dichotomous branching; the branches have parallel sides; the reproductive structures (cystocarps) are internal.

Figure 73. *Caulacanthus ustulatus*: (A) Thalli forming small dense entangled tufts of up to 5 cm, reddish-brown color, which blackens by desiccation, with rough touch; (B) ramifications with acute apices and behaving small triangular-shaped spines (S.M.25X).

Figure 74. *Chondracanthus acicularis*: (A) Dark-red or blackish, sometimes bleached yellow, cartilaginous, cylindrical, erect or re-curved or prostate, branched thalli, with 7 cm long; branches are irregular, curved and sharply pointed; *Chondracanthus teedei*: (B) upper thallus-branches cylindrical, lower ones flattened, dark crimson to black-red; branching repeatedly irregular-pinnate, cartilaginousfirm, lateral branches distant, pointed, the yougest terminal sections thorn-like; discoid base.

Figure 75. *Dilsea carnosa* (drift specimen): Dark red, frequently becoming yellow above, thickest of the foliose red algae in the NE Atlantic, flattened cartilaginous fronds, arising in groups of small, medium and large from a thick, discoid holdfast, obtuse, ovate with tapered base, to 500 mm long, 250 mm broad.

Figure 76. *Gigartina pistillata*: thalli are erect, up to 20 cm tall, dark-red or red-brown, cartilaginous, elastic, dichotomously branched, attached to the substrate through a small disk; presence of external, rounded cystocarps in female gametophyte fronds.

Figure 77. *Sphaerococcus coronopifolius*: (A) Narrow, compressed, two-edged, cartilaginous, scarlet fronds, main axes dark brownish-red, to 300 mm long; (B) branching abundant, distichous, sub-dichotomous or alternate, terminal branchlets acute, fringed with short marginal proliferations.

Figure 78. *Liagora viscida*: Thallus tufted, grey-purple to greenish-white or pink, repeated dense branching at almost the same length, branches terete, tapering towards the top; terminal branches usually spreading as wide-angled bifurcations, moderately calcified, texture flexible-firm [32].

Figure 79. *Peyssonnelia coriacea*: Laminar algae with slightly calcified flat thallus, with wavy margins and subject to the fund by the back with concentric grooves in the margins; its diameter is about 3 cm; color can vary from red to yellow with greenish hues.

Figure 80. *Plocamium cartilagineum*: (A) Narrow, compressed, cartilaginous, bright scarlet fronds, to 300 mm long, tufted, much divided; (B) branching irregularly alternate, pinnules alternately second in twos to fives (arrow), with acute apices, lowest of each set a simple spur, others increasingly strongly pectinate (arrow) (S.M.25X).

Legend: L.M. - Light Microscope; S.M. - Stereo Microscope.

Figure 81. *Champia parvula*: (A) Soft, gelatinous, pinkish red, much-branched fronds, densely matted, with blunt apices, to 100 mm high (S.M.25X); (B) axes segmented, with nodal diaphragms (arrow), segments about as broad as long, filled with a watery mucilage (S.M.45X).

# **ABSTRACT**

Problems of environmental deterioration and energy demand could be alleviated by the paradigm shift from fossil to biofuels. Innovative strategies, such as the use of microwave irradiation, sonochemical treatment and solar irradiation were recently developed for the exploitation of biomass for biofuel production. The concept of biomass itself can be understood in an unconventional sense. Apart from terrestrial plant resources, nowadays, seaweed, industrial emissions such as CO2, and organic remains such as glycogen are being explored as new feedstock for biofuels/chemicals production. Our research group in Israel is working on converting biomass (terrestrial and marine) to biofuels (bioethanol) and biochemicals (levulinic acid, furfural, formic acid) using microwave, sonochemical, and hydrothermal methods. Among several types of biomass, marine algae are a promising choice due to several advantages. Marine algae form an abundant and rich source of biomass. Bioethanol production process based on marine algae could be sustainable. A mild sonication-assisted simultaneous saccharification and fermentation (SSF) process for the conversion of *Ulva rigida* to bioethanol in a single step is developed in the current study. Bioethanol is a potential biofuel owing to the similarity of its energy density value (23 MJ/L) to that of gasoline (35 MJ/L). Bioethanol could also be a feedstock for the production of  $C_2$  hydrocarbons. Any progress in the direction of development of a marine-algae-based bioethanol process would open up a new avenue towards sustainable biorefinery. *Ulva rigida*, comprising 37 wt%

<sup>\*</sup> Corresponding Author's Email: gedanken@mail.biu.ac.il; Fax: +972-3-7384053; Tel.: +972-3-5318315.

carbohydrate was used as a feedstock for the SSF process. Initially, saccharification process of *Ulva rigida* (with amylases and cellulases) was carried out under mild sonication conditions (40 kHz, 37°C); 3.1 times higher glucose yield was obtained using sonication of *Ulva rigi*da relative to conventional incubation. The hydrolysate was found to contain glucose exclusively. Subsequently, the SSF process for converting the algae (*Ulva rigida*) to bioethanol in a single step was also accelerated using sonication. The improvement was observed in the total carbohydrate content of the algae using multitropic aqua culture. 27-41 times higher specific growth rates were achieved using this approach. Under specific optimal conditions of growth, a starch amount as high as 32 wt% was accumulated. The high-carbohydrate algae were subjected to the sonicationbased SSF process. Under optimal process conditions, an ethanol yield as high as 16 wt% was achieved. A unique solar-energy-based continuous flow process for the direct conversion of *Ulva rigida* to bioethanol is outlined. The conversion of macroalgae to the strategically significant chemical, levulinic acid is discussed. In an acid-catalysed hydrothermal process, 12.8 wt% levulinic acid was produced from *Ulva rigida*. We therefore elaborate in this chapter on the unconventional strategies developed for the farming as well as conversion of *Ulva rigida* to biofuels and biochemicals.

# **INTRODUCTION**

Growing population and increasing standards of living demand additional resources. The emphasis of this chapter is on two major sectors of human well-fare, namely, energy needs and the environment. Petroleum alternatives are an additional resource that would improve the standard of living of human societies. Biomass encompasses a renewable and costeffective source of petroleum alternatives for fuel and chemical use. The US Department of Energy has listed twelve major chemicals that can be produced from biomass which would act as building blocks for producing a variety of other fuels and chemicals that are used for transportation and materials applications. The term biomass should not be restricted to conventional terrestrial lignocellulosic and algal resources but should be extended to abundant natural resources such as CO2, another potential carbon feedstock for biorefinery. However, for the sake of brevity, the present compilation is restricted to the exploitation of seaweeds (macroalgae) for the production of biofuels and biochemicals. Oceans make up 70%  $(2/3<sup>rd</sup>)$  of the earth's surface and offer a wide unused space. Seaweeds possess bioenergy-production potential similar to that of land plants. Thus, cultivating and harvesting huge quantities of seaweed as an energy crop and devising energy-efficient strategies for its conversion to biofuels generate a new alternative energy source that could replace fossil fuels and in turn substantially reduce the  $CO<sub>2</sub>$  emissions that lead to global warming and environmental deterioration [1].

Energy insecurity and environmental pollution are the major problems facing mankind in the 21st century. Reduced dependence on fossil-based fuels is the need of the hour. Problems of environmental deterioration and energy demands could be alleviated by the paradigm shift from fossil fuels to biofuels. Innovative methods of activation, such as the use of microwave irradiation, sonochemical treatment and solar irradiation were recently developed for the exploitation of seaweeds for biofuels production. Among several types of biomass, seaweeds

(marine algae) are a promising choice owing to several advantages such as (i) absence of lignin which is a hindrance to hydrolysis and fermentation, (ii) absence of food vs fuel conflict, (iii) absence of the requirement of land for growing the biomass and (iv) availability of vast sea shores (2/3 of Earth's surface is ocean). Marine algae forms an abundant and rich source of biomass and biofuels (especially, bioethanol) so that production processes based on marine algae could be sustainable.

Algal biomass is classified into two main groups, namely, microalgae (bluegreen algae, dinoflagellates, bacilloriophyta) and macroalgae (seaweeds like green, brown and red algae). Red algae (*Gelidum, Palmaria, Poryphyra*) capture light with the reddish protein pigments (phycoerythrins) and as a result have the characteristic reddish colour. Green algae (*Ulva, Codium*) have chlorophyll as the light-absorbing pigments. Brown algae (*Laminaria*, *Fucus*, *Sargassum*) contain the carotenoid, fucoxanthin, as the dominant light-capturing pigment. Brown and red algae can grow deeper than the green algae. Most seaweeds grow bound to the substrate (rocks near-shore or artificial surfaces) except certain species like *Sargassum* that float freely on the surface of water. Microalgae are a rich source of highly bioactive compounds found in marine resources. Red algal seaweeds are an active metabolite. The conventional use of seaweeds includes human food resources and as a source of gum (phycocollides such as agar agar, alginic acid and carrageenam) [2]. Unconventional applications being explored include biofuels and biochemicals.

Seaweeds are multicellular, macroscopic marine algae classified as non-vascular plants. Global production of seaweeds is more than a million tons (dry weight matter) relative to no more than 20,000 tons of microalgae production. As a result, the cost of macroalgae is nearly ten times lower than that of microalgae. Macroalgae have higher carbohydrate and lower protein and lipid contents compared to microalgae and so the macroalgal seaweeds are an ideal candidate for bioethanol and biochemicals production via the conversion of the carbohydrate component. The carbohydrate content in macroalgae can be up to 80% organic matter (ash-free dry weight) with about 20% protein and 15% lipids. Depending on the method of analysis, growth conditions of the seaweeds and the species under study, the composition varies [3].

#### **Seaweeds as Biofuel Feedstock**

The macroscopic nature of the seaweeds allows simple and low-cost harvesting. Methane, bioethanol and biobutanol are the three common fuels that can be derived from macroalgae. *Ulva species* have relatively high carbohydrate content and can be readily digested to methane gas and subjected to simultaneous scharrification and fermentation (SSF) processes for bioethanol production. As early as 1960's, Howard Wicox suggested the production and exploitation of macroalgae as a solution to the energy crisis and global warming [4]. During the period from 1970-1980, extensive research efforts were devoted in the US to developing open-ocean macroalgae farms as a substitute to natural gas. Despite nearly half a century of research in the area of macroalgae conversion to biofuels, the R&D is still at the initial stage with several practical challenges to be surmounted. The major challenge pertains to the economically competitive sustainable production of the macroalgae. The extension of cultivation systems to deeper, less protected ocean areas without anchoring facilities is a challenge. Even in the cultivation systems near the shore, the production costs are high and

major breakthroughs in the cultivation of algal seaweeds are awaited. In spite of these hurdles, beyond doubt, seaweed holds the promise of a sustainable feedstock for food, feed, fuels and chemical production. Motivated by the challenges and rewards, during the last decade, there has been renewed interest in the exploitation of seaweeds for biofuel production with the growing energy demands.

Japan's efforts (Ocean Sunrise Project) were focused on the harvesting of *Sargassum fulvellum* and its conversion to bioethanol in unused maritime areas around Japan [1]. A farming technology was used for *Laminaria* and *Undaria pinnatifida* in both coastal and offshore areas. The aim of the project is to produce seaweed bioethanol by farming and harvesting Sargassum horneri, utilizing the world's sixth largest (4.47 million km<sup>2</sup>) areas of the exclusive economic zone (EEZ) and maritime belts of Japan. The research was conducted by Tokyo Fisheries Promotion Foundation. Japan's long-term plan is to proudce 6 million kL of biofuel by 2030. The key to achieving the target lies in farming large quantities of seaweed at low cost.

The UK and Ireland's BioMara joint project aims at the production of sustainable fuels (methane and ethanol) from marine biomass by studying the process feasibility and economics. The objectives of the project comprise of chemical characterization of selected seaweeds (*Laminaria digitata* and byperborea, *Alaria esculenta*, *Saccharina latissima*, *Palmaria palmata* and *Ulva lactuca*), pretreatment (thermal/enzymatic), and fermentation. Utilization of the alginate component of the seaweed by employing alginate lyase for breaking down the alginate matrix exposes the polysaccharide. The action of alginate lyase is similar to hemicellulase. 20% enhancement in ethanol yield was observed upon pretreatment of *Laminaria digitata* with alginate lyase. Successful utilization of alginate component of seaweeds for bioethanol production is projected to enhance the bioethanol yield as high as  $\sim$ 400%. German researchers have developed an offshore ring system for farming *Laminaria Saccharina* for food and fuel applications The methodology comprises growing the macroalgae sporophytes in the lab to the appropriate length and then placing them in the ring structures. The ring structural design was found to be stable for offshore farming [5]. China has successfully demonstrated the sustained commercial cultivation of *Laminaria japonica* with yields of  $\sim$  25 t/ha [6]. Similar attempts were made in Korea for the conversion of *Gelidium amansii* to bioethanol [7]; in India for the conversion of *Kappaphycus alvarezii* to bioethanol; in Denmark for the conversion of *Ulva lactuca* to bioethanol [8]. In Israel, Gedanken's group has developed innovative strategies for the farming of carbohydate-rich marine macroalgae *Ulva rigida* and has designed unconventional pathways, based on sonication and solar energy for the single-step conversion of the *Ulva rigida* to bioethanol, which will be descibed in the following sections [9-13].

# **Unconventional Strategies for the Farming and Conversion of** *Ulva rigida* **to Bioethanol**

Bioethanol has relevance to major sectors of human activity such as energy, chemicals, materials and the environment. Bioethanol is a potential biofuel owing to the similarity of its energy density value (23 MJ/L) to that of gasoline (35 MJ/L). Bioethanol production is important not only for transportation applications, but also for its use as feedstock for the production of  $C_2$  hydrocarbons [13]. Fermentation is one of the intrinsic and crucial reactions

involved in the conversion of biomass carbohydrate fraction to bioethanol and is usually slow. Glucose fermentation reaction carried out under mild sonication  $(40 \text{ kHz})$  at  $30^{\circ}\text{C}$  using baker's yeast (*Saccharomyces cerevisiae*) was accelerated by a factor of 2.3. The acceleration of the fermentation process was observed for glucose concentrations as high as 40 wt%. The kinetics of the glucose fermentation reaction was monitered by  $^{13}C$  NMR spectroscopy as well as by measuring the weight loss of the fermentation broth during the course of the reaction. Theoretically, 1 mol of D-glucose yields 2 mol of ethanol and 2 mol of CO<sub>2</sub> during the fermentation process by yeast. The evolution of  $CO<sub>2</sub>$  is reflected in the weight decrease which can be correlated to the amount of ethanol produced. However, this method of evaluation is not very accurate as the substrate glucose is not only converted to ethanol and CO<sup>2</sup> but also to the inevitable secondary metabolite glycerol. So another method based on the use of  $^{13}$ C NMR spectroscopy was developed for the evaluation of the kinetics of glucose fermentation. A fairly good correlation between the two methods for the measurement of glucose conversion values and calculation of reaction rate constants of glucose fermentation was observed as depicted in Figure 1.

Figure 1. Effect of ultrasound (40 kHz) irradiation on the kinetics of glucose fermentation at 30°C. [Indra Neel Pulidindi, Aharon Gedanken, Rakefet Schwarz and Eleonora Sendersky (2012) Mild sonication accelerates ethanol production by yeast fermentation, *Energy and Fuels*, 26, 2352-2356]. Adopted by permission of the American Chemical Society.

The glucose conversion values in the fermentation process under mild sonication and conventional stirring at 30°C, measured by the weight decrease of the fermentation broth and by <sup>13</sup>C NMR spectra, are shown in Figure 1. The mean rate constant values deduced from weight-loss measurements (13.4 x 10<sup>-6</sup> s<sup>-1</sup>) and <sup>13</sup>C NMR analysis (17.3 x 10<sup>-6</sup> s<sup>-1</sup>) are in good agreement. The average of these values is considered as the reaction rate constant for the fermentation of glucose under sonication at 30 $\degree$ C (15.35 x 10<sup>-6</sup> s<sup>-1</sup>) while the corresponding value under conventional stirring at 30 $\degree$ C is 6.67 x 10<sup>-6</sup> s<sup>-1</sup>. The ratio between these values (2.3) is the enhancement factor in the kinetics of glucose fermentation achieved by carrying out the fermentation reaction under sonication.

Extending this methodology for the acceleration of the fermentation process to real biomass (*Ulva rigida*) is a challenge and was attempted successfully [14]. *Ulva rigida* is a common seaweed with the potential for biofuel and biochemical production. Other potential seaweeds reported in literature for bioethanol production include *Gelidium amansi* [15], *Laminaria japonica* [16], *Codium fragile* [17] and *Nizimuddinia zanardini* [18]. The option of seaweeds as feedstock offers several advantages including rapid growth rates of the biomass relative to terrestrial plants: large sea area (70% of earth surface available in principle even though off-shore cultivation is challenging), higher carbohydrate content, higher theoretical ethanol yields, low concentration of crystalline components (like lignin that hinder the action of enzymes and yeast in the hydrolysis and fermentation reactions respectively), no competition with food crops and cultivable land area, serves as a bioremediation crop by lowering eutrophication impact on in-shore waters [19], no requirement of fresh water supply or nutrients [20, 21]. In spite of these advantages, inefficient methods of harvesting, pretreatment, hydrolysis and fermentation processes have resulted in lower ethanol yields from seaweeds, thereby offering wide scope for further research and development. Any progress in the direction of development of a marine algae based bioethanol process would open up a new avenue towards sustainable biorefinery. In view of these aspects Gedanken *et al.* developed a mild sonication-assisted simultaneous saccharification and fermentation (SSF) process for the conversion of *Ulva rigida* to bioethanol [9, 10]. A schematic representation of the sonication based SSF process for the conversion of *Ulva rigida* to bioethanol is shown in Scheme 1.

Scheme 1. Schematic depiction of the conversion of *Ulva rigida* to bioethanol [9].

*Ulva rigida*, comprising 37 wt% carbohydrate (23.8 wt% cellulose, 7.6 wt% starch, and other components such as ulvan and xylan) was used as a feedstock for the SSF process. Initially, the saccharification process (in the presence of enzymes, amylases and cellulases) of *Ulva rigida* alone was carried out under mild sonication conditions (MRC Clean-01 Ultrasonic cleaner, 40 kHz ultrasound frequency, 120 W ultrasonic power,  $37^{\circ}$ C) without any prior pretreatment. As a control study, the reaction was studied under identical conditions in an incubator under shaking. The progress of the reaction is monitored by estimating the amount of glucose formed with time (Figure 2). The difference in the glucose yields in the sonication-assisted and control process is more pronounced in the initial period (30 min) of the reaction. A higher (by 3.1 times) yield of glucose is obtained in the sonication-assisted hydrolysis process. The advantage of obtaining higher glucose yield in the hydrolysis process

aided by sonication, at any given time, relative to a conventional incubator process under identical conditions is evident from Figure 2. A maximum of  $19.6\pm0.02$  wt% glucose is produced in a sonication-based process in 3 h relative to a yield of  $16.7\pm0.27$  wt% in an incubation process in 24 h. The accelerated release and improved yield of glucose from *Ulva rigida* upon sonication is due to mechanical and thermal effects.

Figure 2. Glucose yields as a function of time in the enzymatic saccharification of *Ulva rigida* under sonication vs incubation at (37°C) [Leor Korzen, Indra Neel Pulidindi, Alvaro Israel, Avigdor Abelson and Aharon Gedanken (2015) Single step production of bioethanol from the seaweed *Ulva rigida* using sonication, *RSC Advances*, 5, 16223-16229]. Adopted with permission from the Royal Society of Chemistry.

Figure 3. <sup>13</sup>C NMR spectra of aliquots from the hydrolysate of *Ulva rigida* produced under sonication (A) and incubation (B) at 37°C at 120 min. [Leor Korzen, Indra Neel Pulidindi, Alvaro Israel, Avigdor Abelson and Aharon Gedanken (2015) Single step production of bioethanol from the seaweed *Ulva rigida* using sonication, *RSC Advances*, 5, 16223-16229]. Adopted with permission from the Royal Society of Chemistry.

The structural rigidity of components of algal biomass is reduced due to sonication. Effective mixing, phase transfer, diffusion of enzymes across the algal cell membranes results in the acceleration of saccharification of *Ulva rigida* during the sonication process [9]. Irrespective of the method of hydrolysis, glucose is produced exclusively as the fermentable sugar. The  $^{13}$ C NMR spectra of the aliquots of the hydrolysate under bath sonication (Figure 3a) and incubation (Figure 3b) at 120 min are shown in Figure 3. Well-resolved intense signals in the range of 60-100 ppm (60.9 (C6), 69.9 (C4), 71.8 (C2β), 73.1 (C2β), 74.5 (C3), 76.2 (C5), 92.4 (C1 $\beta$ ) and 96.2 (C1 $\beta$ )) are typical of the  $\alpha$  and  $\beta$  isomers of D-glucose. An additional signal at 23.6 ppm is attributed to the carbon nuclei of  $CH<sub>3</sub>COONa$  used as buffer for the enzymatic hydrolysis of algae.

Further studies were carried out on the single step conversion of *Ulva rigida* (SSF) to bioethanol under sonication. In addition to the algae and enzymes (amylogucosidase, αamylase, and cellulase), baker's yeast was also added to the reaction medium in glass media bottles with cap (Fisher brand, 100 mL). The progress of the SSF process, under sonication and in an incubator, was monitored by evaluating the amount of ethanol formed at regular intervals of time. The ethanol amount in the analytes was quantified using <sup>1</sup>H NMR. The SSF process was also found to be faster in a sonication driven process as shown in Figure 4 [9].

Figure 4. Ethanol yield as a function of time in the enzymatic hydrolysis of *Ulva rigida* under sonication vs incubation at 37 $^{\circ}$ C (replicate no. n = 3; error bars indicate standard deviation, SD). [Leor Korzen, Indra Neel Pulidindi, Alvaro Israel, Avigdor Abelson and Aharon Gedanken (2015) Single step production of bioethanol from the seaweed *Ulva rigida* using sonication, *RSC Advances*, 5, 16223- 16229]. Adopted with permission from the Royal Society of Chemistry.

Higher ethanol yields  $(4.3 \pm 0.26 \text{ wt\%})$  were observed in a sonication-aided process relative to a process under incubation  $(1.0 \pm 0.13 \text{ wt\%})$  in a short duration of 30 min, reaching a maximum value of  $6.2 \pm 0.13$  wt% in 3 h. The 3H (t, 1.18 ppm) and 2H (q, 3.64 ppm) confirm the formation of ethanol from *Ulva rigida* in the SSF product (Figure 5). The signal, 3H (s, 1.9 ppm) corresponds to the buffer (sodium acetate) used. The peak, 1H, s, at 8.5 ppm, is characteristic of the internal standard (HCOOH) used for the quantification of ethanol. Thus an unconventional sonication-based SSF process for the single step conversion of *Ulva rigida* to bioethanol is developed. Compared to a conventional incubation process (4.9 wt% ethanol in 48 h), the current process is faster and the ethanol yield is higher (6.2 wt% ethanol in 3 h) [9].

Figure 5. <sup>1</sup>H NMR spectrum of the aliquot of sample collected from the fermentation (SSF) broth under mild sonication at 120 min. [Leor Korzen, Indra Neel Pulidindi, Alvaro Israel, Avigdor Abelson and Aharon Gedanken (2015) Single Step Production of Bioethanol from the Seaweed *Ulva rigida* using Sonication, *RSC Advances*, 5, 16223-16229]. Adopted with permission from the Royal Society of Chemistry.

\*Reaction conditions: biomass (dry weight) = 1.68 g; distilled water = 40 mL; cellulase = 0.1 g (0.3 units per mg);  $\alpha$ -amylase = 40 µL (250 units per mL); amyloglucosidase = 100 mL (300 units per mL); sodium acetate buffer  $= 40$  mL.

Although the SSF process of algae is accelerated upon sonication, the process efficiency (64.7%) remained similar to that of the conventional incubation process (66.6%) (Table 1). Moreover, the bioethanol production process is still a batch process rather than a continuousflow process with large scope for further improvement.

Typical challenges in the exploitation of seaweed include production in large quantities and also the lower fermentable sugar content available currently. For the commercial-scale production of bioethanol, it is imperative to develop farming strategies resulting in carbohydrate-rich as well as fast growing biomass. Towards attaining this target Gedanken *et al.* developed integrated multi-tropic aquaculture (IMTA) as an alternative farming strategy to the conventional algal mono-culture. The concept of IMTA involves reuse and recycling of internal feed within a culture system minimizing the wastage of resources (nutrients, water and energy). Integrating seaweed farming with aquaculture operations has several advantages. Seaweed turns waste into productive resources and reduces the impact of wastes on the ecosystem. Integration of seaweed cultivation with fed mariculture facilitates recapturing of waste nutrients, leading to increased growth rate, improved fermentable sugar contents in the *Ulva rigida* farmed downstream to fish-culture net pens. So far, the methodology of integrated culture of fish and algae in marine open-waters is focused towards economic and environmental aspects but not towards energy (bioethanol) and chemical (levulinic acid) production which has been the focus of the study of Gedanken's group [10].

The seaweed *Ulva rigida* was co-cultured with fed-fish culture (*Sparus aurata*) in an offshore fish cage aquaculture complex with the objective of obtaining high-yield carbohydraterich biomass. *Ulva rigida* cultivation is carried out in an open sea fish farm (Lev-Yam aquaculture Ltd) located off the Michmoret coast, Israel. The specific location is shown in the map (Figure 6a).

Figure 6. Schematic (a) map of the study area showing the fish farm, (b) scheme of the fish cage and the algal culture cages, (c) algal culture cage suspended at 3 m depth, (d) scheme of an algal culture cage and (e) *Ulva rigida* in culture cage. [Leor Korzen, Indra Neel Pulidindi, Alvaro Israel, Avigdor Abelson and Aharon Gedanken (2015) Marine integrated culture of carbohydrate rich *Ulva rigida* for enhanced production of bioethanol, *RSC Adv* 5, 59251-59256]. Adopted with permission from the Royal Society of Chemistry.

About 500 g of *Ulva rigida* were placed in nylon net cages (Figure 6e). The cages were attached to buoys and placed at two positions. One site is located within the fish cage surroundings, 15 m downstream to the cages' main water current direction and the control site is located 150 m upstream to the fish cages (Figure 6b). Algal culture cages were placed at a depth of 3 m (Figure 6c). Specific growth rates and the starch content of *Ulva rigida* cultured during Sept/Oct. 2013 (Figure 7 a & c) and during Nov. 2013 (Figure 7 b & d) were shown pictorially in Figure 7. The initial culture or grow-out period is for 14 days and an additional 5 days in a low-nutrient site. Remarkable enhancement in the growth rate of *Ulva rigida* grown under nutrient-rich conditions downstream from the fish cages was observed (Figure 7a & b). The enhancement in the specific growth rates is by a factor of 27 and 41 for the Sept. (Figure 7a) and Nov. (Figure 7b) trials respectively. The availability of inorganic nutrients is the vital parameter facilitating the growth and productivity of seaweed *Ulva rigida*.

Figure 7. *Ulva rigida* culture and starch content. [Leor Korzen, Indra Neel Pulidindi, Alvaro Israel, Avigdor Abelson and Aharon Gedanken (2015) Marine integrated culture of carbohydrate rich *Ulva rigida* for enhanced production of bioethanol, *RSC Adv* 5, 59251-59256]. Adopted with permission from the Royal Society of Chemistry.

In both trials (Sept. Figure 7c and Oct. Figure 7d), the carbohydrate (starch) content was higher at the control site (31.5 wt% of dry weight, Sept. trial) compared to the nutrient- rich site downstream to the cages (24 wt%). This observation is in inverse proportion to the ambient seawater nutrient concentrations. However, the starch contents bounced up and levelled with values similar to those at the control site on culture manipulation for two days at the low-nutrient site. High nutrient concentrations altered the proximate composition in seaweeds and caused a shift to lower levels of starch. Thus, the developed strategy based on IMTA resulted in the accelerated production of *Ulva rigida* with high starch content (31 wt%). The high-carbohydrate *Ulva rigida* was subsequently converted to bioethanol in a sonicationbased SSF process.

Under optimized process parameters (enzyme loading, 1 wt%; algal consistency in the broth, 15 wt%, sonication time, 4 h) a high bioethanol yield of 16 wt% is produced (Figure 8).

Figure 8. Effect of tailoring the carbohydrate content of *Ulva rigida* on the ethanol yield in the sonicationbased SSF process with 15 wt% solid consistency and 1 wt% enzyme loading (replicate no. n = 3; error bars indicate standard deviation, SD). [Leor Korzen, Indra Neel Pulidindi, Alvaro Israel, Avigdor Abelson and Aharon Gedanken (2015) Marine integrated culture of carbohydrate rich *Ulva rigida* for enhanced production of bioethanol, *RSC Adv* 5, 59251-59256]. Adopted with permission from the Royal Society of Chemistry.

Formation of bioethanol from *Ulva rigida* is confirmed by the two characteristic signals at 17.5 and 58.1 ppm typical of ethanol (Figure 9).

Figure 9. <sup>13</sup>C NMR spectrum of aliquot of sample collected from the fermentation (SSF) broth under optimal reaction conditions. [Leor Korzen, Indra Neel Pulidindi, Alvaro Israel, Avigdor Abelson and Aharon Gedanken (2015) Marine integrated culture of carbohydrate rich *Ulva rigida* for enhanced production of bioethanol, *RSC Adv* 5, 59251-59256]. Adopted with permission from the Royal Society of Chemistry.

Scheme 2. Strategy adopted for the production of starch-rich *Ulva rigida* and its conversion to highconcentration bioethanol [10].

Additional signals at 63.2 and 72.7 ppm correspond to the inevitable secondary metabolite glycerol and the signal at  $23.8$  ppm corresponds to the buffer (CH<sub>3</sub>COONa) used in the SSF medium. The absence of signals in the range 60-100 ppm indicates the complete metabolism of glucose by yeast and the effectiveness of the SSF process under sonication. The whole process of farming the high-carbohydrate *Ulva rigida* by the integrated multitropic aquaculture (IMTA) and its subsequent conversion to high-concentration bioethanol in a single-step sonication-assisted SSF process is represented in Scheme 2.

# **Continuous-Flow Solar-Energy-Driven SSF Process for the Conversion of**  *Ulva rigida* **to Bioethanol**

The exploitation of solar energy, which is abundant, renewable and environmentally friendly, for the production of bioethanol is an innovative idea. Successful utilization of solar energy for bioethanol production from biomass has the potential to solve the fuel-shortage problem. Utilization of solar energy for the production of bioethanol has never been tested experimentally so far. Gedanken's group was the first to envisage the prospects as well as potential benefits in using solar radiation for biofuel production [22]. Using solar energy for bioethanol production has economic, energy and environmental benefits. The product, bioethanol, has diverse applications apart from being a potential transportation fuel. Bioethanol could act as an economic driver for the upcoming biorefinery industry as it could be a feedstock for alkanes as well as ethers. Moreover, the solar-energy-driven bioethanol process is sustainable owing to the abundance of solar radiation and also because of the wide range of biomass that could serve as feedstock for carbohydrates that are converted to bioethanol in the process of SSF. The feasibility of using the bioethanol produced in a solarenergy-driven process (from glucose and starch as feedstock) was demonstrated for generating electricity from fuel cells, and the performance of the fuel cells was on a par with commercial ethanol of similar concentrations. Such an application is the first of its kind in the literature and can be regarded as a breakthrough and prelude to several other applications (in the field of transportation sector and chemical industries) which are currently unanticipated [12, 13]. The use of this alternate green renewable resource may provide a solution to meet the growing energy demands. The utilization of solar thermal energy for biofuel production has a significant impact on the overall energetics (energy return on energy invested, EROEI) of the process. The exploitation of solar energy for the direct conversion of biomass to bioethanol has not been attempted before and hence the invention has potential for easy adaptation by industry. Moreover, the unique design of the solar reactor (Figure 10) not only accelerates the simultaneous saccharification and fermentation (SSF) process for the conversion of biomass to bioethanol but also facilitates the *in situ* separation of the ethanol formed in the broth by an evaporation-condensation process [11].

Figure 10. Continuous-flow solar reactor for the single-step conversion of marine macroalgae *Ulva rigida* to bioethanol; (a) complete experimental setup, (b) stable 5 wt% aqueous *Ulva rigida* suspension with enzymes, and (c) fermentation chamber loaded with baker's yeast on activated carbon cloth [11].

A typical continuous-flow process for the solar-aided conversion of an aqueous suspension of *Ulva rigida* to bioethanol consists of feeding the algal solution (500 mL, 5 wt%, prepared by ultrasonication) mixed with specific amounts of enzymes  $(\alpha$ -amylase, amyloglucosidase, endo-cellulase, exo-cellulase, and β-glucosidase) into the fermentation chamber of the solar reactor (at a flow rate of 3.9 mL/h) loaded with instant baker's yeast (*Saccharomyces cerevisiae*) covered with activated carbon cloth. In this solar-energy-driven continuous-flow SSF process, the enzymes led to the hydrolysis of starch and cellulose components of the algae to glucose which was further fermented by the yeast and converted to ethanol. When 500 mL *Ulva rigida* feedstock was completely fed to the reactor, DDW was flown through the reactor (with the same flow rate, 3.9 ml/h) in order to convert the residual carbohydrates of the algae to bioethanol. When the DDW was completely fed, additional 500 mL of the feedstock was fed to the reactor to test the reusability of the enzymes and the yeast bed as well as the continuous operability of the system. Again, when the feedstock was completely fed to the reactor, DDW was allowed to flow in order to convert the residual carbohydrate content of the algae to bioethanol. It is important to note that similar bioethanol results were observed when the same experiment was repeated by loading the enzymes and the baker's yeast on activated carbon prior to SSF process.

# *Time-on-Stream Studies of Solar-Energy-Driven Bioethanol Production from Continuous-Flow SSF of Ulva rigida*

The continuous-flow SSF process of 5 wt% *Ulva rigida* was monitored for 37 days in the solar reactor (with the same enzymes and the yeast) at 31/24°C average day/night temperature. The fermentation was continuous; most of the evaporation occurred during the day and only a negligible amount occurred at night. The aliquots of products were collected at regular time intervals and quantified for ethanol using proton nuclear magnetic resonance (<sup>1</sup>H NMR) spectroscopy and high performance liquid chromatography (HPLC). The ethanol yield (deduced from <sup>1</sup>H NMR analysis) as a function of time is depicted in Figure 11.

Figure 11. Time-on-stream studies of solar-energy-driven bioethanol production in a continuous-flow SSF process of *Ulva rigida* (5 wt%) (Taverage day/night: 31/24°C) [11].

High ethanol yields (84.2 wt% of the theoretical ethanol yield) were observed throughout the SSF process of *Ulva rigida* (7.4 g ethanol in 37 days, 2.64 g ethanol/day/m<sup>2</sup> ), based on the fermentable sugar content of the biomass. Thus the solar-aided conversion of *Ulva rigida* to bioethanol is highly energy- and atom-efficient.

# **Can Seaweeds Be a Sustainable Feedstock for the Production of Levulinic Acid, a Key Economic Driver for the Biorefinery?**

Levulinic acid is a chemical of strategic significance. In fact, production of levulinic acid from cellulose would be more advantageous than converting cellulose to bioethanol. The theoretical yields of levulinic acid and bioethanol from cellulose are 64 [23] and 51 wt% [14 ] respectively. Not only is the atom efficiency of levulinic acid production process higher than that of the bioethanol production process, but also owing to the multifunctionality of levulinic acid, it could be a building block for several other fuel-grade chemicals such as  $\gamma$ valerolactone (Scheme 3).

Although the production of levulinic acid has been attempted from a variety of carbohydrate feedstock including direct conversion of widely available agricultural wastes

such as *cicer arietinum*, cotton, *Pinus radiata*, sugar cane bagasse and rice straw [23, 24], very few attempts have been made for the exploitation of seaweeds as feedstcok for levulinic acid production [25, 26]. Gedanken's group made preliminary studies towards the utilization of the seaweed, *Ulva rigida*, for the production of levulinic acid. An acid (HCl, 3 M) catalyzed hydrothermal process (150°C, 3 h) yielded 12.8 wt% levulinic acid from *Ulva rigida*. However, the process needs to be optimized further with respect to reaction temperature, reaction time, and acid concentration to obtain improved yields of levulinic acid. Using marine algae for levulinic acid production is advantageous and makes the process sustainable. In addition to conventional mineral acid, alternate solid acid catalysts such as (polyoxometallates) need to be developed for the conversion of *Ulva rigida* to levulinic acid.

Scheme 3. Reactivity of levulinic acid making it a key strategic chemical [Amudhavalli Victor, Indra Neel Pulidindi, Aharon Gedanken (2014) Levulinic acid production from *Cicer arietinum*, Cotton, *Pinus radiata* and Sugar cane bagasse, *RSC Advances*, 4, 44706-4471]. Adopted with permission from the Royal Society of Chemistry.

The design of diverse process pathways for product diversification makes the biorefinery sustainable. Thus strategies should be developed for converting the carbohydate component of seaweeds to various products apart from levulinic acid and bioethanol by devising innovative strategies for improving the yields and reducing the process severity. For instance, in principle, the theoretical limit on the yield of bioethanol from cellulose can be raised from 51 wt% by capturing and reusing the  $CO<sub>2</sub>$  evolved in the fermentation process by charging the fermentation broth with cyanobacteria that could be metabolizing  $CO<sub>2</sub>$  and synthesizing glycogen which could be further converted to bioethanol. Such efforts need to be made in near future. Likewise, the current commercial levulinic-acid production processes use conventional mineral acid as catalyst. However, the process could be environmentally benign as well as profitable if a reusable solid acid catalyst like activated-carbon-supported heteropoly acids is employed [24]. Development of such pathways requires further research. In addition, the inevitable reaction byproduct of the bioethanol production process, glycerol, could be a valuable feedstock for the production of propane diols which are nearly 20 times more costly and value added [27]. Conversion of glycerol to valuable chemicals is another avenue in biofuel production from seaweed.

# **CONCLUSION**

Typical challenges in the farming and conversion of seaweeds to biofuels and biochemicals are outlined. Solutions, such as the adoption of integrated multi-tropic aquaculture for the effective utilization of resources and production of high carbohydrate (32 wt%) *Ulva rigida* with accelerated growth rates (by a factor of 41), were offered. In addition, unconventional methods, such as ultrasound irradiation and solar energy for the simultaneous saccharification and fermentation (SSF) of seaweeds to bioethanol were demonstrated successfully. The marine seaweed, *Ulva rigida*, is a potential feedstock for the high-yield production of bioethanol (16 wt%) and levulinic acid (12.8 wt%). Solar-energy-driven continuous-flow process for the SSF of *Ulva rigida* to bioethanol is appealing for industrial adaptation owing to its atom and energy efficiency.

# **ACKNOWLEDGMENTS**

The authors thank the Israel Science Foundation (ISF, grant no. 12/586) and the Israeli Ministry of Science and Technology (grant no. 3-99763) for the generous funding.

# *BIOGRAPHICAL SKETCHES*

# *Dr. Indra Neel Pulidindi*

**Affiliation:** Hanyang University, Ansan campus, Korea

**Education:** Dr. Pulidindi received his primary and secondary education from APPMills Model High School, Rajahmundry, India from 1985 to 1995. He received his MSc from Andhra University, India in 2002. He received his PhD from IIT Madras, India in 2010 with the doctoral thesis entitled "Development and exploitation of carbon materials from plant sources."

**Address:** Department of Materials Science and Chemical Engineering, Hanyang University, Korea-15588.

# **Professional Appointments:**

Dr. Pulidindi was given an opportunity to work in the laboratory of Professor Tae Hyun Kim at Kongju National University, Korea (1.11.20116 to 28.2.2017) and at Hanuyang University, Ansan campus, Korea (1.3.2017 to till date) as a visiting scientist. He was a

postdoctoral researcher under the supervision of Prof. Aharon Gedanken in Department of Chemistry, Bar-Ilan University, Israel for six year (2.9.2010 to 30.10.2016).

#### **Research and Professional Experience:**

Dr. Pulidindi's research interests include nuclear chemistry, catalysis, materials science, renewable energy, and biofuels. He has published 33 peer-reviewed manuscripts, two book chapters and has applied for 5 patents. He has an h-index of 10 and i10-index of 10 with 428 citations. He is passionate about identifying solutions for societal problems such as energy crisis or environmental pollution by means of utilizing natural resources such as solar energy, CO2, and biomass. Energy crisis and environmental deterioration are the two major problems human society is currently facing. His research focuses on developing alternate renewable energy sources. Towards realization of this goal, it is imperative that one should utilize the solar energy which is abundantly available and also devise strategies to utilize  $CO<sub>2</sub>$  as an organic raw material for the production of fuels and chemicals. Dr. Pulidindi is currently working exclusively on the conversion of both terrestrial lignocellulosic and algal biomass to biofuels and biochemicals using solar energy for fuels production and lignin valorization. Mankind need to learn and mimic nature for sustainability and wellbeing; therefore, he focuses on understanding and mimicking nature by utilizing natural resources and trying to solve societal problems.

#### **Honors:**

Recipient of advanced scientific-brain fellowship of the Korean Federation of Science and Technology Societies, 2016-2017. Editorial board member of Journal of Catalyst and Catalysis, Editorial board member of Emerging trends in Chemical Engineering, Prof. M. N. Sastry Shastaibdpoorthi Celebration Gold Medal (2002, for 1<sup>st</sup> ranking in M. Sc.,  $2<sup>nd</sup>$  year), Prof. B. S. V. Raghava Rao Memorial Prize (2001, for 1<sup>st</sup> ranking in M. Sc., 1<sup>st</sup> year), Prof. R. Sambasiva Rao Prize (2001, for 1<sup>st</sup> ranking in M. Sc., 1<sup>st</sup> year), Gold medalist (Best outgoing student in X<sup>std</sup>, 1995, APPMills Model High School, Rajahmundry).

*Dr. Leor Korzen*

**Affiliation:** Tel-Aviv University, Israel

**Education:** Leor Korzen received his BSc in Bio-Medical Sciences from Tel Aviv University (2006) and MSc in Marine Ecology from Tel-Aviv University (2009). He received his PhD from Tel-Aviv University in 2017 with doctoral thesis entitled "Macroalgae as a Feedstock Source for Bioethanol Production."

#### **Research and Professional Experience:**

Leor's research interests include finding sustainable solutions to global problems, namely aquaculture of marine biomass and the conversion and production into value-added products.

#### **Publications Last Three Years:**

- (1) Korzen, Leor, Avigdor Abelson, and Alvaro Israel. "Growth, protein and carbohydrate contents in *Ulva rigida* and Gracilaria bursa-pastoris integrated with an offshore fish farm." *Journal of Applied Phycology* (2015): 1-11.

*Betina Tabah*

### **Affiliation:** Bar-Ilan University, Israel

**Education:** Betina Tabah received her BSc in Biological Sciences and Bioengineering with minor honors in Chemistry from Sabanci University (2009), Turkey and MSc in Biotechnology from Ben-Gurion University of the Negev (2012), Israel. She is currently a PhD candidate in Department of Chemistry and Institute for Nanotechnology and Advanced Materials at Bar-Ilan University, Israel.

**Address:** Department of Chemistry, Bar-Ilan University, Ramat-Gan, Israel 5290002

### **Professional Appointments:**

PhD candidate under the supervision of Prof. Aharon Gedanken in Department of Chemistry and Institute for Nanotechnology and Advanced Materials at Bar-Ilan University.

#### **Research and Professional Experience:**

Betina's PhD thesis focuses on novel methods for the conversion of biomass to bioethanol. She is passionate about finding green solutions to global problems. Her research interests include potential alternative energy sources, biofuels and renewable energy studies, utilizing different biomass for energy applications, developing biofuel production systems and up-scaling to industrial applications, and conversion of wastes and plant residues into value-added products.

#### **Honors:**

Betina was selected as a 2014 Rieger-JNF Fellow and 2015 Marshall Tulin Fellow in Environmental Studies by Rieger Foundation, USA. She has received many awards including Jewish National Fund-Keren Kayemeth LeIsrael prize for excellence in research (2011), The Robert Equey prize for excellence in desert studies (2011), Selim and Rachel Benin award of merit (2013), David Brekovsky award for academic excellence (2014), Turkish Union in Israel award of merit (2014), The Salti Foundation award of merit (2015), and Cyd Hessner prize for academic excellence and contribution to the community through volunteer work (2015). Her recent manuscript published in *ChemSusChem* was selected as a Key Scientific Article by Renewable Energy Global Innovations (Canada) for contributing to the excellence in energy research (2016). Her poster presentation entitled "Solar-energy driven solid-state fermentation for continuous flow bioethanol production" has won the "Best Poster Award" at NanoIsrael 2016 conference.

*Amudhavalli Victor*

# **Affiliation:** Bar-Ilan University, Israel

**Education:** Mrs. Amudhavalli received her BSc and MSc degrees in Pharmacy from the Tamil Nadu Dr M G R Medical University. Mrs. Amudhavalli carried out her doctoral studies in the field of renewable energy under the supervision of Prof. Aharon Gedanken and submitted her doctoral thesis titled "Can biomass be a sustainable feedstock for biorefinery?" to the Department of Chemistry, Bar Ilan University, Israel on 22/09/2016.

**Address:** Department of Chemistry, Bar-Ilan University, Ramat-Gan, Israel 5290002.

### **Professional Appointments:**

Mrs. Amudavalli was a doctoral researcher at the department of Chemistry, Bar Ilan University from 01/03/2013 to 22/09/2016. She has six years (2006-2012) of teaching experience as a lecturer at the SRM college of Pharmacy, SRM university, Chennai, India.

### **Research and Professional Experience:**

Environmental deterioration and energy insecurity are the vital challenges society is facing currently. Mrs. Amudhavalli's research emphasis is on developing alternate chemical and electrochemical energy sources that are renewable and sustainable. Utilization of natural and abundant resources (biomass, agricultural and forest wastes, food wastes, kitchen wastes, municipal wastes,  $CO<sub>2</sub>$  and solar energy) for attaining this objective is one of the strategies that she has adopted. Currently, she is developing microwave, sonochemical and solar energy based strategies for the production of biofuels and biochemical, especially from lignin. Also her interest is centered around activation of  $CO<sub>2</sub>$  via chemical and photochemical means. Another area of her research focus is to develop cost effective and selective sensors for biomolecules like dopamine that have relevance to health sector. She has 3 peer-reviewed publications to her credit during the last four years of research in the area of renewable energy.

#### **Publications in the Last Three Years:**

- (1) Amudhavalli Victor, Indra Neel Pulidindi, Tae Hyun Kim, Aharon Gedanken, (2016) Design of a selective solid acid catalyst for the optimization of glucose production from Oryza sativa straw, *RSC Adv*., 6, 31.

- (3) Amudhavalli Victor, Indra Neel Pulidindi, Aharon Gedanken (2014) Levulinic acid production from *Cicer arietinum*, cotton, *Pinus radiata* and sugarcane bagasse, *RSC Adv*., 4, 44706.

*Prof. Alvaro Israel*

**Affiliation:** Israel Oceanographic & Limnological Research, Ltd. The National Institute of Oceanography. Tel Shikmona 8030, Haifa 31080, Israel.

**Email:** alvaro@ocean.org.il; Tel: +972-4-8565262; Fax: +972-4-8511911

**Education:** Prof. Israel received his MSc and PhD from Tel Aviv University

#### **Research and Professional Experience:**

After his post-doctoral research at UCLA, US, he joined the Israel Oceanographic Institute in Haifa, Israel in 1992 where he is currently a senior scientist and Head of Department of Marine Biology. He contributed to the understanding of photosynthesis in seaweeds in response to environmental factors particularly those related to climate change. He lead several national and international projects in marine macroalgae cultivation and biotechnology including development of land- and sea-based cultivation systems. Israel's research interests include carbon fixation and ecology of marine algae, taxonomy of seaweeds applied phycology and renewable energy (biomass conversion to biofuels and biochemicals). Israel has published over 60 papers in peer-reviewed journals.

#### **Publications in the Last Three Years:**

*Prof. Aharon Gedanken*

**Affiliation:** Bar-Ilan University

**Education:** Prof. (Em.) Gedanken received his MSc from Bar-Ilan University and his PhD from Tel Aviv University, Israel

**Address:** Department of Chemistry, Bar-Ilan University, Ramat-Gan, Israel 5290002

#### **Professional Appointments:** Emeritus Professor at Bar-Ilan University

#### **Research and Professional Experience:**

After his post-doctoral research at USC, USA, Prof. (Em.) Gedanken returned to Bar-Ilan University in 1975 as a senior faculty in Chemistry Department. He was a visiting scientist at AT&T Bell Laboratories several times in 1980-1988, and at NIDDK, NIH, USA in the summers of 1989-1991. **In 1999-2001, he was the** chairman of national committee for strategic studies in advanced materials and chemical technologies. In the EC program FP7, he was the Israeli representative to the Nanotechnology, Materials, and Processes (NMP) committee. He was also a partner in 12 EC projects, in which two of them were coordinated by him. From 2012 to 2016, he was a visiting chair professor in Department of Materials Science and Engineering, NCKU, Taiwan. Gedanken's research interests include sonochemistry, surface coating, synthesis of nanomaterials, microwave superheating, synthesis reactions under autogenic pressure at elevated temperatures, fuel cells, renewable energy (biomass conversion to biofuels), carbon materials, sensors, medicinal chemistry, and polymers. Gedanken has published over 725 papers in peer-reviewed journals, has 38 patent applications, and his h-index is 87.

#### **Honors:**

He is the recipient of 2009 Israel Vacuum Society and 2012 Israel Chemical Society awards of excellence in research.

#### **Publications in the Last Three Years:**

- (1) Graphene-Based "Hot Plate" for the Capture and Destruction of the Herpes Simplex Virus Type 1. A. R. Deokar, A. P. Nagvenkar, I. Kalt, L. Shani, Y. Yeshurun, A. Gedanken, R. Sarid, *Bioconj. Chem.*, DOI: 10.1021/acs.bioconjchem.7b00030, (2017).

## **ABSTRACT**

A laboratory experiment was performed, in tidal artificial conditions, with natural defaunated sediments that were artificially contaminated with aluminium salts. Benthic diatoms were cultivated on these contaminated sediments in a tidal mesocosm with natural seawater, in order to assess the aluminium impact on the growth of benthic diatom. The sediments were also leached by HCl (1M) to estimate the available/mobile part of the aluminium in the sediment.

This experiment highlighted that Al-contamination sediments had a strong effect on diatom communities growing at sediments surface. Drastic negative effect is perceptible beyond 10 mg of aluminium salts added by kg of natural sediment (which is a low contamination stress with regard to the Al initial content). The 1M HCl-extraction, widely used in the literature for metals mobility evaluation in marine sediments seems to underestimate aluminium availabilities for phytobenthic communities.

**Keywords:** marine sediment, HCl extraction, aluminium, phytobenthos

### **1.INTRODUCTION**

Heavy metals contamination in sediments is often assessed by the determination of their total contents and comparison with either established national guidelines or some background reference values (Covelli and Fantolan, 1997; Giancoli Barreto et al., 2004; Leleyter and Baraud, 2005; Dubrulle et al., 2007; Meybeck et al., 2007; Chand and Prasad, 2013). However metal concentrations derived from these total digests do not necessarily provide biologically meaningful data. The alternative is to use a partial extraction that only targets the labile mineral phases, as these are most likely to exert an influence on biota (Tam et al., 1989; Scouller et al., 2006). Thus, other studies focused on the potential mobility of these heavy metals in the sediments, estimated by either simple or sequential extraction procedures (Tessier et al., 1979; Leleyter and Probst, 1999; Sutherland, 2002; Rousseau et al., 2009; Devesa-Rey et al., 2010; Leleyter et al., 2012; Roussiez et al., 2013; El Azzi et al., 2013; Alvarenga et al., 2014; Islam et al., 2015; Hamdoun et al., 2015a and b).

For marine sediments, HCl (1M) extraction is recommended by many authors (Doherty et al., 2000; Snape et al., 2004; Burton et al., 2005; Scouler et al., 2006; Larner et al., 2008; Leleyter et al., 2012; Pena-Icart et al., 2014; Hamdoun et al., 2015a and b), as HCl is assumed to extract heavy metals thanks to its acidic properties combined with the chelatant property of Cl- . For a comprehensive environmental risk assessment, both approaches (total and labile contents) are generally complementary in order to fully characterize the degree of sediments contamination.

Natural aluminium (Al) is the third most abundant element in the earth crust (around 8%, Allègre and Michard, 1973). Aluminium is known as a refractory element, typically not diagenetically labile. Moreover, anthropological activities (aluminium industry, water treatments, steel protection with aluminium sacrificial anodes, ...) release aluminium in the environment. As aluminum is more stable in solid than in aqueous phase, the anthropological aluminum poured in marine waters tends to be sorbed onto surrounding sediments (Pineau et al., 2008; Gabelle et al., 2012), which could act as a sink of aluminium to biota. Only a small part of Al in sediments is available (i.e non-silicate-bound), involving reactions such as solubilization, polymerization, complexation, crystallization, which are strongly controlled by the pH conditions (Tam et al., 1989; Gunkel et al., 2011). Many studies have proved that Al toxicity is an important factor affecting the growth of plant and aquatic biota in acidic ecosystems (Meiri et al., 1993; Platt et al., 2001; Lu et al., 2011). However, detecting anthropogenic aluminium contamination could be especially difficult. Indeed, the usual trace metals contaminations studies (using background references comparisons) could not be easily transposed into a major element study (such as aluminum), because anthropological quantities are often negligible with regard to the natural amount. Partial extractions seem to provide more sensitive indication of aluminium contamination, as the first tests on natural sediments (Gabelle et al., 2012; Leleyter et al., 2012) highlighted some differences in the mineralogical partitioning of natural or anthropological aluminium.

The processes controlling the fate of dissolved aluminium are still not well understood (Wang et al., 2015) and up to now, the complex biogeochemical cycle of this element has been poorly understood (Gunkel et al., 2011). Benthic diatoms are an important component of phytobenthos inhabiting the intertidal mudflats by constituting the first primary producer in muddy estuaries (Underwood and Kronkamp, 1999) by biofilms at the sediment surface

(Decho, 1990; Wingender et al., 1999). Benthic diatoms can be used as bioindicators of metallic pollution (Gold et al., 2003a; Lai et al., 2003; Cunningham et al., 2005; Morin et al., 2007), because of their high level of primary productivity in coastal sediments (Underwood and Kronkamp, 1999), their sensitivity to changes in water quality (Dixit et al., 1992; Stevenson and Pan, 1999), and their fundamental role in the food webs (Lefebvre et al., 2009). *In situ* studies conducted at sites exhibiting a high level of metals and microcosm experiments have demonstrated a decrease in productivity, diversity and changes in species composition of diatom communities (Takamura et al., 1989; Hill et al., 1997; Sabater, 2000). As reported by Gold et al. (2003b) and Duong et al. (2010), metal contamination had a strong effect on the density of diatom communities, possibly corresponding to a reduction in the rate of cell division of diatom species as demonstrated by Rivkin (1979), cessation or interruption of cell division (Dickman, 1998), the development of teratogenic forms (Arini et al., 2013), and also physiological impairments regarding photosynthesis, mitochondrial metabolism (Arini et al., 2012) and gene expression (Kim Tiam et al., 2012). Thus changes in benthic diatoms have been revealed to be a good estimator to assess heavy metal contamination (such as Cd, Cu, Zn, …) in freshwater ecosystems (Say and Whitton, 1980; Foster, 1982; Medley and Clements, 1998; Sabater, 2000). However, benthic diatoms in rivers can handle high concentrations of metal pollution such as cadmium, and biomonitoring surveys show the bioremediation process exerted by benthic diatoms (Arini et al., 2012) while reverse potential of teratogenic forms can show cadmium decontamination after experimental contamination (Arini et al., 2013). The behaviour of Al at the water-sediment interface is important for controlling dissolved concentrations in bottom waters via resuspension processes. The major processes removing dissolved Al from the water column include active biological uptake by diatoms (Wang et al., 2015), as benthic diatoms are ecosystem engineers capable of bioremediation of metallic pollution (Arini et al., 2012).

A mesocosm experiment was performed, with natural defaunated sediments that are contaminated with aluminium salts. Benthic diatoms are cultivated on these contaminated sediments in a tidal Mesocosm (Ubertini et al., 2015), in order to evaluate the aluminium impact on the growth of benthic diatom. The sediments are also leached by HCl (1M) to estimate the available/mobile part of the aluminium in the sediment. The aim of the present work is to study the potential uptake by benthic diatoms of non-natural Al in marine sediments, levels of toxicity for benthic diatoms and the capacity of the aluminium geochemical characterization procedures (total and labile) to be used in the evaluation of aluminum environmental risk.

## **2. MATERIAL AND METHODS**

#### **2.1. Sediments**

A stock of fine sediment was collected in the Orne estuary (WGS84, 49.28°N, -0.24°W) from 10 to 20 cm below the surface and brought back to the lab. After 1 month in darkness, this sediment was sieved on  $a < 1$  mm mesh to remove the macro-fauna, then crushed and homogenized in an agate mortar and sieved at 80 µm. Control experiment consisted of Al natural sediment (T). Some aliquots of T-sediment were mixed thoroughly with variable

quantities of aluminium sulphate  $(Al_2(SO_4)318,H_2O$ , from Riedel-Haën, puriss quality, > 99%), in order to obtain five Al-contaminated sediments, designed hereafter as C1 to C5 with added content of Al from 1 to 1000 mg. $kg^{-1}$  (Table 1). Then, contaminated sediments (C1 to C5) were sprayed with ultra-pure water and manually mixed. After drying  $(40^{\circ}C)$ , the Csediments were crushed and homogenized in an agate mortar.

**Table 1. Total Al contents measured in the sediments after Al contamination, values are expressed per kg of dry sediment; SD: Standard Deviation (3 replicates); Normalisation ratio with [Cx] and [T] = total concentration in sediment Cx and T respectively**

Al total contents in all the sediments were obtained after solubilisation of the solid matrix by an alkaline fusion procedure (NF ISO 14869-2, AFNOR 2002): 0.2g of dried sediment was thoroughly mixed with 0.8g of lithium metaborate and 0.2g of lithium tetraborate in a Pt crucible. The mixture was heated at 1000°C for 45 min and then the fusion product was immediately put in 60 mL of 1 mol. $L<sup>-1</sup>$  HNO<sub>3</sub> solution until total dissolution of the occurred residue. The recovered solutions were made up to a volume of 100 mL with 1 mol. $L^{-1}$  HNO<sub>3</sub> solution.

The aluminium concentrations were measured by Inductively Coupled Plasma- Atomic Emission Spectrometry (ICP-AES, Varian, Vista MPX). The analytical quality of the chemical data was controlled using the standard certified material HR-1 (Canada Center for Inland Waters National Laboratory for Environmental) and the standard marine sediment (PACS2) (Gabelle et al., 2012; Hamdoun et al., 2015a).

Single extraction with 1 mol.  $L^{-1}$  HCl was also applied to all the sediments (T, C1 to C5). 1g of dry sediment was mixed with 10 mL of 1 mol. $L<sup>-1</sup>$  HCl solution under agitation (200tr/min) at room temperature for 1h. The resulting mixture was centrifuged (3000 rpm; 2min), filtered at 0.45 µm (syringe filter, Millex - SLHN033N). The obtained leachates were analyzed by ICP-AES.

## **2.2. Sediment Preparation and Benthic Diatom Cultivation Experiment in Response to Contamination by Aluminium**

24 PVC cores (diameter: 15 cm, height: 20 cm) were filled with 2 layers: bottom layer with natural sediment and a superficial mud layer  $(1<sup>st</sup> cm of each core)$  that was treated with different levels of contamination (T and C1 to C5 sediments; 4 replicates) before being inoculated with fresh benthic diatoms. The first upper cm was then homogenized with an epipelic MPB inoculum collected from a mudflat located in the Orne estuary (WGS84, 49.28°N, -0.24°W) in Basse-Normandie during April 2011. It was collected by scratching the sediment surface. The biofilm was mainly composed of pennate diatoms including small *Navicula sp.* (length ~17µm, >95% of total MPB), *Amphora sp*., *Pleurosigma sp*., *Niztschia sp.* and *Cylindrotheca closterium*. The cores were positioned in trays (1.20 m x 1 m x1m, 12 cores capacity) (Figure 1). The first tray (called series I) contained T, C1 and C2 sediments, whereas the other tray (called series II) was performed with C3 to C5 sediments cores. The surface of the sediment was gently smoothed and cores were cultivated in a tidal mesocosm able to simulate a high/low tide alternation every 6 hours in order to simulate immersion and emersion phases.

Figure 1. Unit (series I and II) with the 12 cores each.

The experimental mesocosm consists of two trays placed one on the top of the other (Figure 2). The lower unit served as seawater reservoir, to produce high and low tide, thanks to submersible pumps. The upper unit is used for the implementation of sediment cores (series I or II) and is covered with a roof equipped with a light intensity of 1600 μmol photons m<sup>2</sup>.s<sup>-1</sup> (LUMINUX, 36W Osram), to reproduce day (during low tide) and night cycles. The experimental design was carried out according to Orvain et al. (2003) with 6h light: 18h dark regime. Natural seawater filtered over filters  $(1\mu M)$  was used for this experiment.

Water samples were collected at  $0, 5$  and  $9$  days and filtered through a  $0.45 \mu m$ (Millipore) in polyethylene flask. The filtrates (14 mL) obtained were then acidified with  $HNO<sub>3</sub>$  (suprapur: 60%) and stored at 4<sup>o</sup>C for Al and trace metal analysis by Inductively Coupled Plasma Atomic Emission Spectrometry (ICP-AES, Varian, Vista MPX).

Phytobenthic biomass was assessed by measuring the chlorophyll *a* (Chl *a*) content. Sediments samples were taken from the experimental cores at 5 and 9 days at the beginning of diurnal emersion periods in order to access respectively the growth and stationary phases of the biofilm (Orvain et al., 2003). The first upper cm of the sediment (2 replicates) was sampled with a 2-cm diameter cut syringe. The uppermost first centimeter was cut and mixed in 50 mL Falcon tubes. All frozen samples were lyophylised. Chl *a* extraction was applied on a given amount of dry sediment, with approximately 150 mg of sediment that was accurately

weighed. Phytobenthic biomass was estimated by quantifying fluorometrically the chloropigments after extraction in 90% acetone and in the dark overnight under constant agitation at  $4^{\circ}$ C and centrifugation ( $4^{\circ}$ C, 5 minutes, 3500 rpm). The chlorophyll extracts were measured on a Turner Designs TD 700 fluorometer (USA) following the method of Welschmeyer (1994). In order to avoid the dewatering over the emersion period (Perkins, 2003), water content and the bulk density of sediments could be used to express the Chl*a* as a content per  $m^{-2}$ .

Figure 2. Tidal mesocosm reproducing the alternation of diurnal daytime low-tide period lasting 6 hours (8:00AM – 2:00 PM), and nocturnal high-tide period lasting 18 hours (2:00 pm – 8:00).

## **3. RESULTS AND DISCUSSION**

### **3.1. Sediments Contamination**

The measured quantities (Table 1) for all the contaminated sediments indicated that the contamination procedure was correct, without any loss or excessive contaminations. We noticed no meaningful difference  $(<5\%$ , Table 1) between the Al total content in the background (T sediment) and the Al total content in contaminated sediments (low contamination with regard to the Al initial content which is naturally a major element in sediments).

Mobile metals concentrations are measured (3 replicates) in the tested sediments (T, C1 to C5, see Table 2) in the leachates after the HCl extraction and the mobile part is expressed as the percentage of the total Al content initial measured in the corresponding sediment. The quantities of labile Al remain quite stable  $(521 \text{ to } 564 \text{ mg} \text{ kg}^{-1})$  for the low contamination rates (0 to 100 mg.kg<sup>-1</sup>). On the opposite, the extracted quantities increased for the highest contamination rates (500 and 1000 mg.kg<sup>-1</sup>), respectively 873 and 1311 mg.kg<sup>-1</sup>, suggesting that an important part of the added aluminium is scavenged in the labile fraction of the sediment.

The resulting percentage of aluminium extracted by HCl 1M in contaminated sediments (C4 and C4, i.e., 500 or 1000 mg.kg-1 of sediment) increased (respectively 4 and 6%) and thus doubled the quite stable percentage (2 to 3%) in sediments with low contamination rate (T and C1 to C3, from 0 to 100 mg.kg $^{-1}$  of added Al).

Various authors (Agamian and Chau, 1976; Sutherland et al., 2001; Matus*,* 2007) reported that dilute HCl mainly extracted (from soils and sediments) Al species connected with anthropogenic contamination of the environment. Gabelle et al. (2012) also discriminated marine sediments contaminated by Al sacrificial from uncontaminated sediments thanks to similar results. They determined that Al mobilised by 1M HCl represented  $2 \pm 1\%$  of the total Al present in the uncontaminated, whereas 5% to  $11 \pm 1\%$  of the total Al was extracted by HCl from the sediments at the vicinity of Al sacrificial anodes.

#### **3.2. Water Contamination**

The average concentrations of the total Al determined in water throughout the 9 days of experimentation range from  $0.04$  to  $0.07$  mg. L<sup>-1</sup> (Figure 3); these values are similar to concentrations previously reported for estuarine and marine waters. For example, concentrations from 9 to 70 µg/L, 5 to 50 µg/L, 10 to 60 µg/L, and 1 to 8 µg/L are reported for the GPMH (Seaport of Le Havre, France, Gabelle et al., 2012), Les Flamands (Seaport of Cherbourg, France, Mao et al., 2011) some Chinese estuaries (Zhang et al., 1999) and English Channel (Chou and Wollast, 1993) respectively.

The initial Al concentrations are similar for the two sets of experiment series (I and II). After 5 days, the concentrations increase in both cases, followed by a decrease for the next 4 days. The decrease is more pronounced for the low contamination set (0 to 10 mg.kg $^{-1}$  of added Al) with Al concentrations in water lower than the initial ones, whereas the final concentrations remain higher than the initial ones for the second set (100 to 1000 mg.kg<sup>-1</sup> of added Al).

The increase noticed after 5 days is probably due to the partial solubilisation of the added aluminum salts. The decrease then observed after 9 days could result from various processes, such as re-adsorption by the sediments, or uptake by the diatoms. Indeed, diatom can use a significant quantity of aluminium for their physiological requirements, but phytobenthic diatoms are above all capable of bioremediating pollutants out of their cells, by producing anionic polymers in the microenvironment (Wingender et al., 1999). These Extracellular Polymeric Substances (EPS) are very efficient to sequester cationic pollutants such as heavy metals, due to the anionic nature of these compounds (Decho, 2000). In case of physiological and environmental stress (contamination by heavy metals, pesticides, sediment evaporation, dehydration, saline stress, nutrient absence), a wide quantity of the photoassimilates of the benthic diatoms are secreted at the water/sediment interface (Orvain et al., 2003; McKew et al., 2011) to preserve cells against pollutants.

Figure 3. Al concentrations in the water throughout the experiment, 5 replicates.

#### **3.3. Impact of Aluminium Contamination on Benthic Diatom Growth**

The chl*a* content measured on the control cores (non contaminated T-sediment) remains stable from 5 to 9 days at 14  $\mu$ g.g<sup>-1</sup> (dry weight sediment, Figure 4) (or 120 mg.m<sup>-2</sup>) because benthic diatoms show a rapid growth phase in 5 days (or less). The Chl*a* measured after 5 days are similar to the control for the two lowest contaminated samples (C1 and C2, with 1 and 10 mg.kg<sup>-1</sup> of added Al). However, after 9 days, the values for C1 and C2 differ from the control: the higher the Al content is, the higher the Chl*a* is. This reflects the stimulation of the growth of benthic diatoms when there is moderately contamination in aluminium. Chl*a* content increases between T and C2 after 9 days of culture.

Figure 4. Influence of increasing stress of additional aluminium on Chlorophyll *a* (Chl *a*) contents in sediments.

In case of a moderate Al contamination  $(\leq 10 \text{ mg} \cdot \text{kg}^{-1})$ , benthic diatoms should resist to the presence of heavy metal under an apparent threshold of 10 mg.kg<sup>-1</sup>. In case of physiological stress and pollution, benthic diatoms are known to secrete EPS in their microenvironment; the stimulation of this process can eventually lead to a better growth of the biofilm. We can hypothesize that benthic diatoms must enhance their photosynthesis activity, productivity and EPS secretion, to exert a phytoremediation process, that is mandatory to resist to the heavy metal contamination. Thus a moderate contamination can have a positive effect on the net growth of benthic diatoms in the epipelic biofilm: these preliminary results must be further investigated to refine the bioremediating strategy of these microalgae In contrast to the algal growth at low contamination rate  $(T, C1$  and  $C2$ , ie, 0 to 10 mg.kg<sup>-1</sup> of added Al), our results indicate a lack of development of microalgae at higher contamination level  $( \geq 100 \text{ mg} \cdot \text{kg}^{-1}$  of added Al, sediments designed as C3, C4 and C5). In agreement with our results, various authors reported the same observations on the inhibitory effects of metals on algal growth capacity (Prasad and Prasad, 1982; Lasheen et al., 1989; Payne and Price, 1999; Nayar et al., 2003; Duong et al., 2010). Benthic diatoms do not grow and Chl*a* concentration remains very low, without any difference between days 5 and 9, revealing that no resilience can occur, even after some days after a strong contamination by heavy metals. The negative effects are so drastic, that this suggests a mass mortality of benthic diatoms, in response to high levels of Al contamination over 100 mg.kg<sup>-1</sup>. Resilience strategies in response to Al contamination are efficient up to the threshold value of 10 mg.kg $^{-1}$ , and this process surprisingly stimulates the growth and probably also the physiological activities in the biofilm.

#### **CONCLUSION**

This experiment has proved that the Al-contamination of sediments has a strong effect on diatom communities growing at the muddy sediments surface. The negative effect can be detected beyond 10 mg of aluminium salts added by kg of natural sediment. Indeed, benthic diatoms show a lethal threshold of aluminium contamination of 10 mg.kg<sup>-1</sup> of sediment. However, at lowest concentrations of added aluminium, phytobenthic are capable of resilience and a stimulation of the growth is observed probably in relation to a stimulation of photosynthetic activity, to produce and excrete more EPS in the biofilm that can absorb aluminium in excess. Further studies must be performed to better refine physiological mechanisms of benthic diatoms to exert a bioremediation of contaminating heavy metals and especially aluminium.

HCl-extraction showed that at high level of Al-salts contamination (500 mg or 1000 mg per kg of sediment), the aluminum mobility increases, respectively of 4 and 6%, compared to the initial values in natural conditions (3%). The Al mobility remained unchanged for the lowest contamination rates (1, 10 or 100 mg of salt per kg of sediment). The 1M HClextraction, widely used in the literature for metals mobility evaluation in marine sediments, underestimates aluminium availability for phytobenthic communities, in such case. Indeed, the % HCl for the C2 sediment (100 mg, kg<sup>-1</sup> of added Al), is similar to the ones obtained for lower contamination levels, whereas drastic effects on the diatoms are only observed for this specific concentration rate. On the opposite the increase of the % HCl for the highest contamination level (100 mg.kg<sup>-1</sup> of added Al) can be considered as a good prediction of the negative impact of Al on the diatoms that is actually observed.

Finally, in case of aluminium contamination, HCl extraction can be helpful for risk assessment only for significant contamination levels, that induces HCl mobility superior to 4%. When lower % HCl is measured complementary investigations might be necessary. Thus, an abnormal result (over 3%) for Al lability (after 1M HCl extraction) allows classifying the studied sediment as Al contaminated with important negative effects for benthic diatom. However a more 'classic' result  $(\leq 3\%)$ , does not allow the discrimination of contaminated or uncontaminated sediments.

## **ABSTRACT**

Magnetic techniques that use anisotropy of magnetic susceptibility (AMS) act as a proxy of preferred permeable orientation in basin-filling sediments, when it is applied on samples impregnated with a magnetic suspension. The unique method for quantifying heterogeneity in rocks is reviewed and its value for reconstruction of the preferred direction of pore fluid flow is reassessed critically. The authors also present results of their experiments, which dealt with secondary fracture networks developed in tight sandstones burying a foreland basin on an arc-arc collision zone. Directional analysis of AMS ellipsoid implies tectonic control on rupture development under strong transcompressive regime. Micro-focus three-dimensional density imaging of test pieces has shown a substantial variation in pore fabric reflecting inhomogeneous impregnation of magnetic fluid within rocks.

## **1.INTRODUCTION**

Micro-fabric of marine sediments is a versatile petrophysical information reflecting clast alignment for the reconstruction of sediment transport mechanism, direction of paleoflow and preferred permeable orientation of formation fluids since basins remote from hinterlands are filled with fine deposits lacking in visible manifestation of sedimentary structure. Hence

 $\overline{a}$

many studies have explored standardized procedures for acquisition of grain fabric through conventional microscopy, which was summarized as an extensive review (Baas et al., 2007).

Baas et al., (2007) also evaluated a brand-new method utilizing magnetic techniques based on anisotropy of magnetic susceptibility (AMS) as a proxy for grain orientation, which benefits greatly from being able to measure a large number of grains in a three-dimensional space, in a short amount of time and with a lower sensitivity to user bias. The magnetic technique applied on samples impregnated with liquid containing suspension of ferromagnetic powder was originally developed for the purpose of oil exploration by Hailwood and his colleague (e.g., Hailwood et al., 1999) on the theoretical background of Pfleiderer and Halls (1994).

Because the rock magnetic method was first applied to continental setting where high porous sediments are widely distributed, previous studies tend to concentrate on evaluation of fabric of intact detrital grains and their interstitial pore geometry, omitting tectonic control on fracture generation and enhancement of effective permeability. The authors' preliminary study (Itoh et al., 2014a) on collision-related turbidite samples showed wider variety in micro-fabric reflecting secondary fracture network under strong tectonic stress. In this paper, we aim at verification of AMS usability as a textural indicator of rocks, with special emphasis on origin of fluid pathway within tight turbidite sandstones burying a foreland basin.

## **2. METHODOLOGY: A REVIEW**

#### **2.1. Anisotropy of Magnetic Susceptibility**

To measure the initial magnetic susceptibility, a rock sample is placed in a low-intensity magnetic field of strength H, and the intensity of the induced magnetization (J) is measured for different orientations of the field. The induced magnetization is related to the field strength through the magnetic susceptibility  $(K)$  of the sample, where:

#### J=*K*H

The magnetic susceptibility of a sample is the summation of the susceptibilities of all mineral species within rock samples, and magnetic susceptibility is rarely identical in all directions of measurement; it more or less is an anisotropic parameter. The degree of anisotropy of magnetic susceptibility (AMS) is dependent primarily on mineral type, but even for a single type of mineral species the magnitude and anisotropy of magnetic susceptibility may considerably vary with many physicochemical properties (Tarling and Hrouda, 1993). Figure 1 presents significant parameters of AMS with typical types of susceptibility ellipsoids.

#### **2.2. Conventional Method**

As for common sedimentary rocks with low content of ferromagnetic minerals, AMS fabric generally reflects alignment of iron-rich silicates such as biotite and amphibole, of which orientations are bound to sedimentary structure. Based on azimuth of untilted AMS principal axes of fine sediments, Itoh et al., (2006) argued that the AMS is controlled by shape anisotropy of minerals laid on bedding plane.

Figure 1. The susceptibility ellipsoids. Significant parameters of anisotropy of magnetic susceptibility (AMS), such as  $P<sub>J</sub>$  and *T*, are calculated based on orthogonal principal susceptibilities ( $K<sub>1</sub>, K<sub>2</sub>, K<sub>3</sub>$ ).

Most igneous rocks are magnetically isotropic in primary state. Secondary structure may, however, cause detectable AMS trend. Based on intensive rock magnetic experiments, Itoh and Amano (2004) found that an enhanced AMS trend near a major fault cutting a granitoid pluton is originated from fine-grained authigenic magnetite grains precipitated on fracture surface.

Although such conventional methods are effective in case the possible AMS-carrying minerals are rather restricted, anisotropy of individual particles is brought about by the magnetocrystalline anisotropy or by the shape anisotropy, of which contributions vary with mineral species. Therefore more direct analytical method is necessary for quantitative description of micro-fabric of rocks.

#### **2.3. Ferrofluid Method**

Figure 2 shows a generalized scheme of analytical method utilizing liquid containing suspension of magnetic powder (hereafter referred to as ferrofluid). Since ultrafine ferromagnetic minerals in ferrofluid (mainly magnetite) are under superparamagnetic limit, coercive force  $(H_C)$  is actually negligible. As a result, maximum axis of AMS  $(K_1)$  of a rock sample impregnated with ferrofluid reflects elongate azimuth of pore network and most permeable direction.

Since the pioneering work of Hailwood, many researchers have applied the attractive method to various research areas. Nabawy et al., (2009) evaluated permeability and magnetic pore fabrics of an aquifer, and stated that pore fabrics of most formations in the Tushka Basin, Egypt are closely linked to paleocurrent directions with minor exception showing structural control (affinity for the main fault trends around the study area).

Figure 2. Generalized basis of analytical method utilizing ferrofluid. (a) Comparison of magnetic hysteresis between conventional ferromagnetic body (a-1) and ferrofluid (a-2). Ultrafine ferromagnetic minerals (mainly magnetite) are under superparamagnetic limit, and Hc is negligible. (b) Grain size distribution of a ferrofluid (provided by FerroTec Co., Ltd.). (c) Schematic view of a rock sample impregnated with ferrofluid (darkened parts).

Figure 3. Geological background of the case study area. (a) Regional index. (b) Cenozoic tectonic context of central Hokkaido. (c) Neogene stratigraphy of the study area. (d) Geology of the study area (simplified from Kawakami et al., 1999), and locations of rock magnetic samples (modified from Itoh et al., 2014a). (e) Dislocation modeling of the Kawabata sedimentary basin (modified from Itoh et al., 2014b). Mapped area is shown by an envelope in (b).

Almqvist et al. (2011) utilized AMS-derived pore shape geometry for prediction of elastic properties for porous and anisotropic synthetic aggregates. It is noted that they adopted X-ray micro-tomography density contrast imaging, where attenuation of X-rays is related to the density contrast of the material, of dry and ferrofluid-processed specimens, and visually evaluated completeness of fluid saturation. At the end of this paper, we attempt to visualize various patterns of impregnation using similar apparatus.

Reflecting highly porous nature of samples in continental setting, the above studies used a vacuum chamber to impregnate ferrofluid. Although Baas et al., (2007) made a comment on high pressure treatment for complete saturation with ferrofluid, detailed experimental condition was not shown.

## **3. CASE STUDY**

#### **3.1. Geological Background**

Sedimentary basins on convergent margins are rapidly filled by voluminous clastics, part of which is volcaniclastic reflecting active volcanism, then deformed and exhumed under compressive stress provoked by various tectonic events. On such condition, tight sedimentary rocks suffering diagenesis are less porous and instead studded by numerous secondary fractures. One presumable theory is that micro-fabrics of rocks are different from those in stable continental setting.

Our focus is set on a turbidite sequence, Kawabata Formation, widespread in central Hokkaido, which deposited during a middle Miocene arc-arc collision event. Figure 3 presents geological background of the case study area. Hokkaido is located on the northeastern margin of Eurasia, and has suffered various tectonic events through the Cenozoic. Reflecting backarc spreading and subsequent collision events, Neogene sequence of the study area shows a transgression-regression cycle (see Figure 3c). Recently a numerical modeling was executed on the Kawabata sedimentary basin (Itoh et al., 2014b) and clarified that transpressional regime followed by strong compression on the NNW-SSE regional fault zone is essential to restore the basin configuration (Figure 3e).

#### **3.2. Previous Studies**

The authors executed preliminary rock magnetic studies on the Kawabata Formation (Itoh et al., 2013, 2014a). Rock magnetic samples were taken along the Rubeshibe river in Hobetsu district in central Hokkaido, where Kawakami et al., (1999) reported detailed stratigraphic and structural data (see Figure 3d).

Itoh et al., (2013) collected samples of the Kawabata Formation with a battery-powered electric drill at 21 sites along the Rubeshibe route. The bedding attitudes were measured on outcrops to compensate for tectonic tilting later. Between seven and sixteen independently oriented cores 25 mm in diameter were obtained at each site using a magnetic compass. Cylindrical specimens 22 mm in length were cut from each core and the natural remanent magnetization (NRM) of each specimen was measured using a cryogenic magnetometer

(model 760-R SRM, 2-G Enterprises). Low-field magnetic susceptibility was measured on a Bartington MS2 susceptibility meter, and the AMS was measured using an AGICO KappaBridge KLY-3 S magnetic susceptibility meter.

Their sedimentological results are shown in Figure 4. AMS fabrics of most raw samples of the Kawabata Formation are highly oblate, as shown by positive *T* parameters near unity. This fabric is essentially confined to the bedding plane under gravitational force, and the authors considered the fabric as being governed simply by the shape anisotropy of paramagnetic minerals, i.e., alignments of elongate or platy grains such as amphibole or mica based on hysteresis study indicative of a negligible amount of ferromagnetic material.

Notably, the imbrication of the oblate AMS fabric matches visible sedimentary structures (Figure 4a), suggesting that AMS data can serve to indicate paleocurrents after the contributors to the magnetic fabric have been identified. It is also indicated that  $K_1$  of prolate samples (with negative *T* parameters) tend to align perpendicular to the paleocurrent direction, implying that elongate grains roll on the sediment surface.

Figure 4. Summary of previous sedimentological analyses modified from Itoh et al., (2013). (a) Paleocurrent map of the Kawabata Formation around the Rubeshibe River route. Formation boundaries are after Kawakami et al., (1999). (b) AMS paleocurrent indicators of the Kawabata Formation. Directions of  $K_1$  (gray arrows) are shown as acute angles from the dotted baseline of  $K_3$  axis imbrication. Downcurrent orientations based on imbrication data are depicted as outlined numbers on the baseline. Vertical positions of the data represent degree of AMS oblateness shown by the *T* parameter. Samples with negative *T* values are excluded from the diagram because such cases have a large scatter in the  $K_3$  directions.

Figure 4b shows a series of paleocurrent indicators identified in the Kawabata Formation as a function of the AMS shape parameter (*T*). The intensity of alignment forcing inferred from AMS data is closely related to sedimentary facies (shown on the right in the figure) determined by field observation. For example, weak hydrodynamic forcing corresponds to

fine rhythmically alternating facies in channel-levee systems. Thus, the sedimentological context of muddy sediments' AMS fabric can be interpreted in the light of sandy sediments' facies analysis.

Based on the sedimentological discussion above, Itoh et al., (2014a) executed ferrofluid experiments on selected Kawabata samples in the Rubeshibe route. Hand samples oriented using a magnetic compass were taken from two sites, RBA011 (muddy channel and levee turbidite) from RB01 and RBA021 (sandy sheet turbidite) from RB07. They were cut into cubic specimens with an approximate volume of  $4 \text{ cm}^3$ . Their permeability measured by a Pressure Decayed Profile Permeameter ranges 0.014∼0.030 md for RBA011 and 0.053~0.151 md for RBA021, respectively. After evacuation for one day, all the samples were soaked in water-based ferrofluid (MSG W10 with saturation magnetization of 185 Gauss; provided by FerroTec Co., Ltd.) contained in a pressure vessel and impregnated under 5 MPa for 30 days.

Figure 5. Tilt-corrected AMS fabric for the Kawabata Formation samples in raw (left) and ferrofluidsoaked (right) states. All the data are plotted on the lower hemisphere. Square, triangular and circular symbols represent orthogonal maximum  $(K_1)$ , intermediate  $(K_2)$ , and minimum  $(K_3)$  AMS principal axes, respectively, and larger symbols show their mean directions. Shaded areas are 95 % confidence limits of Bingham statistics. Anisotropy parameters posted on the equal-area diagrams are calculated based on Tarling and Hrouda (1993). Generally, ferrofluid impregnation results in enhanced anisotropy degree. In site RB01 (upper), processed specimen (RBA011) shows prolate fabric and quite different spatial arrangement of principal axes from the raw data, whereas site RB07 (lower) is characterized by similar AMS trend after ferrofluid treatment (RBA021).

Impregnated samples were washed with purified water, dried and then contained in plastic capsules. Their AMS data were measured using an AGICO KappaBridge KLY-3 S magnetic susceptibility meter, and much more than one digit larger bulk susceptibility indicates successful impregnation of ferrofluid. Measured AMS parameters were compared with those for raw samples in the same sites reported by Itoh et al., (2013). Figure 5 presents tilt-corrected AMS fabrics for the Kawabata Formation samples before and after ferrofluid treatment. Generally speaking, ferrofluid impregnation results in enhanced anisotropy degree (*P*J). In site RB01, processed specimen (RBA011) shows prolate fabric and quite different spatial arrangement of principal axes from the raw data, whereas site RB07 is characterized by similar AMS trend after ferrofluid treatment (RBA021). They attributed such a variety in magnetic fabric to difference in microscopic sedimentary structure.

Figure 6. Experimental apparatuses to impregnate ferrofluid. (a) Vacuum chamber for low-pressure

treatment. (b) Pressure vessel for high-pressure treatment.

#### **3.3. Experimental Scheme**

In the present study, the authors prepared two specimens  $(4 \text{ cm}^3 \text{ oriented cubes cut from})$ 25 mm diameter cores originally taken by Itoh et al., 2013) from 13 sites of the Kawabata Formation to observe lithofacies effect on the AMS fabrics. Using the water-based ferrofluid (MSG W10), one was impregnated in a vacuum chamber (Figure 6a) for 30 days, the other was impregnated in a pressure vessel (Figure 6b) under 5 MPa for 30 days. They were washed with purified water, dried and then contained in plastic capsules. Their AMS data were measured using an AGICO KappaBridge KLY-3 S magnetic susceptibility meter.

#### **4. RESULTS**

Bulk susceptibility of the processed samples were one to two digits larger than raw state indicating successful impregnation of ferrofluid. As shown in Figure 7, magnitudes of magnetic fabrics in ferrofluid-impregnated samples (solid symbol) are much greater than raw samples (open symbol) for 13 sites of the Kawabata Formation. Low-pressure treatment did not so much affect shape parameter *T*, whereas some specimens show clear prolate fabric after high-pressure treatment. Thus we investigate a directional trend of AMS axes in the next section.

Figure 7. Magnitudes of magnetic fabrics in raw samples (open symbol) and ferrofluid-impregnated samples (solid symbol) for 13 sites of the Kawabata Formation. As for the low-pressure treatment, site RB01 is omitted because its processed  $P<sub>J</sub>$  (1.448) is out of the range of transverse axis. Average  $P<sub>J</sub>$  and *T* are arithmetic means of specimen data.

## **5. DISCUSSION**

## **5.1. AMS Fabric**

Figure 8 delineates tilt-corrected AMS axes for 13 sites of the Kawabata Formation samples in raw (left) and ferrofluid-soaked (right) states. Generally, ferrofluid impregnation results in enhanced anisotropy degree. In case of low-pressure treatment (upper), AMS trend is more or less similar before and after ferrofluid experiment, whereas high-pressure treatment (lower) results in considerable decrease in *T* parameter although spatial arrangement of principal axes remained unchanged. This implies that pressurized ferrofluid was impregnated via a pathway which is impermeable under atmospheric pressure.

Figure 8. Tilt-corrected AMS fabric for 13 sites of the Kawabata Formation samples in raw (left) and ferrofluid-soaked (right) states. All the data are plotted on the lower hemisphere. Square, triangular and circular symbols represent orthogonal maximum  $(K_1)$ , intermediate  $(K_2)$ , and minimum  $(K_3)$  AMS principal axes, respectively, and larger symbols show their mean directions. Shaded areas are 95 % confidence limits of Bingham statistics. Anisotropy parameters posted on the equal-area diagrams are calculated based on Tarling and Hrouda (1993). Generally, ferrofluid impregnation results in enhanced anisotropy degree. In case of low-pressure treatment (upper), AMS trend is more or less similar before and after ferrofluid experiment, whereas high-pressure treatment (lower) results in considerable decrease in  $T$  parameter. It is noted that azimuth of the  $K_1$  axis, which is the most permeable direction, is coincident with regional fault system in central Hokkaido (see Figure 3).

#### **5.2. Tectonic Implication**

It is noted that azimuth of the *K*<sup>1</sup> axis after the high-pressure treatment, which is the most permeable direction in subsurface condition, is coincident with regional fault system in central Hokkaido (see Figure 3). Not only in the intensive collision event during the Kawabata stage, the NNW-SSE fault system has been intermittently activated with dextral slips throughout the Cenozoic era (Kusumoto et al., 2013). Thus the AMS data with ferrofluid treatment may delineate an invisible weakness in rocks in quantitative way.

## Low-pressure treatment

# High-pressure treatment

Figure 9. Three-dimensional maximum intensity projection (MIP) images of ferrofluid-processed specimens generated by OsiriX MD. Original image sequences (601 images per sample) were acquired using HMX225-ACTIS+3 Micro-Focus X-Ray CT Scanner at Center for Advanced Marine Core Research, Kochi University with 30  $\mu$ m spatial resolution.

## **CONCLUSION**

Well-organized magnetic experiments utilizing ferrofluid revealed wide variety in microscopic fabric of sedimentary rocks. Visualized spatial distribution of permeable pore spaces in rocks shows considerable diversity reflecting experimental methods (low or high pressure) and variety in lithologic facies. Figure 9 presents three-dimensional maximum intensity projection (MIP) images of ferrofluid-processed specimens generated by OsiriX MD. It is obvious that efficiency of impregnation differs even in the same site reflecting small-scale structural disturbance, some amount of which should be owing to bioturbation that is delineated by sinuous pathway of the dense fluid. A series of movies (13 files in .mov format each for low- and high-pressure treatments) of micro-focus X-ray CT scanning images  $(601$  per sample at 30  $\mu$ m spatial resolution) are available at OPERA:Osaka Prefecture University Education and Research Archives (http://hdl.handle.net/10466/14732).

#### **ACKNOWLEDGMENTS**

The authors are grateful to N. Ishikawa for the use of the rock-magnetic laboratory at Kyoto University and for thoughtful suggestions in the course of the magnetic analyses. Thanks are also due to Y. Yamamoto and support staffs for their kind backup during experiments at Center for Advanced Marine Core Research, Kochi University. We thank M. Nakano and EOR Group staffs of JAPEX Research Center for their kind collaboration and superb operation during preparation of impregnated samples. This work was supported in part by the Grant-in-aid (No. 25400456) from Japanese Ministry of Education, Culture, Sports, Science and Technology (MEXT).

# **ACTINOBACTERIA FROM MARINE SEDIMENTS: DIVERSITY AND SECONDARY METABOLITES**

## *Khomsan Supong and Somboon Tanasupawat\**

Department of Biochemistry and Microbiology, Faculty of Pharmaceutical Sciences, Chulalongkorn University, Bangkok, Thailand

## **ABSTRACT**

The widely distributed component of marine sediments in many areas such as in USA, Mexico, Bahamas, Papu New Guinea, the Republic of Palau, Guam, Fiji, Chile, Antarctica, Norway Mediterranean, Australia, India, China, Republic of Korea, Japan and Thailand, associated microbial communities represented different taxonomic groups at the phylum level including Acidobacteria, Planctomycetes, Actinobacteria, Gamma-, Alpha -and Delta-proteobacteria based on the 16S rRNA gene sequences and phylogenetic analyses .This divergence was mainly triggered by the dominance of Acidobacteria and Actinobacteria .A majority of Actinobacteria in sediment samples contained predominantly the genera *Streptomyces*, *Micromonospora*, *Actinocorallia*, *Actinomadura*, *Knoellia*, *Glycomyces*, *Nocardia*, *Nocardiopsis*, *Nonomuraea*, *Pseudonocardia*, *Rhodococcus*, *Saccharomonospora*, *Streptosporangium*, *Salinispora*, and *Sciscionella.* Actinomycetes in marine sediments produced a wide variety of secondary metabolites with diverse biological activities. *Streptomyces* strains produced various anti-cancer and anti-tumor bioactive compounds such as actinoranone, chlorizidine, galvaquinones, glucopiericidin, grincamycins, lobophorins, marfuraquinocins, nitropyrrolins,spiroindimicins,strepnonesides and sungsanpin while the rare actinomycetes in genera *Actinoalloteichus*, *Actinomadura*, *Marinactinospora*, *Marinispora*, *Micromonospora*, *Nocardiopsis*, *Saccharomonospora*, *Salinispora*, and *Verrucosispora* produced cyanogrisides, fijiolides, fluostatins, marthiapeptide, marinactinones and nocardiopsins. At present, bioactive metabolite of obligate marine actinomycete, *Salinispora tropica*, salinosporamide A is a potent proteasome inhibitor being used as the anticancer agent that currently being evaluated in phase I clinical trials as monotherapy. Additionally, many compounds firstly reported from marine sediment actinomycetes may be guides for drug discovery, for example, abyssomicin C from

 $\overline{a}$ \* Corresponding Author's Email: Somboon.T@chula.ac.th.; Tel.: +66-2-2188376; Fax: +66-2-2545195.

*Verrucosispora*, showed *in vivo* activity against *Mycobacterium tuberculosis*, and marinomycin A from *Marinispora* is potent antitumor agent with substantial activities against selected human tumor cells and drug-resistant pathogenic bacteria. In this chapter, the isolation, taxonomic approach, diversity, secondary metabolites and activities of actinobacteria are described.

## **1.INTRODUCTION**

The component of marine sediments associated microbial communities represented different taxonomic groups mainly by the dominance of Acidobacteria and Actinobacteria (Polymenakou et al. 2009). The class *Actinobacteria* (Stackebrandt et al. 1997) Grampositive bacteria with a high  $G + C$  content are a well-known source of secondary metabolites and the marine counterparts are proving to be a rich source of novel bioactive compounds (Bérdy, 2005; Fiedler et al. 2005; Blunt et al. 2007). The diversity of actinobacteria in marine habitats is little known based on the description of the first sea-water dependent actinobacterial genus *Salinispora* (Maldonado et al. 2005a) that supports the view of marine ecosystem, an untapped source of microorganisms of economical importance .It is only more recently that marine-derived actinomycetes have become recognized as a source of novel antibiotics and anti-cancer agents with unusual structures and properties (Bredholt et al., 2008). Some of the unusual structures and properties of compounds isolated from marine sources and the fact that 58 %of the isolated actinomycetes from marine sediments collected around Guam in the Pacific ocean required sea water for growth (Jensen et al., 2005) implies that one may find microorganisms adapted to the marine environment and producing compounds not found among microorganisms adapted to the terrestrial sources . Actinomycetes are best known as soil bacteria and were generally believed to occur in the ocean largely as dormant spores that were washed into the sea (Goodfellow and Haynes, 1984).

The distributions and ecological roles of actinomycetes in the marine environment, and the extent to which obligate marine species occur, have remained an unresolved issue in marine microbiology .Recently, Jensen et al. (2005) reported the cultivation from marine sediments of a major new group of marine actinomycetes (originally called MAR1, *Micromonosporaceae*) for which the generic epithet '*Salinospora*' was proposed (Mincer et al., 2002) and later wasrevised to be *Salinispora* gen. nov., which comprised only three species *Salinispora aenicola*, *Salinispora tropica* and *Salinispora pacifica* (Maldonado et al., 2005a; Ahmed et al., 2013). All *Salinispora* strains required seawater and more specifically, sodium for growth indicating a high level of marine adaptation.This new taxon is the source of novel secondary metabolites including salinosporamide A, a potent anticancer agent specifically targeting the 20S subunit of the mammalian proteasome (Feling et al., 2003). The discovery of this taxon provides clear evidence for the existence of autochthonous populations of marine actinomycetes, and the compounds being discovered from them indicate that cultured strains are an important resource for novel secondary metabolites. In addition, the taxon has proven to be a productive source of structurally unique and biologically active secondary metabolites (Feling et al., 2003; Jensen et al., 2005). To enhance the chance of recovering the novel actinobacteria from the sea by improving the selective isolation strategies, sample pretreatments, selective isolation media and the

dereplication of isolate collections can still help us to recover putative novel species from one of the most important biotechnologically microbial groups. Thus, there is evidence that marine actinobacteria represent an autochthonous yet little understood component of the sediment microbial community as well as a useful resource for pharmaceutical discovery.

## **2. SAMPLES COLLECTION,ISOLATION AND CULTIVATION OF ACTINOBACTERIA**

#### **2.1. Samples Collection**

Samples for the selective isolation procedures were taken from various places such as the samples were obtained from the first 1 to 5 cm of sediment by scuba collection at depths of 10 to 40 m, collected at the Bismarck Sea, in Madang Province, the northern coast of Papua New Guinea, and to the Solomon Sea, in Milne Bay Province, and placed in sterile 50-ml conical tubes and the samples were kept at room temperature during the expedition and at 4°C upon return to the laboratory (Magarvey et al., 2004) while the marine sediments from a depth of 300 m was kept under liquid nitrogen until processing (Maldonado et al. 2009). Each wet sediment sample (approximately 50 mg) was used to inoculate on NaST21Cx agar plate supplemented with 25  $\mu$ g of cycloheximide/ml. (Magarvey et al., 2004) as shown in Table 1. Whatman no.1 sterile filter paper disks (precut to fit the agar surface) were placed on the agar, and the sediment material was dispersed evenly on the surfaces of the cellulose disks. The plate was incubated in a humidified chamber at 30°C for 30 to 90 days. Following incubation, selected colonies were streaked on ISP-2 medium (BD Diagnostics, Sparks, MD.) prepared with artificial seawater (ISP-2/ASW) and containing cycloheximide (25  $\mu$ g/ml) and nalidixic acid (25 *µ*g/ml). Mincer et al. (2002) collected the top 1 cm of sediment samples in sterile 50 ml plastic Whirl-Pak bags (NASCO, Modesto, Calif.) by divers using scuba gear. Sediment sample depth ranges, numbers, locations, and dates were as follows: 0 to 30 m, Sea of Cortez, Mexico. The samples were processed as soon as possible after collection (generally, 4 h) using the selective methods of (i) stamping and (ii) dilution and heat shock or both (as described below) and were inoculated onto isolation media (M1 to M5). The dilution-andheat-shock method was carried out as follows: 1 ml of wet sediment was added to 4 ml of sterile seawater, heated for 6 min at 55°C, vigorously shaken, and further diluted (1:4) in sterile seawater, and 50 l of each dilution was inoculated by spreading with a sterile glass rod onto agar-based isolation media. The stamping method was carried out as follows: 10 ml of wet sediment was aseptically placed into a sterile aluminum dish, dried (ca. 24 h) in a laminar flow hood, ground lightly with a pestle, pressed into a sterile foam plug (14 mm in diameter), and inoculated onto agar media by stamping eight or nine times in a circular fashion, giving a serial dilution effect. All media were prepared with 100% filtered natural seawater. Bredholdt et al., (2007) collected the marine sediment samples by scuba divers close to shore outside the Trondheim Biological station, Norway, 63 ′27 'N and 10 ′21-′E.) Only the upper 5 cm of the sediments were collected. The samples including, sample 2: Depth 28 m, fine mud and clay, no vegetation, sample 5: Depth 27 m, fine mud and sand, no vegetation, sample 7: depth 6 m, clay and stones, vegetation, brown layer from sedimented algae and sample 10: depth 4.5 m, fine mud with small stones, upper layer covered with diatom and bacteria, some vegetation.

Sediments from 4.5, 6.0, 27 and 28 m depths were collected by scuba divers, while sediments from 450 m depth were sampled with a box-corer .The upper 5 cm of the sediments were collected in zip-lock bags (scuba) or with a sterile spade (box–corer) and transferred to 1 liter sterile plastic containers (Bredholdt et al., 2008).

#### **2.2. Selective Isolation Procedure**

The wet sample from marine sediment (1 g) of each Gulf, was transferred to a 15 ml centrifuge tube which contained 9 ml of seawater solution (3.5%; Instant Ocean, USA) and 1 g of sterile glass beads  $(710 - 1.180 \text{ lm})$ ; Sigma, USA). Each centrifuge tube was then shaken for 1 h in a blood tube rotator model SB2 at fixed speed (Fischer Scientific, USA). A second and third series of dilutions (1 ml into 9 ml of sea water) were then prepared for each sample ( $10<sup>2</sup>$  and  $10<sup>-3</sup>$ ). The three dilutions were then employed to inoculate ( $100 \mu$ l) a set of selective isolation plates by duplicate (Maldonado et at. 2009). Bredholdt et al. (2007) prepared the samples by aseptically diluting the wet sediment (1 ml each in 9 ml sterile water). The actinobacteria selective treatments were performed on dried sediments (Speed vac. 30°C, 16 h (including dry heat)  $120^{\circ}$ C, 60 min), phenol (1.5%, 30 min at 30 $^{\circ}$ C), dry heat and phenol, dry heat and benzethonium chloride (0.02%, 30 min at 30°C), as well as pollen baiting as previous reported (Hayakawa et at. 1991; Palleroni, 1980). Ten microlitres of the dilution were spread over the surface of isolation media in Petri dishes. Isolation plates were incubated at  $20 - 28$ °C for  $2 - 6$  weeks (Bredholdt et al. 2008; Maldonado et at. 2009). Actinomycetes generally appeared after 2 to 6 weeks of incubation and were considered to be any colony with a tough leathery texture, dry or folded appearance, and branching filaments with or without aerial mycelia. They were detected by eye and by using a binocular microscope (Olympus Optical Co., Ltd, Tokyo, Japan) fitted with a long working distance objective.

Medium 1 (AMM)	Agar, 8 g; starch, 10 g; yeast extract, 4 g; peptone, 2 g in $11$ of natural seawater	Jensen et al., 2005
Medium 2 (NPS)	Noble agar, 8 g; NPS (nutrient poor sediment) extract, 100 ml in 11 of natural seawater. NPS extract was prepared by washing (extracting) 900 ml (wet volume) of sand collected from a high- energy beach with 500 ml of sea water	Jensen et al., 2005
Medium 3 (NRS)	Noble agar, 8 g; NRS (nutrient rich sediment) extract, 100 ml in 11 of natural seawater. NRS extract was prepared as above using 300 ml (wet volume) of sediment collected at low tide from a mangrove channel	Jensen et al., 2005
Medium 5 (SMC)	Noble agar, 8 g; mannitol, 500 mg; casamino acids, 100 mg; nystatin (50 $\mu$ g/ml) in 1 l of natural seawater	Jensen et al., 2005
Medium 4 (SHG)	Noble agar, 8 g; humic acid sodium salt, 100 mg; galactose, 500 mg; nystatin $(50 \mu g/ml)$	Jensen et al., 2005

**Table 1. The isolation media for actinomycetes from marine sediments**

#### **2.3. Media for Selective Isolation**

Mincer et al. (2002) isolated actinomycetes using various media (M1 to M5): M1, 10 g starch, 4 g yeast extract, 2 g peptone, 18 g agar, and 1 liter of natural seawater; M2,6 ml glycerol, 1 g arginine, 1 g  $K_2HPO_4$ , 0.5 g  $MgSO_4$ , 18 g agar, and 1 liter of natural seawater; M3, 6 g glucose, 2 g chitin (United States Biochemical, Cleveland, Ohio), 18 g agar, and 1 liter of natural seawater; M42 g chitin, 18 g agar, and 1 liter of natural seawater; and M5, 18 g agar and 1 liter of natural seawater. All isolation media were amended with filtered (0.2-m pore size) cycloheximide (100 g/ml) and rifampin (5 g/ml), after autoclaving. Mincer et al. (2005) collected marine sediment samples around the islands of the Bahamas .Sediment samples ranged from fine carbonate muds to coral rubble and were collected using SCUBA or a modified, surface deployed sampler. All sediment samples were processed in the field as soon as possible after collection by using desiccation and heat shock as selective cultivation methods. These methods were designed to reduce the numbers of Gram-negative bacteria and to enrich for slow-growing, spore-forming actinomycetes. Treated samples were then inoculated onto medium M1 or M5 (Table 1) and incubated for 4 to 8 weeks at room temperature. Novobiocin (10  $\mu$ g/ml) or rifampin (5  $\mu$ /ml) was added to reduce the number of unicellular bacteria. The antifungal agent cycloheximide (100  $\mu$ g/ml) was added to all isolation media. Enrichment cultures were prepared in 20-ml vials by adding 1.5 g of wet sediment (homogenized and previously frozen) to either 10 ml of seawater enriched with crude chitin (0.1% w/v), 10 ml of sediment extract [SE; autoclaved supernatant from a 0.5% (w/v) sediment-seawater solution], or 10 ml of medium M1 low (0.2% starch, 0.08% yeast extract, 0.04% peptone, seawater). Each of the three enrichment conditions was supplemented with either 5  $\mu$ g of rifampin/ml or 25  $\mu$ g of novobiocin/ml (final concentrations). Similar enrichments were prepared in the field with 0.5 g sediment and one of the following antibiotics (final concentrations): kanamycin (20 *µ*g/ml), novobiocin (10 *µ*g/ml), vancomycin (5  $\mu$ g/ml), gentamicin (2  $\mu$ g/ml), or tetracycline (4  $\mu$ g/ml). All enrichment cultures were incubated for 4 to 15 weeks at room temperature and observed at x10 to x64 magnification using a stereomicroscope. Bacteria that formed visible mycelia were harvested directly from

the enrichment cultures by using a sterile pipette, serially washed three times in 10 ml of sterile seawater, and plated on medium M5.

Jensen et at. (2005) collected shallow sediments from the depths of 1–20 m, Guam Island while the remaining sediments were collected using a modified, surface-deployed sediment sampler to depths of 570 m. All samples were processed within a few hours of collection using a variety of techniques designed to reduce the numbers of Gram-negative bacteria and to enrich for slow-growing, spore-forming actinomycetes. Samples were processed and inoculated onto various agar media [medium 1 to medium 12, [Medium 1 (AMM), Medium 2 (NPS), Medium 3 (NRS), Medium 4 (SHG), Medium 5 (SMC), Medium 6 (SMP), Medium 7 (SNC), Medium 8 (SPC), Medium 8 (SPC), Medium 9 (SRC), Medium 10 (SSC), Medium 11 (STC), Medium 12 (SMY)] (Table 1) using one, or in some cases (especially for the deeper sediments) as many as three, of the eight methods described below. All algal samples were processed using method 1 (with grinding) while all sponges were processed using method 3. Method 1 (dry/stamp). Sediment was dried overnight in alaminar flow hood and, when clumping occurred, ground lightly with an alcohol-sterilized mortar and pestle. An autoclaved foam plug (2 cm in diameter) was pressed onto the sediment and then repeatedly onto the surface of an agar plate in a clockwise direction creating a serial dilution effect. Method 2 (dry/scrape). This method was used for small rocks that had been dried overnight in a laminar flow hood and then scraped with a sterile spatula generating a powder that was processed as per method 1. In some cases, the powder was collected with a wet cotton-tipped applicator or the rock was rubbed directly with the applicator which was then used to inoculate the surface of an agar plate. Method 3 (dry/dilute). Dried sediment (*c* .0.5 g) was diluted with 5 ml of sterile (autoclaved) seawater (SSW). The diluted sample was vortex mixed, allowed to settle for a few minutes, and 50 ml of the resulting solution inoculated onto the surface of an agar plate and spread with an alcohol-sterilized glassrod. Method 4 (dilute/heat). Dried sediment was volumetrically added to 3 ml of SSW (dilutions 1:3 or 1:6), heated to 55°C for 6 min, and 50 – 75 ml of the resulting suspension inoculated onto an agar plate as per method 3. Method 5 (dilute/heat/2). Dried sediment was treated as per method 4 (dilution 1:6) with the addition of a second heat treatment at  $60^{\circ}$ C for 10 min. Method 6 (dry/stamp+dilute/heat). The surface of an agar medium was inoculated using a sample treated as per method 1. The dried sediment was then processed using method 4 and the same agar plate inoculated a second time with the heat-treated samples. Method 7 (freeze/dilute). Wet sediment was frozen at -  $20^{\circ}$ C for at least 24 h, thawed, volumetrically diluted in SSW  $(1:3-1:120$  depending on particle size), and 50 ml of the resulting suspension inoculated onto the surface of an agar plate asper method 3. Method 8 (freeze/dilute/2). Wet sediment was treated as per method 7 except that the thawed and diluted sample was incubated at room temperature for 48 h before inoculation onto the surface of an agar plate. Processed samples were inoculated as described above onto the surface of from one to eight of the following agar media. All media were prepared with 1 l of natural seawater and contained the anti-fungal agents cycloheximide (100 mg/ml) and, when listed, nystatin (50 mg/ml). Inoculated Petri dishes were incubated at room temperature (*c*. 28°C) and monitored periodically over 3 months for actinomycete growth . Actinomycetes were quantified on each plate by eye and with the aid of a Leica MZ6 stereomicroscope  $(x10-x64)$ .

Bredholdt et at. (2007) isolated actinobacteria using the following media: *soil agar*: 1 l of filtered soil extract, 20 g agar, pH 7.0 (soil extract was prepared by mixing 200 g soil in 1 l water, followed by boiling the mixture for 30 min); 1 ml of vitamin complex solution (10.0)
mg of calcium pantothenate, 10.0 mg of nicotinic acid, 1.0 mg of thiamin chloride, 1.0 mg of biotin, 20 ml of tap water) was added into soil agar. *Soil agar* with 3% sea salt added. *Modified organic agar 2 Gause:* 5.0 g of peptone, 3.0 g of tryptone, 10 g of glucose, 5.0 g of NaCl, 1 l of tap water. *Modified organic agar 2 Gause* with 3% sea salt added. *Modified organic agar 2 Gause* supplemented with tobramycin (10 mg/ml) (Terekhova et al., 1991). *Modified organic agar 2* Gause supplemented with rubomycin (5 mg/ml) (Lavrova et al., 1972). *Mineral agar 1 Gause*: 20.0 g of starch-soluble, 0.5 g of K2HPO4, 0.5 g of MgSO4, 1.0 g of KNO3, 0.5 g of NaCl, 0.01 g of FeSO4, 20.0 g of agar, 1 l of tap water. *Soy-bean meal agar*: 3.0 g of soy-bean meal, 0.2 g of KNO<sub>3</sub>, 0.5 g of  $K_2HPO_4$ , 0.4 g of MgSO<sub>4</sub>, 20.0 g of agar, 1 l of distilled water. *Soy-bean meal agar* with 3% sea salt added. *Yeast-corn-starch agar*: 10.0 g of starch-soluble, 10 g of yeast extract, 10.0 g of corn meal extract, 2.0 g NaCl, 20 g of agar, 1 l of water. *Pea-meal agar*: 10.0 g of pea meal, 10.0 g of glucose, 5.0 g of NaCl, 1.0 g of CaCO<sub>3</sub>, 20 g of agar, 1.0 l of tap water. The pH of all media was adjusted to 7.0 – 7.5. Nalidixic acid (10 mg/ml) and nystatin (50 mg/ml) were supplemented to all media to inhibit the growth of Gram-negative bacteria and fungi. For isolation, a variety of methods was used, including the pretreatment of sediment samples with physical factors: UV irradiation (Galatenko and Terekhova, 1990), super high frequency (SHF) radiation (Bulina et al., 1997, 1998), extremely high frequency (EHF) radiation (Li et al., 2002), cold-shock by freezing sediment samples at -18°C. UV-irradiation of the wet sediment suspension (5 ml) was performed in open Petri dishes for 30 s. with the use of UV lamp at emission wavelength of 254 nm and power of 15 W. The distance from the irradiation source was 20 cm. SHF radiation treatment of the suspension (2.5 ml) placed into sterile Eppendorf tubes was carried out in a microwave oven at a frequency of 2460 MHz and power of 80 W for 45 s. EHFradiation treatment of the suspension (5 ml) was carried out in Petri dishes from the bottom. Emitted radiation had a non-thermal intensity and was amplitude-modulated at a frequency of 1 kHz within wavelength band of 8 – 11.5 mm using industrial generator (Russia). In addition, the two-layer soil agar with the following transfer of the upper layer to organic agar 2 Gause was used (Galatenko et al., 2004). Before inoculation agar media in Petri dishes were dried for 30 min to prevent water condensation on agar surface. The isolation plates were incubated at 28°C for 2 weeks. Colonies showing the characteristic appearance of filamentous actinomycetes were selected for isolation and the colonies growing on agar plates were examined under the microscope *in situ* using the long working distance condenser and objectives. Actinomycete colonies were picked up and inoculated onto oatmeal agar slants (40 g oatmeal, 20 g agar, 1 l tap water, pH 7.2.) which were incubated at  $28^{\circ}$ C for  $2 - 3$ weeks.

Bredholdt et al. (2008) reported to use isolation media consisted of the following: IM5 (humic acid agar, Hsu and Lockwood, 1975), with sea water), humic acid  $(1 \text{ g})$ , K<sub>2</sub>HPO<sub>4</sub> (0.5) g), FeSO<sub>4</sub>.7H<sub>2</sub>O (1 mg), agar (20 g), vitamin B solution (1ml), natural sea water (0.5 1) and distilled water (0.5 1); IM6 glycerol (0.5 g), starch (0.5 g), sodium propionate (0.5 g), KNO<sub>3</sub> (0.1 g), asparagine (0.1 g), casein (0.3 g), K<sub>2</sub>HPO<sub>4</sub> (0.5 g), FeSO<sub>4</sub>.7H<sub>2</sub>O (1 mg), agar (20 g), vitamin B solution (1 ml), natural sea water  $(0.5 1)$  and distilled water  $(0.5 1)$ ; IM7 (chitin agar, with sea water) chitin (Sigma),  $K_2HPO_4$  (0.5 g), FeSO $4.7H_2O$  (1 mg), agar (20 g), vitamin B solution  $(1 \text{ ml})$ , natural sea water  $(0.7 \text{ l})$  and distilled water  $(0.3 \text{ l})$ ; IM8, malt extract  $(1 \text{ g})$ , glycerol  $(1 \text{ g})$ , glucose  $(1 \text{ g})$ , peptone  $(1 \text{ g})$ , yeast extract  $(1 \text{ g})$ , agar  $(20 \text{ g})$ , natural sea water (0.5 l) and distilled water (0.5 l). The pH of the isolation media was adjusted to pH 8.2. Vitamin B solution consisted of the following: thiamine-HCl (50 mg), riboflavin (50 mg), niacin (50 mg), pyridoxine-HCl (50 mg), inositol (50mg), Ca-pantothenate (50 mg), p- aminobenzoic acid (50 mg), biotin (25 mg) and distilled water (100 ml). All isolation media were amended with filtered) 0.2-µm pore size (cycloheximide) (50  $\mu$ g/ml), nystatin (75  $\mu$ g/ml) and nalidixic acid (30  $\mu$ g/ml). Seventeen media were used according to well known recipes or from known suppliers (Maldonado et at. 2009) and they were supplemented with nystatin (antifungal; 50 mg/ml) and rifampicin (5 mg/ml). Some media were also supplemented with nalidixic acid (10 mg/ml to diminish the growth of marine bacteria using both distilled and sea water (35 g/1 l; Instant Ocean, USA).

## **3.IDENTIFICATION AND DIVERSITY OF ACTINOBACTERIA**

#### **3.1. Identification Techniques**

Actinomycetes strains were taxonomic studied by employing the polyphasic approach. The isolates were subcultured onto two media, glucose-yeast-malt extract agar (ISP 2 medium; Shirling and Gottlieb 1966), and glucose-yeast extract agar (GYEA; Gordon and Mihm 1962) prepared with normal and sea water, incubated for up to 3 weeks at 28  $^{\circ}$ C and then checked for purity by a light microscope (Maldonado et al., 2009). The suspensions of hyphal fragments or spores of isolates were preserved in 20% glycerol (w/v) at -20 $^{\circ}$ C and -80C for long term maintenance. Morphological grouping assigned the isolates from each sample on the basis of the properties of the colonies (i.e., colour, pigment formation, etc.) when they grew on the solid media. If aerial mycelium or spores were evident, the microorganisms were then also prepared for scanning electron microscopy (SEM) by examining gold-coated, dehydrated material, prepared from up to 28-days-old cultures.

The phenotypic characteristics of isolates compared with the type strains including morphological, cultural, physiological and biochemical characteristics such as carbon utilization, the ability to produce acid from sugars, the temperature tests and the pH tolerance test were determined by following the standard protocol of the International Streptomyces Project (ISP) (Shirling and Gottlieb 1966; Arai, 1975; Williams and Cross, 1971; Gordon et al. (1974).The chemotaxonomic characteristics including the determination of menaquinone (Collins 1977), polar lipid composition of isolate (Minnikin et al. 1984), mycolic acids (Minnikin et al. 1980), the DNA G+C mol% content (Gonzalez and Saiz-Jimenez, 2002) and DNA-DNA hybridization in microdilution-well plates, as reported by Ezaki et al. (1989) were conducted. 16S rRNA gene sequencing analyses was determined using the method of Kim et al. (1999) for which the chromosomal DNA, PCR amplification and direct sequencing of the PCR products of isolates were carried out. The 16S rRNA gene sequence was multiplealigned with selected sequences obtained from the GenBank/EMBL/DDBJ databases by using CLUSTAL W version 1.81 (Thompson et al., 1997). Phylogenetic trees were reconstructed by using the neighbour-joining (Saitou and Nei, 1987), maximum-parsimony (Kluge and Farris, 1969) and maximum-likelihood (Felsenstein, 1981) methods in the program MEGA5.0 (Tamura et al., 2011). The confidence values of nodes were evaluated by using the bootstrap resampling method with 1000 replicates (Felsenstein, 1985).

## **3.2. Diversity of Actinobacteria**

The novel actinomycetes from marine sediments are proposed including *Verrucosispora gifhornensis* HR1-2 T , a new genus, isolated from a peat bog near Gifhorn, Lower Saxony, Germany (Rheims et al., 1998); *Pseudonocardia antarctica* DVS 5a1, isolated from McMurdo Dry Valleys, Antarctica (Prabahar et al., 2003); *Sciscionella marina* SCSIO 00231<sup>T</sup> , gen. nov., sp. nov., isolated from a sediment in the northern South China Sea (Tian et al., 2009); *Verrucosispora sediminis* MS426<sup>T</sup> , from a deep-sea sediment sample of the South China Sea, a cyclodipeptide-producing actinomycete from deep-sea sediment (Dai et al., 2010); *Streptomyces glycovorans* YIM M 10366<sup>T</sup> , *Streptomyces xishensis* YIM M 10378<sup>T</sup> and Streptomyces abyssalis YIM M 10400<sup>T</sup> from marine sediments collected from the Xisha Islands in the South China Sea. (Xu et al., 2012); *Spinactinospora alkalitolerans* CXB654<sup>T</sup> gen. nov. in the family *Nocardiopsaceae*, isolated from marine sediment collected at a depth of 17.5 m near the Yellow Sea Cold Water Mass, China (Chang et al., 2011); *Verrucosispora maris* AB-18-032<sup>T</sup> a novel deep-sea actinomycete isolated from a marine sediment which produced abyssomicins (Goodfellow et al., 2012); *Streptomyces pharmamarensis* PM267<sup>T</sup> isolated from a marine sediment, sediment sample in the Mediterranean Sea (Carro et al., 2012); *Micromonospora sediminicola* SH2-13<sup>T</sup> , isolated from a marine sediment sample collected from the Andaman Sea of Thailand (Supong et al., 2013); *Verrucosispora fiedleri* MG-37, an actinomycete isolated from a fjord sediment which synthesized proximicins (Goodfellow et al., 2013); *Verrucosispora qiuiae*, isolated from mangrove swamp sediment (Xi et al., 2012); *Streptomyces chumphonensis* isolated from marine sediments in Thailand (Phongsopitanun et al., 2014) and *Micromonospora fluostatini* PWB-003<sup>T</sup> , which produced fluostatins B and C antibiotics, isolated from nearshore sediment collected from Panwa Cape, Phuket Province, Thailand (Phongsopitanun et al., 2015).

The distribution of obligate marine bacteria from ocean sediments within the order *Actinomycetales* designated MAR 1 has been reported (Mincer et al., 2002). Actinobacterial populations designed as MAR 1 for *Micromonosporaceae* (*Micromonospora* and *Salinispora*); MAR2 and MAR3 and MAR4 for *Streptomycetaceae* (*Streptomyces* and *Kitasatospora*); MAR5 and MAR6 for *Thermomonosporaceae (Actinomadura*) were described by Jensen et al. (2005) based on the small subunit rRNA (*SSU rRNA) gene sequences* data analysis. Stach et al., 2003 investigated bacterial diversity in a deep-sea sediment, Atlantic ocean deep-sea sediment collected from the edge of the Saharan debris flow near the Canary Islands  $(27^{\circ}02.39^{\circ}N 18^{\circ}29.02^{\circ}W)$  at a depth of 3,814 m using a piston corer during a scientific cruise aboard the RRS Charles Darwin by constructing actinobacterium-specific 16S ribosomal DNA (rDNA) clone libraries from sediment sections taken 5 to 12, 15 to 18, and 43 to 46 cm below the sea floor at a depth of 3,814 m. Clones were placed into operational taxonomic unit (OTU) groups with >99 %16S rDNA sequence similarity; the cutoff value for an OTU was derived by comparing 16S rRNA homology with DNA-DNA reassociation values for members of the class Actinobacteria. The 5- to 12-cm sediment actinobacterium community was dominated by bacteria most closely related to *Streptomyces* species (45%), though OTUs from this sediment section were distributed throughout the phylogenetic tree. OTUs from the 15- to 18-cm sediment section were dominated by bacteria most closely related to *Rhodococcus* species (56%), with only one OTU (M16) being most closely related to a *Streptomyces* species. The 43- to 46-cm

community was also dominated by *Rhodococcus* species (62%), with no *Streptomyces* species present.

Magarvey et al. (2004) reported 102 actinomycetes isolated from subtidal marine sediments collected from the Bismarck Sea and the Solomon Sea off the coast of Papua New Guinea. A combination of physiological parameters, chemotaxonomic characteristics, distinguishing 16S rRNA gene sequences, and phylogenetic analysis based on 16S rRNA genes provided strong evidence for the two new genera (represented by strains of the PNG1 clade and strain UMM518) within the family *Micromonosporaceae* including *Micromonospora* and *Verrucosispora.* Actinobacteria isolated from marine environments have been dominated by *Micromonospora*, *Rhodococcus* and *Streptomyces* species (Maldonado et al., 2005). The dominant actinomycete recovered from marine samples collected around the island of Guam belonged to the seawater-requiring marine taxon *Salinispora*, a new genus within the family *Micromonosporaceae* and two major new clades related to *Streptomyces* spp., tentatively called MAR2 and MAR3, including the new genera within the *Streptomycetaceae* and five new marine phylotypes, including two within the *Thermomonosporaceae* (Jensen et al., 2005). Phylogenetic analysis of 189 representative isolates from sediments collected in the Republic of Palau from the intertidal zone to depths of 500 m., based on 16S rRNA gene sequence data, indicated that 124 (65.6%) belonged to

the class *Actinobacteria* including *Micromonosporaceae*, *Nocardiaceae*, *Nocardioidaceae* and *Streptomycetaceae*, spore-forming strains from the *Pseudonocardiaceae* and *Thermomonosporaceae* while the remaining 65 (34.4%) were members of the class *Bacilli* including *Bacillus*, *Pontibacillus*, *Paenibacillus*, and *Laceyella* (Gontang et al., 2007). *Streptomyces*, *Micromonospora*, *Actinocorallia*, *Actinomadura*, *Knoellia*, *Glycomyces*, *Nocardia*, *Nocardiopsis*, *Nonomuraea*, *Pseudonocardia*, *Rhodococcus* and *Streptosporangium* genera were isolated from the shallow water sediments of the Trondheim fjord (Norway) (Bredholdt et al., 2007). *Actinomadura*, *Dietzia*, *Gordonia*, *Micromonospora*, *Nonomuraea*, *Rhodococcus*, *Saccharomonospora*, *Saccharopolyspora*, *Salinispora*, *Streptomyces*, "*Solwaraspora*" and *Verrucosispora* were isolated from marine sediments samples collected in the Gulf of California and the Gulf of Mexico (Maldonado et al., 2009). Actinobacteria from marine sediments were isolated from the Valparaíso bay, Chile, containing *Aeromicrobium*, *Agrococcus*, *Arthrobacter*, *Brachybacterium*, *Corynebacterium*, *Dietzia*, *Flaviflexus*, *Gordonia*, *Isoptericola*, *Janibacter*, *Microbacterium*, *Mycobacterium*, *Ornithinimicrobium*, *Pseudonocardia*, *Rhodococcus*, *Streptomyces*, *Tessaracoccus* and one isolate as a novel phylogenetic branch related to the *Nocardiopsaceae* family (Claverias et al., 2015). The distribution of actinobacteria in marine-sediment is summarized in Table 2.

## **4. SECONDARY METABOLITES AND BIOLOGICAL ACTIVITY OF ACTINOBACTERIA**

#### **4.1. Secondary Metabolites and Biological Activity of** *Streptomyces*

Marine sediment actinomycete in the genus *Streptomyces* are dominantly found while the rare actinomycetes including genera *Actinoalloteichus*, *Actinomadura*, *Marinactinospora*, *Marinispora*, *Nocardiopsis*, *Saccharomonospora*, *Salinispora* and *Verrucosispora* are isolated. *Streptomyces* strains provided valuable source of new bioactive compounds and biological activity. *S. aureoverticillatus* NPS001583from marine sediment, the strain produced aureoverticillactam, a novel 22-atom macrocyclic lactam, novel anticancer and antiinfective agents (Mitchell et al., 2004). Actinomycete (MAR4) strain CNQ-525 from ocean sediments collected at a depth of 152 m near La Jolla, California produced three new chlorinated dihydroquinones and one previously reported analogue (Soria-Mercado et al., 2005). *S. nodosus* NPS007994 from a marine sediment collected in Scripps Canyon, La Jolla, California, was found to produce lajollamycin a nitro-tetraene spiro-β-lactone-*γ* -lactam antibiotic and showed antimicrobial activity against both drug-sensitive and -resistant Grampositive bacteria and inhibited the growth of B16-F10 tumor cells *in vitro* (Manam et al., 2005). *Streptomyces* sp. NPS008187 from a marine sediment collected in Alaska was found to produce three new pyrrolosesquiterpenes, glyciapyrroles A, B, and C, along with the known diketopiperazines cyclo(leucyl-prolyl), cyclo(isoleucyl-prolyl), and cyclo (phenylalanyl-prolyl) (Macherla et al., 2005).

*Streptomyces* sp. M045 produced two novel antitumor antibiotics, chinikomycins A and B including manumycin A .The compounds exhibited antitumor activity against different human cancer cell lines, but were inactive in antiviral, antimicrobial, and phytotoxicity tests (Li et al., 2005). *Streptomyces* sp. KORDI-3238 from deep-sea sediments produced a new

cytotoxic compound, streptokordin, and four known compounds, nonactic acid, dilactone, trilactone, and nonactin, streptokordin. Streptokordin exhibited significant cytotoxicity against seven human cancer cell lines but showed no growth inhibition against various microorganisms including bacteria and fungi (Jeong et al., 2006). *Streptomyces* sp. QD518 produced a new staurosporinone, *N*-carboxamido-staurosporine, and a new sesquiterpene, (5*S*, 8*S*, 9*R*, 10*S*)-selina-4, 7-diene-8, 9-diol (Wu et al., 2006). A marine-derived actinomyces strain NPS554 from a marine sediment collected from Miyazaki Harbor, Japan, at a depth of 38 m yielded two trialkyl-substituted aromatic acids, lorneic acid A and lorneic acid B. Their structural differences affected inhibition activities against phosphodiesterase 5 (Iwata et al., 2006). *Streptomyces* strain CNQ-085 produced four new cytotoxic compounds, designated as daryamides A, B, and C and (2*E*, 4*E*)*-*7-methylocta-2,4-dienoic acid amide. The daryamides show weak to moderate cytotoxic activity against the human colon carcinoma cell line HCT-116 and very weak antifungal activities against *Candida albicans* (Asolkar et al., 2006).

*Streptomyces* sp. CNH990 from marine sediment produced two new cytotoxic quinones of the angucycline class, marmycins A and B. Marmycin A displayed significant cytotoxicity against several cancer cell lines, some at nanomolar concentrations; while compound B, a chloro analogue of A, was less potent. For marmycin A, tumor cell cytotoxicity appeared to coincide with induction of modest apoptosis and arrest in the G1 phase of the cell cycle (Martin et al., 2007). *Streptomyces* sp. KORDI-3973 isolated from the deep sea sediment produced streptopyrrolidine, abenzyl pyrrolidine derivative that exhibited significant antiangiogenesis activity (Shin et al., 2008). *Streptomyces* sp. CNQ-418 furnished the marinopyrroles A and B that possess potent antibiotic activities against methicillin resistant *Staphylococcus aureus* (Hughes et al., 2008). *Streptomyces*. sp. CNQ-617 produced two novel spiroaminals, marineosins A and B, containing two pyrrole functionalities, showed significant inhibition of human colon carcinoma (HCT-116) in an in vitro assay (IC<sub>50</sub>) 0.5  $\mu$ M for marineosin A) and selective activities in diverse cancer cell types (Boonlarppradab et al., 2008). *Streptomyces* sp. 17944 produced three new tirandamycins (TAMs), TAM E, F, and G, along with TAM A and B, that 5 selectively inhibits the *Brugia malayi* AsnRS and efficiently kills the adult *B. malayi* parasite, representing a new lead scaffold to discover and develop antifilarial drugs.

*Streptomyces* sp. 307-9 produced the novel dienoyl tetramic acids tirandamycin C and tirandamycin D with activity against vancomycin-resistant *Enterococcus faecalis* and also the previous compounds tirandamycins A and B (Carlson et al., 2009; Yu et al., 2011). *Streptomyces albidoflavus* NTK 227 from Atlantic Ocean sediment produced albidopyrone, a new  $\alpha$ -pyrone-containing secondary metabolite and found to have a moderate inhibitory activity against protein-tyrosin phosphatase B (Hohmann et al., 2009a). *Streptomyces* sp. NTK 937 produced caboxamycin, a new benzoxazole antibiotic which inhibited against Gram-positive bacteria, selected human tumor cell lines and the enzyme phosphodiesterase (Hohmann et al., 2009b). *Streptomyces* sp. Sp080513GE-23 isolated from a sponge-derived actinomycete, produced tetrapeptides possessing a unique skeleton, JBIR-34 and JBIR-35 (Motohashi, et al., 2010). Actinomycete strain CNQ-509 produced five new farnesyl-*R*nitropyrroles, nitropyrrolins  $A - E$ , several of the nitropyrrolins, nitropyrrolin D in particular, are cytotoxic toward HCT-116 human colon carcinoma cells, but show weak to little antibacterial activity against methicillin-resistant *Staphylococcus aureusus* (MRSA) (Kwon et al., 2010). *Streptomyces tumescens* YM23-260 produced two peptides, tumescenamides A and B. Tumescenamide A induced reporter gene expression under the control of the insulindegrading enzyme promoter (Motohashi et al., 2010).

*Streptomyces* sp. CNQ-027 produced three highly modified peptides, actinoramides A C (Nam et al., 2011). *Streptomyces antibioticus* H74-18 produced antimycins A<sup>19</sup> and A20, two new antimycins. All the antimycins showed potential antifungal activities against *Candida albicans* with MIC of about 5 – 10 *μ*g/ml (Xu et al., 2011). *Streptomyces* sp. CNS-575 produced fijimycins  $A - C$ , three antibacterial etamycin-class depsipeptides. Fijimycins  $A - C$ , and etamycin A, were shown to possess significant in vitro antibacterial activity against three methicillin-resistant *Staphylococcus aureus* (MRSA) strains with MIC 100 values between 4 and 16  $\mu$ g/ml) Sun et al., 2011). *Streptomyces* sp. SCSIO 01127, isolated from the South China Sea sediment, produced two new spirotetronate antibiotics lobophorins E and F, along with two known analogs lobophorins A and B. The new compound lobophorin F showed antibacterial activities against *Staphylococcus aureus* ATCC 29213 and *Enterococcus faecalis* ATCC 29212 with MIC values of 8 *μ*g/ml for both the strains, better than that of lobophorin B. Lobophorin Falso displayed better cytotoxic activities than lobophorin B, with IC<sup>50</sup> of 6.82, 2.93 and 3.16 *μ*M against SF-268, MCF-7 and NCI-H460, respectively (Niu et al., 2011). *Streptomyces* sp. NPS853 from marine sediments, it produced new anthramycin-type analogues, designated usabamycin  $A - C$ . The usabamycins show weak inhibition of HeLa cell growth and selective inhibition of serotonin (5 hydroxytrypamine) 5-HT2B uptake (Sato et al., 2011).

*Streptomyces spinoverrucosus* SNB-032producedfour new anthraquinone analogues including galvaquinones  $A - C$  and an isolation artifact, 5,8-dihydroxy-2,2,4-trimethyl-6-(3methylbutyl- anthra[9,1-de[]1,3]oxazin-7(2*H*)-one. Galvaquinone B was found to show epigenetic modulatory activity at 1.0  $\mu$ M and exhibited moderate cytotoxicity against nonsmall-cell lung cancer (NSCLC) cell lines Calu-3 and H2887 (Hu et al., 2012). *Streptomyces lusitanus* SCSIO LR32, an actinomycete of deep sea origin produced five new *C*-glycoside angucyclines, named grincamycins  $B - F$ , and a known angucycline antibiotic, grincamycin, grincamycin (Huang et al., 2012). A deep-sea-derived *Streptomyces* sp. SCSIO 03032 produced a new bisindole alkaloids spiroindimicins  $A - D$ . Spiroindimicins  $B - D$  with a [5, 5] spiro-ring exhibited moderate cytotoxicities against several cancer cell lines (Zhang et al., 2012). *Streptomyces* sp. WBF-16 produced two new anthraquinone glycosides strepnoneside A and strepnoneside B, together with chromomycin A3. Chromomycin A3 exhibited cytotoxic activities against HCT 116 cell lines  $(IC_{50} = 300 \pm 11 \text{ pM})$  (Lu et al., 2012). *Streptomyces* sp. FMA produced streptocarbazoles A and B, two novel indolocarbazoles. Streptocarbazoles A was cytotoxic on HL-60 and A-549 cell lines and could arrest the cell cycle of Hela cells at the G2/M phase (Fu et al., 2012).

*Streptomyces* sp. CNQ-027 isolated from marine sediment sample collected at a depth of 50 m of the coast of Diego, CA produced a new meroterpenoid, actinoranone that exhibited significantly cytotoxic to HCT-116 human colon cancer cells with an  $LD_{50}2.0 \mu g/ml$ , anticancer and tumor cell lines (Nam et al., 2013). *Streptomyces* sp. TP-A0867 from marine sediment sample collected at a depth 38 m near Miyazaki Harbor, Japan, produced akaeolide, a novel polycyclic polyketide, anti-bacteria and cytotoxicity (Igarashi et al., 2013). *Streptomyces* sp. CNH-287 produced chlorizidine, a cytotoxic 5*H*-pyrrolo [2,1-*a*] isoindol-5 one containing alkaloid, cytotoxicity against HCT-116 human colon cancer cells (Alvarez-Mico et al., 2013). *Streptomyces* sp. 7-145, had the potential to produce glycosidic antibiotic,

an elaiophylin derivatives showed good antibacterial activity against methicillin-resistant *Staphylococcus aureus* and vancomycin-resistant enterococci pathogens (Wu et al., 2013). *Streptomyces* sp. CNT-372 from Fiji produced farnesides A and B, sesquiterpenoid nucleoside ethers. Farneside A exhibited modest antimalarial activity against the parasite *Plasmodium falciparum* (Iland et al., 2013). *Streptomyces niveus* SCSIO 3406 from a South China Sea sediment sample obtained from a depth of 3536 m produced four new sesquiterpenoid naphthoquinones, marfuraquinocins  $A - D$ , and two new geranylated phenazines, phenaziterpenes A and B. Marfuraquinocins exhibited antibacterial activities against *Staphylococcus aureus* ATCC 29213 (Song, et al., 2013). *Streptomyces* sp. RJA2928 obtained from a tropical marine sediment, produced nahuoic acid A, a selective SAMcompetitive inhibitor of the histone methyltransferase SETD8 (Williams et al., 2013). In addition, nahuoic acids  $B - E$  were produced by the marine *Streptomyces* sp. SCSGAA 0027 (Nong et al., 2016), and were found in the strain RJA2928 (Williams et. al., 2016). Nahuoic acid  $B - E$  showed weak antibiofilm activity against Shewanella onedensis MR-1 biofilm. *Streptomyces* sp. SNJ013 isolated from deep-sea sediment collected off Jeju Island, Korea, produced sungsanpin, a new 15-amino-acid peptide. Sungsanpin displayed inhibitory activity in a cell invasion assay with the human lung cancer cell line A549 (Um et al., 2013). *Streptomyces* sp. JAMM992 produced surugamides A − E, cyclic octapeptides with four *D*-amino acid residues (Takada et al., 2013). The metabolites and biological activity of *Streptomycetes* from marine sediments that published on 2010-2016, are summarized in Table 3.

#### **4.2. Secondary Metabolites and Biological Activity of Rare Actinomycetes**

Rare actinomycetes are promising sources in search for new drugs, and their potential for producing biologically active molecules, were studied (Bredholdt et al., 2007). A wide variety of secondary metabolites from marine sediment actinomycetes were used in clinical therapy, and some compounds were originally guided for chemical synthesis such as salinosporamide A, isomeric abyssomicin C, and marinomycin A (Endo and Danishefsky et al., 2005; Nicolaou and Harrison, 2007; Nishimaru et al., 2014). For marine natural products, salinosporamide A is a chlorinated polyketide metabolite that belongs to the class of  $\beta$ lactones. The compound is a potent proteasome inhibitor being used as the anticancer agent .It was produced by obligated marine actinomycete, *Salinispora tropica* which was originally isolated from marine sediments (Feling et al., 2003). This compound is currently being evaluated in phase I clinical trials as monotherapy and in combination with dexamethasome in patients with relapsed/refractory MM. Furthermore, the combination therapy of salinosporamide A studies bearing minimally cytotoxic synergistic effects in MM, leukemia, and lymphoma cell lines, this combination significantly decreased viability in tumor cells from five relapsed MM patients and reduced tumor growth in human MM xenograft mouse model without any noticeable toxicity (Chauhan et al., 2008; Gulder and Moore, 2010).

Atrop-abyssomicin C is the polycyclic polyketide antibiotic that is atropisomer of abyssomicin C. This abyssomicin isomer is produced by the strain in genus *Verrucosispora* (Bister et al., 2004; Riedlinger et al., 2004; Keller et al., 2007). For the abyssomicin C initially discovered with activity against  $\rho$ -aminobenzoate ( $\rho$ ABA) in Gram-positive bacteria *Bacillus subtilis* and *Staphylococcus aureus* (Bister et al., 2004; Riedlinger et al., 2004), in addition, it showed *in vivo* activity against *Mycobacterium tuberculosis* (Freundlich et al., 2010). Marinomycin A is potent antitumor agent with substantial activities against selected human tumor cells and drug-resistant pathogenic bacteria .This compound derived from marine actinomycete *Marinispora* that isolated from the marine sediments (Kwon et al., 2006). Marinomycin A has highly enhanced *in vitro* activity against six of eight melanoma cell lines, with SK-MEL-5 showing the highest sensitivity (concentration lethal to 50 %of animals tested that showed the LC<sub>50</sub> at 5.0 *n*M. Marinomycin A also inhibits the growth of human pathogenic bacteria with a minimum inhibitory concentration (MIC) value of 0.1 *μ*M against methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant *Enterococcus faceium* (VREF). Unfortunately, these polyenes are highly photoreactive and undergo polyene isomerization under room light. This reactivity and general long-term instability detracts from their potential for clinical development. The chemical structure of bioactive substances from marine sediment-derive actinomycetes was shown in Figure 1.

Recently, the diversity of rare actinomycetes from sediments and the secondary metabolites with diverse biological activities have been investigated (Bredholdt et al., 2007).

*Marinactinospora thermotolerans* SCSIO 00652 from the deep South China Sea was found to produce a new sequential tristhiazole-thiazoline-containing cyclic peptide, marthiapeptide A that exhibited antibacterial activity against a panel of Gram-positive bacteria, with MIC values ranging from 2.0 to 8.0 *μ*g/ml, and displayed strong cytotoxic activity against a panel of human cancer cell lines with IC50 values ranging from 0.38 to 0.52 μM (Zhou et al., 2012). This strain produced four new *β*-carboline alkaloids, designated marinacarbolines A-D, two new indolactam alkaloids, 13-*N*-demethyl-methylpendolmycin and methylpendolmycin-14-*O*-*α*-glucoside, and the three known compounds 1-acetyl-*β*carboline, methylpendolmycin, and pendolmycin .The new alkaloid compounds were inactive against a panel of eight tumor cell lines  $(IC_{50} > 50 \mu M)$  but exhibited antiplasmodial activities against *Plasmodium falciparum* lines 3D7 and Dd2, with IC<sub>50</sub> values ranging from 1.92 to 36.03 *μ*M (Huang et al., 2011).

*Micromonospora rosaria* SCSIO N160 from a South China Sea sediment was found to produce three new fluostatins,  $I - K$  together with six known compounds, fluostatins  $C - F$ , rabelomycin and phenanthroviridone .Rabelomycin and phenanthroviridone exhibited good antimicrobial activities against *Staphylococcus aureus* ATCC 29213 with MIC values of 1.0 and 0.25 *μ*g/ml, respectively. Phenanthroviridone also exhibited significant in vitro cytotoxic activities toward SF-268 (IC<sub>50</sub> 0.09  $\mu$ M (and MCF-7 (IC<sub>50</sub> 0.17  $\mu$ M ((Zhang et al., 2012). The marine *Actinomadura* sp. 007 produced the compound ZHD-0501, a novel naturally occurring staurosporine analog showing anticancer activity *in vitro* (Han et al., 2005).

*Actinoalloteichus cyanogriseus* WH1-2216-6, a mutant could produce three new acyclic bipyridine glycosides, cyanogrisides  $E - G$ , and a known cyanogriside H. Cyanogrisides F and G showed cytotoxicities against HCT116 and HL-60 cells, in addition all cyanogriside derivatives showed cytotoxic on K562 cells (Fu et al., 2011). *Actinoalloteichus* sp .NPS702 from marine sediment collected from Usa Bay, Kochi Prefecture, Japan, the strain produced nine new 26-membered macrolides of the oligomycin subfamily, neomaclafungins  $A -$ I.These compounds exhibited significant antifungal activity *in vitro* against *Trichophyton mentagrophytes* ATCC 9533 with MIC values between 1 and 3  $\mu$ g/ml (Sato et al., 2012). *Marinispora* sp. NPS12745 from a marine sediment collected off the coast of San Diego, California. Strain NPS12745 produced a series of chlorinated bisindole pyrroles, lynamicins A E, which showed broad-spectrum biological activity against both Gram-positive and Gram-negative bacteria. Significantly, these compounds were active against drug-resistant pathogenic bacteria such as methicillin-resistant *Staphylococcus aureus* and vancomycinresistant *Enterococcus faecium* (McArthur et al., 2008). Marine-derived *Marinispora* sp. NPS008920 from a sediment collected in Cocos Lagoon, Guam, produced a series of novel 2 alkylidene -5-alkyl-4-oxazolidinones, lipoxazolidinone A, B, and C. Lipoxazolidinones  $A - C$ showed broad spectrum antimicrobial activity similar to that of the commercial antibiotic linezolid (Zyvox), a 2-oxazolidinone .Hydrolysis of the amide bond of the 4-oxazolidinone ring of A resulted in loss of antibacterial activity. The 2-alkylidene-4-oxazolidinone represents a new antibiotic pharmacophore and is unprecedented in nature (Macherla et al., 2007).

Figure 1. Chemical structure of bioactive metabolites from marine actinomycetes.

*Saccharomonospora* sp.CNQ490 from marine sediments collected at the mouth of the La Jolla Submarine Canyon, produced the unprecedented alkaloid lodopyridone .This compound is cytotoxic to HCT-116 human colon cancer cells with  $IC_{50}$ , 3.6  $\mu$ M (Maloney et al., 2009). For the obligae marine actinomycete, *Salinispora tropica* CNB-392 produced the potent proteasome inhibitor salinosporamide A and their seven related γ-lactams. The most important of these compounds were a decarboxylated pyrrole analogue, salinosporamide B. The new *structure*-*activity relationships* (SAR) data for eight compounds, derived from extensive testing against the human colon carcinoma HCT-116 and the 60-cell-line panel at the NCI, indicate that the chloroethyl moiety plays a major role in the enhanced activity of salinosporamide A (Felling et al., 2003; Williams et al., 2005). *Salinispora* sp. CNS103 produced cyanosporasides A and B, chloro -and cyano-cyclopenta[a]indene glycosides (Oh et al., 2006). *Salinispora arenicola* CNR-005 has led to the isolation of two unusual bicyclic polyketides, saliniketals A and B. Saliniketals A and B were found to inhibit ornithine decarboxylase induction, an important target for the chemoprevention of cancer with  $IC_{50}$ values of  $1.95 \pm 0.37$  and  $7.83 \pm 1.2$   $\mu$ g/ml, respectively (Williams et al., 2007). *Salinispora arenicola* strain produced three new macrolide polyketides designated arenicolides  $A - C$ (Williams et al., 2007). *Salinispora pacifica* strain led to the discovery of four new polyketides, salinipyrones  $A - B$ , and pacificanones A and B (Oh et al., 2008). *Verrucosispora* sp. MG-37 produced proximicin A, B and C, novel aminofuran antibiotic that showed anticancer compounds. Proximicins showed a weak antibacterial activity but a strong cytostatic effect to various human tumor cell lines (Fiedler et al., 2008). *Verrucosispora* sp. AB-18-032 could be produced abyssomicins G and H and atrop-Abyssomicin C (Keller et al., 2007).

*Nocardiopsis dassonvillei* HR10-5 produced three new α-pyrones, nocapyrones E − G, and three new diketopiperazine derivatives, nocazines  $A - C$ , together with a new oxazoline compound, nocazoline A. Nocapyrones  $E - G$  showed modest antimicrobial activity against *Bacillus subtilis* with MIC values of 26, 14, and 12  $\mu$ M, respectively (Fu et al., 2011). *Nocardiopsis lucentensis* CNR-712 produced four new 3-methyl-4-ethylideneprolinecontaining peptides, lucentamycins  $A - D$ . Lucentamycins A and B showed significant *in vitro* cytotoxicity against HCT -116 human colon carcinoma (Cho et al., 2007). *Nocardiopsis* strain CNS-653 produced fijiolide A, a potent inhibitor of TNF-R-induced NFκB activation, along with fijiolide B. Fijiolide A is viewed as a promising lead for more advanced anticancer testing (Nam et al., 2010). *Nocardiopsis* sp. CNQ115 from marine sediments collected off the coast of southern California**,** produced two new 4-aminoimidazole alkaloids, nocarimidazoles A and B (Leutou et al., 2015). *Nocardiopsis* sp. CMB-M0232from marine sediment collected off the coast of South Molle Island, Queensland, Australia, yielded two new examples of rare prolinyl-macrolactam polyketides, nocardiopsins C and D, a new highly substituted a-pyrone polyketide, nocardiopyrone A, and the previously reported macrolide polyketides nocardiopsins A and B. PCR amplification of CMB-M0232 genomic DNA revealed the presence of type I and type II polyketide synthase and nonribosomal peptide synthase domains (Raju et al., 2013). The metabolites and biological activity of rare actinomycetes from marine sediments that published on 2010-2016, are summarized in Table 4.

## **CONCLUSION**

Actinobacteria can be recovered from marine sediments like in the terrestrial soils and play important roles in the decomposition of recalcitrant organic matter in the sea floor. They become recognized as a source of novel antibiotics and anti-cancer agents. A rich biodiversity of culturable actinobacteria recovered from marine sediments belonged to genera *Streptomyces*, *Micromonospora*, *Actinocorallia*, *Actinomadura*, *Knoellia*, *Glycomyces*, *Nocardia*, *Nocardiopsis*, *Nonomuraea*, *Pseudonocardia*, *Rhodococcus*, *Streptosporangium* and *Salinispora.Streptomyces* strains produced diverse core structure of metabolites such as peptides, meroterpenoid, carbocyclic polyketide, chlorinatednitrogen-containing carbon skeleton, lactonemacrolide, sesquiterpenoid nucleoside ether, depsipeptide, piericidin glucoside, anthraquinone, spirotetronate glycoside, sesquiterpenoid-naphthoquinone, farnesyl-α-nitropyrrole, bisindole alkaloid, indolocarbazole, dienoyl tetramic acid, pyrrolobenzodiazepine while the rare actinomycetes, *Actinoalloteichus*, *Marinactinospora*, *Micromonospora*, *Actinoalloteichus*, *Saccharomonospora*, *Salinispora*, and *Nocardiopsis* strains produced cyclic bipyridine glycoside, chloroaromatic glycoside, cyclic peptide, *β*carboline alkaloid, *α*- and *γ*-pyrones, macrolactone, and lactam polyketide bioactive compounds. To investigate the marine-derived actinomycetes in the world of diverse ecological habitats as the resource for biotechnology, one must understand the extent to which they are capable of growth in the ocean, the degree to which they display specific marine adaptations and the extent to which these adaptations have affected secondary metabolite production.

Assessment of heavy metal contamination in the marine environment of the Arabian Gulf LCCN: 2012048209 Personal name: Naser, Humood Abdulla. Main title: Assessment of heavy metal contamination in the marine environment of the Arabian Gulf / Humood Abdulla Naser. Published/Produced: Hauppauge, New York: Novinka, [2013] Description: viii, 99 pages: color illustrations, maps; 23 cm. ISBN: 9781624176197 (soft cover) LC classification: GC1451 .N36 2013 Contents: General Introduction -- Valued Ecosystem Components in the Arabian Gulf -- Anthropogenic Sources of Heavy Metals in the Arabian Gulf -- Heavy Metal Levels in Algal Species from the Arabian Gulf -- Heavy Metal Levels in Molluscs from the Arabian Gulf -- Heavy Metal Levels in Fish Species from the Arabian Gulf -- Heavy Metal Concentrations in Seawaters from the Arabian Gulf -- Heavy Metal Concentrations in Sediments from the Arabian Gulf -- Macrobenthic Community Structure as a Bioindicator for Heavy Metal Contamination -- Spatial Distribution of Heavy Metals in Marine Sediments Influenced by Landbased Anthropogenic Sources in Bahrain: A Case Study -- Management of Heavy Metals in the Arabian Gulf -- Conclusions and Recommendations. Subjects: Marine pollution--Persian

Gulf. Heavy metals--Environmental aspects--Persian Gulf. Persian Gulf-- Environmental conditions. Notes: Includes bibliographical references and index. Series: Environmental Health-Physical, Chemical and Biology Factors

Carbonates: sedimentology, geographical distribution and economic importance LCCN: 2013036362 Main title: Carbonates: sedimentology, geographical distribution and economic importance / Bailey A. Hughes and Thompson C. Wagner, editors. Published/Produced: New York: Novinka, [2013] ©2013 Description: ix, 93 pages: illustrations, map; 23 cm. ISBN: 9781629481784 (soft cover) LC classification: QE471.15.C3 C393 2013 Related names: Hughes, Bailey A., editor of compilation. Wagner, Thompson C., editor of compilation. Subjects: Carbonates. Marine sediments. Notes: Includes bibliographical references and index. Series: Chemical engineering methods and technology Geology and mineralogy research developments

Deep-marine systems: processes, deposits, environments, tectonics and sedimentation LCCN: 2015007967 Personal name: Pickering, K. T. (Kevin T.) Main title: Deep-marine systems: processes, deposits, environments, tectonics and sedimentation / by Kevin T. Pickering & Richard N. Hiscott; with contribution from Thomas Heard. Published/Produced: Chichester, West Sussex; Hoboken, NJ: John Wiley & Sons Inc., [2015] Description: pages cm ISBN: 9781118865491 (cloth) 9781405125789 (pbk.) LC classification: GC380.15 .P54 2015 Related names: Hiscott, Richard N. Subjects: Marine sediments. Plate

tectonics. Notes: Includes bibliographical references and index. Additional formats: Online version: Pickering, K. T. (Kevin T.) Deepmarine systems Chichester, West Sussex; Hoboken, NJ: John Wiley & Sons Inc., [2015] 9781118865422 (DLC) 2015017033

Marine geochemistry LCCN: 2012010712 Personal name: Chester, R. (Roy), 1936- Main title: Marine geochemistry / Roy Chester and Tim Jickells. Edition: 3rd ed. Published/Created: Hoboken, NJ: John Wiley & Sons, c2012. Description: vii, 411 p., [12] p. of plates: ill. (some col.), maps (some col.); 26 cm. ISBN: 9781118349076 (cloth) 9781405187343 (pbk.) LC classification: GC111.2 .C47 2012 Related names: Jickells, T. D. (Tim D.) Subjects: Chemical oceanography. Marine sediments. Geochemistry. Notes: Includes bibliographical references and index.

Marine tephrochronology LCCN: 2014451556 Main title: Marine tephrochronology / edited by W.E.N. Austin, P.M. Abbott, S.M. Davies, N.J.G. Pearce and S. Wastegård. Published/Produced: London: The Geological Society, 2014. Description: 213 pages: illustrations (some color), maps (some color); 26 cm. ISBN: 9781862396418 1862396418 LC classification: QE527.56 .M37 2014 Related names: Austin, W. E. N. (William E. N.), editor. Abbott, P. M. (Peter M.), editor. Davies, S. M. (Siwan M.), editor. Pearce, N. J. G., editor. Wastegard, S., (Stefan), editor. Abstract: This Special Publication includes articles presenting recent advances in marine tephrochronological studies and outlines innovative techniques in geochemical

fingerprinting, stratigraphy and the understanding of depositional processes. It represents a significant resource for the palaeoceanographic community at a time when marine tephrochronology is being more widely recognized. It will also serve as a valuable reference to a much wider community of Earth scientists, climate scientists and archaeologists, particularly in highlighting the role of tephra studies in stratigraphy and regional/extra-regional correlations, as well as in tracing the long-term history of regional and global volcanism in the deep-sea archive. Contents: Marine tephrochronology: an introduction to tracing time in the ocean / W.E.N. Austin, P.M. Abbott, S. Davies, N.J.G. Pearce and S. Wastegård -- Marine tephrochronology: a personal perspective / D.J. Lowe -- Preparation of micro- and crypto-tephras for quantitative microbeam analysis / M. Hall and C. Hayward -- Microbeam methods for the analysis of glass in finegrained tephra deposits: a SMART perspective on current and future trends / N.J.G. Pearce, P.M. Abbott, and C. Martin-Jones -- Physical characteristics of tephra layers in the deep sea realm: the Campanian Ignimbrite eruption / S.L. Engwell, R.S.J. Sparks and S. Carey -- Identification of a MIS6 age (c. 180 ka) Icelandic tephra within NE Atlantic sediments: a new potential chronostratigraphic marker / F.D. Hibbert, S. Wastegård, R/ Gwynn and W.E.N. Austin -- Marine Ash Zone IV: a new MIS 3 ash zone on the Faroe Islands margin / S. Wastegård and T.L. Rasmussen -- North Atlantic marine radiocarbon reservoir ages through Heinrich event H4: a new method for marine age model construction / J. Olsen, T.L. Rasmussen and P.J. Reimer -- Last millennium dispersal of air-fall

tephra and ocean-rafted pumice towards the north Icelandic shelf and the Nordic seas / G. Larsen, J. Eiríksson and E.R. Gudmundsdóttir -- Iceberg-rafted tephra as a potential tool for the reconstruction of ice-sheet processes and ocean surface circulation in the glacial North Atlantic / M. Kuhsk, W.E.N. Austin, P.M. Abbott and D.A. Hodell -- Holocene tephra from Iceland and Alaska in SE Greenleaf shelf sediments / A. Jennings, T. Thordarson, K. Zalzal, J. Stoner, C. Hayward, Á. Geirsdóttir and G. Miller - - Quantifying bioturbation of a simulated ash fall event / J.A. Todd, W.E.N. Austin and P.M. Abbott. Subjects: Tephrochronology. Marine sediments. Submarine geology. Paleoceanography. Volcanic ash, tuff, etc. Notes: Includes bibliographical references and index. Series: Geological Society special publication, 0305-8719; no. 398 Geological Society special publication; no. 398.

Organic compounds in soils, sediments & sludges: analysis and determination LCCN: 2012036581 Main title: Organic compounds in soils, sediments & sludges: analysis and determination / [editor], T. Roy Crompton, Retired, UK Rivers Authority, UK. Published/Produced: Boca Raton: CRC Press, Taylor & Francis Group, [2013] Description: xii, 263 pages: illustrations; 26 cm ISBN: 9780415644273 (Hbk: alk. paper) LC classification: S592.6.O73 O74 2013 Related names: Crompton, T. R. (Thomas Roy) Subjects: Soils--Organic compound content. Marine sediments. Soil pollution--Measurement. Sewage sludge. Organic water pollutants-- Measurement. Notes: "A Balkema Book." Includes bibliographical references and index.

Principles of tidal sedimentology LCCN: 2011939475 Main title: Principles of tidal sedimentology / Richard A. Davis, Jr., Robert W. Dalrymple, editors. Published/Produced: Dordrecht; New York: Springer, [2012] Description: xv, 621 pages: illustrations (some color), maps; 27 cm ISBN: 9789400701229 (hbk) 9400701225 (hbk) 9400701233 (e-book) 9789400701236 (e-book) LC classification: QE471 .P748 2012 Related names: Davis, Richard A., Jr., 1937- Dalrymple, Robert W. (Robert Walker) Subjects: Sedimentology. Marine sediments. Notes: Includes bibliographical references and index.

Reconstructing Earth's climate history: inquiry-based exercises for lab and class LCCN: 2011039577 Main title: Reconstructing Earth's climate history: inquiry-based exercises for lab and class / Kristen St John... [et al.]. Published/Created: Hoboken, N.J.: Wiley, 2012. Description: xlii, 485 p.: ill. (some col.), maps (some col.); 29 cm. Links: Cover image http://catalogimages.wiley.com/images/ db/jimages/9780470658055.jpg ISBN: 9780470658055 (hbk.) 9781118232941 (pbk.) LC classification: QC884 .R428 2012 Related names: St. John, Kristen. Summary: "The context for understanding global climate change today lies in the records of Earth's past. This is demonstrated by decades of paleoclimate research by scientists in organizations such as the Integrated Ocean Drilling Program (IODP), the Antarctic Geological Drilling Program (ANDRILL), and many others. The purpose of this book is to put key data and published case studies of past climate change at your fingertips, so that you can experience the nature of paleoclimate reconstruction. Using

foundational geologic concepts you will explore a wide variety of topics in this book, including: marine sediments, age determination, stable isotope paleoclimate proxies, Cenozoic climate change, climate cycles, polar climates, and abrupt warming and cooling events. You will evaluate published scientific data, practice developing and testing hypotheses, and infer the broader implications of scientific results. It is our philosophy that addressing how we know is as important as addressing what we know about past climate change. Making climate change science accessible is the goal of this book. Readership: earth science students at a variety of levels studying paleoclimatology, oceanography, Quaternary science, or earth-system science"-- Provided by publisher. "This project integrates scientific ocean drilling data and research (DSDP-ODP-IODPANDRILL) with education"-- Provided by publisher. Contents: Machine generated contents note: The Authors Acknowledgments Book Introduction for Students and Instructors Geologic Timescale Chapter 1. Introduction to Paleoclimate Records. Part 1.1. Archives and Proxies Part 1.2. Owens Lake - An Introductory Case Study of Paleoclimate Reconstruction Part 1.3. Coring Glacial Ice and Seafloor Sediments Chapter 2. Seafloor Sediments. Part 2.1. Sediment Predictions Part 2.2. Core Observations and Descriptions Part 2.3. Sediment Composition Part 2.4. Geographic Distribution and Interpretation Chapter 3. Microfossils and Biostratigraphy. Part 3.1. What are Microfossils? Why are they Important in Climate Change Science? Part 3.2. Microfossils in Deepsea Sediments Part 3.3. Application of Microfossil First and Last Occurrences

Part 3.4. Using Microfossil Datums to Calculate Rates Part 3.5. How Reliable are Microfossil Datums? Chapter 4. Paleomagnetism and Magnetostratigraphy. Part 4.1. Earth's Magnetic Field Today and the Paleomagnetic Record of Deep-Sea Sediments Part 4.2. Paleomagnetism in Ocean Crust Part 4.3. Using Paleomagnetism to Test the Seafloor Spreading Hypothesis Part 4.4. The Geomagnetic Polarity Time Scale Chapter 5. CO2 as a Climate Regulator during the Phanerozoic and Today. Part 5.1. The Short Term Global Carbon Cycle Part 5.2. CO2 and Temperature Part 5.3. Recent Changes in CO2 Part 5.4. The Long-term Global Carbon Cycle, CO2, and Phanerozoic Climate History Chapter 6. The Benthic Foraminiferal Oxygen Isotope Record of Cenozoic Climate Change. Part 6.1. Introduction Part 6.2. Stable Isotope Geochemistry Part 6.3. A Biogeochemical Proxy Part 6.4. Patterns, Trends and Implications for Cenozoic Climate Chapter 7. Scientific Drilling in the Arctic Ocean: A Lesson on the Nature of Science. Part 7.1. Climate Models and Regional Climate Change Part 7.2. Arctic Drilling Challenges and Solutions Part 7.3. The Need for Scientific Drilling Part 7.4. Results of the Arctic Drilling Expedition Chapter 8. Climate Cycles. Part 8.1. Patterns and Periodicities Part 8.2. Orbital Metronome Part 8.3. A Break in the Pattern Chapter 9. The Paleocene Eocene Thermal Maximum (PETM) Event. Part 9.1. The Cenozoic [delta]13C Record and an Important Discovery Part 9.2. Global Consequences of the PETM Part 9.3. Bad Gas: Is Methane to Blame? Part 9.4. How fast? How long? Part 9.5. Global Warming Today and Lessons

from the PETM Chapter 10. Glaciation of Antarctica: The Oi1 Event. Part 10.1. Initial Evidence Part 10.2. Evidence for Global Change Part 10.3. Mountain Building, Weathering, CO2 and Climate Part 10.4. Legacy of the Oi1 Event: The Development of the Psychrosphere Chapter 11. Antarctica and Neogene Global Climate Change. Part 11.1. What do we Think we Know about the History of Antarctic Climate? Part 11.2. What is Antarctica's Geographic & Geologic Context? Part 11.3. Selecting Drillsites to Best Answer our Questions Chapter 12. Interpreting Antarctic Sediment Cores: A Record of Dynamic Neogene Climate. Part 12.1. What Sediment Facies are Common on the Antarctic Margin? Part 12.2. ANDRILL 1-B The BIG Picture Part 12.3. Pliocene Sedimentary Patterns in the ANDRILL 1-B Core Ch. 13. Pliocene Warmth: Are We Seeing Our Future? Part 13.1. The last 5 million years Part 13.2. Sea Level Past, Present, and Future Chapter 14. Northern Hemisphere Glaciation. Part 14.1. Concepts & Predictions Part 14.2. What is the Evidence? Part 14.3. What Caused It? Index. Subjects: Paleoclimatology. Climatic changes-- Observations. Climatic changes-- History. SCIENCE / Earth Sciences / Meteorology & Climatology. Notes: Includes bibliographical references and index.

Marine tephrochronology LCCN: 2014451556 Main title: Marine tephrochronology / edited by W.E.N. Austin, P.M. Abbott, S.M. Davies, N.J.G. Pearce and S. Wastegård. Published/Produced: London: The Geological Society, 2014. Description: 213 pages: illustrations (some color), maps (some color); 26 cm. ISBN: 9781862396418 1862396418 LC classification: QE527.56 .M37 2014 Related names: Austin, W. E. N. (William E. N.), editor. Abbott, P. M. (Peter M.), editor. Davies, S. M. (Siwan M.), editor. Pearce, N. J. G., editor. Wastegard, S., (Stefan), editor. Abstract: This Special Publication includes articles presenting recent advances in marine tephrochronological studies and outlines innovative techniques in geochemical fingerprinting, stratigraphy and the understanding of depositional processes. It represents a significant resource for the palaeoceanographic community at a
time when marine tephrochronology is being more widely recognized. It will also serve as a valuable reference to a much wider community of Earth scientists, climate scientists and archaeologists, particularly in highlighting the role of tephra studies in stratigraphy and regional/extra-regional correlations, as well as in tracing the long-term history of regional and global volcanism in the deep-sea archive. Contents: Marine tephrochronology: an introduction to tracing time in the ocean / W.E.N. Austin, P.M. Abbott, S. Davies, N.J.G. Pearce and S. Wastegård -- Marine tephrochronology: a personal perspective / D.J. Lowe -- Preparation of micro- and crypto-tephras for quantitative microbeam analysis / M. Hall and C. Hayward -- Microbeam methods for the analysis of glass in finegrained tephra deposits: a SMART perspective on current and future trends / N.J.G. Pearce, P.M. Abbott, and C. Martin-Jones -- Physical characteristics of tephra layers in the deep sea realm: the Campanian Ignimbrite eruption / S.L. Engwell, R.S.J. Sparks and S. Carey -- Identification of a MIS6 age (c. 180 ka) Icelandic tephra within NE Atlantic sediments: a new potential chronostratigraphic marker / F.D. Hibbert, S. Wastegård, R/ Gwynn and W.E.N. Austin -- Marine Ash Zone IV: a new MIS 3 ash zone on the Faroe Islands margin / S. Wastegård and T.L. Rasmussen -- North Atlantic marine radiocarbon reservoir ages through Heinrich event H4: a new method for marine age model construction / J. Olsen, T.L. Rasmussen and P.J. Reimer -- Last millennium dispersal of air-fall tephra and ocean-rafted pumice towards the north Icelandic shelf and the Nordic seas / G. Larsen, J. Eiríksson and E.R. Reconstructing Earth's climate history: inquiry-based exercises for lab and class LCCN: 2011039577 Main title: Reconstructing Earth's climate history: inquiry-based exercises for lab and class / Kristen St John... [et al.]. Published/Created: Hoboken, N.J.: Wiley, 2012. Description: xlii, 485 p.: ill. (some col.), maps (some col.); 29 cm. Links: Cover image http://catalogimages.wiley.com/images/ db/jimages/9780470658055.jpg ISBN: 9780470658055 (hbk.) 9781118232941 (pbk.) LC classification: QC884 .R428 2012 Related names: St. John, Kristen. Summary: "The context for understanding global climate change today lies in the records of Earth's past. This is demonstrated by decades of paleoclimate research by scientists in organizations such as the Integrated Ocean Drilling Program (IODP), the Antarctic Geological Drilling Program (ANDRILL), and many others. The purpose of this book is to put key data and published case studies of past climate change at your fingertips, so that you can experience the nature of paleoclimate reconstruction. Using foundational geologic concepts you will explore a wide variety of topics in this book, including: marine sediments, age

determination, stable isotope paleoclimate proxies, Cenozoic climate change, climate cycles, polar climates, and abrupt warming and cooling events. You will evaluate published scientific data, practice developing and testing hypotheses, and infer the broader implications of scientific results. It is our philosophy that addressing how we know is as important as addressing what we know about past climate change. Making climate change science accessible is the goal of this book. Readership: earth science students at a variety of levels studying paleoclimatology, oceanography, Quaternary science, or earth-system science"-- Provided by publisher. "This project integrates scientific ocean drilling data and research (DSDP-ODP-IODPANDRILL) with education"-- Provided by publisher. # **OVERVIEW OF SEAWEED BY-PRODUCTS**

*María Dolores Torres Pérez\* and Herminia Domínguez González*

Department of Chemical Engineering, University of Vigo (Campus Ourense), Edificio Politécnico, As Lagoas, Ourense, Spain CITI-Universidade de Vigo, Parque Tecnolóxico de Galicia, Ourense, Spain

## **ABSTRACT**

Seaweed is a feedstocks that is both renewable and available worldwide. It has applications in the food, feed, agricultural, chemical, and pharmaceutical industries. During the industrial processing of seaweed, different waste products are generated and discarded. However, such by-products contain a variety of valuable components capable of independent or joint separation and valorization. This chapter presents an overview of the major marine algal components and applications, as well as examples of valorization of the by-products from different algal classes.

**Keywords:** seaweed, by-products, wastes, valorization, biorefinery

## **INTRODUCTION**

Seaweed present advantages over terrestrial raw materials, particularly in relation to their rapid growth, yield, assimilation of nutrients and possibility of reducing atmospheric greenhouse carbon and nutrients promoting eutrofication; without competing for land and water (Kraan, 2013; Jaap et al., 2014). Moreover, seaweeds did not require the use of fertilizers or pesticides.

Marine macroalgae are traditionally used for food in Asian countries, and more recently they are being introduced in healthy and novel diets in other parts of the world. They are also commercially exploited for the extraction of hydrocolloids such as agars, carrageenan and

alginates (Bixler and Porse, 2011). Macroalgae can be also destined for feed or used as fertilizer (Hardouin et al., 2014). Nowadays, they became a valuable feedstock for the development of products with a variety of applications, including nutraceutical, cosmetics, pharmaceutical and energetic uses (Mahadevan, 2015; Tiwari and Troy, 2015; Magnusson et al., 2016). An overview of the potential application sectors is presented in Figure 1.

Figure 1. Sketch of the potential application sectors for the seaweed by-products.

Seaweeds can be collected from both cultivation farms and wildly grown stocks (Barbot et al., 2016). Phycocolloids are one of the main commercial products extracted from seaweed and the wastes coming from their extraction procedure could represent a well characterized, localized and cheaper resource with industrial interest. Also the fractions with lower quality discarded in the food industry could be considered (Quitain et al., 2013).

The valorization of algal wastes can contribute to the optimal valorization of natural resources following a biorefinery approach to achieve an integral utilization of raw materials (Baghel et al., 2015 and 2016; Özçimen et al., 2015; Tiwari and Troy, 2015). In contrast to traditional production processes which are focused on the extraction of a single product and the rest being regarded as a waste, multiproducts processing fits into the biorefinery philosophy for the sustainable utilization of resources (Kumar and Sahoo, 2017; Tedesco and Stokes, 2017; Schiener et al., 2016; Kostas et al., 2017; Baghel et al., 2016; Gajaria et al., 2017). Seaweeds are an ideal feedstock, since they contain a variety of high-value components (Jaap et al., 2014).

## **SEAWEED COMPOSITION**

Macroalgae contain valuable nutritious components such as carbohydrates, proteins, lipids, vitamins and minerals (Holdt and Kraan, 2011). Compared to terrestrial biomass, seaweeds contain higher water contents (90% fresh weight), carbohydrates ( $25 - 50\%$  dry weight), protein  $(7 - 15\%$  dry weight) and low lipid  $(1 - 5\%$  dry weight) contents (Sudhakaer et al., 2018). Table 1 shows the main compositional differences between brown, green and red seaweeds.

The structural polysaccharides (i.e., agar, carrageenan or alginate) in macroalgae can accout for up to 40 - 50% of the dry weight and have gelling properties that makes them important for industrial applications in the food and cosmetic sectors (Sudhakaer et al., 2018).

## **Table 1. Proximate composition (% dry weight) of seaweeds (Sudhakaer et al., 2018; Rohani-Ghadikolaei et al., 2012)**

Seaweeds also contain storage polysaccharides such as laminarin and fucoidan in brown algae, ulvans in green and porphyrans and floridian starch in red ones (Holdt and Kraan, 2013). Fucoidan has a variety of bioactive properties including anticoagulant, antitrombotic, antioxidant, antiinflamatory, anticancer, cardioprotective, among others (Li and Kim, 2011; Balboa et al., 2013; Mayakrishnan et al., 2013; Kwak, 2014; Flórez-Fernández et al., 2017; Phull and Kim, 2017).

The protein content differs widely amond seaweeds, being found in higher amounts in the red algae, followed by green, whereas brown algae contain a low fraction of their weight (3 - 15%) (Fleurence, 1999). Therefore, red seaweeds can be consider a potential source of proteins (Murata and Nakazoe 2001). In addition, the colored proteins (phycobiliproteins) in red algae, and increasingly demanded as natural colours in food and cosmetics show different bioactive properties (Chandra et al., 2017; Sekar and Chandramohan, 2008). The growing population of the world demands a safe and inexpensive source of proteins, and seaweeds could serve this purpose.

Soluble protein and peptides, produced by hydrolysis of protein by-products, present antioxidant, antimicrobial, antiinflammatory, antihypertensive, anticancer, and hypoglycemic actions (Pangestuti and Kim, 2017).

Low lipids content (up to 4%) is commonly found in seaweeds, but they are particularly rich in polyunsaturated fatty acids (Sudhakaer et al., 2018). These compounds are able to control blood pressure, coagulation as well as to reduce the risk of cardiovascular disease, osteoporosis or diabetes.

Minerals are also a relevant elements group in seaweeds. These compounds have an important role for building human tissues and they are essential in a balanced nutrition. The most common minerals in the algae are Na, K, Ca and Mg, and others trace elements such as Fe, Zn, Mn and Cu (Peng et al., 2015). According to the total content of the minerals, 97% of the dry weight, it can be stated that algae are a good source of these elements.

## **MAJOR SOURCES OF SEAWEEDS BY-PRODUCTS**

### **Food**

Many seaweeds are edible and contain important nutrients such as proteins, amino acids, essential fatty acids like omega-3 fatty acids, vitamins or minerals. They are commercially prepared in dried form, but during processing some low quality speciments can be discarded. Cooking also generates waste streams containing a soluble fraction worth recovering.

#### **Industrial Production of Hydrocolloids**

Traditionally the dominant markets for macroalgae has been the food (whole seaweed and phycolloids) and feed industries. However, algal biomass is a renewable source for various products useful for agricultural, bioplastics, dyes, cosmetic, pharmaceutical, energy or bioremediation applications. Emphasis is given to fatty acids, steroids, carotenoids, phycocolloids, mycosporine-like amino acids and halogenated compounds (Cardozo et al., 2007; Holdt and Kraan, 2011).

Different authors have explored the uses of wastes generated after food procesing of seaweeds, including the low quality fractions removed before direct comsumption of the seaweeds and the solid residues discarded after the extraction of phycocolloids.

## **Production of Fertilizers and Plant Growth Stimulants**

Agricultural uses of seaweed are widely known, not only for their high minerals content, but also for the ability of the polysaccharides as soil conditioners to aid in moisture retention. Liquid seaweed extracts are frequently prepared by pressing the fresh seaweed and further clarification and supplementation with preservatives (Mondal et al., 2013; Sing et al., 2016). This liquid phase is usually denoted as sap, and is rich in minerals, amino acids, vitamins and growth-promoting substances (Prasad et al., 2010; Pramanick et al., 2017). It has been reported its ability to improve the germination, plant height, crop yield and quality (Layek et al., 2016; Raverkar et al., 2016).

The solid after pressing is a residue containing valuable fiber components and therefore is useful for other applications.

## **Algal Blooms and Beach Wrack**

The biomass generated by seaweed washed up on shores either due too storm events or seaweed tides is a cheap biomass source which can be proposed as feed (Holdt and Kraan, 2011), for composting (Negreanu-Pirjol et al., 2011) and to provide nutrients to soil (Possinger and Amador, 2016); Michalak et al., 2017; Tang et al., 2009). However, considerations regarding the seasonal variability on composition have to be considered and also the concentrations of toxic metals should be analyzed before utilization (Villares et al., 2016).

In the next section some examples of valorization of by-products from seaweed processing are summarized. Further detail of selected cases is presented in the next chapters.

## **VALORIZATION AND UTILIZATION OF SEAWEED BY-PRODUCTS AND WASTES**

#### **Separate Utilization of the Constituent Fractions**

The separate use of the seaweed consistituent fractions, in terms of alginate, carrageenan, agar or phycolloids, among others, can be found in Tabla 2.

## **Valorization as a Whole**

In addition to the separate valorization of the components, the use of the alga as a whole can be proposed for the production of feed, fertilizer, biofuels or adsorbents.

#### *Biofuel*

Seaweeds are regarded as the third generation feedstock for biofuels and seaweed wastes are regarded as the fourth generation biofuels, because their utilization avoids the costs associated to seaweed farming and harvesting (Goh and Lee, 2010; Fernand et al., 2017). These feedstocks that do not compete with food application would be preferable for energetic uses (Mahadevan, 2015; Kositkanawuth et al., 2017).

Different technologies are available for the production of biofuels, including those based on: i) biochemical transformations, such as anaerobic digestion to produce biogas, bioconversion to ethanol, acetone and butanol or the extraction of hydrocarbons to produce biodiesel; and ii) thermochemical transformations by combustion, liquefaction, gasification and pyrolysis (Chen et al., 2015; Sudhakar et al., 2018).

## **Table 2. Examples of seaweed by-products or underutilized fractions, properties and applications**

Sectors: F: food; A: agricultural; P: pharmaceuticals; E: energy; M: materials.

Since seaweed composition differs from that of terrestrial biomass, the required approaches are also different (Michalak, 2018). In comparison to the use of lignocellulosics, the use of seaweed has limitations derived from the high moisture and ash content of seaweeds, aspects limiting the energy-efficient conversion into biofuels (Kraan, 2011; Kumar et al., 2013; Jaap et al., 2014). However, the lack of lignin facilitates some stages, i.e., in the conversion to bioethanol, pretreatment before hydrolysis of polysaccharides monosaccharides is facilitated in comparison to terrestrial biomass (Goh and Lee, 2010; Schultz-Jensen et al., 2013; Harun et al., 2014; Seghetta et al., 2014; Baghel et al., 2016). However, the carbohydrates are very different among seaweeds. *Saccharomyces cerevisiae*, can ferment glucose, galactose, but also mannitol and laminaran can be utilized (Horn et al., 2000; Lee and Lee, 2012), but the mixture of different seaweeds and adapted microorganisms has also been reported (Sunwoo et al., 2017).

Anaerobic digestion to produce biogas is a highly energy efficient process and seaweeds are suitable for this transformation, offering yields comparable to those attained from land feedstocks (Hughes et al., 2012; Jung et al., 2013). Since the cost of the algae is the highest in this process, the utilization of wastes is recommended for biogas production (Barbot et al., 2016). The combined energetic valorization was also suggested. Park et al. (2012) reported the anaerobic digestibility of the seaweed wastes after saccharification and bioethanol production processes, and found that the energy recovered by anaerobic digestion of the residue was more than twice the value from the ethanol produced in the main process.

The direct combustion of the whole algal biomass is a valid approach, but it is limited by the high ash content (Maceiras et al., 2015), although the high metal content could also act as catalysts (Lee et al., 2014). Pyrolysis was proposed for green tides (Ceylan and Goldfarb, 2015; Roberts and de Nys, 2016) and for waste seaweed fractions (Jung et al., 2016; Poo et al., 2018). Das et al. (2017) valorized the *Kappaphycus alvarezii* solid waste obtained after recovery of sap from fresh alga for energy application using pyrolysis. Jung et al. (2016)

processed *U. pinnatifida* roots, the main waste in farming sites, by pyrolysis to produce an eco-friendly alternative fertilizer. Hydrothermal carbonization, performed under slightly acidic and pressurized conditions, produces a hydrochar with energetic value comparable to that of a low ranking coal (Smith and Ross, 2016).

However, processing of seaweeds for biofuels exclusively is not economical and the joint utilization of the valuable feedstock components is also required to compensate the high production cost of biofuel (Shukla et al., 2016).

#### *Adsorbent*

The solid wastes after energetic valorization have been proposed as an adsorbent (Das et al., 2017). The most attractive material for this purpose are invasive seaweeds and blooms, which are low cost adsorbents useful to remove heavy metals and colorants from water, i.e., *Caulerpa racemosa* for methylene blue (Cengiz and Cavas, 2008); *Sargassum* for Cd, Cu and Ni (Padilha et al., 2005; De França et al., 2006; Lodeiro et al., 2006) and for phenols. The stability and adsorption capacity being improved with CaCl<sub>2</sub> treatment (Rubín et al, 2006). Combination of *Sargassum sp*. biomass was reported, i.e., coating with hydroxides for removing As from water (Vieira et al., 2017) or combination with clay for hexavalent chromium removal (Aprianti et al., 2017).

When the whole seaweed is used as feedstock, the salt removal is required in order to further utilization for food, feed, fertilizer, feed or fuel applications, since during hydrothermal liquefaction the high mineral content of seaweeds increased mechanical wear on processing equipment and the content of metals in the crude could limit its value and difficult the refining stage; the high salinity also difficults bioconversion to ethanol and to biogas (Zhang et al., 2017; Boakye et al., 2018). The removed salt can be crystalyzed and used for food purposes. Magnusson et al. (2016) and Glasson et al., (2017) reported the water washing of *Ulva sp.* biomass to obtain ulvan and protein fractions and to reduce algal mineral content. Furthermore, the salt of marine algae offers a healthy balance of minerals, K and Mg, and the salts produced after evaporation of the washing water can be used for functional foods. In addition, the remainig biomass composition showed enhanced properties as fuel or feed, since it increased the energy content of the biomass by  $20 - 50\%$  up to 18 MJ/kg and protein contents up to 27% (Magnusson et al., 2016).

## **EXAMPLES OF VALORIZATION OF SEAWEED WASTES**

## **Brown Seaweeds**

The extraction of alginate represents an industrial process generating important volumes of brown seaweed wastes. After alginic acid extraction, both the solid residue and a filtrate phase are disgarded as waste. Initially, they were considered as a potential source of iodine (Dave and Sharma, 1974), but other valuable components are focusing interest more recently. Some authors have designed cascade processes for the sequential extraction of fucoidans, alginates and phlorotannins from brown seaweeds (Lorbeer et al., 2017), or fucoidan, alginate, ethanol and antioxidants and antimicrobials from *Laminaria digitata* (Kostas et al., 2017). Likewise, Qi et al. (2017) reported the proteolytic hydrolysis of the by-products

remaining after polysaccharide extraction from *Undaria pinnatifida* to obtain a flavouring product with umami taste.

Brown seaweed by-products have also been proposed for feed purposes, some examples are mentioned here. Choi et al. (2014) supplemented broilers diet with *Undaria pinnatifida* and *Hizikia fusiformis* wastes fermented with *Bacillus subtilis* and *Aspergillus oryzae*, and observed enhanced body weight gain and immune response and lower mortality rate compared to the control group. Hwang et al. (2014) found that supplementation of 2% *Undaria pinnatifida* by-product improved the average daily gain and gain:feed ratio in steers, without affecting composition, quality of meat and carcass yield. Hong et al. (2015) supplemented brown seaweed by-products up to 4% of basal diet in dairy cows without affecting milk yield and composition. Islam et al. (2016) supplemented Hanwoo cows diets at 10% with fermented *Undaria pinnatifida* by-product and found greater weight of their calves. Also, the red seaweed *Gracilaria* wastes supplementation enhanced the carcass characteristics and production efficiency of ducks (Santoso et al., 2016).

Cosmetic applications were tried for the cooking liquid from *Hizikia fusiformis*, a byproduct of the food industries, containing large amount of protein, carbohydrates, and phenolic compounds. After irradiation, which can be used to inactivate pathogens, the antiradical and the tyrosinase-inhibiting properties were improved. Since the angiotensin Lconverting enzyme inhibitory activity was enhanced, pharmaceutical uses could also be proposed (Kim et al., 2014; Choi et al., 2011). Wijesinghe et al. (2013) confirmed that the phlorotannin-rich extract from the *Ecklonia cava* processing by-product showed antiinflammatory activity.

The residue after alginate extraction could be valorized as adsorbent (Aderhold et al., 1996; Williams and Edyvean, 1997; Mištová et al., 2010; Costa et al., 2016; Belattmania et al., 2017; Cardoso et al., 2017; Moino et al., 2017).

The polymeric applications were also validated. Poly(lactic acid) composites filled with algae industrial by-product after the industrial scale extraction of alginate were prepared using melt-mixing process (Bulota and Budtova, 2016).

Cherad et al. (2014) proposed the catalytical supercritical water gasification of *L. hyperborea* to produce hydrogen and methane and Lee and Lee (2015) addressed the biogas production from by-products of *Saccharina japonica* after a sludge freezing pretreatment. Also the solid by-product resulting from the energetic valorization were valid adsorbents; *Sargassum* chars produced by pyrolysis and chemically modified were used to capture Hg from flue gas (Yang et al., 2018).

The biorefinery concept is suitable for brown seaweeds. The sequential production of fucoidan, alginate, sugars and biochar was proposed for *Ascophyllum nodosum* (Yuan and Macquarrie, 2015).

## **Green Seaweeds**

After the production of liquid fertilizers, the remaining solids can be an excellent source of food ingredients. Highly digestible crude protein from *Ulva lactuca* was obtained from the sap free biomass with further recovery of minerals, lipids, ulvan and cellulose (Gajaria et al., 2017).

Energy and biofuels can be the final products from green seaweed processing. The whole algae can be used as substrate, as reported by Ben Yahmed et al. (2016). Latter authors proposed an integrated biorefinery for the production of bioethanol and biogas from *Chaetomorpha linum*, including pressurized pretreatment, enzyme production and enzymatic digestion, fermentation to ethanol and valorization of the mycelium from the fungal bioconversion to produce the enzymes the residual solid biomass and all effluents using anaerobic digestion to biogas. The bioconversion was also proposed by Sellami et al. (2013), who explored the lipase production by *Staphylococcus xylosus* and *Rhizopus oryzae* using a culture medium based on a mixture of synthetic medium and supernatants generated from tuna by-products and *Ulva rigida* biomass.

The final use as adsorbent, was reported by Lu et al. (2017), who applied hydrothermal carbonisation and chemical activation of *Ulva prolifera* biochar to produce an efficient adsorbent for the removal of bisphenol A.

The biorefinery of green seaweeds has been proposed (Bikker et al., 2016; Glasson et al., 2017). Later work using *Ulva lactuca* green seaweed was aimed at cascading valorisation of both protein and non-protein seaweed constituents is required to realise an economically feasible value chain.

## **Red Seaweeds**

Red seaweeds have high potential for biorefinery since they contain valuable proteins with nutritious and coloring properties, minerals, lipids, cellulose and agar, which are of considerable commercial value (Kumari et al., 2013; Baghel et al., 2014). Diferent integrated biorefinery approaches for the production of valuable components from red seaweeds have been proposed.

Fresh *K. alvarezii* was used to produce a juice rich in potassium salts and the remaining granular residue is rich in κ-carrageenan. After its extraction can be destined to produce 5 hydroxymethyl furfural, levulinic acid and formic acid and finally be used as a fertilizer (Mondal et al., 2013). Khambhaty et al. (2012) washed this residue with water to remove salt, and proposed and acid hydrolysis and saccharification before fermentation with *S. cerevisiae* for ethanol production and finally, in order to completely utilize the seaweed, biogas production from waste fractions (Ingle et al., 2018).

After the extraction of agar and carrageenan, with application in the food industry as gelling, emulsifying, thickening, and stabilizing agents,  $70 - 85\%$  of the seaweed remains as solid or as a waste effluent, susceptible of being valorized (Pereira et al., 2015). These byproducts remaining after phycocolloid extraction from red seaweed have been proposed as a source of protein. Cian et al. (2012 and 2013) used the protein from the cold washing stages from the traditional method to obtain phycocolloids and hydrolyzed it with trypsin, alcalase and a combination of both sequentially. The hydrolysates were enriched in peptides with low molecular weight, showing immunosuppressive, antihypertensive and antioxidant properties. Laohakunjit et al. (2014) reported the use of *Gracilaria fisheri* agar extraction by-products as a source of protein and amino acids, after enzyme hydrolysis to obtain a product rich in free amino acids (arginine, lysine, and leucine) and odourant compounds conferring umami taste and seaweed odour, and roasted seafood flavour after thermal processing.

Different processes are also aimed at extracting the valuable proteins from the fresh seaweed. A cascade processing approach of *Gracilaria gracilis* consisted on the extraction of phycobiliproteins and further pyrolysis of the residue to produce bio-oil and biochar (Francavilla et al., 2013 and 2015). Baghel et al. (2015) proposed a scalable process consisting on the aqueous extraction of phycobilins, further purified by ammonium sulphate precipitation. Note here that the supernatant was used as liquid fertilizer. The residues were treated with organic solvent to obtain lipids and the remaining residue was extracted with distilled water to obtain agar and the residual solid remaining after agar extraction were used for hydrolysis and ethanol fermentation. Baghel et al. (2016) developed an aqueous extraction process of *Gracilaria corticata* to obtain R-phycoerythrin, R-phycocyanin, crude lipid, agar, soil conditioner, bioethanol and a mineral rich liquid fertilizer.

Energetic valorization has also been tried. Tan and Lee (2014) reported the enzyme hydrolysis with cellulases and fermentation to ethanol with Saccharomyces cerevisiae either sequential of simultaneous of the seaweed solid wastes remaining after κ-carrageenan extraction from *E. cottonii*. The waste sludges generated after the extraction of alginate from *Laminaria hyperborea* and *Ascophyllum nodosum* were treated by anaerobic digestion to produce methane (Kerner et al., 1991). The pulp after recovering a liquid fertilizer from *Kappaphycus alvarezii* (Khambhaty et al., 2012) and after agar extraction from *Gracilaria verrucosa* (Kumar et al., 2013; Shukla et al., 2016) or from carrageenan extraction (Uju et al., 2015) can be used, after enzymatic hydrolysis, for ethanol production.

The adsorbents prepared from the solid wastes remaining after the ethanol fermentation of some red seaweeds (*Gelidium amansii*, *Gracilaria verrucosa*, *K. alvarezii* and *Eucheuma denticulatum*) was successfully applied to the adsorption of Cd(II), Pb(II) and Cu(II) (Sunwoo et al., 2016). The additional modification of the material was proposed for Pb and Cu sorption (Vilar et al., 2008). Johansson et al. (2016) used slow pyrolysis to obtain a Fe-biochar from Gracilaria waste with high affinity for oxyanions. This product was useful for the adsorptive removal of Se, As and Mo from complex effluents.

Biobased composites prepared with polysaccharides obtained from seaweeds by-products are advantageous regarding renewability and sustainability (Leceta et al., 2014). Madera-Santana et al. (2015) proposed the utilization of the filtration by-product after agar extraction from *Hydropuntia cornea* as a filler for incorporation by melt blending into a polylactic acid matrix. Alamsjah et al. (2017) reused the seaweed waste from *K. alvarezii* and *Gracilaria verrucosa*, to obtain pure fibre, which was mixed with epoxy adhesive and with sawdust to produce medium density fibreboard. Jumaidin et al. (2017a and b) proposed *Eucheuma cottonii* wastes as renewable filler improved the tensile, flexural, and impact properties of the composites as well as the thermal stability and soil biodegradation.

An overview on some industrial applications of by-products above-mentioned from brown, red and green seaweeds with the corresponding sector of use can be found in Table 2.

## **CONCLUSION**

Seaweeds can be used for food and feed or can be industrially processed to obtain high value added products, such as hydrocolloids, food, cosmetics and fertilizers, leaving one or more fractions as by-products or residues. Since these by-products stil contain compounds susceptible of further valorization, their utilization is promoted for achieving an integral utilization of the natural resources offering a sustainable processing scheme that fits in the concept of biorefinery. However, some challenging aspects have still to be considered, particularly, the variation in the content of bioactives with season, location or processing, both in seaweed by-products and in seaweed biomass from blooms (Adams et al., 2011; Kumar and Sahoo, 2017). This volume presents a survey of the valorization of seaweed byproducts into different commercially valuable products.

## **ALGAE AND MICROALGAE BIOREFINERY**

*Rocío Gallego, Mónica Bueno and Jose A. Mendiola\**

Foodomics Laboratory, Institute of Food Science Research (CIAL-CSIC), Madrid, Spain

## **ABSTRACT**

In the present work, we present an introduction to biorefinery techniques and their applications in obtaining high, value-added products from algae and microalgae. Extraction and characterization techniques are reviewed, taking into account a Green Chemistry point of view.

**Keywords**: biorefinery, seaweeds, algae, green, microalgae

## **INTRODUCTION**

In 2015, the European Union published the "action plan for the Circular Economy" (Commission of the European Communities 2015) where the value of products, materials, and resources are maintained in the economy for as long as possible, and the generation of waste minimized. This is to be an essential contribution to the EU's efforts to develop a sustainable, low carbon, resource efficient, and competitive economy.

In this sense, biorefineries play an essential role. Biorefining as defined by the International Energy Agency, is the sustainable processing of biomass into a spectrum of biobased products (food, feed, chemicals, materials) and bioenergy (biofuels, power and/or heat). This kind of "refinery" corresponds to classical petroleum refining, where multiple types of fuels and products are obtained from the same raw material. One of the first biorefineries was to produce of bioenergy, biofuels, and biochemicals. Replacing petro-chemical refineries with biorefineries can significantly contribute to mitigating climate change. Estimates from the British government show that the conversion of bio-based wastes into bio-based materials

 $\overline{a}$ 

<sup>\*</sup> Corresponding Author's Email: j.mendiola@csic.es.

alone could reduce emissions by up to  $633$  million tonnes of  $CO<sub>2</sub>$  (Department for Business Enterprise and Regulatory Reform 2009). Biomass energy and material recovery is maximized, if a biorefinery approach is considered, where many technological processes are jointly applied to different kinds of biomass feedstock for producing a wide range of bioproducts. Many biorefinery pathways, from feedstock to products, can then be established, according to the different types of feedstock, conversion technologies, and products (Cherubini 2010).

The ideal Biorefinery should be highly energy efficient and tend to zero-waste production processes, but the "waste" products can be considered as co-products and may be reallocated for added value use or conversion processes. The purpose of the biorefinery is to optimize the use of resources and minimize waste, thus maximizing the benefits and profitability (Ferreira 2017).

Mabee *et al*. emphasized that there is an important choice of biomass and final products in biorefinery design, due to the large-scale production implications. Initial biomass availability, its potential use, and its characteristics need to be considered (Mabee, Gregg and Saddler 2005). Each biomass has its advantages and disadvantages. The biomass from forests, aquaculture, agriculture, and residues from households and industry can be used in the biorefinery, including wood wastes, agricultural wastes, bagasses, waste paper, sawdust, biosolids, grass, and organic residues (e.g., waste from food industries), aquatic plants and algae, animal wastes, among others (Demirbas 2005). Detailed and accurate characterization of biomass feedstocks, intermediates, and products is necessity to understand how the individual biomass components and reaction products interact at each stage in the process. Based on biomass feedstock, the biorefineries can be classified as lignocellulosic or marine (Ferreira 2017).

Another important issue in biorefining is evaluating the economic sustainability, which is extremely important to understand energy, environmental burdens, and costs of any production/conversion system, giving insight into its sustainability. One of the most used methodologies is the life cycle assessment methodology (LCA), which analyzes a product during its lifetime from its production, to its utilization, and end of life, including its recycling process. In this methodology, each step of the processes should be considered, such as biomass feedstock (culture, harvesting, drying, transport, etc.), conversion process (extraction, reactions, fermentation), and use of the product. Moreover, economic viability and evaluation of the costs has to be taken into account, without forgetting socioeconomic costs.

There is a further step in biorefining. The integrated thermo-biorefinery or advanced biorefinery is considered a biorefinery of the future. The concept of advanced biorefineries is similar to a conventional biorefinery, however, in this case, multiple feedstocks, products, and platforms are considered. An integrated biorefinery produces various products, which include electricity produced from thermochemical and bioproducts from the combination of sugar, and other existing conversion technology platforms.

In this chapter, we will focus on marine biorefineries, which are based on marine biomass such as aquatic plants, macroalgae (e.g., seaweed), and microalgae. This type of biomass has some advantages, such as high areal productivities, no need for arable land, and a wide range of biobased products and energy depending on culture conditions. However, industrial processing has a long way to go to be at the level of traditional terrestrial agriculture.

#### **Macroalgae**

Macroalgae or seaweed are multicellular organisms from marine sources that are able to carry out photosynthesis, and are characterized by simple reproductive structures. Seaweeds have been extensively utilized as food, animal feed, and fertilizer, and thus farmed commercially in a number of countries (Baghel et al. 2015) (over 30 million tons in 2016) (FAO 2018). Dependingon the seaweed type, whether green, red, or brown, macroalgae and related species can produce different fatty acids, biofuel, proteins, natural pigments, antioxidants, or polysaccharides (Balina, Romagnoli and Blumberga 2017). Furthermore, most macroalgae produce highly valuable metabolites with biological activities due to the adaptation to the extreme environments of light, salinity, and temperature (Ibañez et al. 2012). That is why, the study of a macroalgae biorefinery has attracted lot of attention in the recent years, either from a bioeconomic point of view (Van Hal, Huijgen and López-Contreras 2014; Seghetta et al. 2016), or from the green chemistry approach (Kerton et al. 2013; Herrero and Ibañez 2018).

On one hand, there are biorefinery processes in which more interesting products are obtained through fermentation processes, providing an effective utilization of the remaining by-products. The polysaccharides glucose, rhamnose and xylose from *Ulva lactuca* biomass were enzymatic hydrolyzed and used as substrate for the fermentative production of acetone, butanol, ethanol, and 1,2-propanediol, while a protein-enriched extracted fraction was studied for use in animal feed (Bikker et al. 2016). Another example of this type deals with the enzymatic hydrolysis of *Saccharina latissima* (Marinho, Alvarado-Morales and Angelidaki 2016). In this application, the hydrolysis generates a phenolic fraction, whose fermentation produces succinic acid, a concentrated macro - (Ca, K, Na, Mg, P, N and Fe), and micronutrients solid residue that can be use as fertilizer. On the other hand, downstream processes are found in the literature for the valorization of *Sargassum muticum* (Pérez-López et al. 2014; Balboa, Moure and Domínguez 2015).

In both examples, firstly, there is a supercritical  $CO_2$  (ScCO<sub>2</sub>) extraction of fucoxanthin, followed by the extraction of polysaccharides, such as alginate or fucoidan, and finally, an antioxidant extract rich in phenols, such as phlorotannins, produced by autohydrolysis.

In the work of Pérez-López *et al*. (Pérez-López et al. 2014), different scenarios were studied from an economic and environmental point of view. It was concluded that the most efficient biorefinery approach is the one that obtains only alginate and antioxidants. Including the fucoxanthin extraction at the beginning of the process implies an electricity consumption that drifts to environmental burdens.

Balboa *et al*. (Balboa, Moure and Domínguez 2015) highlighted that it is possible to carry out a biorefinery approach only using green processes and techniques (Microwave drying,  $SCO<sub>2</sub>$  extraction, and membrane microfiltration), in addition to Generally Recognized As Safe (GRAS) solvents (water, ethanol, ethyl acetate and  $CO<sub>2</sub>$ ).

#### **Microalgae**

Microalgae are a diverse group of photosynthetic microorganisms, which can be considered as a potential source for the production of several highly valuable and bioactive compounds. They have many advantages since they can rapidly produce biomass using

sunlight and carbon dioxide, and they can also grow in extreme climatological conditions, such as non-arable lands or wastewater (Trivedi et al. 2015).

One of the main applications of microalgae is biodiesel production, because of the high level of triglycerides they contain (Yen et al. 2013). These microorganisms are one of the most promising renewable feedstock within bio-oil production areas, thanks to the inexpensive and effective harvesting of biomass, and the extraction of lipids (Enamala et al. 2018). Other than biofuel, microalgae contain rich compounds such as carbohydrates, polyunsaturated lipids, proteins, and pigments, which are widely used in cosmetic and pharmaceutical industries (Goh et al. 2009; Mimouni et al. 2012; Matos et al. 2017).

Up to now, several researchers have been using microalgae as raw material to obtain these highly valuable compounds using green solvents, not only in single-step processes (Paula R. F. Canela et al. 2002; Soh and Zimmerman 2011; Castro-Puyana et al. 2013), but also in a biorefinery approach. As an example, Gilbert-López *et al*. (2017) developed an efficient method using several green extraction steps to obtain different valuable fractions from *Scenedesmus obliquus*. These steps included supercritical fluid extraction (SFE), gas expanded liquids (GXL), and pressurized liquid extraction (PLE), using  $\text{ScCO}_2$ , a mixture of ScCO<sub>2</sub>/ethanol, and pure water, respectively. Thus, they could efficiently fractionate triglycerides, and pigments such as lutein and β-carotene (Gilbert-López et al. 2017). A similar study was done where *Isochrysis galbana* was obtained using pressurized green solvents such as ScCO<sub>2</sub>, mixtures of ScCO<sub>2</sub>/ethanol, pure ethanol, and water. Furthermore, fucoxanthin, polar lipids, and other bioactive compounds with high antioxidant activity were recovered in different fractions during the whole biorefinery process (Gilbert-López et al. 2015).

It is important to mention that there are around 13,000 species of microalgae, with huge differences in terms of their compositions (Guiry 2012). For example, astaxanthin can be effectively extracted from *Haematococcus pluvialis,* and β-carotene from *Dunaliella salina* (Trivedi et al. 2015). This means that not only is it important to design a suitable integrated green platform to obtain/extract different products from microalgae, but also to design it specifically for each species of microalgae.

## **CONCLUSION**

The biorefinery offers a plethora of opportunities to produce an array of fuels and organic chemicals from biomass. Even though marine biorefineries are still under development, and not currently producing at the industrial scale, there are a wide range of applications, both using micro and macro algae, that are highly promising.

## **ACKNOWLEDGMENTS**

This work was supported by the European Union through the ABACUS project (BBI - Grant agreement - 745668). M.B. acknowledges MINECO for a "Juan de La Cierva-Formación" postdoctoral grant FJCI-2016-30902.

## **ABSTRACT**

Seaweeds are aquatic plants, also known as macroalgae, and they have gained much attention recently, due to them being an alternative renewable feedstock that yield large biomass, as well as due to their fast growth rate, and ability to be produced without the use of any terrestrial land for cultivation. A wide variety of seaweeds, which are also cultivated to extract polysaccharides (i.e., alginate, agar, and carrageenan) and these gelatinous substances (hydrocolloids) are used in the food industry and as biomaterials. Moreover, seaweeds comprise a broad spectrum of functional ingredients (high-valued components) with pharmaceutical and nutraceutical properties. Nevertheless, the byproducts from the residual biomass from seaweed processing are recognized to contain bioactive and therapeutic compounds. However, the discovery of new functional components, activities, and applications from seaweed by-products has rarely been discussed in the literature. In this chapter, we will review the application of seaweed byproducts with the purpose of obtaining value-added products and materials.

**Keywords:** seaweeds by-products; biomaterials, bioactive compounds, biofuels, biocomposites

## **INTRODUCTION**

Algae or seaweed are autotroph unicellular (eukaryotes or prokaryotes) organisms of single structure without complex tissues and low cellular differentiations (tallophytes). They are classified into three groups: Clorophyta (green algae), Phaeophyta (brown algae) and Rhodophyta (red algae) [1, 2]. Furthermore, they can be classified according to their size either as macroalgae, commonly known as "seaweed", and microalgae, microscopic singlecell organisms ranging in size from a few micrometers (μm) to a few hundred micrometers. Seaweeds have been extensively explored since the beginning of civilization and are used in the pharmaceutical, cosmetics, and food industries, and more recently for the production of biofuels. Algae also represent a source of fiber, minerals, pigments, vitamins, steroids, lectins, polysaccharides, proteins, lipids (polyunsaturated fatty acids), and halogenated compounds. Indeed, thus many countries consume algae as a food, and there is interest in the development of new products with high added value [3].

Among the principal advantages of seaweeds is that they do not require agricultural land for their cultivation, and many species can grow in saline water and residual water, and so do not compete for the land and fresh water required for the cultivation of plants [4]. Additionally, their high growth rate produces more biomass yield per unit area than the terrestrial plants [5]; for example, brown seaweeds grown under cultured conditions show yields of  $\sim$  13.1 kg dry weight m-2•yr-1 compared to  $\sim$  10 kg dry weight m-2•yr-1 from sugarcane [6].

Seaweeds are considered among the most potentially significant future sources of sustainable biofuels. Lee et al. (2012) reported high yield of lipids from the microalgae (59 m3 ha-1•yr-1) that can be used to obtain biofuels. Furthermore, seaweeds have been described as potential sunlight-driven cell factories for the conversion of carbon dioxide to biofuels and chemical feedstocks [7, 8]. Nevertheless, despite their obvious potential, there are no economically-viable commercial-scale quantities of fuel from either micro- or macroalgae [9]. This is because it is necessary to adequately control several parameters including the microalgae species, metabolic mechanism, culture and operation conditions, as well as the bioreactor design. The present chapter offers an overview of the products with added value derived from seaweeds and their possible commercial applications.

## **COMMERCIAL APPLICATIONS OF SEAWEEDS**

## **Food Products**

Seaweeds have a wide range of applications in the cosmetics, pharmaceutical, and energy industries, but it is the nutrition sector that seems most promising for algae technology [10]. Seaweeds have been consumed since ancient times. In Japan, seaweed is a traditional food consumed as a seasoning or sea vegetable, and represents 10 - 25% of food intake. Seaweeds, such as *Undaria pinnatifida*, *Monostroma nitidum*, and *Sargassum fusiforme* are consumed in Japan as they contain several nutrients and functional ingredients in their makeup, making them an excellent healthy food source [11]. However, new strategies in food technology open up the possibility of using sustainable productions with a lower negative impact on the environment. This has increased the focus on seaweeds as a global food source.

Currently, the seaweed market as a global food is very limited and has only two branches: 1) dried microalgae (e.g., *Chorella* and *Spiruline*, rich in vitamin B12 and D2, respectively); and 2) extracted-products from microalgae, such as pigments (astaxanthin), proteins (phycocyanin), antioxidants (β-carotene) and fatty acids (DHA, EPA). Sathasivam and Ki [12] mentioned that pigment extracted from seaweeds (i.e., chlorophyll, phycobiliproteiins, and carotenoids) represent a multi-billion dollar food industry due to the fact that in the USA alone, the food color market is projected to be worth 3.75 billion USD by 2022. Barba et al. [13] reported that seaweeds and microalgae represent an excellent alternative to improve the functionality of food products (e.g., organoleptic, health and technological products), since they can be used to make products with high added value such as emulsifiers, hydrocolloids, proteins, essential amino-acids, polyunsaturated fatty acids, antioxidants and antimicrobials bioactive compounds. Such products not only have nutraceutical importance, but are also important for the pharmaceutical industry. Besides, Agatonovic-Kustrin et al. [14] proposed the seaweeds as a functional food because the diterpenes and fucoxanthin present in *Dictyota dichotoma* they bind with nitric oxide, reducing the threat of cardiovascular diseases (hypertension and heart failures). However, food regulations in the USA and Europe have impeded the launch of new products from microalgae [15].

#### **Agriculture**

Since the first green revolution, the use of chemical fertilizers, such as pesticides and herbicides, have been commonly used in modern high-intensity agricultural ecosystems, decreasing soil quality and fertility. In this context, seaweeds are an excellent alternative as a biofertilizer. Bai et al. [16] discussed the beneficial effects of seaweed extracts in agriculture, such as early seed germination and seedling establishment, improved crop yield and quality, increased resistance to environmental stresses, and regulation of soil micro-ecosystems. Wang et al. [17] reported that the use of seaweeds (Sargassum horneri) as fertilizer increased bacterial diversity and shifted the microbial community structure significantly in treated soils. Moreover, the application of seaweed fertilizer can induce soil enzyme activity and microbial activity, thus promoting the improvement of soil quality. Wang et al. [18] investigated the use of seaweeds (*Lessonia nigrescens* and *Lessonia flavicans*) as fertilizer on the growth of apple (*Malus hupehensis* Rehd) and show that it significantly increased plant height and dry weight, promoted the activities of antioxidant enzymes, and inhibited lipid peroxidation in plant cells.

Recently, seaweed extracts have been applied as foliar bio-stimulants in plants, and several reports have indicated beneficial responses, including improved root and shoot growth, higher yields and greater resistance to antibiotic and biotic stress [19]. Other authors such as Stirk et al. [20] and Mosa Salim [21] have reported that hormones, vitamins, amino acids (e.g., cytokinins, auxins, polyamines, abscisic acid, gibberelins and brassinos-teroids) and trace elements (e.g., Fe, Cu, Zn, Co, Mo, Mn and Ni) used together with seaweed extracts for foliar applications, can help to reduce the application use of chemical fertilizers.

Mosa Salim [21] also reported that foliar applications of seaweed extracts improved the growth and yields of wheat plants, due to their ability to enhance cultivation and use sandy soil efficiency by increasing water-holding capacity, ion exchange and nutrient availability. Moreover, Kasim et al. [22] pointed out that seaweed extract (*Sargassum* or *Ulva*) decreased the damages caused by oxidative stress and provides hormones and micro nutrients essential for wheat growth, especially root depth, shoot height and leaf area. Singh et al. [23] reported the use of *Kappaphycus alvarezii* seaweed extract as a bio-stimulant of sugar cane, enhancing the productivity by 12.5 and 8%, respectively, in plant and root crops. The strategy of increasing sugarcane productivity without any negative implications to the environment is challenging.

## **Biomaterials**

Seaweeds represent an important source of biomaterials due to their structural composition as they contain cellulose, alginates, carrageenans and several sulfated polysaccharides, commonly present in their cell wall. Sulfated polysaccharides (fucans) can be extracted from brown seaweeds while, ulvans can be extracted from green seaweeds. Alginates, carrageenans and agars are commonly obtained from brown and red seaweeds, with a combined market value of 130 million  $\epsilon$  in Europe alone [24]. Commercial carrageenans have been extracted from *Chondrus*, *Gigartina*, and *Eucheuma sp* and are used as food thickeners in yogurt, ice cream and pudding. Agar is extracted from red seaweeds namely *Gelidium* sp and *Gracilaria sp* and is applied as a hydrocolloid in the food, pharmaceutical, and biological industries [25].

Moreover, Sealy [26] reported obtaining a super-tough biomaterial based on alginate from seaweed that could overcome the shortcomings of conventional polyurethanes used in the repair of damaged or diseased cardiac and vascular tissue. Indeed, due to its biocompatibility, biological, biodegradability [27], one of the main areas of applications of seaweed polysaccharides is in biomedicine, such as carrageenan for drug delivery, tissue engineering and wound healing and dental applications. However, the use of seaweed polysaccharide in biological and biomedical applications is still in its infancy. Moreover, several researchers have performed investigations into the chemical modification of seaweed polysaccharides. These procedures involve oxidation, acetylation, amination, sulfonation, and phosphorylation and provides several advantages in terms of mechanical and biological characteristics that could see them be used as anticancer, antioxidant, antihyperlipidemic, anticoagulation, and anti-inflammation agents [28].

However, one of the current challenges in reducing the costs of biopolymers recovered from seaweed concerns improving extraction methods used. Several novel and interesting techniques to isolate and to characterize seaweed polysaccharides have been developed recently including microwave assisted extraction, enzymatic extraction techniques, conventional methods, ultrasonic assisted methods, and supercritical extraction.

## **Bioactive Compounds**

From seaweeds can be obtained a great variety of bioactive molecules that are not produced by terrestrial plants. The beneficial properties of these bioactive compounds for humans, animals, and plants have been recognized throughout history and are appreciated nowadays in the development of new biotechnological products. Among the most common

are the proteins, carbohydrates, proteins, polyunsaturated fatty acids, omega-3 fatty acids, minerals as well as pigments (phycobilins, chlorophylls, and fucoxanthins), polyphenols, and mycosporine-like amino acids (MAAs). These biomolecules are functional as antimicrobial, antifungal, antioxidant, anti-inflammatory, antivirus, anticoagulant, anticancer, antitumor, anti HIV, antidiabetic, immunomodulatory, even as probiotic and cholesterol-lowering effects [29, 30].

Respect to nutraceutical compounds of seaweeds Wang et al. [31] reported that edible brown (*Undaria pinnatifida*) contain a large number of nutrients such as dietary fiber, proteins, vitamins, minerals, and bioactive molecules; sterols, alkaloids, flavonoids, and fatty acids. Even, mentioned that seaweeds have many advantages due to its non-toxicity compared with chemical synthetic compounds, so it has recently been promoted for use such as a therapeutic agent or as a nutritional supplement. For several years, sulfated polysaccharides with potential pharmacological, nutraceutical, functional food, and cosmeceutical characteristics have been obtained or isolated from brown seaweeds and published in the literature [32]. Sanjeewa et al. [33] mentioned the bioactive potential of sulfated polysaccharides (fucoidans) isolated from seaweed *Sargassum spp*, showing anticancer activity against Lewis lung carcinoma cells and melanoma B16 cancer cells *in vitro* studies. Also, mentioned the antivirus activity and suggested that high molecular weight and the higher levels of sulfation increase the antiviral activity against herpes simplex virus (HSV-1) and HSV-2. The active compounds of seaweeds also have been used in the development of new cosmetic. The phlorotannins isolated from brown seaweeds (e.g., *Ecklonia stolonifera*, *Ecklonia cava*) have an inhibitory effect of the tyrosine, decreasing the melanin production, so showing whitening properties. Besides, they have anti-wrinkling properties, it is due to include a matrix of metalloproteinase (MMP) inhibitory activities and hyaluronidase inhibitory activity [34]. Products with functional properties containing organic compounds derived from natural sources are being increasingly demanded by consumers in contrast to those resulting from heavy organic synthesis [35].

## **PRODUCTS DERIVED FROM SEAWEED BY-PRODUCTS**

Several plant-derived natural products have been recommended as sources of bioactive compounds [36], in spite of the fact that research has already begun on other common natural sources such as macroalgae (or seaweeds) and microalgae. Indeed the marine environment is considered a wealthy, unexploited source of bioactive compounds [37]. Macroalgae and microalgae have attracted the most attention from researcher due to their potential a source of bioactive compounds with useful biochemical properties [38, 39].

#### **Products Obtained by Solvent Extraction**

Seaweed extracts can be produced using different strategies yielding interesting new chemical compounds with biological activity that can be used in cosmetics, pharmaceuticals, and food applications. The high abundance of seaweeds in the marine ecosystem means that they have a strong potential to end up as sources of bioactive compounds such as dietary fiber, omega-3 fatty acids, carotenoids, vitamins, polysaccharides, proteins, and minerals. However, it must be remembered that bioactive compounds are sensitive to extraction strategies based on the use of heat or solvents. These days, researchers in the field of seaweeds have been working to develop novel methods that are more productive in terms of time, yield, and cost, whilst also being environmentally friendly [40]. There are different strategies that can be used to identify these compounds. Firstly, an appropriate extraction procedure should be chosen. For extraction, different mechanical, chemical, and biological procedures can be used. The selection of an appropriate method depends on several variables, including the type of seaweeds involved in the extraction process and the type of bioactive compounds that will be obtained (e.g., polysaccharides, oils, dietary fibers, nutritional elements, etc.). A key issue is the solvent chosen for the extraction. The solvent used will lead to the extraction of different groups of compounds that can have several different end uses. Extraction techniques include the use of single solvents, binary solvent mixtures, and timebased extractions [41, 42]. The main challenge currently is to optimize the extraction conditions to obtain bioactive components and value-added products from seaweeds with high yield and activity.

#### **Table 1. Biocompounds obtained from seaweeds by different extraction methods [45]**

EtOH: Ethanol; MeOH: Methanol; Hex: Hexane; C4H4O4: Acetic acid; C3H6O: Acetone; CHCl3: Chloroform.

The different techniques mentioned allow for the extraction of seaweed products for potential application in agriculture. For instance, liquid seaweed fertilizer or biostimulants can be used to treat different crops, replacing commercial chemical fertilizers and reducing production costs. Biostimulants are attractive because they contain large quantities of organic matter, micro and macroelements, vitamins, fatty acids, and growth regulators [43]. The European Biostimulant Industry Council (EBIC) defines an agricultural biostimulant as a substance that acts on the physiology of plants through different pathways to improve crop vigor, yields, quality, and post-harvest shelf life/conservation [44]. The methods employed to
produce seaweed extracts can be divided into three groups: biological methods (e.g., enzymatic degradation method), chemical hydrolysis methods (using organic or inorganic solvents), and physical extraction methods (using high pressure and low temperature, supercritical fluid extraction, etc.). It is important to point out that the method of extraction can have great deal of influence on the active substances and nutrients obtained in the final product. Some bioactive compounds obtained from seaweeds by the different extraction processes using biological and chemical methods are presented in Table 1 [45].

Figure 1 provides a general idea about the treatments that seaweed biomass must be subjected in order to obtain extracts using biological and chemical methods. The commercial seaweed extracts available are solutions (aqueous) and are prepared with different solid content, viscosities, pH (alkaline to acid), odors and colors (from colorless to dark brown or black) [46]. The commercial biostimulant formulated from seaweed extract can contain a dry matter content of  $10 - 30\%$  and a pH of  $6.4 - 10$ . Moreover, liquid formulations for foliar applications are produced with a pH of  $4 - 5$  (acid) using an organic acid and can be fortified with micronutrients with the added advantage of adding the chelating properties developed by the polysaccharides in extracts [47].

Figure 1. General representation of preparation and extraction process of seaweeds [45].

#### **Products Obtained Using the Enzymatic Extraction Process**

The presence of sophisticated cell wall polysaccharides can reduce the efficiency of extraction procedures employed to obtain active compounds from seaweeds. The degradation of cell wall polysaccharide structures could aid the release of such active components. The biological method is based on the principle that several kinds of enzymes are created by microorganisms in the metabolic process that use seaweeds as nutrients. Biopolymers from seaweeds can be degraded into low molecular weight biopolymers and water soluble biocompounds. According to Lianfeng Bio [48] the conditions that should be used include gentle temperature or pH in order to maximize the retention of the bioactive and alimentary substances in seaweed. The challenge within the extraction of seaweeds is to optimize conditions for extracting bioactive compounds. For instance, the presence of assorted polysaccharides in large quantities within the cell-wall of seaweed is powerfully reduced by the extraction efficiency used in traditional extraction procedures. Therefore, totally different extraction techniques are required. Recently, a novel technique called enzymolysis was developed by Wijesinghe and Jeon [49]. Li et al. [50] have reported that this technique involves chemical process such as catalytic efficiency, high specificity, gentle reaction conditions, and the conservation of the initial efficacy of bioactive compounds.

To perform an enzymatic hydrolysis of biomass, it is important to take into account the suitable hydrolytic enzyme or optimum mixture of enzymes to obtain the expected production and also to select the correct processing conditions to be applied to obtain the maximum retrieval of bioactive compounds. Nevertheless, there are several factors (such as temperature and pH) that could have an influence on the ability of enzymes to degrade cell wall polymers and release bioactive compounds [49]. As reported by Heo et al. [51] enzymatic extraction techniques provide outstanding benefits such as being safe and having excellent water solubility, in addition to being a convenient large-scale method for the production of antioxidants from seaweeds. These authors reported an innovative extraction technique using digestive enzymes in wich they used carbohydrases and proteases to degrade seaweed tissues and to facilitate the release of several bioactive phenolic compounds from different seaweeds (i.e., *Ecklonia cava*, *Ishige okamurae*, *Sargassum fulvellum*, *Sargassum horneri*, *Sargassum coreanum*, *Sargassum thunbergii*, and *Scytosiphon lomentaria*) [51, 52]. The authors report that the enzymes are able to convert water insoluble seaweeds into water-soluble materials. Moreover, Heo et al. [52] reported that enzymatic extracts from seaweeds could be used in applications in the food and pharmaceutical industries, because they exhibited noteworthy inhibitory effects against DNA damage.

In fact, the relatively high antioxidant activities of enzymatic extracts from seaweeds reported by Heo et al. [52] (i.e., *E. cava*, *I. okamurae*, *S. fulvellum*, *S. horneri*, *S. coreanum*, *S. thunbergii*, and *S. lomentaria*) are in contrast to those from commercial antioxidants (e.g., αtocopherol, BHA -butylated hydroxyanisol-, and BHT -butylated hydroxytoluene). Moreover, the production of alginate from seaweed by the enzymatic method was reported by Choi et al. [53]. As is well-known, alginate is used in different applications (e.g., food, textile, oil, cosmetics, and pharmaceutical applications) and the authors reported the use of liquozyme for liquefaction, while for saccharification they applied dextrozyme, viscozyme, and rapidasee [53]. There are many reports describing the extraction of proteins from several seaweeds such as *Chondrus crispus* by carrageenase and cellulose, *Gracilaria verrucosa* with agarase and cellulose, and *Ulva pertusa* by cellulose and a macerozyme mixture [54, 55].

#### **Biofuels**

Seaweeds are a plentiful and varied category of "aquatic plants", including both unicellular and multi-cellular forms, that typically possess chlorophyl, although without true stems and roots. Seaweeds are divided into two groups: macroalgae, commonly known as "seaweed", and microalgae, referred to as microscopic single cell organisms. The latter

usually have a size of a few micrometers  $(\mu m)$  to a couple of hundred micrometers [56]. In contrast to terrestrial plants cultivated to produce biofuel, seaweeds do not require agricultural land or irrigation for their cultivation. These plants grow in salt water, and therefore do not compete for land and water to grow [57]. Moreover, if we compare the yield of seaweeds per unit area, it is much higher than that of terrestrial plants. Brown seaweeds grown under suitable conditions show yields of  $\sim$ 13.1 kg dry weight m2/yr, compared to  $\sim$ 10 kg dry weight m2/yr from sugarcane [58, 59]. Despite their obvious potential, there are no reports of the production of economically-viable commercial-scale quantities of fuel from either micro- or macroalgae in the literature [60].

It has been reported that microalgae have a low energy return on investment –EROI– compared to crude oil and diesel. Nevertheless, this can be presently addressed by a raft of study initiatives aimed toward considering the whole spectrum of product, from micro to macroalgae to produce biofuel in biorefineries [61]. There has been a lack of studies directed towards producing fuels or developing feedstocks for fuels from macroalgae [62]. However, the use of macroalgal cultivations of non-fuel is currently a hundred times larger in wet tonnage terms in comparison with microalgae. Today, some cities of the world consumes biofuels obtained from macroalgae and it could be a multi-billion dollar business, with Asia being the most important market [63]. Seaweeds are currently used in human foods, fertilizers, cosmetics, pharmaceutical, and phycocolloids. The most important phycocolloids are agars, alginates, and carrageenans, which are widely used by the food industry with a global production is around 86,000 tonnes. About 221 species of seaweeds are known, 66% of which are used as food [64, 65]. Seaweed biomass is derived from a small number of species from five genera, namely *Laminaria* (or *Saccharina*), *Undaria*, *Porphyra*, *Euchema*, and *Gracilaria*, representing 76% of the total tonnage of cultivated macroalgae [66].

#### **Biocomposites and Composite Materials**

The substitution of petroleum-derived plastics with novel bio-based materials from inexpensive and renewable natural resources will greatly impact the plastics industry (i.e., coatings, composites, etc.) where biodegradable matrices and seaweed by-products are used as fillers [67]. Bio-based items from renewable resources can display comparable and sometimes superior properties than commercial petroleum-based items. Moreover, they (biocomposites) may have progressed reusing and improve its biodegradability capabilities [68]. PLA is a biodegradable polymer matrix (bioplastic), synthesized by the condensation polymerization of lactic acid, which shows promise as a biodegradable aliphatic polyester. PLA is refered to as a "green" polymer since it is available from renewable agricultural resources; thus, its production requires less fossil fuels in comparison to petroleum-based plastics. Nevertheless, this bioplastic has a few disadvantages such as relatively high resin cost, low impact strength and distortion temperature, and brittleness. To overcome the existing limitations and improve the mechanical performance of PLA, some authors have examined the impact of using renewable and biodegradable fillers (e.g., starch, sisal, hemp, and wood fibers) in the PLA matrix [69, 70]. Beyond conventional fillers, seaweed wastes or by-products have recently been generated through the utilization of novel fillers derived via the phycocolloid industry.

Polymer-matrix composites (PMC) can be classified according to whether the matrix is a thermoset or a thermoplastic polymer. Thermoset matrix composites have traditionally received far more attention, though thermoplastic-matrix composites are currently undergoing rapid development. One advantage of thermoplastic-matrix composites compared over thermoset-matrix composites is the lower manufacturing costs involved (i.e., no curing, unlimited shelf-life, reprocessing, low moisture content, weldability, etc.). Disadvantages of thermoplastic PMCs include high viscosities, high processing temperatures, and the need to perform fiber or particle surface treatments.

During the industrial production of agar, huge quantities of seaweed wastes are produced from the filtration step, in which a "filter cake" is produced and eliminated. According to the literature, the filter cake is around 70% of the raw material used. This filter cake consists mainly of residual seaweeds enriched with cellulose, hemicellulose, agar residues, and small amounts of floridean starch. The filter cake also contains diatomite earth, used as a filtration aid in the filtration step. The seaweed by-product is a material enriched with different polysaccharides and can be used as an inexpensive hybrid filler in biocomposites.

Raw seaweed biomass is used as a reinforcement in biocomposites with PBS, PP, high density PE, and PLA have been reported by several authors [36, 71-73]. The filler used in these biocomposites was formulated using seaweeds (i.e., green, brown, and red algae) in a polymeric matrix. The results reported by the authors indicate that seaweeds could be used to produce composite materials using polymeric matrices. These composite materials have potential applications in the automotive, construction, and packaging industries.

#### **CHALLENGES**

Seaweed by-products represent a promising renewable feedstock for applications in the food, energy, pharmaceutical, materials, and environmental industries. It is well known that the industrial production of biopolymers (phycocolloids) from seaweeds produces large amounts of residues, referred to as seaweed wastes (SWWs), which can be used as fillers to produce composite materials or biocomposites. The research in this field is under development and is having a high impact in the environmental and economic fields.

It is important to point out that three aspects that determine the economic viability and environmental sustainability of seaweed production have been highlighted in the literature, namely carbon and energy balance, environmental impact, and cost of production. The production of systems of microalgae under controlled conditions provide good results and the scale-up process is being developed by different research groups and industry. Moreover, during the chemical analysis of the components of seaweed by-products, it is very important to use biomass or its components in different applications such as food, animal feed, agriculture, biodiesel, and cosmetics. The chemical compounds in seaweed by-products include saccharides, proteins, lipids, micronutrients, vitamins, and many other molecules that are yet to be indentified. Some of the algae metabolites, namely lipids, carotenoids, sterols, are compounds that can be extracted by emergent technologies, such as the supercritical carbon dioxide extraction technique. The metabolites can be extracted using co-solvents or different organic solvents, which is sometimes accepted by some regulator agencies when they are used within a limited range. The development of new products for the

pharmaceutical and food industry is representing an opportunity to take advantage of the seaweed by-products of high added value.

# **COLOR STABILITY AND PIGMENT CONTENTS OF POWDERED LAVER (***PYROPIA YEZOENSIS***)**

# *Yoshiyuki Watanabe\* , Masakazu Ikeda, Atsushi Seno, Yu Murabayashi and Masato Nomura*

Department of Biotechnology and Chemistry, Faculty of Engineering, Kindai University, Takaya, Higashi-Hiroshima, Japan

# **ABSTRACT**

Laver, a type of seaweed, is primarily cultivated in the Far East countries of Japan, Korea, and China. Laver gets its color from several pigments, including chlorophylls, carotenoids, and phycobiliproteins; these pigments strongly affect its grade. Because its color depends on the levels of the pigments, the stability of each pigment during storage is important for maintaining the quality of the laver. In this chapter, the color stability of powdered laver (*Pyropia yezoensis*) and the transient changes in its chlorophyll, carotenoid, and phycobiliprotein levels are examined at different temperatures and relative humidities. The color difference,  $\Delta E$ , was found to increase with increasing temperature and relative humidity. Additionally, the amount of chlorophyll decreased and that of pheophytin increased. These findings indicate that the magnesium ion in the chlorophyll molecule dissociates during storage. Pheophytin formation resulted in a decrease in the *L*\* value, which is an index of brightness. The levels of carotenoids, phycoerythrin, and phycocyanin also decreased over time. However, despite the decrease in phycoerythrin levels, the chromatic value, *a*\*, which indicated red/magenta, increased under certain storage conditions, probably owing to the significant decrease in chlorophyll levels, thereby affecting the green color of the laver.

**Keywords:** carotenoid, chlorophyll, color stability, phycobiliprotein, laver

# **1.INTRODUCTION**

Laver is an edible and highly nutritious seaweed; it contains various proteins, minerals, vitamins and functional components, such as polysaccharides and porphyrans [1-3]. It is primarily cultivated in the Far East countries of Japan, Korea, and China, and is examined for utilization as a material for a fermentation culture medium and development of a fermented seaweed sauce [4, 5]. Laver gets its color from several pigments, including chlorophylls (green), carotenoids (yellow), and phycobiliproteins (red and blue), which strongly affect its grade. Chlorophylls are exclusively distributed in green plants as a photosynthetic pigment; chlorophylls a and b are present in higher plants, and the abundance of chlorophyll a in the chloroplast is three times greater than that of chlorophyll b [6]. Chlorophylls have a porphyrin ring with a centrally substituted magnesium ion esterified with a phytol group. Chlorophyll a has a methyl group at the C7 position of the ring, whereas chlorophyll b has an aldehyde group at that same position [7, 8]. Carotenoids are naturally hydrophobic pigments; they are located in intracellular chloroplasts and chromoplasts in colored fruits and green leafy vegetables and belong to the tetraterpene class of hydrocarbons, which contain eight isoprene units [9, 10]. Carotenoids also play important roles in photosynthesis, as do chlorophylls [11]. Phycobiliproteins are hydrophilic pigment-containing proteins and are mainly found in the cytoplasm or stroma of chloroplasts in the Cyanophyceae and Rhodophyceae classes of algae [12]. Phycobiliproteins, which include phycoerythrin (red), phycocyanin (blue), and allophycocyanin (light blue), have different protein structures, phycobilin contents, and chemical properties [13]. Linear tetrapyrrole chromophores, such as phycoerythrobilin and phycocyanobilin, are covalently linked via thioether bonds to a specific cysteine residue in the protein moiety of these molecules [14]. Phycobiliproteins have unique photochemical characteristics [15-18] and various nutraceutical and physiochemical properties, such as antioxidative ability and protective effect on liver injuries and alpha-synuclein toxicity [19- 24]. Therefore, many methods for isolation of phycobiliproteins and preparation of phycobilins have been reported [25-34]. Lots of researchers examined various usages of these phycobiliproteins, such as a photoinduced electron transfer device [35], a microcapsule with polysaccharides [36], a rapid assay for virus antibody detection [37] and a biomaterial grafted to N-succinyl chitosan [38]. Because the color of laver depends on the specific levels of these pigments it contains, the stability of each pigment during storage is important for maintaining its quality. In addition, the region wherein the laver is cultivated and its cultivation style may also influence pigment composition and color quality.

In this chapter, the color stability of powdered laver (*Pyropia yezoensis*) and the transient changes in its chlorophyll, carotenoid, and phycobiliprotein contents are examined at different temperatures and relative humidities.

# **2. MATERIALS AND METHODS**

#### **2.1. Materials**

Laver (*P. yezoensis*) was cultured in Kawazoe-cho, Saga prefecture, Japan, using a polestaking method. Acetone, disodium hydrogen phosphate, lithium chloride, methanol, potassium sulfate, sodium chloride, and sodium dihydrogen phosphate were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Hexane was purchased from Yoneyama Yakuhin Kogyo Co., Ltd. (Osaka, Japan). All chemicals were of analytical grade.

#### **2.2. Preparation and Storage of Powdered Laver**

A specific amount of milled laver powder was placed in flat-bottomed glass cups (1.5-cm internal diameter, 3.0-cm high). Each cup was placed in a plastic container containing a Petri dish filled with saturated lithium chloride, sodium chloride, or potassium sulfate solutions to maintain relative humidities of 12%, 75%, or 96%, respectively. The containers were then stored at 30 $^{\circ}$ C, 45 $^{\circ}$ C, or 60 $^{\circ}$ C in the dark. Each cup was periodically removed from its container, and several measurements of color stability and pigment levels of the powdered samples were carried out.

#### **2.3. Color Analysis of Powdered Laver**

For the color analysis of the laver, 0.5 g of powdered sample was placed in glass cups, which were taken from the plastic containers after storage, as described above. Color analysis of the sample was conducted by colorimetry (ZE 2000, Nippon Denshoku Industries Co., Ltd., Tokyo, Japan). The colorimeter was calibrated with a standard white and black reflective plate. The instrumental values  $L^*$ ,  $a^*$ , and  $b^*$  were recorded; from these values, the color difference,  $\Delta E \left( \sqrt{\Delta L^* + A a^{*2} + \Delta b^{*2}} \right)$ , was estimated. All color measurements were carried out in triplicate, and the mean values were calculated.

#### **2.4. Measurement of the Amount of Chlorophyll**

First, 0.02 g of the laver sample was placed in glass cups. After storage, each sample was moved into a plastic microfuge tube. One milliliter of methanol was added to the tube, and the tube was fully mixed using a vortex mixer (Vortex Genie 2, Scientific Industries, Inc., NY, US). After resting for 5 min, the mixture was centrifuged at 10,000 rpm for 10 min using a centrifugal separator (MX-100, Tomy Seiko, Tokyo). The absorbance of the supernatant was measured at 650 and 665 nm by spectrophotometry (DR4000, HACH Company, CO, USA), and the amounts of chlorophyll a and b were determined using the following formulas [39]:

Chlorophyll a 
$$
[\mu g/g] = 16.5 \times A_{665} - 8.3 \times A_{650}
$$
 (1)

Chlorophyll b 
$$
[\mu g/g] = 33.8 \times A_{650} - 12.5 \times A_{665}
$$
 (2)

All measurements were carried out in triplicate, and the mean values were calculated.

#### **2.5. Measurement of Pheophytin Content**

The laver powder  $(0.05 \text{ g})$  in each glass cup was removed from its respective plastic container after storage and subsequently transferred to a centrifuge tube. After the addition of 10 mL acetone, the tube was incubated in a water bath at  $30^{\circ}$ C for 30 min with vigorous shaking. The tube was then centrifuged at 3,000 rpm for 5 min, and the absorbance of the supernatant was measured at 534 and 556 nm by spectrophotometry [40]. The amount of pheophytin was estimated from the ratio,  $R$ , of  $A_{534}$  to  $A_{556}$ .

#### **2.6. Measurement of Carotenoid Levels**

A simple spectrophotometric procedure for estimating b-carotene levels was applied for the measurement of carotenoid levels [41]. After storage, 0.2 g of the laver sample was transferred from the glass cup to a centrifuge tube. Then, 10 mL hexane was added to the tube and mixed using a vortex mixer. After centrifugation at 3,000 rpm for 5 min, the absorbance of the supernatant was measured at 479, 645, and 663 nm by spectrophotometry. The concentration of carotenoid was calculated using the following formula:

Carotenoids  $[mg/L] = 4.338 \times A_{479} + 1.5835 \times A_{645} + 0.1980 \times A_{663}$ (3)

#### **2.7. Analysis of Phycobiliproteins**

The laver sample (0.1 g) in each cup was transferred to a conical beaker after storage and mixed with 100 mL of 0.05 M phosphate buffer (pH 6.5). After centrifugation at  $7,000 \times g$  for 30 min, the absorbance of the supernatant was measured at 563, 615, and 650 nm by spectrophotometry [42]. The concentrations of allophycocyanin, phycocyanin, and phycoerythrin, which are expressed as *C*AP, *C*PC, and *C*PE, respectively, were calculated using the following formulas:

 $A_{650}=63.5\times C_{AP} + 2.5\times C_{PC} + 0.48\times C_{PE}$ (4) A615=45.0× *C*AP <sup>+</sup> 65.0× *C*PC <sup>+</sup> 1.45× *C*PE (5) A563=17.2× *C*AP <sup>+</sup> 30.6× *C*PC <sup>+</sup> 81.5× *C*PE (6)

# **3. RESULTS AND DISCUSSION**

#### **3.1. Effect of Relative Humidity on Color Stability and Pigment Levels**

The transient changes in color parameters,  $L^*$ ,  $a^*$ ,  $b^*$ , and  $\Delta E$ , for powdered laver at 60°C and three different relative humidities are shown in Figure 1. The psychometric lightness value, *L*\*, was significantly affected by relative humidity. The *L*\* value at 12%

relative humidity was nearly constant during storage for 48 h, whereas the *L*\* value at 96% relative humidity rapidly decreased during the first 5 h. The  $a^*$  and  $b^*$  values are points in a system of coordinates called color space and represent the positions between red/magenta and green, and between yellow and blue, respectively. A positive  $a^*$  value indicates red/magenta, whereas a negative value indicates green. On the other hand, a positive  $b^*$  value indicates yellow, whereas a negative value indicates blue. When the relative humidity was high, the *a*\* value was high but the  $b^*$  value was low. The magnitude of the change in both chromatic values during storage were small compared to the *L*\* value. A transient change in the color difference,  $\Delta E$ , increased with increasing relative humidity. Low humidity during storage was found to suppress the change in the color of the powdered laver. In addition, a decrease in lightness strongly affected the color difference.

Chlorophyll was found to contribute to the degree of green in the color of the laver. Figure 2 shows the transient changes in chlorophyll a and b levels in powdered laver at 60°C and different relative humidities. The amount of chlorophyll a hardly changed during storage, regardless of the relative humidity level. On the other hand, the amount of chlorophyll b was significantly influenced by the level of humidity, drastically decreasing at 96% relative humidity. These results for chlorophyll b are consistent with the dependence of *a*\* on relative humidity, as shown in Figure 1b. Chlorophyll b contains an aldehyde group at the C7 position of a porphyrin ring in the molecule, whereas chlorophyll a contains a methyl group at the same position. Therefore, the stability of chlorophyll b is lower than that of chlorophyll a and is thought to be affected by humidity and adsorbed water molecules on the powder due to the polarity of the aldehyde group.

Figure 1. The transient changes in color parameters (a)  $L^*$ , (b)  $a^*$ , (c)  $b^*$ , and (d)  $\Delta E$  for powdered laver at 60°C and ( $\Diamond$ ) 12%, ( $\Box$ ) 75%, and ( $\triangle$ ) 96% relative humidities. Statistical significance was determined at  $P < 0.05$ .

Figure 2. Dependence of (a) chlorophyll a and (b) chlorophyll b in powdered laver on relative humidity at 60 $^{\circ}$ C and ( $\Diamond$ ) 12%, ( $\Box$ ) 75%, and ( $\triangle$ ) 96% relative humidities. Statistical significance was determined at  $P < 0.05$ .

Next, the formation of pheophytin in powdered laver was measured under the same conditions used to examine the degradation of chlorophyll in more detail. Figure 3 shows the effect of relative humidity on the formation of pheophytin, which is a chlorophyll molecule lacking a central magnesium ion. The formation of dark green pheophytin resulted in a decrease in the *L*\* value, as shown in Figure 1a. As pheophytin formation is affected by humidity, formation was greatest at 75% relative humidity. The reason for this finding remains unclear; the magnitude of the contribution of pheophytin formation to the stability of chlorophyll could not be estimated, although the water activity of powdered laver seems to influence pheophytin formation.

Figure 3. Effects of relative humidity on pheophytin formation in powdered laver at 60 °C and ( $\Diamond$ ) 12%,  $(\square)$  75%, and  $(\triangle)$  96% relative humidities. *R* and  $R_0$  represent the amounts of formed pheophytin and the initial amount of pheophytin, respectively.

Carotenoids are natural yellow pigments that are found in laver as well as in many plants. The stability of carotenoids in powdered laver was measured under the same conditions mentioned above (Figure 4). The carotenoid levels of the laver decreased in a roughly inverse proportion to the level of relative humidity during storage. The results nearly correspond with those shown in Figure 1c, indicating that carotenoid levels affect the stability of the yellowish color of the laver. Since carotenoids are lipophilic compounds with some conjugated double bonds, their molecular structures and chemical properties are similar to those of polyunsaturated fatty acids. Polyunsaturated fatty acids are quite susceptible to oxidation; their oxidative stability depends on the water activity of the food system in which they are found [43]. Thus, oxidation would be expected to affect the stability of carotenoids in powdered laver. The oxidative stability of the carotenoids was found to be influenced by humidity.

To investigate the effects of phycobiliproteins on color stability, transient changes in the amounts of phycoerythrin and phycocyanin in powdered laver at 60°C and different relative humidities were measured (Figure 5). Both phycobiliproteins were stable during storage; their stabilities were nearly independent of humidity, unlike the other pigments examined. Thus, the high stability of phycobiliprotein in conditions of changing water activity was confirmed. Phycoerythrin and phycocyanin appear red and blue, respectively, but their *a*\* and *b*\* values changed over time, despite the consistency of their levels. This finding indicates that the color parameters reflect a relative balance among all the pigments in powdered laver.

Figure 4. Time course of changes in carotenoid levels in powdered laver at 60 $\degree$ C and ( $\diamond$ ) 12%,  $\Box$  75%, and  $(\Delta)$  96% relative humidities.

Figure 5. The transient changes in the concentrations of (a) phycoerythrin and (b) phycocyanin in powdered laver at 60°C and ( $\Diamond$ ) 12%, ( $\Box$ ) 75%, and ( $\triangle$ ) 96% relative humidities.

#### **3.2. Temperature Dependence of Color Stability and Pigment Levels**

The changes in the color parameters of powdered laver were measured at different temperatures and 75% relative humidity (Figure 6). Each *L*\* value promptly decreased over time, plateauing after 24 h. The transient changes in  $a^*$  and  $b^*$  were found to be temperature dependent, with the  $a^*$  value increasing and the  $b^*$  value decreasing over time. Larger changes were associated with higher temperatures. The  $\Delta E$  value, which represents a comprehensive change in color, was also high at high temperatures. The color stability of powdered laver was significantly stable at high temperatures.

Figure 6. The transient changes in color parameters (a)  $L^*$ , (b)  $a^*$ , (c)  $b^*$ , and (d)  $\Delta E$  for powdered laver at ( $\Diamond$ ) 30°C, ( $\Box$ ) 45°C, and ( $\circ$ ) 60°C and 75% relative humidity. Statistical significance was determined at  $P < 0.05$ .

Figure 7. Dependence of (a) chlorophyll a and (b) chlorophyll b in powdered laver on temperature at 75% relative humidity at  $(\diamond)$  30°C,  $(\square)$  45°C, and  $(\square)$  60°C. Statistical significance was determined at  $P < 0.05$ .

The transient changes in chlorophyll a and b levels in powdered laver at different temperatures and 75% relative humidity are shown in Figure 7. Chlorophyll a was stable at all tested temperatures. The decrease in chlorophyll b levels at 30°C was relatively small at 24 h but considerably decreased at 45°C and 60°C. The thermotolerance of chlorophyll b was much lower than that of chlorophyll a.

Figure 8 shows the effects of temperature on pheophytin formation in powdered laver. The formation of pheophytin at 60°C was approximately three-fold greater than at either 30°C or 45°C. Pheophytin was easily formed at high temperatures and did not appear to be associated with the decrease in chlorophyll b levels.

Figure 9 shows the changes in carotenoid levels in powdered laver over time at three different temperatures and 75% relative humidity. Carotenoid levels rapidly decreased at every temperature for first several hours, eventually leveling out. Carotenoid stability depended on storage temperature, decreasing at high temperatures. However, these results were not consistent with those shown in Figure 6c.

Figure 8. Effects of temperature on the formation of pheophytin in powdered laver at 75% relative humidity at  $(\diamond)$  30°C,  $(\square)$  45°C, and  $(\diamond)$  60°C. *R* and *R*<sub>0</sub> represent the amount of formed pheophytin and the initial amount of pheophytin, respectively.

Figure 9. Time course of changes in carotenoid levels in powdered laver at  $(\diamondsuit)$  30°C,  $(\square)$  45°C, and  $\circ$  60°C and 75% relative humidity.

Figure 10. The transient changes in the concentrations of (a) phycoerythrin and (b) phycocyanin in powdered laver at 75% relative humidity at  $(\diamondsuit)$  30°C,  $(\square)$  45°C, and  $(\circ)$  60°C.

The transient changes in the levels of phycoerythrin and phycocyanin at 75% relative humidity are shown in Figure 10. Both phycobiliproteins were stable at 30°C and 45°C, but their levels significantly decreased at 60°C. These results suggest that the chromophore groups in the phycobiliproteins decompose between  $45^{\circ}$ C and  $60^{\circ}$ C and/or the protein moieties denature at these temperatures. Furthermore, the decrease in phycocyanin levels was larger than that of phycoerythrin, indicating the low thermotolerance of phycoerythrin.

#### **CONCLUSION**

The effects of humidity and temperature on the color stability of powdered laver and the transient changes in its chlorophyll, carotenoid, and phycobiliprotein levels have been described in this chapter. Both humidity and temperature significantly affect color stability. The color parameters on color space were confirmed to be comprehensive indices for evaluating the color stability of powdered laver, although of all the pigments examined, chlorophyll b levels affected color differences most strongly. Phycobiliproteins were stable in conditions of varying water activity and unstable at high temperatures. A more detailed and quantitative analysis of color parameter values and pigment levels in laver is needed in the future.

#### **ACKNOWLEDGMENT**

Dried laver was supplied by Mikuniya Co., Ltd., Hiroshima, Japan. The authors are grateful to the company for its co-operation in this study.

# **ABSTRACT**

Currently, there is concern about the increasing number of invasive species Worldwide. These species can displace autochthonous flora and fauna leading to significant negative economic and environment impacts. Invasive seaweeds are a good representative example. They proliferate in coastal areas with consequent negative effects on tourism, fisheries and sea-related industries. In order to revalorise invasive seaweed species, it is therefore necessary to find a potential use for them, which would thereby favour their removal from the environment. In this chapter, we review the potential revalorisation of the seaweed *Sargassum muticum*, an invasive species of concern in European waters. This macroalga presents well-known properties as ion exchanger, with an excellent applicability for pollutant removal. There are many biosorption studies investigating interactions between the biomass of *S. muticum* and different ions, such as Ca, Pb, Cd, Cu, Hg or Cr. In addition, its redox properties applied to the synthesis of nanoparticles, and related applications, are also important. A deep understanding of the interactions between metals/protons and *S. muticum* represents the first step for its commercial valorisation either as a biosorbent or a bioreductant material. This review critically analyses what has been done so far regarding crucial factors that must be investigated prior the potential commercial use of *S. muticum*. An overview is provided of its structural and acid base properties, thermodynamic/kinetic aspects of its interactions with metallic and non-metallic compounds, and column or pilot plant applications.

**Keywords**: *Sargassum muticum*, biosorbent, bioreductant, acid-base, metals

# **INTRODUCTION**

Marine macroalgae, especially brown seaweed species (Phaeophyta division), contain in their structure pigments such as fucoxanthins and xanthophylls, storage products such as laminaran, and also vitamins and minerals, alongside other bioactive compounds. The presence of these compounds makes the use of brown marine macroalgae very attractive for medical, health and nutritional applications (Liu et al. 2012, Kumar, Sahoo, and Levine 2015). Moreover, brown seaweeds have been tested for many years as biosorbents due to their high retention capacity and selectivity for several different contaminants, such as heavy metals or organic compounds (Mazur et al. 2018, Rubín et al. 2010).

The adsorption properties of macroalgae are usually associated with their rigid skeleton form of cellulose fibres, and especially to the specific chemical compounds present in their cell wall;alginates, and to a lesser extend fucoidans. These polysaccharides are the main chemical groups responsible for the adsorption capacities attributed to brown seaweeds (Davis, Volesky, and Mucci 2003). Alginic acid or its salt, alginate, is formed of 1,4-linked  $\beta$ d-mannuronic (M) and  $\alpha$ -l-guluronic (G) acid residues. The alginate's structure and its M:G ratio determine its binding capacity (Davis et al. 2003). The main functional groups present in this polysaccharide are carboxylic acids that present a pK of about 3.2 (Rey-Castro, Herrero, and Sastre de Vicente 2004a). Sulfonic acid ( $pK= 1.5$ ) is the main chemical active group of fucoidans, and the second most abundant acidic functional group present in brown seaweeds, after carboxylic acids (Davis, Volesky, and Mucci 2003). Fucoidans are formed of sulphate esters with l-fucose 4-sulphate units.

The brown macroalga *Sargasum muticum* (Yeldo) Fensholt originated from the northwest Pacific coast of China, Japan and Russia. At present, it is established as an invasive species from Mexico to Canada (East Pacific) and widely distributed around Europe's Atlantic coastal waters, from Portugal to Norway, (Schwartz et al. 2016). *Sargassum muticum* is included in the Global Invasive Species Database, and it is classified as one of the worst invasive alien species on a global scale (Josefsson and Jansson 2011). This seaweed has a high growth and reproduction rate, which favours its competitive behaviour displacing and/or affecting indigenous organisms. Moreover, its uncontrolled proliferation can harm coastal fisheries, aquaculture industries and tourist-based economies (Smetacek and Zingone 2013).

The eradication of *S. muticum* from the coastline by mechanical and manual removal has been unsuccessful. It is important therefore to valorise this seaweed and its by-products in order to make its recovery from the environment a profitable activity. Its by-products, e.g., extracted polysaccharides, polyphenols and fucoxanthins, have been used as antibacterial, antifouling, anticancer, insecticide and cytotoxic compounds, or as sources for the production of active drug substances (Bazes et al. 2009, Vinayaga Moorthi and Balasubramanian 2015, Madhiyazhagan et al. 2015, Casas et al. 2016, Marín et al. 2009). The raw macroalga is also considered an edible substance with nutritional value, but this should be considered cautiously due to its high potentially high content of heavy metals. Moreover, *S. muticum* has been tested as potential biofuel and fertiliser (Balboa, Moure, and Domínguez 2015, Soto et al. 2015, Milledge, Nielsen, and Bailey 2016). Besides these applications, *S. muticum* has

been extensively used in water treatment as an adsorbent for different organic and inorganic species, especially heavy metals (Vieira et al. 2017, López-García et al. 2012, Davis, Volesky, and Vieira 2000, Rubín et al. 2006). Another important application with a broad application range is the use of the aqueous extract from *S. muticum*, which presents high antioxidant potential, for green nanoparticle synthesis (Sanaeimehr, Javadi, and Namvar 2018, Namvar, Rahman, Mohamad, Rasedee, et al. 2015, Madhiyazhagan et al. 2015). Therefore, we review here the potential valorisation of *S. muticum* from two complimentary perspectives: the use of the solid residue of this seaweed as biosorbent, and the use of its liquid extract as reductant agent for nanoparticle synthesis. The economically successful valorisation of seaweed will depend on extensive prior knowledge of its:

- 1) Structural and acid-base properties
- 2) Chemical composition and natural environment
- 3) Binding capacity for metals and other species
- 4) Physicochemical properties in continuous processes, e.g., column studies at laboratory scale and pilot plants
- 5) Redox capacity (of the aqueous extract) e.g., for nanoparticle synthesis

The main goal of this work is therefore to review knowledge in each of these fundamental categories numbered above for the specific case of the invasive seaweed *Sargassum muticum*. This will provide a solid background of knowledge regarding the potential revalorisation of this harmful alga species based on its interaction with inorganic compounds (metals and/or metalloids). A schematic view of the topics that will be addressed is shown in Figure 1. This review supplements other works either focused on the analysis and valorisation of liquid extracts obtained from *S. muticum* (Pérez-López et al. 2014, Balboa, Moure, and Domínguez 2015) or addressing general potential uses and applications of this invasive seaweed (Milledge, Nielsen, and Bailey 2016).

Figure 1. Schematic view of the topics addressed in this review based on interactions of *Sargassum muticum* biomass with metals.

# **METHODS**

The experimental methods normally used on physicochemical studies using *S. muticum* are described below.

#### **Pre-Treatment**

After collection from beaches or at sea, *S. muticum* needs to be washed. The superficially bound sea salts, sand and other residuals can be easily removed after extensive washing with tap or deionised water. Afterwards, drying at mild temperature (c.a. 60ºC) should be performed to avoid putrefaction and damage to the algae structure. The next step is to ground and sieve the dried material in order to obtain homogeneous particles (from c.a. 0.10 to 10 mm) with a high surface area, which will have a significant positive effect on their binding properties. The obtained final material is readily to be used. Nevertheless, further improvement to its physical and chemical properties, e.g., better biomass stability and controlled weight losses, can be made by applying additional specific treatments. The native biomass is stabilised with the main cations present in seawater (Na, K, Ca and Mg). These ions can be displaced from the chemical groups where they are bound in order to modify the alga's structure and its chemical properties. The alga *S. muticum* has been modified by protonation, chemical cross-linking with CaCl<sub>2</sub>, KOH, citric acid and formaldehyde, or esterification of carboxylic groups, by methylene blue, by treatments with acetone, chloroform and methanol to extract the lipid fraction of the algae, and by coating its surface with iron hydroxides (Lodeiro et al. 2004, Carro et al. 2013, Rubín et al. 2010, Vieira et al. 2017). Further details about the experimental design of these treatments can be found in the cited references.

#### **Effect of pH and Ionic Strength**

Protons are always present in solution and have a great impact on the electrical charge of the *S. muticum* surface; the study of the effect of pH on the interactions between *S. muticum* and different species should be therefore investigated in detail. Moreover, the presence of light metals such as Na, K, Mg and Ca in solution also influences the availability of chemical groups for binding. The ionic strength (I) is a variable that accounts for the charge and concentration of ions in solution. In addition to the crucial role of pH, the ionic strength has a tuning action on ionic interactions, and should be also considered when investigating potential applications of *S. muticum*. The experimental approach for pH and ionic strength studies is simple. Different experiments at several pHs, ionic strengths and/or electrolyte types should be performed. Moreover, temperature effects should be also taken into account. The pH must be continuously adjusted until a constant value at equilibrium is reached. It is also important to maintain a constant and gentle stirring to ensure the mixing of the solution and avoid damaging the alga structure. Moreover, not only the salts originally present in solution, but also all the acid/base additions must be considered when calculating the ionic strength. A pH range from 1 to 8 has been used to investigate the performance of *S. muticum*

in biosorption studies. This pH range is limited by the algal integrity and the chemical speciation of compounds in solution. For example, basic pH values can result in the precipitation and subsequent unavailability of specific metals in solution, and the swelling and destruction of the algal structure. A few authors have also investigated the effect of ionic strength and electrolyte type on heavy metal removal using *S. muticum*. A range of ionic strength values from 0.001 to 2 M provided by NaCl,  $KNO<sub>3</sub>$  and NaNO<sub>3</sub> salts were used in these studies (Lodeiro et al. 2004, Carro et al. 2011, Schiewer and Volesky 1997).

#### **Potentiometric Titrations**

Potentiometric titration with a glass electrode is a very simple and accurate technique. It measures the electromotive force between a glass and a reference electrode immersed in a solution. Potentiometric titrations have been used to study the proton binding onto *S. muticum*, and to thereby obtain its maximum proton-exchange capacity, and the equilibrium dissociation constants of its chemical groups. The potentiometric titration of *S. muticum* is very similar to acid-base titrations of simple substances. Nevertheless, the experimental setup requires some additional considerations: for example, a gentle stirring that maintains the alga in suspension but avoids its physical disintegration is required; it is important that the chemical groups of the alga are occupied by protons, and not other cations, since the number of total acid sites can be influenced by the initial protonation state; in addition, the glass electrode readings during a seaweed titration are more unstable than in a common acid-base titration, and as a consequence, the titrations take a long time (c.a. 6-7 hours for protonated *S. muticum*). Titrations should be performed in a close thermostated vessel under inert gas bubbling to remove the effects of  $CO<sub>2</sub>$  and  $O<sub>2</sub>$ . It is also important to use an inert electrolyte in both the suspension containing the alga and the titrant added, in order to minimize the change in proton activity coefficient. The *S. muticum* dose required to obtain quantitative and accurate results is 5 g/L. Please refer to the book chapter Lodeiro et al. (Lodeiro et al. 2018) for further experimental and theoretical details about acid-base properties of biosorbents.

#### **Isotherms and Kinetics**

The experimental determination of *S. muticum* adsorption capacity and binding strength is achieved through batch experiments at constant pH, ionic strength and temperature, using increasing concentrations of sorbate. The initial experimental concentration depends on the sorbate type and the applied pre-treatment of the seaweed. For example, for metals the concentration ranges which have investigated are, As: 0.013-0.53 mmol/L (Vieira et al. 2017), Cd: 0.09-3.1 mmol/L (Lodeiro et al. 2005, Freitas et al. 2008), Cr(III): 0.20-9.6 mmol/L (Lodeiro et al. 2008, Vilar et al. 2011), Cu: 0.10-5 mmol/L (Herrero et al. 2011), Hg: 0.25-5 mmol/L (Carro et al. 2009, Carro et al. 2015), Ni: 0.02-2.5 mmol/L (González Bermúdez et al. 2011) and Sb: 0.02-0.41 mmol/L (Ungureanu et al. 2017). In the case of organic compounds the concentration ranges investigated are wider, with 0.042-0.21 and 0.031-31.3 mmol/L for the dyes Basic Violet 10 (Devi, Murugappan, and Rajesh Kannan 2015) and Methylene Blue (Rubin et al. 2005), respectively; and with 0.078-77.8 mmol/L for phenol and 0.11-5.31 mmol/L for chlorophenols (Rubín et al. 2006). Biosorption kinetic

experiments using *S. muticum* are relatively fast. The necessary time to achieve constant adsorption capacities is between 20 and 600 min for metals and organics. The *S. muticum* dosage used on isotherm and kinetic experiments varies between 0.5 and 10 g/L.

#### **Column Studies at Laboratory Scale and Pilot Plants**

Continuous column experiments allow a more efficient use of seaweeds on biosorption studies. Moreover, laboratory column design experiments are a required step to extrapolate the obtained results to pilot plants and promote industrial/market applications. A fixed-bed column design has been used with *S. muticum* in laboratory scale experiments. A porous sheet or geotextile material was used to support the biomass, while the top of the bed is usually covered with glass beads to ensure good packing and low material loss. Glass columns of c.a. 25–50 cm length and 1–5 cm of diameter, filled with 5–30 g of *S. muticum* and a flow rate range from 0.5–20 mL/min were tested (Lodeiro, Herrero, and Sastre de Vicente 2006b, a, López-García et al. 2012, Carro et al. 2011, Ungureanu et al. 2017). To the best of our knowledge, the group of M. E. Sastre de Vicente at University of A Coruña is the only one that has used *S. muticum* in a pilot plant (unpublished work). This pilot plant consisted of 4 columns of 2.4 m height each and 5 (2x) – 12 (2x) cm of diameter (Figure 2). A geotextile material was used to support the biomass (up to 15 Kg). The pilot plant was tested with wastewaters from an aluminium factory at flow rates between 0.5 and 5 L/min.

#### **Redox Capacity of the Aqueous Extract: Formation of Nanoparticles**

Several authors have studied the synthesis of nanoparticles using the aqueous extract of *S. muticum*. Specifically, this extract was used to obtain ZnO (Azizi et al. 2014, Sanaeimehr, Javadi, and Namvar 2018), Fe3O4, (Mahdavi et al. 2013, Namvar et al. 2014), Ag (Azizi et al. 2013, Madhiyazhagan et al. 2015, Moorthi, Balasubramanian, and Mohan 2015) and Au (Namvar, Azizi, et al. 2015) nanoparticles. The aqueous extract was obtained by heating 0.2– 10 g of *S. muticum* in 100 mL of deionised water at 60–100ºC for 5–20 minutes. The obtained extract was then filtered and stored frozen until use. Different experimental conditions are required for the preparation of each specific nanoparticle, depending on the nanoparticle type and specific characteristics such as size and shape. Moreover, it is also possible to obtain nanoparticles after direct contact in solution between *S. muticum* and specific metals (Namvar, Rahman, Mohamad, Rasedee, et al. 2015, Lodeiro and Sillanpää 2013b).

# **STRUCTURAL AND ACID–BASE PROPERTIES**

*Sargassum muticum* is a brown algae that contains anionic polysaccharides, alginates and fucoidans in its cell wall, which is supported by cellulose fibres. The alginate content of *S. muticum* can account for c.a. 15–20% of its dry weight; while in other brown seaweed species (e.g., *Ascophyllum nodosum* or *Laminaria* spp.) the alginate percentages can reach up to 40% (Davis et al. 2003). Despite this relatively low alginate content, *S. muticum* shows other key

characteristics that make it exceptional. For example, the M:G ratio of the Na–alginates extracted from *S. muticum* is c.a. 0.31 (Davis et al. 2003). This low ratio reflects the high content of guluronnic blocks, and represents a unique feature compared to other brown algae. Only the brown seaweed *Laminaria hyperborea* presents a similar ratio; nevertheless, it leaches more polysaccharide matrix at low pH values than *S. muticum*, which makes *L. hyperborea*, and other similar brown seaweeds, less attractive for practical adsorption/desorption applications.

Structural integrity of *S. muticum* is necessary for large scale operations over prolonged time periods. The use of raw alga, after a simple wash, dry, ground and sieve process is therefore not recommended for industrial and practical approaches. Some treatments can improve the raw seaweed mechanical properties and performance through modification of the chemical groups present on the alga surface. Raw *S. muticum* can lose c.a. 30% of its weight and release 122 mg/L of total organic carbon (TOC) in aqueous solution (Table 1). The application of different treatments to *S. muticum* to extract its lipid fraction, cross–link or esterificate its chemical groups has been shown to lead to considerable decreases in the TOC (up to 96%) and mass lost in solution of this invasive seaweed (Table 1) (Lodeiro et al. 2004, Rubín et al. 2010). Despite improving its structural integrity the treatment can however also reduce the alga adsorption capacity. For example, with extraction of Hg or Cr(VI) the dominant removal mechanism is the reduction of the metal ion; treatments that modified or interact with the hydroxyl groups of *S. muticum*, e.g., citric acid, are therefore not recommended. This is because hydroxyl groups, involved in the reduction mechanism, interact with some chemicals used for the treatment. Another example is the use of Ca pre– treated *S. muticum* for Cd removal; the similar ionic ratio of Ca and Cd results in very low selectivity of the alga for the heavy metal, which decreases the adsorption capacity of treated material compared to the raw biomass. The combination of high structural stability and high guluronic acid content is one of the key aspects that makes *S. muticum* a unique material for biosorption processes.

## **Table 1. Weight loss of native and pre-treated Sargassum muticum after 3-4 h of stirring in water, weight loss due to the treatment, and total organic carbon (TOC) measured in solution after treatment. These values show a considerable improvement of the alga structural integrity. Adapted from Lodeiro et al. (Lodeiro et al. 2004)**

Other important structural parameters that can be used for modelling purposes and account for swelling, are the specific surface area and Donnan volume (see acid–base properties below). Experimental determination of these parameters is a challenge and therefore empirical values are usually assumed. The specific surface area of *S. muticum*  $(537 \times 10^3 \text{ m}^2/\text{Kg})$  has been experimentally obtained by dye adsorption (Rubin et al. 2005). This value is one order of magnitude lower that the calculated from proton binding (4400–  $4800x10^3$  m<sup>2</sup>/Kg) by Rey–Castro et al. (Rey-Castro, Herrero, and Sastre de Vicente 2004b). This disparity can be attributed to the different adsorption mechanisms of protons and dyes onto *S. muticum*. Schiewer and Volesky have experimentally established a correlation for the gel volume (total volume) of Sargassum genus algae with pH (Schiewer and Volesky 1997); the values found were between 5 and 10 L/Kg. Rey–Castro et al. obtained similar Donnan volumes for *S. muticum* from fitting proton binding data (5.2–5.7 L/Kg), yet these volumes correspond only to the effective or active volume where the proton binding reaction takes place, and are therefore lower than the ones determined experimentally, which account for the total gel volume (Rey-Castro et al. 2003). Therefore, despite the importance of the Donnan volume and specific surface area for proton binding modelling, these parameters have a limited physical significance.

The research groups of Sastre de Vicente at University of A Coruña (Spain) and Boaventura at University of Porto (Portugal) have investigated the acid–base properties of *S. muticum* using simple potentiometric titrations with glass pH electrodes. The total amount of alginate and other polymers containing active functional groups depends not only on the seaweed species (*S. muticum* in this case), but also on the specific water conditions where the alga was harvested, such as salinity or organic content, and the season, light conditions, etc. The maximum proton binding capacities for *S. muticum* were between 2.40–2.61 mol/Kg of alga (Lodeiro et al. 2004, Vieira et al. 2017). These values were calculated considering only one type of acidic group obtained from the fitting of titration experimental data to a Langmuir–Freundlich (L–F) isotherm or from calculating the inflection point of the titration curves. This approach is valid over a pH range from 2 to 9, which is the pH range of interest in biosorption studies. When two different acidic groups were considered, Lodeiro et al. found 1.78 and 1.33 mol/Kg (Lodeiro et al. 2008), while Ungurenau et al. obtained 1.31 and 1.10 mol/Kg (Ungureanu et al. 2017) of carboxyl and hydroxyl groups, respectively. Values for conditional proton affinity constants ( $log K$  or  $pK$ ) were 3.85, calculated using the Katchalsky model at 0.5 dissociation degree, and 3.80, obtained from least–squares fit of the NICA (L–F) or Langmuir isotherms to the proton binding data. The values of pK obtained using a polyacid expression were 3.41 and 10.2 for carboxylic and hydroxyl groups, respectively, both in 0.05 mol/L NaNO<sub>3</sub>. Applying a continuous model for the proton binding based on the Langmuir isotherm and Sips distribution Ungurenau et al. (Ungureanu et al. 2017) obtained a pK of 3.38 and 9.8 for carboxylic and hydroxyl groups, respectively, in NaCl 0.1 mol/L. Moreover, the heterogeneity degree parameter was between 0.53 and 0.66, depending on the electrolyte type and expression used to account for the water content of the alga. The ionic strength of the medium does not influence the obtained number of acid sites, but it strongly affects their apparent conditional affinity constants. Moreover, it is worth mentioning that the accuracy of the charge and pH data calculated for the titration curve analysis decreases drastically above pH 10 (Rey-Castro et al. 2003). Therefore, the study of acid groups at high pH values  $(>=0-10)$  using potentiometric techniques will invariably be affected by large errors.

Rey–Castro et al. proposed the use of the L–F isotherm to account for the specific proton binding, combined with the Donnan model, which describes the electrostatic contribution to the proton binding assuming the interphase to behave as a permeable three–dimensional gel (Rey-Castro et al. 2003). This model, in combination with the master curve approach, accounts for the effect of pH and ionic strength on proton binding to *S. muticum* allowing the estimation of two isotherm parameters describing the intrinsic heterogeneity, and a geometric parameter (Donnan volume) to be calculated independent of the titration conditions. The obtained log K value was 3.18, while the maximum proton binding capacity was 2.61 mol/Kg and the heterogeneity parameter 0.58. In subsequent work, these authors also fitted the proton binding data to a surface charge model that describes the alga as a non–permeable twodimensional surface with a specific surface area as its main feature (Rey-Castro, Herrero, and Sastre de Vicente 2004b). Both models seemed to describe the titration data equally well, although the Donnan model additionally provides a simple way to account for the effect of activity coefficients and the non–specific binding.

## **CHEMICAL COMPOSITION AND NATURAL ENVIRONMENT**

Different authors have measured the presence of metals, micronutrients and other elements in native *S. muticum* (Tables 2, 3 and 4). The presence of metal and/or metalloids in the algal structure reflects the interactions of *S. muticum* with the natural media where it has grown. The algal elemental composition is in fact also associated with seasonal factors such as temperature, light, salinity and nutrient concentrations. In addition, the chemical composition can also reflect the pollution present in specific sampling sites.

The interactions of metals and algae in seawater are part of a complex system and occur through different mechanisms involving adsorption and redox processes (Morel and Price 2003). Most of the bio–limiting metals (e.g., Fe, Zn, Mn, Ni, Cu, Cd and Co) exist as cations complexed to organic and inorganic ligands that promote the bioavailabity of these essential metals in seawater. Despite their extraordinarily low concentrations  $(<0.1 \mu M$ ) in seawater these metals play crucial roles in most cellular processes (Sunda and Huntsman 1998). Algae uptake and store essential metals through membrane transport proteins and specialized enzymes. Nevertheless, these compounds are not entirely specific for essential metals, and toxic metals (e.g., Ag, As and Pb) can be also taken up into cells, rendering proteins and associated metabolic pathways dysfunctional (Lodeiro et al. 2017). In addition, neutral/non– polar compounds such as HgCl or AgCl can directly diffuse across the cellular membranes of seaweeds. The general mechanism underlying metal uptake by seaweeds in a natural environment can be simplistically described in two steps: metal fixation (adsorption) onto the seaweed surface, and consequent metal internalization involving metabolic activity. In some cases the seaweed can reduce metal ions, such as  $Fe(III)$  to  $Fe(II)$ , extracellularly to access otherwise unavailable metals through enzymatic pathways (Morel and Price 2003).

In the absence of metabolic activity (non–living seaweed) the uptake of metal ions process is the so–called biosorption (Volesky 2003). Whereas, if metabolic activity is involved the uptake mechanism is known as bioaccumulation. In natural environments both biosorption and bioaccumulation occur widely and so the chemical elements measured in algae are consequence of both processes (Tables 2, 3 and 4). As mentioned, the chemical

composition of the algae depends on its physiological stage, the season, and physicochemical properties of the environment where it was harvested. This variability, together with the different experimental protocols used for the analysis of elemental composition makes it challenging to quantify, evaluate and compare the chemical composition of *S. muticum*. The inorganic content of *S. muticum* harvested at different locations and seasons has been investigated in a few works (Tables 2 and 3). As expected, the major ions present in seawater, i.e., Na, Mg, Ca and K, are the main elements in the alga structure, with values from c.a. 0.32 to 1.50 mmol/g for Na, 0.43 to 1.09 mmol/g for Mg, 0.23 to 1.74 mmol/g for Ca and 0.35 to 2.1 mmol/g for K (Table 2). Of particular concern is the accumulation level of potentially toxic metals such as Cd, Pb, Ni, Hg or As; for example, *S. muticum* contains As in relatively high concentrations compared to other macroalgae not belonging to the *Sargassum* genus (Whyte and Englar 1983). The concentrations of As, Cd, Hg or Pb have been found in *S. muticum* at levels of 0.099–3.04, 0.0023–0.0133, 0.00011 or 0.0053–0.079 µmol/g, respectively (Table 2). Therefore, potential applications of *S. muticum* as an edible species, fertiliser, animal feed and in other applications closely related to human nutrition, should be considered cautiously due to the risks associated with the presence of toxic heavy metals in its structure and the restrictive legislation regarding these harmful metals (Besada et al. 2009, Rubio et al. 2017). *Sargassum muticum* also exhibits high ash content and this, as stated by Milledge et al. (Milledge, Nielsen, and Bailey 2016), can be a problem for applications in combustion or the gasification of biofuels. Some commercially available seaweeds even present radioactive isotopes in their structure (van Netten et al. 2000), although as far as we are aware no presence of radionuclides has been measured in *S. muticum*. Moreover, macroalgae are considered as a useful biomonitor or bioindicator of environmental contamination due to their high metal uptake capacity (Chakraborty et al. 2014). Essential micronutrients with potential control over *S. muticum* growth were found at relatively high concentrations; for example Fe, Mn and Zn are present at concentrations ranges of 1.22– 18.26, 0.15–7.64 and 0.19–4.70 µmol/g, respectively (Table 3).

Light metals, e.g., Na, K, Mg or Ca are electrostatically bound to charged chemical groups in the alga. These hard counterions cannot therefore displace other elements that form covalent bonds such as protons or heavy metals, but can affect their bond by reducing their local concentration. Therefore, the concentration of light metals in *S. muticum* should provide a qualitative indication of its proton binding capacity. For example, the total amount of Na, Mg, K and Ca found in the alga *S. muticum* used in different works of Lodeiro et al. is 2.94  $mEq/g$  (Table 4). This value is c.a. 13% higher than the total proton binding obtained from potentiometric titrations when considering one type of acid group (2.61 mmol/g), and only c.a. 5% lower when considering two main acid groups in the alga  $(3.11 \text{ mmol/g})$ . This small discrepancy can be ascribed to the inaccessibility of some light metals, which are not displaced by protons and/or some multidentism in the proton bound.

#### **BINDING CAPACITY FOR METALS AND OTHER SPECIES**

The alga *S. muticum* has been used as biosorbent for many different metals and organic compounds (Table 5). The ion–exchange properties of this invasive seaweed make it potentially useful for decontamination or preconcentration processes in aqueous solutions. The binding capacity of *S. muticum* depends on environmental factors such as pH, ionic strength, temperature, the presence of competitive agents and adsorbate´s speciation; moreover, other factors such as the time required to achieve adsorption equilibrium, the alga dose and its specific chemical composition will also affect the binding. Several authors investigated all these factors in order to determine optimal operational conditions (Carro et al. 2015, Freitas et al. 2008, González Bermúdez et al. 2011, Herrero et al. 2011, Lodeiro et al. 2004, Ungureanu et al. 2015, Vieira et al. 2017, Vilar et al. 2011).

To date *S. muticum* has been used to decontaminate solutions containing As, Cd, Cu, Cr, Hg, Ni, Pb, Sb or Zn (Table 5). The alga efficiency, under optimal operational conditions, present a broad range of adsorption values depending on the metal type; for metals that are positively charged in solution over the pH range of study, e.g.,  $Cu^{+2}$ ,  $Cd^{+2}$ ,  $Ni^{+2}$  and  $Cr^{+3}/Cr(OH)^{+2}$ , the maximum adsorption capacities are 1.12 (Herrero et al. 2011), 1.20 (Lodeiro et al. 2005), 1.29 (González Bermúdez et al. 2011) and 1.42 (Lodeiro et al. 2008) mmol/g, respectively. This series is in agreement with the divalent metal–alginate selectivity  $(Ni > Cd > Cu)$ , evidencing the role of alginates in the binding. Moreover, these metals present their maximum adsorption capacities at pH values near the dissociation constant of carboxylic acids observed for *S. muticum*. This also demonstrates the key role of these chemical groups that form part of the alginates. The adsorption capacity of alginates for divalent cations depends on the ratio of mannuronic and guluronic acids (M:G) that forms their structure, and their macromolecular conformation. Divalent metals present a higher affinity for guluronic acids due to the formation of the so–called egg–box structure, and therefore the adsorption capacity of *S. muticum* for toxic divalent metals will be increased with its content of guluronic acids.

Other metals such as As and Sb present a neutral or negatively charged form in solution, and their adsorption (0.045–0.093 mmol/g) is therefore not favoured (Vieira et al. 2017, Ungureanu et al. 2017). Nevertheless, if the adsorption mechanism involves not only ionic exchange or ionic/covalent binding but also a redox process, the removal of negatively charged or neutral metal species can be considerably improved. This is the case of Cr(VI), which is present in solution as HCrO4, or Hg, which occurs as two neutral forms (HgCl<sub>2</sub> and HgClOH) at pH values between 1 and 6. The presence and abundance of chemical groups in *S. muticum* with reduction capacity is critical when a redox process is involved in the removal mechanism (López-García et al. 2012, Carro et al. 2013). This seaweed presents hydroxyl, phenol and amino groups that can act as electron donors. These groups form part of the polysaccharide structure, and the internal cell wall composed of cellulose. Moreover, it should be also considered that the *S. muticum* reduction potential is favoured at acidic pH values, which implies that most chemical groups are protonated and can attract negatively charged compounds.

Synthesis of nanoparticles from Sargassum muticum aqueous extracts. **Table 6. Synthesis of nanoparticles from Sargassum muticum aqueous extracts.**

The removal of organic compounds present variable results depending on the *S. muticum* pre–treatment. For example, raw and acetone treated *S. muticum* present a maximum uptake capacity of cationic dyes between 0.16 and 2.69 mmol/g, for Basic Violet 10 (Devi, Murugappan, and Rajesh Kannan 2015) and Methylene Blue (MB) (Rubín et al. 2010), respectively (Table 5). The adsorption of these cationic dyes is favoured at low pH values, for which the seaweed is protonated, and therefore not only pure electrostatic but also hydrophobic interactions account for the adsorption. Moreover, treatments that extract the lipid content (e.g., acetone treatment) of the alga clearly improve the MB adsorption. On the other hand, *S. muticum* adsorption capacity for chlorophenols (1.95 mmol/g) is much higher than for phenol  $(0.049 \text{ mmol/g})$  (Table 5). In the case of phenolic adsorption hydrophobic and donor acceptor interactions have been suggested to play a key role, and their adsorption is reported to agree with the corresponding octanol–water partition coefficients (Rubín et al. 2006). The donor–acceptor interactions occur between the aromatic ring activated by the -OH and -Cl substituents and the surface groups of *S. muticum*; in addition the interactions of phenols with the algae can also occur due to complex formation or the distribution of these neutral phenols between the aqueous solution and the wall cell structure of the alga. As a result, the more hydrophobic organic compounds are the better will be adsorbed.

# **COLUMN STUDIES AT LABORATORY SCALE AND PILOT PLANTS**

Continuous flow studies constitute an essential step towards large scale/commercial applications of *S. muticum* as a biosorbent. Fixed–bed columns packed with this seaweed have been used in continuous flow experiments. Useful information, e.g., the service and exhaustion times, can be obtained from the characteristic breakthrough curves. For example, breakthrough curve areas were used to calculate sorption and reduction percentages for mercury elimination using *S. muticum* (Carro et al. 2013). Best operational conditions can be found by modelling the dynamic behaviour of the fixed–bed columns, which is also useful to scale–up the system (Mazur et al. 2018). The effect of flow rate and bed depth on the biosorption of metals was investigated in order to obtain the shortest column mass transfer zones (Lodeiro, Herrero, and Sastre de Vicente 2006b, Ungureanu et al. 2017).

*Sargassum muticum* biomass was used in fixed–bed column experiments to decontaminate solutions containing Cr (López-García et al. 2012), Hg (Carro et al. 2011, 2013), Cd (Lodeiro, Herrero, and Sastre de Vicente 2006b, a), Sb (Ungureanu et al. 2017) and MB (Carro et al. 2013). An improvement on the mechanical, physical and/or chemical properties is recommended for continuous flow operational modes; thus a treatment of the raw seaweed is usually performed. Raw, protonated and ethanol–treated *S. muticum* were used in these continuous flow experiments. For species that show a sorption–reduction removal mechanism, protonated *S. muticum* cleaned up to 3.6 L of a solution containing 0.5 mmol/L of Hg (Carro et al. 2011), or 46.2 L of a 50 mg/L Cr(VI) solution (López-García et al. 2012). Using the raw seaweed the treated volumes for the same Hg solution increased up to 13.5 or 24 L at similar residence times, while using an ethanol–treated biomass 16.7 L were decontaminated (Carro et al. 2011, 2013). Cadmium is positively charged in solution and no–redox reactions are involved in its removal; in this case, a maximum concentration of Cd in the effluent of 0.05 mg/L was obtained after treating 6.2 L of 50 mg/L initial concentration solution using protonated *S. muticum* (Lodeiro, Herrero, and Sastre de Vicente 2006b). For antimony oxyanions only 2.6 L of a solution containing 1 mg/L Sb were decontaminated obtaining a maximum effluent concentration of 0.1 mg/L using the native seaweed (Ungureanu et al. 2017).

The elution and regeneration of the columns is also essential for continuous operational modes. To the best of our knowledge there is only one paper that shows uninterrupted sorption–desorption cycles in a fixed-bed column using *S. muticum* (Lodeiro, Herrero, and Sastre de Vicente 2006a). In this work, a column was operated for the removal of 50 mg/L of Cd from solution during 605 h for sorption, and 66 h for desorption using  $HNO<sub>3</sub> 0.1$  mol/L. This is equivalent to continuous use over 28 days, with no apparent loss of sorption performance, despite the 27% weight lost found at the end of the process.

Briefly, we would also like to highlight the first test of *S. muticum* in a pilot plant carried out by the group of M. E. Sastre de Vicente at The University of A Coruña. Here experiments were performed to investigate the potential use of pre–treated *S. muticum* to decontaminate wastewaters from an aluminium factory. Very promising results (unpublished) were obtained that encourage us to persevere with the idea of revalorising the invasive seaweed *Sargassum muticum* as adsorbent/ion-exchanger material.

# **REDOX CAPACITY OF THE AQUEOUS EXTRACT: SYNTHESIS OF NANOPARTICLES**

The interactions of S*. muticum* biomass with some metals in solution may lead, depending on the physicochemical environment and nature of the system, to the formation of metal nanoparticles (Figure 1). Metal nanoparticles have important applications in many technological areas of interest, i.e., from medicine or pharmacy to electronics. There is therefore a sustained interest in the development of synthetic routes to obtain metal nanoparticles. Currently, there is an unequivocal trend to adopt greener synthesis processes when possible. Thus, researchers are starting to use so–called biological synthesis, biosynthesis or biogenic synthesis methods to manufacture nanoparticles. These eco–friendly syntheses are cleaner, safer and cheaper than the commonly used chemical or physical methods. The main aim is to eliminate or reduce toxic solvents and energy input requirements. Therefore, water is the first choice of solvent and the experiments are performed at ambient pressure and temperature. Moreover, the biological synthesis use renewable resources from inexpensive biomass as feedstock, with adaptation to a wide range of systems and to large–scale possible applications (Asmathunisha and Kathiresan 2013, Vijayan et al. 2016, Dahoumane et al. 2017). Marine biomass meets these criteria and is becoming a promising feedstock material in the area of nanobiotechnology. Algae are rich in bioactive compounds such as polyphenols, polysaccharides, carotenoids and proteins. These chemical species have a high reducing capacity. They are able not only to generate metallic nanoparticles from aqueous soluble salts of metals, but simultaneously supply, non–toxicstabilizing agents for the nanoparticles formed. The process is commonly performed starting from aqueous extracts of algae biomass.

Nanoparticles with different sizes and shapes were obtained by green synthesis using the invasive seaweed *S. muticum* (Table 6). Moreover, some of these works also included preliminary experiments on the biological activity (e.g., anticancer, cytotoxic effect or insecticidal activity) of the manufactured nanoparticles (Sanaeimehr, Javadi, and Namvar 2018, Namvar, Rahman, Mohamad, Rasedee, et al. 2015, Namvar et al. 2014, Moorthi, Balasubramanian, and Mohan 2015, Madhiyazhagan et al. 2015). The size and shape of nanoparticles have a crucial role on their properties. Thus, future research should be focused on obtaining reproducible results for homogeneous and monodisperse nanoparticles. Therefore, it is important to investigate different experimental parameters such as temperature, ionic strength, pH, extract concentration, and reaction time that yield high– quality nanoparticles to use for industrial or medical applications.

Finally, it is worth mentioning that there is an urgent need for understanding the mechanism of the biosynthesis of nanoparticles, and to identify and quantify the chemical components involved in the process (Adil et al. 2015). Despite this lack of knowledge, there is already an ongoing effort to extract and quantify natural antioxidant products, e.g., phenolic compounds and polysaccharides, from *S. muticum* (Anaëlle et al. 2013, Casas et al. 2016, Flórez-Fernández et al. 2017, Rodrigues et al. 2017, Mazumder et al. 2016, Balboa et al. 2016).

# **THE SORBIGAL PROJECT**

The SORBIGAL project was the first attempt of large–scale industrial valorisation of the invasive alga in Europe *Sargassum muticum*. The spin–off SORBIGAL project was funded and promoted by M. E. Sastre de Vicente at The University of A Coruña.

The idea for the valorisation of the seaweed *S. muticum* was based on its great properties as an adsorbent/ion exchanger, and the need for an alternative commercial use to subsidise its extremely difficult eradication. Essentially, we wanted to obtain a biosorbent (low cost adsorbent/ion exchanger of biological origin) by harvesting and processing *S. muticum*. A previous solid knowledge on the physicochemical properties of *S. muticum* was crucial for the SORBIGAL project. The group of Sastre de Vicente at The University of A Coruña acquired this expertise after investigating the interactions of this seaweed with metallic and non– metallic compounds in solution from laboratory basic research to pilot plant scale. A brief summary of the itinerary followed is schematically reflected in Figure 2.

The SORBIGAL idea (M. E. Sastre de Vicente, private files of SORBIGAL project; unpublished personal communication) was awarded in 2009 by The University of Santiago de Compostela. As recently pointed out by Milledge (Milledge and Harvey 2016), we thought in that moment that to valorise *S. muticum* as biosorbent was a "golden" opportunity. The marketisation process of using *S. muticum* as a biosorbent however presented many challenges and was finally cancelled after some years of effort. We think that the main possible causes for the lack of success were:

- 1) The idea of *S. muticum* valorisation as adsorbent/ion exchanger was not good enough for the market.
- 2) The financial crisis in Spain, which activated a considerable cut in the budget of research and development (R&D) activities. In addition, the absence of private investors and/or seed money.
- 3) Bureaucratic limitations due to necessary administration permissions for harvesting invasive biomass that is considered an exploitation of resources.
- 4) The lack of experienced people in management and market related activities.
- 5) The absence of cooperation with other research groups and industries/companies.
- 6) The focus in only one specific valorisation of *Sargassum muticum* as biosorbent, and not considering other alternative uses of this invasive seaweed as a whole.

Figure 2. Schematic view of the main experimental stages carried out to revalorise *S. muticum* as adsorbent/ion exchanger material. The SORBIGAL project stopped at the stage 4, before starting the potential commercialization of the pre–treated seaweed.

Looking back, we currently think that the best way to valorise *S. muticum* would be the cooperation of a consortium involving research–companies and universities with the participation of market experts. In addition, the valorisation should be oriented to obtaining multiproducts from *S. muticum* biomass. Is this task easy? Is the effort worth it? We hope to answer these and other related questions in the near future.

# **CONCLUSION**

Currently, there is a considerable amount of information regarding the interactions of *Sargassum muticum* with metals. This is due to several years of investigations by different

research groups worldwide. Most of this work can be easily related with the potential use of *S. muticum* as biosorbent.

The behaviour of *S. muticum* in aqueous solutions has been studied at different levels. For example, initially investigating the fundamental acid–base properties of this biomaterial, and finally running pilot plant tests with apparently successful results.

The biogenic synthesis of nanoparticles from *S. muticum* extracts also presents interesting perspectives. This area has been less developed than the biosorption topic, and thus requires more research. For example, the identification and quantification of the chemical species involved in the formation and stabilization of nanoparticles should be further investigated.

In addition to the valorisation routes described in this article, we think that to success place *S. muticum* on the market the participation of different stakeholders such as administrations, research groups and companies is required. The valorisation should considered *S. muticum* as a whole, exploiting also its properties in medicine, cosmetics and/or its potential use as a fuel.

More than forty years after the entry of *Sargassum muticum* in Europe as an invasive alga there are still many open paths for continuing with new revalorisation research ideas.

# **NEW INSIGHTS INTO SEAWEEDS ON NUTRITION AND FUNCTIONALITY**

# *Antonio Jiménez-Escrig\**

Spanish National Research Council (CSIC), Madrid, Spain

# **ABSTRACT**

Epidemiological studies have provided evidence that plant-based foods play a crucial role in the prevention of chronic diseases. The association between dietary vegetable intake and chronic diseases is mainly attributed to vegetables providing dietary fiber, as well as a wide range of secondary compounds called phytochemicals. Seaweed research is an emerging trend in functional foods for the prevention of degenerative diseases. Seaweeds are rich sources of vitamins, minerals and dietary fiber required by the human body for optimal health. In addition, seaweeds are diverse in promising bioactive compounds such as soluble dietary fibers, peptides, phlorotannins, carotenoids, and fucosterol which are amongst the most promising of macroalgae's compounds in terms of functional foods/nutraceuticals. Polyphenols from seaweeds are gaining dietary importance due to their influence over diabetes mellitus and the role as a vital source of high-value nutraceutical. The objective of this chapter is to highlight recent advances made in the search of seaweeds as sources of new functional ingredients, highlighting the new challenges and opportunities regarding healthy effects of the seaweeds.

**Keywords:** alginate, biomass extraction, fucosterol, fucoxanthine, functional, nutrition, phlorotannins, prebiotics

# **INTRODUCTION**

Seaweeds or macroalgae are classified into three higher taxa: brown (*Class Phaeophyceae*), red (*Phylum Rhodophyta*) and green (*Phylum Chlorophyta*) (Guiry 2013). Seaweeds are harvested and used globally for many different applications, such as ingredients

 $\overline{a}$ 

<sup>\*</sup> Corresponding Author's Email: a.jimenez.escrig@csic.es.

in food and cosmetic formulations, and have considerable economic importance (Tierney 2010). At present, around 31 million tons (wet weight basis) of seaweeds and other aquatic plants are produced/captured annually (FAO 2016). Recently, the production, marketing and consumption of seaweeds in food products have increased significantly, not only in countries where there is a traditional use such as Japan and China, but also in many Western countries (Tierney 2010). However, currently seaweed species are still under-exploited bio-resources (Khanw 2009).

Marine macroalgae are gaining attention among the scientific community as a significant source of functional food ingredients. Due to the harsh environments in which macroalgae survive, they produce unique bioactive compounds that are not found in terrestrial plants (Murray 2018). The most promising sources of new bioactive molecules, seaweeds represent valuable, but still underexploited, biofactories for drug discovery and product development (Lopes 2017).

Seaweeds are presently pointed out as the plant-based food of the future, since besides not competing with food crops for the use of arable land and fresh water resources, they are a good supply of key nutrients including carbohydrates, protein and minerals (Lordan 2011). Moreover, they are a rich source of health-promoting compounds capable of acting on a wide spectrum of disorders and/or diseases. This latter fact is becoming particularly evident as macroalgae are presently under the spotlight of many investigations. All these facts are pushing the Western culture to increase the interest in the manufacturing and consumption of high-value products derived from macroalgae, with the main aim of taking advantage of their potential health effects (Cardoso 2015).

Besides, it is worth to mention that seaweeds have been considered over the past few decades as promising organisms for providing both, novel biologically active substances and essential compounds for human nutrition, with high potentially economic impact in food and pharmaceutical industry and public health (Cardozo 2007). In addition, it is stated that much research, such as their role in nutrition and disease prevention, remains to be done before science-based dietary recommendations can be given for edible seaweeds (Smit 2004).

# **SEAWEEDS AS FUNCTIONAL FOOD SOURCES**

Global demand for macroalgal and microalgal foodstuff is growing, and seaweed are increasingly being consumed for functional benefits beyond the traditional considerations of nutrition and health. There is substantial evidence for the health benefits of algal-derived food products, but there are considerable challenges in quantifying these benefits, as well as possible adverse effects. The limits to our understanding fall broadly into three areas. First is the variation of nutritional and functional composition of algae across species, seasons, and different coastal environments. It should be also considered the effect of harvesting, storage, and food processing techniques, which can increase or decrease the nutritional quality. The second, it is quantifying which fractions of algal foods are bioavailable to humans or fraction of nutritional or functional components that actually have effect in relation to their residence time in the digestive system. Another issue is quantifying which fractions of algal foods are bioavailable to humans, and which factors influence how food constituents are released, ranging from food preparation through genetic differentiation in the gut microbiome. There is

an increasing literature on digestive reactor analytical methods. Bioaccessibility will be a complex function of the chemistry of the substance, the processing methods used to prepare the alga as food, the specific algal matrix containing it, the consortium of bacteria and their enzymatic competency, and the presence of other foods that may interfere or enhance uptake. The third limitation lies in understanding how algal nutritional, and particularly functional constituents interact in human metabolism and intermediary metabolic processes. It is needed to highlight the rapidly advancing area of algal science with a particular focus on the key research required to assess better the health benefits of an alga or algal product. There are rich opportunities in this emerging field, requiring exciting new experimental and collaborative approaches, to develop a rich and rewarding collaboration among psychological, nutritional, medical, analytical, and industrial groups investigating algae such as nutritional and functional foods (Wells 2017).

# **SEAWEEDS AS EMERGENT SOURCES OF PREBIOTICS**

Dietary fiber (DF) -polysaccharides known to be resistant to enzymatic hydrolysis by digestive enzymes- in brown seaweeds is essentially composed of four families of polysaccharides, laminaran, alginate, fucan, and cellulose. Laminaran, the reserve polysaccharide in brown seaweeds (Jiménez-Escrig 2000), is a small alfa-glucan of 5kDa, composed of D-glucose with beta-(1,3) linkages and beta-(1,6) interchange branching (Rioux 2010). The major structural component in brown seaweeds is a gelling polyuronide, alginate, outlined as alternating sequences of (1,4)-linked beta-D-mannuronic acid and its C5-epimer alfa-L-guluronic acid residues. The structural polysaccharide fucan, is primarily composed of fucoidan -(1,2)-linked alfa-L-fucose-4-sulphate- linked to D-xylose, D-galactose, D-mannose, and uronic acids (Jiménez-Escrig 2000, Rioux 2010). Among structural polysaccharides, fucans are the most interesting for their potential biological activities, whereas alginate is mostly used as a food ingredient (Rioux 2010).

Algal oligo- and polysaccharides (PSs) show effects on health similar to and sometimes more effective than other oligosaccharides from different sources. Their chemical structures include some of these oligosaccharides and some of the PSs produced by seaweeds that are not degraded by enzymes in the upper part of the GI tract. Therefore, algal PSs present a great potential for emergent prebiotics to be used as dried biomass or nutraceuticals, after extraction from the biomass or from the culture medium. They may be included in food and/or feed, or administered as pills. The development of new enzyme technologies together with new enzymes from marine bacteria and mollusks will enable us to tune these PSs and produce novel prebiotics. (Jesus-Raposo 2016).

Prebiotics enhance immune response through the modulation of intestinal microbial activities, production of short chain fatty acids (SCFA), direct interaction with toll-like receptors and mucin production. These non-digestible food components are utilized as carbon source for the growth of beneficial bacteria population through the process of fermentation. Brown seaweed polysaccharides have been described as emerging prebiotics due to their potential to stimulate gut microbiota activities at *in vitro* and *in vivo* stages (Okolie 2017).

Based on their composition red seaweeds, are good potential functional foods for gut health. Intestinal mucosal barrier function refers to the capacity of the intestine to provide

adequate containment of luminal microorganisms and molecules. The components of red seaweeds play a role on the regulation of mucosal barrier function. Special attention has been paid to unique components of red seaweeds such as proteins and derived peptides (e.g., phycobiliproteins, glycoproteins that contain cellulose binding domains, phycolectins and the related mycosporine-like amino acids) together with polysaccharides (e.g., floridean starch and sulphated galactans, such as carrageenans, agarans and dl-hybrid) and minerals. These compounds have been shown to exert prebiotic effects, to regulate intestinal epithelial cell, macrophage and lymphocyte proliferation and differentiation and to modulate the immune response. Molecular mechanisms of action of peptides and polysaccharides are starting to be elucidated, and evidence indicating the involvement of epidermal growth factor receptor (EGFR), insulin-like growth factor receptor (IGFR), toll-like receptors (TLR) and signal transduction pathways mediated by protein kinase B (PKB or AKT), nuclear factor-B (NF-B) and mitogen activated protein kinases (MAPK). The need for further research is clear, but *in vivo* experiments point to an overall antiinflammatory effect of these seaweeds, indicating that they can reinforce membrane barrier function (Cian 2015).

# **FUCOIDAN AS ANTICANCER AGENT IN PRECLINICAL DEVELOPMENT**

Fucoidan is a fucose-containing sulphated polysaccharide derived from brown seaweeds, crude extracts of which are commercially available as nutritional supplements. Recent studies have demonstrated antiproliferative, antiangiogenic, and anticancer properties of fucoidan *in vitro*. Accordingly, the anticancer effects of fucoidan have been shown to vary depending on its structure, while it can target multiple receptors or signalling molecules in various cell types, including tumour cells and immune cells. Low toxicity and the *in vitro* effects of fucoidan mentioned above make it a suitable agent for cancer prevention or treatment. However, preclinical development of natural marine products requires *in vivo* examination of purified compounds in animal tumour models. Recent *in vivo* results on the effects on animal models of systemic and local administration of fucoidan on tumour growth, angiogenesis, and immune reaction are likely applicable to the development of fucoidan as a marine anticancer drug.

In addition, diverse potential of fucoidan has created intense interest to review the existing scientific literature, specifically focusing on prevention, associated molecular mechanisms in inflammation related ailments. Fucoidan inhibited inflammatory responses, both *in vitro* and *in vivo* experimental models. Inflammation is a complex response of living systems and involved in pathogenesis of different diseases, including arthritis, cancer and allergies. Sulphated glycans play a crucial role in inflammation related events such as they partake in the regulation of chemokines, rolling of leukocytes along the endothelium at inflammatory sites, and provide the structural assembly of subendothelial basement membrane. These functions make fucoidan as suitable exogenous sulhated polysaccharide to ameliorate the inflammatory events like regulating pro inflammatory targets. Recent studies have been performed to provide the anti-inflammatory properties and underlying molecular mechanisms of this bio-functional molecule (Kwak 2014).

#### **PREVENTION OF SYNDROME METABOLIC BY FUCOXANTHINE**

Obesity, which results from an imbalance between energy intake and energy expenditure, has become a major health risk factor worldwide, causing numerous diseases such as diabetes, hypertension, and cardiovascular diseases. Fucoxanthin, a specific carotenoid in brown algae, has garnered much attention for its anti-obesity and anti-diabetic effects attributable to a unique mechanism. Fucoxanthin induces uncoupling protein 1 (UCP1) expression in white adipose tissue (WAT). That inner membrane mitochondrial protein, UCP1, can dissipate energy through oxidation of fatty acids and heat production. Furthermore, fucoxanthin improves insulin resistance and ameliorates blood glucose levels through down-regulation of adipocytokines related to insulin resistance in WAT and upregulation of glucose transporter 4 (GLUT4) in skeletal muscle. Algae fucoxanthin is a novel beneficial compound for the prevention of the metabolic syndrome (Maeda 2015).

# **PREVENTION OF OBESITY THROUGH ALGINATE MEDIATED BY ENZYME DIGESTION INHIBITION**

Regulation of food intake through modulation of gastrointestinal responses to ingested foodstuff is an ever-growing component of the therapeutic approaches targeting the obesity epidemic. Alginates, viscous and gel-forming soluble fibers isolated from the cell wall of brown seaweeds and some bacteria, are recently receiving considerable attention because of their potential role in satiation, satiety, and food intake regulation in the short term. Enhancement of gastric distension, delay of gastric emptying, and attenuation of postprandial glucose responses can constitute the basis of their physiological benefits. Offering physical, chemical, sensorial, and physiological advantages over other viscous and gel-forming fibers, alginates constitute promising functional food ingredients for the food industry. Therefore, alginates are claimed to exert positive effect in glycemic regulation (El Khoury 2015).

# **PHLOROTANNINS AS PROMISING FUNCTIONAL INGREDIENT**

Fucaceae is the most dominant algae family along the intertidal areas of the Northern Hemisphere shorelines, being part of human customs for centuries with applications as a food source either for humans or animals in agriculture and as remedies in folk medicine. These macroalgae are endowed with several phytochemicals of great industrial interest from which phlorotannins have gathered much attention during the last few years due to their numerous possible therapeutic properties. Phlorotannins are a class of polyphenols that are unique to marine sources. Several biological activities have been attributed to phlorotannins over the years. The range of activity of phlorotannins is remarkable against including antioxidant effects through scavenging of reactive oxygen species (ROS) or enhancement of intracellular antioxidant defenses. Also, including antidiabetic properties through their acarbose-like activity, stimulation of adipocytes glucose uptake and protection of -pancreatic cells against high-glucose oxidative stress; anti-inflammatory effects through inhibition of several proinflammatory mediators; antitumor properties by activation of apoptosis on cancerous cells

and metastasis inhibition, among others. Diabetes mellitus is a group of metabolic disorders characterized by hyperglycaemia, and predicted by the World Health Organization as the expected  $7<sup>th</sup>$  leading cause of death in 2030. Diabetes mellitus type 2 (DMT2) comprises the majority of diabetic individuals around the world (90%-95%). Pathophysiologically, this disorder results from a deregulation of glucose homeostasis, worsened by overweight and by a sedentary lifestyle, culminating in life-threatening cardiovascular events. The currently available anti-diabetic drugs are not devoid of undesirable side effects, sometimes responsible for poor therapeutic compliance. This represents a challenge for contemporary medicine, and stimulates research focused on the development of safer and more efficient anti-diabetic therapies. Phlorotannins are not only promising to avoid hyperglycaemia, through their extraordinary capacity to inhibit glucose absorption, but also they are capable of treating diabetes-associated disorders through their capacity of protecting -cells from glucose-induced toxicity, in diagnosed DMT2 individuals (Lopes 2017). These multiple health properties render phlorotannins great potential for application in numerous therapeutically approaches. Over the past two decades, 20 different bioactive polyphenols/phlorotannins have been isolated and studied from 10 different brown algae. Their assorted beneficial effects on human health include competitive inhibition of digestive enzymes, varying the activity of hepatic glucose-metabolizing enzymes, lowering the plasma glucose levels, and lipid peroxidation, delaying the aging process. Despite the recent advancements in isolating bioactive compounds from seaweeds with potential health benefit or pharmaceutical behaviour, studies on the polyphenol effectiveness on glucose homeostasis in human beings are very few. Further research in this area is required to confirm the close connection of polyphenol rich seaweed-based diet consumption with glucose homeostasis and the exciting possibility of prescribing polyphenols to treat the diabetes pandemic (Chao 2018, Murray 2018).

# **FUCOSTEROL STILL NEEDS TO REINVENT ITSELF**

Recent studies have been focused on the biological and pharmacological activities of seaweeds and their highly bioactive secondary metabolites because of their potential in the development of new pharmaceutical agents. Although several varieties of bioactive novel compounds such as phlorotannins, diterpenes and polysaccharides from seaweeds have already been scrutinized, fucosterol as a phytosterol still needs to reinvent itself. Fucosterol (24-ethylidene cholesterol) is a sterol that can be isolated from seaweeds and diatoms. Fucosterol exhibits various biological therapeutics, including anticancer, antidiabetic, antioxidant, hepatoprotective, antihyperlipidemic, antifungal, antihistaminic, anticholinergic, antiadipogenic, antiphotodamaging, anti-osteoporotic, blood cholesterol reducing, blood vessel thrombosis preventive and butyrylcholinesterase inhibitory activities (Abdul 2016).

# **SULPHATED POLYSACCHARIDES AS INHIBITORS OF CALCIUM OXALATE RENAL STONE FORMATION**

Sulphated polysaccharides (SPSs) from various seaweeds are known to play a significant inhibitory role in calcium oxalate (CaOx) kidney stones. CaOx stone formation is a multistep

process, which includes crystal nucleation, growth, aggregation, and crystal retention. Renal tubular cell injury is one of the determining factors leading to crystal retention and formation of stone in the nidus. The therapeutic mechanisms of action of seaweed SPSs on CaOx renal stone formation are known through the inhibition of crystal nucleation, growth, and aggregation. SPSs prevent renal tubular cell damage because of its antioxidant properties, thereby preventing crystal adherence and internalization. Therefore, seaweed SPSs could be considered promising molecules because of their role in renal stone prevention (Bhadja 2016).

Innovative technology that uses extracts obtained by supercritical CO2 extraction, as a method of isolation of biologically active compounds from algal biomass, is presented (Michalak 2017).

# **ALGAE INGREDIENTS AS ANTIMICROBIALS**

The increasing efforts to use ingredients that are as natural as possible in the formulation of innovative products has given rise to-the introduction of macro and microalgae in food industry. Up to date, scarce information has been published about algae ingredients as antimicrobials in food. The antimicrobial potential of algae is highly dependent on: (i) type, brown algae being the most effective against foodborne bacteria; (ii) the solvent used in the extraction of bioactive compounds, ethanolic and methanolic extracts being highly effective against Gram-positive and Gram-negative bacteria; and (iii) the concentration of the extract. The validation of the algae antimicrobial potential in real food matrices is still a research niche, being meat and bakery products the most studied substrates (Pina-Pérez 2017).

# **INNOVATIVE EXTRACTION TECHNOLOGY OF ALGAL BIOMASS**

Algal extracts are gaining increasing interest due to their unique composition and possibilities in industrial applications. Various extraction techniques are used for conversion of algal biomass into extracts. Recently, scientist attention has been paid to innovative technology, such as enzyme-assisted extraction, microwave-assisted extraction, pressurized liquid extraction, supercritical fluid extraction, and ultrasound-assisted extraction, as novel methods of isolation of biologically active compounds from algal biomass, without their degradation (Michalak 2017).

Polysaccharides obtained from macroalgae have promising prospects and could contribute greatly to the future of a marine based bio-economy. Specifically, laminarin and fucoidan from brown macroalgae have a wide variety of potential industrial applications including functional foods and nutraceuticals, due to their broad range of biological activities. These beneficial biological activities are related to the chemical composition and structure of the macroalgal polysaccharides. The molecular weight, monosaccharide composition and sulphate content of these polysaccharides could be influenced by both macroalgal biology (i.e., variations in polysaccharide composition due to macroalgae species and their biological cycle) and different extraction/purification techniques employed to obtain polysaccharide enriched products (i.e., de-sulphation or fragmentation of sulphated polysaccharides). The

application of innovative extraction technologies (such as ultrasound, microwave and enzyme-assisted extractions), as well as new purification techniques (i.e., membrane separation) are promising technologies for the challenges concerning molecule structurefunction relationship and macroalgal variability (Garcia-Vaquero 2017).

The complex structure and distinctive components of seaweed cell walls, which differ significantly from terrestrial plants, presents a major challenge for the effective extraction of bioactive compounds from inside the cells. Enzyme technologies have been used to improve the extraction, hydrolysis and structure modification efficiently with a high degree of environmental sustainability. Future directions in applying enzyme technologies to improve the extraction and processing of bioactive compounds from seaweeds and their potential applications in functional foods and nutraceuticals have been evidenced to assist the extraction by breaking down the seaweed cell walls, and degrade or hydrolyse macromolecules including polysaccharides and proteins. These enzymatic processes can improve the yield and recovery of bioactive compounds and enhance their biological properties with regard to prebiotic, antioxidant, ACE inhibitory, anti-inflammatory, and antiviral effects. Seaweed-derived bioactive compounds from these processes present significant new opportunities in developing novel food applications (Suvimol 2017).

# **CONCLUSION**

It should be highlighted recent advances on the significant health benefits of seaweeds in the nutraceutical field. Seaweed components offer opportunities and a multitude promising health benefits for the construction of novel and enhanced functional food. Future research should focus on new experimental and collaborative approaches, to develop integration among physiological, nutritional, medical, analytical, and industrial groups investigating seaweed as functional foods.

# **MICROALGAE BIOMASS AS A FOOD INGREDIENT TO DESIGN ADDED VALUE PRODUCTS**

*Anabela Raymundo\* , Maria Cristiana Nunes and Isabel Sousa*

LEAF - Linking Landscape Environment Agriculture and Food Research Centre, Instituto Superior de Agronomia, Universidade de Lisboa,

Lisboa, Portugal

# **ABSTRACT**

The use of microalgae as a food ingredient has recently attracted considerable interest worldwide, due to their potential to design value-added products, with remarkable functional activity and health impact. Microalgae are photosynthetic organisms that grow in a wide range of different environmental conditions, from aquatic habitats, including lakes, pounds, or oceans, in wastewater or even on non-arable land. The microalgae culture can be considered as a renewable and sustainable new crop, which can tolerate variable conditions of temperature, salinity, pH or light intensities. Modelling the growth conditions leads to biomasses with different compositions in nutritional terms and bioactive compounds. This crop can be an alternative source of good proteins, polyunsaturated fatty acids and carbohydrates, which may be needed in the near future. Today, microalgae can be considered an underexplored natural source of bioactive ingredients. They are attracting our attention, as they have promising applications in the development of new foods, with improved nutritional profiles and a strong impact on health.

Microalgae are an interesting natural source of bioactive compounds: pigments, enzymes, sugars, lipids with valued fatty acids, sterols, and vitamins, with a recognised positive impact on health. These compounds can be extracted from the microalgae biomass and marketed as nutraceuticals, high added-value products, but the use of the whole microalgae cell, can also be considered, as a functional ingredient. A strong argument to support this approach is that bioactive compounds are naturally encapsulated and protected within the microalgae cell. Thus, it is important to consider the possibility to perform a biomass pre-treatment in order to promote a controlled release of the active compounds trough a partial cell wall disruption. This step can be considered as a biomass

 $\overline{a}$ 

<sup>\*</sup> Corresponding Author's Email: anabraymundo@isa.ulisboa.pt.

preparation step. The downstream operations (freeze-drying or spray-drying) can impart different levels of cell wall disruption. In addition, a controlled cell disruption can also be induced by specific methods, such as high-pressure homogenization or microwaves.

Another important issue to address, when the use of microalgae as a food ingredient is considered, is the level of technological processing applied (e.g., temperature, pressure, pH). Examples of food preparations, with different thermal severity, will be discussed in terms of the impact on the bioactivity of the natural compounds. The effect of baking on antioxidant activity of cookies enriched with different types of microalgae is a relevant example. Maintenance of the fatty acid profile, including PUFA's, before and after cooking of pasta enriched with *Isochrysis galbana* and *Diacronema vlkianum* biomass are other examples to be pointed out.

The use of *Arthrospira*, *Chlorella vulgaris*, *Haematococcus pluvialis*, *Diacronema vlkianum*, *Isochrysis galbana* and *Tetraselmis chuii* in different food matrixes – mayonnaise and salad dressings, puddings, pasta and biscuits have been extensively investigated and will be revised. The bioaccessibility of the bioactive compounds *in vivo* and *in vitro* will also be discussed.

**Keywords:** microalgae, food-rheology, bioactivity, cell wall disruption

# **1.INTRODUCTION**

#### **1.1. What Are Microalgae?**

When we take a low tide walk by the sea side, there is a green band where the water stands still, the green is intense and dark, these are microalgae. They have been in the planet from 450 million years ago, at least, and primordial microalgae were very similar to the present ones. Although primordial habitat was totally different, these cells have been able to survive practically unchanged until now, and considering their massive distribution, they are still dominating the planet, being the main part of the planet biomass (Nicoletti, 2016).

Microalgae are amazing beings that survive harsh conditions and can grow almost everywhere, as long as there is light, water (either sweet or salty), enough  $CO<sub>2</sub>$ , and a few nutrients. In fact, they produce about half of the atmospheric oxygen and they are also great CO<sup>2</sup> capturers, playing a fundamental role in terms of environment balance (Richmond, 2004).

Although they are autotrophic, i.e., they synthetize their own nutrients from inorganic compounds through photosynthesis, they are extremely well equipped and can synthetize the most complex substances. Microalgae cover almost 75% of algae species and despite the apparent simplicity of their cells they spread over at least 40,000 species in phytoplankton (Singh and Dolly, 2011), as they are able to metabolize a myriad of complex substances, this is the key for their success for food supplementation.

The detailed composition of *Chlorella*, a food grade green microalgae, can be seen in Table 1 (gently shared by A4F, Portugal), where all kinds of complex molecules can be found, powerful nutrients from amino acids and vitamins to hormone like and polyunsaturated fatty acids (PUFA), and this is the reason why *Chlorella* is considered as a superfood.

Nevertheless, the consumption of microalgae in food is still very limited, considered as a nutraceutical, mostly sold in capsules and pills. Though there are some dry powdered *Chlorella* and *Spirulina* commercially available, the price is still very high to be easily generalized as a food ingredient. It is a high potential business that soon will be a huge opportunity.

**Table 1. Composition of Chlorella, a food grade green microalgae**

Source: A4F, Portugal.

The biodiversity in microalgae is very large - it is estimated that there are from 200,000 to 800,000 species, of which only about 50,000 species are described, therefore this is a resource almost unexplored. More than 15,000 new compounds have been chemically identified from microalgae biomass (Cardoso et al., 2018), of which carotenoids, proteins, peptides, fatty acids, polysaccharides, enzymes and sterols are noteworthy. These compounds have specific functional requirements and play important roles in terms of the cellular life, they can be simply natural dyes and/or exhibiting high biological activity and since they are chemically very active, their extraction poses a few problems related to stability against oxidation and other deterior phenomena. Therefore, conveyed by staple foods they can strongly impact health, with major benefits when consumed regularly. For this reason, it is important to address this subject from the point of view of the use of the whole microalgae cell, as a functional ingredient, in common or in staple foods. A strong argument to support this approach is that bioactive compounds are naturally encapsulated and protected within the microalgae cell. Other relevant issues are how these bioactives are going to be released from the cells and affected during food processing, and obviously, what is the final bioavailability and bioactivity of these powerful health improver substances.

With the expectation of a demographic burst from currently seven billion to nine billion people in less than three decades, the production of food, especially proteins, must be increased by about 70% to answer the population nutrition needs. The production of microalgae can be an interesting, complementary food production system, alternative to conventional agriculture, in the context of climate change, and the scarcity of water and farming land, with greater photosynthetic efficiency and low energy consumption. In addition, microalgae can achieve higher biomass productivity, faster growth rate, high rates of  $CO<sub>2</sub>$  fixation and  $O<sub>2</sub>$  production compared to conventional plants. These microscopic unicellular organisms can be cultivated under strictly controlled environmental conditions (e.g., pH, temperature, salt, light, nutrients), which may stimulate or inhibit the biosynthesis and accumulation of bioactive compounds (e.g., pigments) in amounts greater than those occurring in spontaneous growth situations (Gouveia et al., 2008a).

The commercial production of microalgae is limited to a reduced number of species (Tredici, 2004), and the most popular for food are *Chlorella vulgaris* and *Spirulina platensis*. The production of microalgae in lagoons and other open systems, despite having many advantages in terms of resource utilization, present some strong limitations in terms of safety and quality control of the final product, as they can be easily contaminated even with species that produce toxins. These limitations are especially important for food or pharmaceutical purposes and closed systems – photo-bioreactors (tubular: cylinders and sleeves with transparent walls of glass or plastic), that can be easily controlled, are taking the lead. These systems have much lower risks of contamination and accommodate the development of a specific microalgae, with a tight control of the culture medium, to meet the market specifications.

Microalgae have been used by indigenous populations for centuries (Jensen et al., 2001). However, the cultivation of microalgae has only existed for a few decades and among the 30,000 species that are surveyed, only a few thousand strains are kept in collections, a few hundred are investigated for chemical content, and just a handful are cultivated in industrial quantities (Olaizola, 2003).

Some of the most biotechnologically relevant microalgae are the green algae (*Chlorophycea*) *Chlorella vulgaris*, *Haematococcus pluvialis*, *Dunaliella salina*, *Tetraselmis chuii* and the blue cyanobacteria *Spirulina platensis* which are already widely commercialized and used, mainly as nutritional supplements for humans and as animal feed additives. Many studies are focused on the biological activities of natural products from microalgae (e.g.,

Plaza et al., 2009; Larsen et al., 2011; Freitas et al., 2012; Nicoletti, 2016; López et al., 2017; Sathasivam et al., 2017; Khan et al., 2018). They span from antioxidant to anti-angiogenic, cytotoxic and anticancer activities; reduction of cholesterolemia and diabetes; antimicrobial and anti-obesity activities as well as some toxic metabolites, with strong impacts including death, generally known as cyanotoxins including neuro, hepato and dermotoxins. The food grade microalgae are completely free of toxic effects, the problem can only arise from contaminations with other cyanobacteria and for this reason the use of closed systems for production, and an accurate quality control implemented, are necessary. Nevertheless, some of these toxins are being studied for antitumoral activity.

This section is focused on *Chlorella* and *Spirulina*, the most popular food grade microalgae:

- *Chlorella vulgaris* has been used as an alternative medicine in Asia since ancient times, where it is also known as a traditional food. It is widely produced and marketed as a food supplement in many countries, including China, Japan, Europe, Canada and the US. *Chlorella* is being considered as a potential source of a wide spectrum of nutrients (e.g., carotenoids, vitamins, minerals – see Table 1), being widely used in the healthy food market as well as for animal feed and aquaculture. *Chlorella* is long known as a health promoting factor on many kinds of disorders such as gastric ulcers, wounds, constipation, anemia, hypertension, diabetes, infant malnutrition and neurosis, with a preventive action against atherosclerosis and hypercholesterolemia by glycolipids and phospholipids, and antitumor actions by glycoproteins, peptides and nucleotides (Yamaguchi, 1997 and Plaza et al., 2009). However, the most important substance in *Chlorella* seems to be a beta-1,3-glucan, which is an active immune-stimulator, a free-radical scavenger and a reducer of blood lipids (Spolaore et al., 2006).
- *Spirulina platensis* (Arthrosphira) is a cyanobacteria that grows profusely in certain alkaline lakes in Mexico, Africa and India and has been used as food by local populations since ancient times (Yamaguchi, 1997). It is extensively produced around the world (5,000 tons/year) and broadly used in food and feed supplements, due to its high protein content (up to 70%) and its excellent nutritive value, such as high  $\gamma$ -linolenic acid level. In addition, this microalgae has various possible health promoting effects: the alleviation of hyperlipidemia, suppression of hypertension, protection against renal failure, growth promotion of intestinal *Lactobacillu*s, suppression of elevated serum glucose level (Spolaore et al., 2006, Plaza et al., 2009 and Sathasivam et al., 2017), anticarcinogenic effect and have hypocholesterolemic properties (Reinehr and Costa, 2006). Spirulina is also the main source of natural phycocyanin (blue colour extract), used as a natural food and cosmetic coloring, among other.

Phycocyanin is currently used in Japan and China as a natural coloring, in food products like chewing gums, candies, dairy products, jellies, ice creams, soft drinks (e.g., Pepsi® blue) and also in cosmetics such as lipsticks, eyeliners and eye shadows (Sekar and Chandramohan, 2007). In a previous study, phycocyanin was considered a more versatile blue colorant than gardenia and indigo, providing a bright blue color in jelly gum and coated soft candy, despite

its lower stability towards heat and light (Jespersen et al., 2005). A considerable number of investigations revealed several pharmacological properties attributed to phycocyanin including, antioxidant, anti-inflammatory, neuroprotective and hepatoprotective effects as well as antimicrobial potential. Plaza et al., (2009), Sathasivam et al., (2017) and Raja et al., (2008) demonstrated that this blue pigment stimulates hematopoiesis, emulates the effect of hormone erythropoietin and regulates the production of white blood cells.

#### **1.2. New Trends in Microalgae Food Applications**

The commercial production of microalgae for human nutrition is already a reality. In Portugal there are two main companies, one located in mainland, at Pataias, Leiria and the other in the Porto Santo Island, both producing food grade microalgae. The gastronomy people, scientists and chefs, are dedicating their creative knowledge developing attractive dishes with high amounts of microalgae inside. *Chlorella* and *Spirulina* in the dried powder form is readily available on every supermarket in Europe as well. In some countries (Germany, France, Japan, USA, China, Thailand), food production and distribution companies have already started serious activities to market functional foods with microalgae and cyanobacteria (Pulz and Gross, 2004). Food safety regulations for human consumption are the main constraint for the biotechnological exploitation of microalgae resources, but successful cases such as the approval (9 December, 2002) of the marine diatom *Odontella* aurita by Innovalg (France) as a novel food, following EC Regulation 258/97, are encouraging.

Over the last decade, our research group in Portugal has been extensively working to develop a range of novel attractive healthy foods, prepared from microalgae biomass, rich in carotenoids and polyunsaturated fatty acids with antioxidant effect and other beneficial properties (Gouveia et al., 2006; Gouveia et al., 2008a; Gouveia et al., 2008b; Batista et al., 2006; Batista et al., 2012; Batista et al., 2013; Batista et al., 2017; Raymundo et al., 2005). At the same time toxicological studies (Gouveia et al., 2013) involving the microalgae used were also conducted. A strategy to avoid the hassled of changing food habits was used adding the microalgae to staple and traditional foods, like mayonnaises, gelled desserts, biscuits, bread, pasta and breakfast cereals, largely consumed on daily basis on different European diets. The impact of natural substances introduced in the diet via "usual" foods is proved to be efficient at long term and do not present the drawbacks of traditional therapeutic actions based on medicines of short term impact.

The viability of incorporating microalgal biomass in food systems is conditioned by the applied processing type and intensity (e.g., thermal, mechanical), by the nature of the food matrix (e.g., emulsion, gel, aerated dough systems) and to the interactions with other food components (e.g., proteins, polysaccharides, lipids, sugars, salts). Besides colouring and nutritional purposes, introducing microalgae ingredients in food systems, can also impart significant changes in its microstructure and rheological properties (Batista et al., 2012). In addition, the microalgae biologically active compounds, such as the brain active PUFA: EPA and DHA, antioxidant colorants, etc. are naturally very sensitive to degradation when exposed. The option to work with the microalgae biomass and not with the bio-extracts, has two strong reasons. The bioactives are naturally encapsulated within the cell structure, which

contributes decisively to their preservation during food processing and, of course, it is very expensive to extract and preserve these bioactives. However, the question of how effectively/efficiently these bioactives are absorbed and metabolized comes at front. These aspects are particularly focused in our research.

In fact, it is important to highlight microalgae as an excellent source of natural bioactives including colorants, that present a high potential for their culinary application, at home or at industrial level, as a natural food dye. They present a wide diversity of colors and shades, which enhance their use in different types of food and gives an extra appealing strength.

# **2. MICROALGAE PRE-TREATMENT**

The suitability of microalgae for use in various food and feed applications must be based on functionality parameters such as palatability, odour, nutritional profile, digestibility and bioavailability. However, cell wall integrity may significantly limit nutrient availability, since structurally the microalgae are covered with multiple layers of resistant thick cellular walls that hinder the liberation of cell constituents.

The controlled disruption of this cell wall (=cell disruption), resulting from the downstream process of biomass production, or induced by additional microalgae pretreatment, has an important impact on the bioavailability of microalgae contents, although disruption of microalgae cells may also promote oxidation. Cell rupture have been described by several authors as a spectrum, ranging from minor damage of the cell wall with release of internal components to complete cell fragmentation.

A variety of cell disruption methods is currently available, but depending on the cell wall structure, the size, and the shape of algae, cell disruption can be challenging. Applicability on large industrial scale required cell disruption technologies to be low cost and energy efficient and result in high product quality. Employing an appropriate cell disruption technique, prior to extraction, is undoubtedly one of the most crucial preliminary steps in downstream processing for the maximum recovery of cell contents from microalgae (D´Hondt et al., 2017, Khan et al., 2018, Phong et al., 2018).

Researchers are focusing their interest in algae and algal products that may be used in beverages and functional foods (Khan et al., 2018) and nutraceutical and pharmaceutical products (Phong et al., 2018). To facilitate the release of the cell contents, the complex cell wall structure must be disrupted to allow the liberation of the internal components into the liquid medium. In a recent work, concerning rheological properties of microalgal suspensions as affected by mechanical and thermal processing (Bernaerts et al., 2017), the authors concluded that whereas some microalgae species hardly affect the structural properties of the food product, other microalgae species show large potential for use as a structuring agent in food applications, as it had been previously reported by our research team in different food systems, e.g., emulsions (Batista et al., 2006) and gels (Gouveia et al., 2008a; Batista et al., 2011). Differences in cell rupture were found between the investigated microalgae species, which can be related to size and rigidity of the cells. The effect of subsequent thermal processing on the microstructure and rheological properties is affected by the previous pretreatment, as thermal processing was shown to enhance interactions between the released cell material (Bernaerts et al., 2017).

Besides the structural morphology of each microalgal cell wall, the selection of the cell disruption method depends upon the nature of the desired product or final application. Exposure of the microalgae cells to harsh conditions, such as high temperature, high shear or high pressure, might change the structure of some fragile intracellular compounds, with subsequent impact in their functionality or activity. For example, gentle breakage is necessary to promote the release of bio-functional proteins and peptides from microalgae, while preserving the functionality and biological activity of the molecules. Thus, the current research attention toward microalgae should focus on mild disruption methods, to release various types of intracellular components without degradation (Phong et al., 2018).

#### **2.1. Cell Disruption Methods**

Depending on the purpose of the pretreatment chemical, biological, thermochemical, or thermophysical methods are used, sometimes in combination, but there is still no optimal, highly productive method, even for biofuels production (Khan et al., 2018). Recently, the most used and promised methods have been reviewed, for instance, by Günerken et al., (2015), Kim et al., (2016), D´Hondt et al., (2017), Lee et al., (2017), Khan et al., (2018) and Phong et al., (2018). To select the most appropriate method, factors such as yield, cost, quality and bioactivity should be considered, but also sustainability, environmental pollution and residues.

Pretreatment of algae biomass involves the degradation or disruption of biomass (algae wall lysis) to convert, accumulate, and process the constituents it contains. Among those constituents, large-scale utilization of lipids is the most desirable alternative to plant-based lipid sources, although biodiesel production is not yet economically viable (Lee et al., 2017). Fermentation of the algal sugars are used to generate bioethanol. Pretreatment of the algal biomass for fermentation involves the release of the carbohydrates from inside the cells and saccharification of the accumulated sugars to monomeric sugars to be used by fermenting microorganisms. Thus, mechanical methods of pretreatment yield biodiesel, while enzymatic and chemical methods are used in bioethanol production, because fermentative bioethanol production requires degradation of cellulose, hemicellulose and starch (Khan et al., 2018).

Chemicals may influence the quality of the products due to the formation of by-products and, additionally, a pretreatment applied to release one fraction can solubilize and degradate other biomass components. Enzymes achieve high product quality but still remain expensive and oxidizing agents could promote oxidation of sensitive compounds (D´Hondt et al., 2017).

Physical methods for cell wall disruption are preferred, in most cases, as this avoids chemical contamination of the bioproducts and preserves most of the functionality of intracellular material (Khan et al., 2018). Physical pretreatment could be subdivided into thermal: freeze-fracture, freeze-drying and autoclaving (D´Hondt et al., 2017) and mechanical methods.

The most traditional physical pretreatments (Figure 1) include bead milling, highpressure homogenization, microwave irradiation and ultrasonication. Bead milling and highpressure homogenization are industrially well known for the extraction of algal products, but are less favourable as mild processes. Microwave and ultrasound greatly reduce working times, increase yields and often the quality of the extract (D´Hondt et al., 2017).
Bead milling causes direct mechanical damages to cells, with high disruption efficiency, high biomass loading, commercial available equipment and easy scale-up operations (Günerken et al., 2015). It is composed of a rotating agitator, in a fixed vessel, filled with beads. The grinding effect is achieved through the physical collision of the solid beads against the cells, through compressive and shear stresses. The disruption efficiency depends on the size and composition of the beads, the speed and design of the agitator, residence time and characteristics of the suspension such as viscosity and concentration (Lee et al., 2012). The energy transfer from the rotating shaft to the beads and the energy conversion into heat due to friction would lead to a rise in temperature. However, with recent design improvements it is possible to control the temperature as the milling chamber is equipped with cooling jackets (Lee et al., 2017, Phong et al., 2018). Thus, bead milling is an interesting cell disruption method with high potential for industrial use. Bead mills have been successfully applied for the disintegration of microalgae for the release of intracellular products under low energy inputs and mild conditions (Postma et al., 2015, 2017).

High-pressure homogenization or French press is one of the earliest techniques developed to disrupt algal cells. Microalgal suspension is pumped through a narrow orifice  $(80-200 \,\mu m)$ in a valve under high pressure (138-400 MPa), and the suspension is then released into a lowpressure chamber (D´Hondt et al., 2017). The cell suspension flows radially across the valve, strikes an impact ring, exits the valve, and flows to a discharge hole (Günerken et al., 2015). Mechanical effects, including turbulence, shear stress and cavitation promote cell lysis. The disruption efficiency is a function of the pressure at the valve and the cell-suspension properties, such as viscosity, cell size, cell concentration (Lee et al., 2017). Other operating parameters, which affect the disruption efficiency, are the temperature, number of passes, the valve and orifice design and the medium flow rate. In addition, for heat sensitive products, cooling is essential (Lee et al., 2012).

Figure 1. Classification of the cell disruption methods (Günerken et al., 2015).

Microwave treatment is a no-contact method that transfer radiation to the biological material. The mechanism is based on the interaction of electromagnetic waves with dielectric and polar molecules provoking local heating because of frictional forces from inter and intramolecular movements. Biomass concentration, treatment time and power of microwaves are the main operating parameters (Günerken et al., 2015, D´Hondt et al., 2017). The intracellular heating causes the water vapour to disrupt the cells from within - electroporation effect (Lee et al., 2012). Several studies indicate that microwave irradiation is highly effective as a microalgal extraction method.

The severity of thermal treatment induced by some methods depends on several factors, such as particle size, temperature, pressure and time. Severe conditions result in higher digestibility but also in higher bioproduct degradation. Ultrasound pretreatment induces degradation of microalgal compounds through cavitation, although temperature control could reduce this degradation, but also the process effectiveness. Microwave irradiation provides high temperature control but has high operational costs, however, studies for scale-up would be necessary (D´Hondt et al., 2017).

The emerging technologies for cell disruption are continuous explosive decompression, where carbon oxide or nitrogen is introduced in a pressure vessel under high pressure, microfluidization, which functions as a high-pressure homogenizer, and pulsed arc technology, such as pulsed electric fields and high voltage electrical discharges. Extraction and immobilized (bio)chemical agents are also important since they operate at low temperature and avoid solvents (D´Hondt et al., 2017, Phong et al., 2018). From a practical point of view, it is imperative to optimize the balance between product yield, processing cost and energy consumption (Phong et al., 2018).

## **2.2. Impact of Cell Disruption on Rheological Properties of Wheat Bread with** *Chlorella vulgaris* **Incorporation**

The cell wall of *Chlorella* varies among species and strains and depends on growth conditions. Generally, the inner cell wall has high cellulose content and the outer cell wall may include algaenan which is a highly resistant aliphatic polymer (D´Hondt et al., 2017).

The use of microalgae as a functional ingredient in food has been limited to a narrow niche market and the research on food products with microalgae is still considered as scarce. This work is part of a project that intends to explore the microalgae potential to be a lowcarbon-footprint healthy food ingredient for future foods. One of the objectives is to explore the potential to increase nutritional quality of bread by addition of microalgae biomass, while maintaining its high sensory quality.

Bernaerts et al., (2017) suggested that *Chlorella vulgaris* (Cv) find applications as a multifunctional ingredient in food products which are processed mechanically and/or thermally. In our working group, the use of Cv as a food ingredient has been demonstrated to be a promising way to enrich a staple food like bread in bioactive compounds, but a technological limitation for biomass incorporation higher than 3.0 g  $Cv/100$  g of wheat flour was noticed (Graça et al., 2018).

In the present study, Cv biomass (approved as food grade by European Food Safety Authority, with 60.7 Protein, 13.8 Carbohydrates and 2.3g Fat / 100g) was pre-processed using microwave irradiation as cell disruption method. The morphological changes on the cells were observed by optical and scanning electron microscope (SEM). Since cell disruption promotes the release of intracellular products it can impart structure modifications on bread, resulting from affecting the rheology properties of wheat doughs, therefore breads prepared with addition of microalgae (3% w/w) were investigated. The impact of disruption on the bread antioxidant capacity was also studied.

#### *2.2.1. Morphological Changes on the Cells*

Microalgal suspensions can be described as complex systems consisting of algal cells and cell debris that are dispersed in a continuous phase containing water, dissolved salts and polymeric compounds. Gerken et al., (2013) reported for *Chlorella vulgaris* that rigid wall based on cellulose are embedded within a more plastic layer composed of uronic acids, rhamnose, arabinose, fucose, xylose, mannose, galactose, glucose and pectin. The most common skeletal polysaccharide is cellulose, but during maturation the cell gradually increases in thickness due to a chitosan-like layer (Safi et al., 2015). Cv appears as spherical cells of various sizes, ranging from 1 to 3 µm (Lee et al., 2017). When Cv is grown under favourable conditions, it is capable of accumulating 1-2% chlorophyll of its dry weight. This pigment gives it the dense green colour and is in the chloroplast (Safi et al., 2015).

Some other authors studied the impact of microwave in microalgae cells disruption. Heo et al., (2017) investigated the possibility of the utilization of both lipids and glucose from Cv, and microwave irradiation appeared to be a promising method, damaging the cells severely. In other study (Silva et al., 2014), microwaving achieved the highest lipid extraction efficiencies for mixed cultures of microalgae. Cheng et al., (2013), found that pectin and cellulose structures are severely damage. The disruption level of microalgal cell walls was enhanced when temperature increased. The spherical structures of microalgal cells subjected to microwave treatment at 100ºC for 5 min were completely destroyed. The cells size showed negligible changes with treatment time, but the cell wall thickness and pore diameters in cell walls increased, the outer pectin layers of cell walls gradually detached, and the porosity of inner cellulose layers increased with microwave treatment time. After 30 min, the microalgal cell walls were completely disrupted and all the microalgal cell contents flowed out.

From our microscopic images (Figure 2), some damage on the microalgae cell walls is observed in commercial Cv since it was dehydrated via spray-drying during the downstream process. In light microscope images, aggregation of these commercial Cv cells can be observed. After microwave treatment, there was a reduction on the number of cells and disintegration of the aggregates, although small size colonies are still present. Different sizes of cells should be related with a size distribution observed within Cv at various stages of the reproductive cycle. Comparing SEM images with observations of *Chlorella* sp. obtained by Heo et al., (2017), for several cell disruption methods including microwave, and Spiden et al., (2013), after treatment with high-pressure homogenization, our SEM images suggest that the cell walls have not suffered great extent of damage after microwave treatment at 540W-5min and confirm the disintegration of the microalgae agglomerations. However, a small hole in the cell wall is sufficient to extract content from the cells (Heo et al., 2017), but with the magnification used in SEM observations, we were not able to conclude about that.

Figure 2. Light microscope (Leica DMR) images (above) and SEM (Hitachi TM 3030 Plus, EDX – Mix mode, after freeze-drying of the suspensions) images (below) of *Chlorella vulgaris* cells suspensions (1g/100mL) processed (images on the right) or not (images on the left) by microwave irradiation.

#### *2.2.2. Impact on Rheological and Colour Properties of Wheat Doughs and Breads*

Doughs were characterized by empirical rheology methods (alveograph and texturometer – penetration and extensibility tests) and by fundamental small amplitude oscillatory stress (SAOS) rheology through frequency sweeps after fermentation. In the loaves, colour, appearance and puncture tests during the aging process were used to investigate the impact of cell disruption method on bread production.

In the Alveograph test (AACC 54-30.02) the water level added to the flour is fixed (50% hydration), and after mixing, the dough is extruded and shaped. After a resting period, a biaxial extension is applied during dough bubble inflation. The height of the peak relates to the resistance of the dough to deformation (maximum overpressure P), while the length of the curve relates to its extensibility (L). The curve configuration ratio (P/L) expresses the equilibrium between the tenacity and the extensibility. A P/L ratio of about 1.0 is preferred for the baking of raised breads, P/L ratios of about 0.2 correspond to weak and extensible doughs, suitable for cake and cookie production, while P/L ratios of 2 or higher indicate that the dough lacks the desired degree of extensibility (Preston and Williams, 2003). W is the dough baking strength and this area is generally much larger for hard wheat flours than for soft wheat flours. P and W values of wheat dough had a significant decrease ( $p < 0.05$ ) with the microalgae addition (Table 2), attributed to the reduction of gluten strength (Graça et al., 2018). However, when microalgae cells are disrupted by microwave (Cv-MW) an increase in P and P/L values was observed.

#### **Table 2. Alveograph parameters of wheat doughs with Chlorella vulgaris incorporation, according to AACC 54-30.02 method. Different letters in the same column correspond to significant differences (p < 0.05)**

Control wheat flour and Cv doughs were also prepared using the water absorption values from the farinographic analyses (AACC 54-21.02). Water absorption increased from 61.8% for wheat flour to 64.3% with 3% Cv addition. This may be related with the extra protein content from the microalgae, since high water absorbing capacity of microalgae and other protein sources has also been attributed to their ability to compete for water with other constituents in the dough systems (Dervas et al., 1999, Doxastakis et al., 2002, Graça et al., 2018). All the formulations include 1.7% salt, 0.5% SSL (E481), 4.0% dehydrated yeast and 1.0% sugar (in relation to flour  $+$  Cv content).

Figure 3. Firmness and adhesiveness values obtained from texture profile analysis (TA.XTplus, 10 mm cylindric probe) after dough fermentation. Resistance to extension and extensibility values obtained from extensibility tests (Kieffer dough rig). Different letters in the same graph correspond to significant differences  $(p<0.05)$ .

After fermentation at 37ºC for 60 min, doughs were characterized by penetration, in a puncture test, and extensibility tests (Kieffer Dough rig) in a texturometer TA. XTplus. Firmness values of control dough are higher than Cv and no significant differences ( $p < 0.05$ ) are noticeable with microwave microalgae cells treatment. However, there was a decrease in adhesiveness values for Cv-MW (Figure 3). Cv-MW dough showed a stronger resistance to extension and similar extensibility at t0 (without fermentation), in accordance to the alveographic results (P and L parameters). Fermented dough (t60) Cv and Cv-MW showed

similar resistance to extension, lower than Control, but Cv-MW presented greater extensibility than Cv, i.e., better bread-making quality. Baking performance may be measured by means of dough resistance and stretching ability ratio – R/E. Fermented loaves Cv-MW and control showed no significant differences (p < 0.05) R/E numbers (8.6 and  $8.2 \times 10^{-3}$ N/mm, respectively), slightly lower than for the Cv dough ( $10.8 \times 10^{-3}$  N/mm).

Frequency sweeps were performed to evaluate the impact of Cv microalgae addition on dough structure after fermentation (Figure 4). Doughs have a viscoelastic behaviour with  $G'$  and a destructuring effect with microalgae addition (3% Cv) was probably due to the disruption of the gluten matrix, as previously suggested by Graça et al., (2018). The frequency dependence of G´ (elastic modulus) and G´´ (viscous modulus) could be described by the power law equation:

$$
G' = \alpha' f^{b'} \tag{Eq. 1}
$$

$$
G^{\prime\prime} = \alpha^{\prime\prime} f^{b^{\prime\prime}} \tag{Eq. 2}
$$

Values of  $\alpha$  and b are determined by performing a linear regression on log G' and G'' versus log frequency, where  $\alpha'$  and  $\alpha''$  are the y-intercepts and b' and b'' are the slopes of the resulting line (Bernaerts et al., 2017). According to b´ and b´´ values all the materials have a similar level of structure, but the magnitudes of  $\alpha'$  and  $\alpha''$  decreased with Cv incorporation (Table 3), reflecting that the gluten network got weaker, in agreement with firmness and resistance to extension (t60) texture parameters.

In respect to cell disruption, Bernaerts et al., (2017) observed for Cv suspensions no reliable value of G´ upon High-pressure homogenization (HPH) at pH 6, concluding that rheology of the control suspensions was pH-dependent. The pH of our doughs varied between 5.2 and 5.4 and the results are in line with that study since microwave cell disruption had no significant impact ( $p < 0.05$ ) on the dough's viscoelastic behaviour.

Figure 4. SAOS rheology (Haake Mars III) - Mechanical spectra at 5ºC of fermented dough.

Dough and bread colour was measured with a colorimeter and results are expressed in the CIELAB system - L\* (lightness), a\* (greenness/redness) and b\* (blueness/yellowness) (Table 4). Cell disruption had no significant impact ( $p < 0.05$ ) on bread colour, while Cv dough presented higher negative a\* (green hue) than Cv-MW. The total colour difference  $\Delta E^*$ between Cv and Cv-MW is equal to 3.7 in the dough and 1.2 in the bread. Some authors consider that total colour differences bellow 1 are not obvious for the human eye, for  $1 < \Delta E^* < 3$  values colour differences are not appreciative, being  $\Delta E^* > 3$  the threshold value for obvious colour differences (Francis and Clydesdale, 1975), while others consider than the human eye is only able to differentiate colours for  $\Delta E^* > 5$  (Castellar et al., 2006).

	a'	h′	a''	$\mathbf{b}^{\prime\prime}$
Control	49256 a	0.318a	26617 a	0.270a
Cv	25721 h	0.290 a	12497 b	0.219a
Cv-MW	30709 b	0.301a	15206 b	0.235a

**Table 4. CIELAB colour parameters of dough and bread. Different letters in the same column correspond to significant differences (p < 0.05)**

Texture characterisation of breads was performed using a puncture test in penetration mode (Bourne, 2002). The evaluation of crumb firmness during the storage time at room temperature aimed to observe the effect of microalgae biomass on the kinetics of bread aging.

Figure 5. Firmness values obtained from texture profile analysis (TA.XT plus, 10 mm cylindric probe) during bread aging (0, 24, 48, 72 and 96 h).

From Figure 5 a positive linear relation between bread firmness and storage time can be observed, according to a linear equation:

$$
Firmness = A \times time + B \tag{Eq. 3}
$$

where, A is the aging velocity and B the initial firmness. A similar aging velocity (A) was obtained for all breads, but crumb firmness is significantly  $(p<0.05)$  affected by microalgae concentration with Control  $(1.18N) > Cv-MW (0.99N) > Cv (0.59N)$  at t0.

After 96 h of storage, firmness of bread with microwaved Cv cells is closer to the control and both higher than Cv, demonstrating the positive impact of the microalgae cell disruption in the bread texture. In fact, Bernaerts et al., (2017) observed no reliable value of G´ for Cv suspensions upon HPH at pH 6, but subsequent sterilization of the suspension resulted in a large increase of G´, implying that a stiff network structure is created by an intense thermal treatment. Indeed, thermal processing might damage cell walls and result in solubilization of components and agglomeration/aggregation of cell debris. As Cv biomass contains high protein content, this result was ascribed to aggregation of the denatured proteins.

#### *2.2.3. Impact on the Bread Antioxidant Capacity*

Antioxidants are very important substances used by the human body to protect itself from the hazardous effects of free radicals, preventing many severe diseases. Microalgae are one of the richest and most economical sources of natural compounds with a strong antioxidant effect. Green microalgae *Chlorella* has an antioxidant activity thanks to the high content of chlorophylls (a and b) and vitamin E. As reported by Lanfer-Marquez et al., (2005), chlorophylls can inhibit the DPPH radical.

To evaluate the antioxidant compounds from breads, bread samples have been air-dried at room temperature, crumbled fined into homogeneous powder using an electric blender, and shacked during 24 h in 80% methanol at the room temperature. After the filtration, the solvent was evaporated *in vacuo*. Dried extracts were dissolved in DMSO to obtain 100 mg/mL (stock solution) and stored at -4°C until the experiments. Bread extracts were tested for the scavenging effect on the DPPH radical (Sánchez-Moreno et al., 1998). Extract solutions, in 10 μL volume each, were added to 100 μL (90 μmol/L) DPPH solution in methanol and the mixture was diluted with 190 μL of methanol. In control, the exact amount of the extract was substituted with solvent, and in a blank probe, only methanol (290  $\mu$ L) and extract (10  $\mu$ L) were mixed. After 1 h absorbance was measured at 515 nm. The percentage of *Radical Scavenging Capacity (RSC)* was calculated using the following equation*:* 

$$
RSC\left(\% \right) = 100 \times (A_{blank} - A_{sample}) / A_{blank} \tag{Eq. 4}
$$

where, A<sub>blank</sub> was the absorbance of the control reaction and A<sub>sample</sub> was the absorbance of the examined samples, corrected for the value of the blank probe. Synthetic antioxidants, ascorbic acid and Trolox were used as a positive control.

Compared to the control bread, the incorporation of microalgae led to an increase in the antioxidant capacity of the microalgae-based breads. As expected, bread with *Chlorella* cells pretreated with microwave irradiation showed a higher antioxidant capacity compared with bread with commercial Cv (Figure 6). Even upon baking, the RSC values are interesting, especially when microalgae cells were disrupted by microwave (46.77% compared with

54.27% and 67.27% of Trolox and C-vitamin, respectively). Batista et al., (2017) have studied the incorporation of several microalgae in cookies, concluding that all microalgaebased cookies showed higher total phenolic content, and in vitro antioxidant capacity, compared to the control.

Figure 6. Scavenging effect on the DPPH radical of Cv, Cv-MW and control breads. Synthetic antioxidants, trolox and ascorbic acid, were used as a positive control. Absorbance was measured at 515 nm. RSC (%) =  $100 \times (A_{\text{blank}} - A_{\text{sample}}) / A_{\text{blank}}$ .

A recent study of Shen et al., (2018) provides useful information towards understanding and manipulating Maillard Reaction products formation to maximize antioxidant potential in white bread products, which may explain the RSC value obtained for the control bread (22.33%). These authors reported that breads with sucrose or [fructose](https://www.sciencedirect.com/topics/food-science/fructose) had a good balance of antioxidant capacities.

Concluding this section, it is important to note that a significant improvement in the nutritional composition of the wheat bread with *Chlorella* substitution was observed. This microalgae can be used as one innovative ingredient to enhance functional and technological properties of breads. Differences between bread produced with ruptured cells and bread with microalgae cells, without pretreatment, were found. Thermal processing of breads, after pretreatment of microalgae suspensions using microwave irradiation, should enhance interactions within released cell material.

Microalgae pretreatment contributes to a better baking performance of breads fortified with Cv biomass. An increase in P and P/L alveographic values was observed. Fermented loaves Cv-MW and control sample showed not significantly different ( $p < 0.05$ ) R/E numbers, slightly lower than for the Cv bread. Bread with disrupted Cv cells showed higher firmness than bread with Cv, closer to the control. However, cell disruption by microwave had reduced impact on dough texture, slightly lower adhesiveness and similar firmness, and similar viscoelastic behaviour was found for Cv and Cv-MW doughs.

# **3.IMPACT OF PROCESSING ON THE MICROALGAE PERFORMANCE AS A FOOD INGREDIENT**

Taking into account the diversity and complexity of bioactive compounds present in microalgae and consequent ability to color food, their incorporation into food matrices determine the final characteristics of the products, such as:

- Color stability, whether in terms of culinary or in terms of industrial processing, it is essential to ensure that the color achieved through the incorporation of a certain microalgae remains stable throughout the shelflife period of the product. This aspect is of great relevance either in industrial products or in the catering industry, since it can be assumed as an important acceptance/rejection factor.
- Considering the high concentrations of macromolecules present in microalgae, namely proteins and polysaccharides, which in some species, such as *Spirulina*, can sum up to 60% of the total weight of the microalgae (Batista et al., 2013), the incorporation of microalgae biomass in food matrices necessarily induces structural changes. Thus, it is fundamental to adjust the recipes or formulations that include microalgae, in order to account for the contribution of these macromolecules to the final structure of the product.
- According to the type of processing involved in the preparation of the food product (time and temperature combinations, mixing processes - mechanical energy, shear and high pressure processing, etc.), the degradation of some of the microalgae bioactive compounds can occur. Therefore, it is fundamental to optimize the culinary or processing technologies to preserving the maximum activity of the bioactive compounds. In this chapter, this issue will be highlighted in foods with very different processing techniques: emulsions (mayonnaises), gels (puddings), biscuits, pasta and bread.

#### **3.1. Antioxidant Activity Microalgae Biomass on Food Emulsions**

Food emulsions are thermodynamically unstable systems formed by two immiscible liquids and an interface. Generally, two types of single emulsions can be considered: oil in water (o/w) emulsions, where the oil droplets are dispersed in the aqueous phase and water in oil (w/o) emulsions for which water droplets are dispersed in the oil phase. Combinations of these pairs are possible into multiple emulsions, where emulsions are dispersed concomitantly. Emulsion stabilization is achieved by the addition of emulsifying agents, with an important role in reducing the surface tension of the interface, often including the addition of texture modifiers, with a contribution to the viscosity increase of the continuous phase.

Emulsifiers are surface active molecules with amphiphilic properties - they have both hydrophilic and hydrophobic residues and position themselves in the oil/water interface, therefore reducing the surface tension. In food emulsions, either macromolecules, such as proteins, or smaller surfactant molecules, can be used. When adsorbed at the interface, proteins will form a strong viscoelastic film around the droplet and they will adopt a conformation, which allows the hydrophobic domain to interact with the oil phase and the hydrophilic domain to be inside the aqueous phase, preventing the coalescence of the droplets, contributing to the emulsion stabilization. Traditionally, egg yolk is used as the emulsifier to produce mayonnaise and salad dressings and other hydrocolloids, such as guar gum and xanthan gum, can be used to stabilize the emulsion and to reduce the oil content in low-fat emulsions. However, alternative proteins have been studied as emulsifiers, with advantages in terms of sustainability and nutritional aspects, like pea or lupine proteins (Raymundo et al., 1998). The addition of xanthan gum to reduce the oil content was also

investigated, with a positive impact on the nutritional profile of these emulsions (Raymundo et al., 2002).

The improvement of the nutritional profile of the mayonnaise-like emulsions can be achieved by the addition of several ingredients that contribute to the increase of the bioactive molecules and simultaneously do not disturbed the emulsion stability. Several condiments such as aromatic herbs, oils or seeds can be considered for this purpose. The addition of microalgae as a color ingredient for food emulsions will also contribute to the improvement of their functional behavior. Raymundo et al., (2005) verified that the incorporation of microalgae biomass into food emulsions may not destabilize its structural properties and, depending on the nature of the microalgae, could even present a synergistic effect, increasing emulsions firmness and reducing the oil content of the emulsion, acting as a fat-mimetic agent. Gouveia et al., (2006) prepared pea protein emulsions with incorporation of *Chlorella vulgaris* (green and orange, after carotenogenesis) and *Haematococcus pluvialis* (red, carotenogenic) biomass and evaluated their antioxidant activity. The primary and secondary oxidation products of the emulsions were evaluated, and an enhanced resistance to oxidation was evidenced by emulsions containing microalgae.

It is important to refer that the lipid oxidation is a major cause for quality loss in food emulsions (Mc Clements and Decker, 2000) due to the formation of undesirable volatile compounds, off-flavors (rancidity) and potentially toxic reaction products (Halliwell et al., 1995) which contribute to consumer's rejection.

Microalgae biomass are composed by multi-component antioxidant systems, which are generally more effective due to synergistic or additive interactions between the different antioxidant components (Decker, 1998; Kiokias and Gordon, 2003). Carotenoid pigments, which are the main antioxidant components, under certain conditions, can retard lipid oxidation in a lipidic food matrix, such as a mayonnaise, acting as antioxidants (Bast et al., 1998; Nenadis et al., 2003). The mechanisms associated to the antioxidant performance, in multiphase systems depend on the impact on the interfacial properties and the inhibition of lipid oxidation in bulk (Mc Clements and Decker, 2000).

Considering the results obtained by Gouveia et al., (2006), the impact of microalgae biomass on the formation of primary oxidation compounds (peroxide value) in o/w pea protein emulsions can be illustrated on Figure 7 The addition of *Chlorella vulgaris* (Cv) and *Haematococcus pluvialis* (Hp) to the emulsions tested in strong oxidative conditions (rancimat equipment), yielded smaller values of primary oxidation products in high oxidative environment. However, a considerable increase of oxidation products in the 3rd week for all the emulsions, namely for the control (without microalgae biomass addition) was verified. In the 6th week, primary oxidation compounds decreased, probably due to the conversion into secondary oxidation products. This was confirmed by the results from Table 5, that reveal an increase of secondary oxidation compounds from the  $1<sup>st</sup>$  to the 6th week, assessed by the panisidine value.

From the results of Table 5 it is also possible to observe that the incorporation of Hp and Cv green microalgae biomass provided a higher oxidation stability over time, in comparison with Cv orange. Nevertheless, Cv orange revealed lower peroxide value, suggesting a rapid transformation of the primary oxidation compounds into the subsequent secondary ones.

Figure 7. Peroxide value (PV), from oil-in-water emulsions with: (a) *Haematococcus pluvialis,*  (b) *Chlorella vulgaris* green and (c) *Chlorella vulgaris* orange biomass (Gouveia et al., 2006 - adapted).

The studied microalgae have a predominance of different pigments, which could justify their different behaviour as an antioxidant. Astaxanthin is the predominant pigment in Hp (Gouveia and Empis, 2003) and is recognized as one of the most effective antioxidant compounds (Yen and Chen, 1995), canthaxanthin is the dominant pigment of Cv (orange), and lutein the main of Cv (green) (Gouveia et al., 2006). Hp showed a better performance as an antioxidant, resulted from the production of lower primary and secondary oxidation compounds, which should be related to the higher pigment concentration and to the effectiveness of astaxanthin as antioxidant agent.

The use of microalgae biomass as an ingredient to produce food emulsions can be an interesting way to prevent the oxidation process associated to this type of products. In addition, these emulsions presented creative colours and a potential positive impact on health, resulted from the presence of the antioxidant compounds.

**Table 5. Secondary oxidation products concentration: p-anisidin value, from oil-inwater emulsions, incorporated with Haematococcus pluvialis, Chlorella vulgaris green and Chlorella vulgaris orange biomass (Gouveia et al., 2006 - adapted)**

Biomass concentration (% $w/w$ )	1st week		6th week	
	0.75	1.25	0.75	1.25
Haematococcus pluvialis	1.04	0.32	4.05	4.84
Chlorella vulgaris green	0.97	0.95	4.59	2.41
Chlorella vulgaris orange	1.18	1.18	5.73	6.23

The emulsification process occurred at room temperature, as the result of speed and time. For similar emulsifying conditions, the increase of temperature was monitored and 55ºC was the maximum value achieved (Franco et al., 1998). This temperature should have a small impact on antioxidant stability. In addition, the mechanical energy should impart a certain degree of cell wall disruption, which could be associated with a controlled release and availability of the antioxidant compounds.

## **3.2. Incorporation of Microalgae as a Source of Omega-3 Polyunsaturated Fatty Acids in Pasta Products**

Pasta is an Italian word to describe an extruded and dried hard wheat product. After cooking it is a universally enjoyed food, easy to store and manufacture: it is easy to cook, and is rich in proteins and complex carbohydrates. Traditionally, pasta is obtained from a mixture of water and semolina wheat flour, in a specific proportion. Semolina has a lower starch content and a higher protein content than flour, and after cooking is easily digested. Several ingredients can be added to pasta dough to enhance the nutritional profile and to provide functional activity. Eggs are commonly added to improve color and to increase protein content. Vegetables such as spinach, beetroot, tomato, and carrot, can also be added for color and taste. In recent years, the addition of herbs and spices such as garlic, basil, and thyme has become popular. The addition of different species of microalgae biomass has also been investigated, in order to promote pasta bioactivity.

Zouari et al., (2011) evaluated the effects of semolina enrichment with blue-green algae (*Spirulina platensis*) free radical scavenging activity and observed that microalgae addition resulted in higher swelling index and lower cooking loss than the control sample, revealing the structural reinforcement resulted from the biomass incorporation. Similar results were obtained by Özyurt et al., (2015) for the same algae. In addition, an increase in the free radical scavenging activity was observed, comparing to the control (with no microalgae incorporation). This behavior results from the *S. platensis* free radical scavenging activity, due to its higher content on vitamin E, carotenoids, chlorophyll and phycobiliproteins, which are able to decrease DPPH radicals by their hydrogen-donating ability (Gad et al., 2011). Even considering the processing operations for the pasta production and its cooking, it was verified that *spirulina* enriched pasta enhanced the nutraceutical property by increasing the antioxidant activity.

Kadam and Prabhasankar (2010) revised the impact of the incorporation of different marine as functional ingredients in bakery and pasta products and observed that these products have shown considerable improvement in EPA and DHA contents, leading to a reduction of cardiovascular diseases which is a major health concern of the 21<sup>st</sup> century.

El-Baz et al., (2017) studied the impact of *Dunaliella salina* addition on the nutritional quality of pasta and a reinforcement of the pasta structure, followed by a significant increase of the fatty acids on the final product, was observed. In a previous work (Fradique et al., 2013), the impact of *Isochrysis galbana* (Ig) and *Diacronema vlkianum* (Dv) biomass incorporation in pasta products as PUFA's source was already studied. As an example, on Table 6. the fatty acids profile of raw (R) and cooked (C) pasta prepared with different contents of Ig are presented and similar results were obtained with Dv microalgae.

**Table 6. Main saturated, monounsaturated and polyunsaturated fatty acids in raw (R) and cooked (C) control and enriched pasta with 0.5, 1.0 and 2.0 g/100 g DW of Isochrysis galbana biomass (Ig). Expressed as average values (three replicates) of the percent of total fatty acids (Fradique et al., 2013 – adapted)**

Different letters in the same row correspond to significant differences ( $p < 0.05$ ).

It is possible to observe that palmitic  $(16:0)$ , oleic  $(18:109)$  and linoleic  $(18:206)$  acids were the main saturated, mono and polyunsaturated fatty acids found, respectively, in both pastas prepared with microalgae biomass addition. A significant increase of eicosapentaenoic acid  $(20:5\omega^3, EPA)$  and docosahexaenoic acid  $(22:6\omega^3, DHA)$ , that were absent in raw control pastas was also found. In addition, it was observed that the cooking process, in boiled water, does not imply a reduction of the omega-3 fatty acids levels, i.e., leaching of the microalgae does not occur, which was retained in the pasta structure. This fact is reinforced by the observation that the incorporation of microalgae implies a reduction of the loss of soluble solids as a consequence of cooking, comparing to the control.

#### **3.3. Gelled Desserts Enriched with Microalgae**

The gelled desserts are traditionally obtained from milk, starch and egg yolk, presenting a yellow coloration. The creation of attractive color desserts can be achieved through the incorporation of microalgae, which simultaneously improves the nutritional performance of the products and presents health benefits.

However, it is important to consider that the addition of microalgae biomass can promote modifications on the gel structure, resulting from their high protein content (Batista et al., 2012). Although, it was also verified that the gelling mechanism is ruled by the biopolymers, while microalgae seem to be embedded in the gel network acting as active particle fillers (Batista et al., 2011).

The impact of *Spirulina maxima* and *Diacronema vlkianum* biomass addition to vegetable-based gelled desserts (similar to ''dairy desserts'') prepared with pea protein isolate, rich in essential fatty acids: omega-3 polyunsaturated fatty acids (PUFA), was investigated by Gouveia et al., (2008a). It was stated that the addition of these microalgae biomass to vegetable gelled deserts, resulted in a novel alternative food product, with PUFA's (e.g., EPA, DHA and GLA), with favourable texture characteristics, particularly for *Diacronema*, due to the gel structural reinforcement observed, representing a new food market opportunity.

### **Table 7. Fatty acid composition (percentage of total fatty acids) of the microalgae Spirulina (Sp) and Diacronema (Di), gels prepared with these algae (at 75 and 90 C) and control gel (without alga addition). (Gouveia et al., 2008 – adapted)**

Notes: SFA, saturated fatty acid; MUFA, monounsaturated fatty acid; PUFA, polyunsaturated fatty acid

To prepare protein gels a thermal treatment, previously optimised by Nunes et al., (2006a, b), with some severity, needs to be applied: temperatures ranging from 75ºC to 90ºC, during at least 5 min. This thermal conditions, that are usually used to prepare food gels, had a slight impact on the PUFA's presented in the gel formulations. On Table 7 the impact of thermal treatment on the fatty acids profile is summarised. It can be observed that both microalgae are a rich source of carotenoid omega-3 fatty acids: EPA 20:5 $\omega$ 3 and GLA 18:3 $\omega$ 3, respectively.

The range of temperatures used in the preparation of the gels seems to not affect GLA, EPA and DHA percentage, suggesting that these microalgae cells could resist heavy thermal processing. This resistance of the microalgae bioactive molecules to the wet heat transfer processes evidences the potential of microalgae as food ingredients and/or nutraceutical delivery systems.

#### **3.4. Bioactive Cookies**

Cookies are a generalized and convenient food that can be considered as a nutritious dense snack, which can be produced from a wide variety of raw materials. In this baking product, gluten formation takes on less prominence than in bread, so the incorporation of bioactive ingredients (e.g., proteins, fibers, antioxidants) is more widespread.

Regardless of the type of cookies to be prepared, the production process always involves a high temperature heat treatment, for a given time, so that the final product can acquire the typical sensory characteristics, namely the crunchiness. In this case a dry heat transfer mechanism occurs, which will have different implications than the previously analyzed wet process, involved in the gels formation. For cookies, more severe conditions of heat transfer are expected (about 180ºC, 30 min), which may have a more pronounced impact on the bioactive compounds that are incorporated through microalgae biomass.

Functional biscuits enriched with 1 and 3% of *Isochrysis galbana* (Ig), as a source of PUFA- $\omega$ 3, were developed by Gouveia et al., (2008b). On these biscuits the  $\omega$ 3-fatty acids (DHA, EPA and DPA), coming from the microalgae, remained present after the thermal processing of baking. This can be observed in Figure 8. whereas all the other fatty acids, mainly provided by butter, showed large variations. The authors suggested that the microalgae cells could resist thermal treatment, encapsulating the fatty acid molecules, thus protecting them from oxidation.

Ig biscuits presented PUFA-ω3 levels (EPA+DPA+DHA) of 100mg/100g and 320mg/100 g biscuit, for 1% and 3% microalgae biomass incorporation, respectively. Considering these values, the importance of Ig as a source of PUFA-ω3 should be highlighted, although Ig has not received yet clearance, to be used as food, from EFSA.

In addition to the PUFA's resistance to the heat treatment involved in the biscuits production, it is important to ascertain the stability of other bioactive compounds which are also naturally encapsulated in the microalgae cells. Batista et al., (2017) studied the incorporation of microalgae (*Arthrospira platensis* - Ap, *Chlorella vulgaris* - Cv, *Tetraselmis suecica* – Ts and *Phaeodactylum tricornutum* - Pt) in cookies, as innovative ingredients to enhance its functional properties.

Cookies prepared with *A. platensis* and *C. vulgaris* presented significant (p < 0.05) higher protein content compared to the control, which is an important issue in terms of nutritional improvement.

Figure 8. Evolution of ω3-polyunsaturated fatty acids, of biscuits with 0%, 1% and 3% *Isochrysis galbana* biomass incorporation, at 0 and 12 weeks. EPA, eicosapentaenoic acid (20:5ω3); DPA, docosapentaenoic acid (22:5ω3); and DHA, docosahexaenoic acid (22:6ω3). Gouveia et al., (2008b) – adapted.

Phenolic compounds - simple phenols, flavonoids, phenyl-propanoids, tannins, lignins, phenolic acids, and their derivatives, synthesized as secondary metabolites are natural antioxidants and have been extensively incorporated into foods, considering their recognized health benefits (El-Baki et al., 2009; Machu et al., 2015). Total phenolic content (expressed as gallic acid equivalents mg/g dry weight) of four microalgae strains studied and in cookies enriched with different levels was evaluated and can be compared in Figure 9, as well as the respective *in vitro* antioxidant capacity, accessed by the FRAP Method (Ferric Reducing Antioxidant Power) - Figure 10.

Figure 9. Total phenolic content (expressed as gallic acid equivalents mg/g dry weight) of four microalgae strains (a) and in cookies enriched with different levels of microalgae (b) (Ap – *A. platensis*, Cv – *C. vulgaris*, Ts – *T. suecica*, Pt – *P. tricornutum*). Results are expressed as average ± standard deviation ( $n = 3$ ) Batista et al., (2017) – adapted.

The addition of microalgae resulted in an effective supplementation of phenolic compounds of the biscuits, which are practically absent in the control biscuit. A. *platensis*  with 6% (w/w) biscuit presented the highest phenolic content (0.90 mg GAE/g), followed by *P. tricornutum* 6% cookie (0.62 mg GAE/g). Both *A. platensis* and *P. tricornutum* 2% cookies also showed much higher phenolic content than the chlorophyte algae at the highest concentration (*C. vulgaris* and *T. suecica*).

When submitted to baking, at 110°C, during 40 min, *Chlorophyceae* algae presented high phenolic losses: about 50% for *C. vulgaris* and 80% for *T. suecica*. However, *P. tricornutum* cookies showed high final phenolic content and no considerable losses, compared to the initial microalgae biomass, after baking. The authors explained this different behavior based on the differences of cell wall of *P. tricornutum*. This species presents silica bands or an amorphous silica matrix according to the morphotype (Tesson et al., 2009), when compared to the other microalgae. In this case, an additional protection of the phenolics from thermal degradation should be considered.

Comparing the antioxidant capacity of microalgae-enriched cookies and respective biomass (Figure 10), *P. tricornutum* presented the highest (p < 0.05) anti-oxidant capacity (248 mmol TEAC/kg), followed by *C. vulgaris* (193mmol TEAC/kg), and by *A. platensis* and *T. suecica* (about 160 mmol TEAC/kg). In addition to phenolic content, *P. tricornutum* has a high content of the carotenoid fucoxanthin with a noticeable antioxidant activity (Gilbert-López et al., 2017; Mikami, and Hosokawa, 2013). The antioxidant activity of green microalgae - *Chlorella* and *Tetraselmis* results from the high content of chlorophylls (Wang and Wink, 2016) and vitamin E (Zittelli et al., 2006).

Figure 10. Antioxidant capacity (expressed as mmol of Trolox Equivalent Antioxidant Capacity, TEAC, per kg) of four microalgae strains (a) and in cookies enriched with different levels of microalgae (b) (Ap – *A. platensis*, Cv – *C. vulgaris*, Ts – *T. suecica*, Pt – *P. tricornutum*). Results are expressed as average  $\pm$  standard deviation (n = 3). Batista et al., (2017) – adapted.

All the microalgae-based cookies, even at low levels of incorporation  $(2\% \t w/w)$ , promoted a significant ( $p < 0.05$ ) increase in the antioxidant capacity, comparing to the control cookie (without microalgae). Generally, cookies with 2% microalgae showed values from 7.0 to 9.5 mmol TEAC/kg1  $(+ 65\%$  and  $+ 125\%$  compared to the control cookie, respectively) while 6% cookies showed values from 11.8 to 15.4 mmol TEAC/ kg1 (+ 178% and + 262% compared to the control cookie, respectively). The reported results are in agreement with the studies performed by El Baky et al., (2015) and Singh et al., (2015), which verified that after baking, *S. platensis* cookies showed a high content of phycocyanin, supposedly responsible for the observed anti-oxidant activity.

Batista et al., (2017) also studied the *in vitro* digestibility (IVD) analysis, reproducing the chemical-enzymatic catalysis that occurs in the proximal tract of the monogastric digestive system, according to the procedures described by Boisen and Fernández (1997). The results revealed that *T. suecica* and *P. tricornutum* microalgae biomass presented the lowest IVD (around 50%). The differences among the microalgae tested could be related to their different cell wall structure (e.g., Andersen, 2013). However, no significant difference ( $p < 0.05$ ) in IVD (87–95%) between microalgae cookies and the control was found.

#### **3.5. Bioaccessibility of Microalgae Biomass**

The incorporation of microalgae in food products, with different levels of processing, adds bioactive compounds, namely fatty acids and antioxidants, to the final products. The resistance of the bioactivity to different levels of food processing could result from the fact that the bioactive molecules are naturally encapsulated within the microalgae, which gives them a certain degree of protection, makes microalgae a promising functional ingredient.

However, in addition to the activity of the bioactive ingredients in a specific food matrix, it is important to evaluate their bioavailability, i.e., to what extent do conditions exist for the human body to assimilate the active ingredient. This is the only way to effectively guarantee the alleged health benefits. To perform this type of evaluation, different strategies could be applied. Clinical trials in humans are the most direct method to quantify the real benefit of such ingredient on health, resulting from its regular consumption. However, this type of approach, is expensive and involves ethical issues difficult to overcome. The performance of animal tests leads to the same arguments. As an alternative, the *in vitro* studies can give a realistic prediction of the bioavailability of the functional ingredients.

In the latter described works, the resistance of *Diacronema vlkianum* to the processes associated with the production and cooking of pasta and the preparation of gel desserts was verified. In these two types of products, it was found that, despite the severe heat treatment conditions associated with production, the fatty acids present in the microalgae remain at high levels in the final products, i.e., the process losses are minimal. Mello-Sampayo et al., (2017) evaluated *in vivo* the assimilation of fatty acids present in this microalgae. A single-dose (CD1-mice) studies were followed by 66-days repeated-dose study in Wistar rats with the highest tested single-dose of microalgae equivalent to 101 mg/kg eicosapentaenoic acid + docosahexaenoic acid (EPA+DHA). Microalgae-supplementation modulated EPA and docosapentaenoic acid enrichment at arachidonic acid content expenditure in erythrocytes and liver, while increasing EPA content of heart and adipose tissues of rats. Those fatty acid (FA) changes confirmed the *D. vlkianum*-biomass FA assimilation. Brain was discriminated from other tissues, using a principal component statistical analysis, forming two other groups (erythrocytes, liver, and heart separated from kidney and adipose tissues), pointing to a distinct signature of PUFA deposition for the brain and for the other organs. The improved serum lipid profile, omega-3 index and erythrocyte plasticity support the cardiovascular benefits of *D. vlkianum*. The results obtained in this work support the potential of *D. vlkianum*-biomass to be used as a functional food ingredient, providing a safe source of bioavailable omega-3 PUFA.

Cilla et al., (2018) revised the main issues related to the *in vitro* evaluation of bioaccessibility of bioactive compounds (carotenoids, minerals, ascorbic acid, tocopherols and polyphenols). The authors pointed out some concepts that should be considered. The definition for bioavailability (BAv) is not universally accepted. From a nutritional point of view, it is defined as the fraction of ingested component available for utilization in normal physiological functions. However, two additional terms - bioaccessibility (BAcs) and bioactivity (BAct) are associated with BAv (Fernández-García et al., 2009). BAcs has received two alternative definitions: i) it is considered as the fraction of a compound that is released from its food matrix in the gastrointestinal tract and thus becomes available for intestinal absorption; or ii) it is the fraction of a compound that is released from its food matrix in the gastrointestinal tract and thus becoming available for intestinal absorption including absorption/assimilation into the cells of the intestinal epithelium and, lastly, presystemic intestinal and hepatic metabolism (Cardoso et al., 2015). BAct is related to how the bioactive compound has reached systemic circulation and it is transported and reaches the target tissue, interaction with biomolecules metabolism in these tissues, and all the cascade of physiological effects it generates. *In vitro* methods can evaluate BAcs and/or BAct (Fernández-García et al., 2009; Cardoso et al., 2015). Bioaccessibility of elements in green seaweeds from pond aquaculture were recently studied by Afonso et al., (2018), using an innovative *in vitro* digestive model of the human gastrointestinal tract. The study highlighted the importance to take into account bioaccessibility results to estimate the dietary intakes.

Similar work is underway with the same research group to determine the bioavailability of various bioactive compounds of *Chlorella vulgaris* and *Tetraselmis chui* in bakery products.

#### **CONCLUSION**

Microalgae are already recognized as an important source of bioactive compounds or phytochemicals, that may benefit health beyond the role of basic nutrition. Nevertheless, the consumption of microalgae in food is still very limited and only a small number of species are allowed for human consumption. The use of whole microalgae as a food ingredient has a high exploitation potential for the production of value-added functional foods.

The bioactive ingredients are naturally encapsulated within the microalgae, which garanties a considerable degree of protection during processing. However, a limited disruption of the cell wall may have advantages in terms of release of bioactive compounds, in particular antioxidants.

The mechanical and thermal food processing conditions may imply a certain degradation of the bioactive compounds. Nevertheless, it was found that due to the natural protection of the cell wall, even for more severe processes, the degradation of fatty acids and antioxidants is limited, in various food matrices - e.g., emulsions, puddings (gels), cookies.

In addition to the processing level and cell disruption associated issues, the bioaccessibility of the different nutrients should also be taken into account for the establishment of recommended dietary intakes when a real impact on health, from the microalgae consumption, is foreseen.

#### **ACKNOWLEDGMENTS**

The authors acknowledge all partner institutions, researchers and students involved in these projects, in particular Luísa Gouveia, Ana Paula Batista, Patrícia Fradinho, Narcisa Bandarra, Alberto Niccolai, Sanya Vlaisavljević, Carla Graça, Christine Macedo, João Fernandes, Ana Lima, Cristiana Alves.

## **ABSTRACT**

Seaweed has received remarkable interest for its potential in assessing the environment, as well as in biomonitoring aquatic pollution of organic and inorganic pollutants. The macroalgae by-products are also used for biological treatment of wastewaters, due to their fast growth, high biomass production and their ability to accumulate and degrade different pollutants. In addition to the environmental applications, the algae produce high added-value compounds that could be used in pharmaceutical industry and for the production of renewable energy. Seaweed biomass is also considered as a potential source of biomass for the aquaculture production sector. In this sense, a considerable attention has been paid, in the last years, to the use of macroalgae as a potential and renewable ingredient for aquafeeds; as a consequence of the rising costs of the two most important ingredients used traditionally in diets for aquatic organisms (fishmeal and fish oil). This chapter aims at discussing the use of seaweed by-products for both heavy metal accumulation and food production for aquatic organisms.

**Keywords**: seaweed, biomass, bioremediation, aquaculture, fishmeal, fish oil

## **1.INTRODUCTION**

Seaweeds have attracted considerable attention as potential agents of bioremediation for their capacity to eliminate heavy metals and organic pollutants and for their role in biomonitoring (Ben Chekroun and Baghour, 2013; Ben Chekroun et al. 2013; Ben Chekroun et al., 2014). Similarly, the seaweeds are potential sources of high biotechnological interest due to their production of a great diversity of compounds with a broad spectrum of biological activities (Pereira and Costa-Lotufo, 2012).

Biomonitoring offers an appealing tool for the assessment of metal pollution in aquatic ecosystem (Zhou et al., 2008). Biomonitors can be used to establish geographical and/or temporal variations in the bioavailabilities of heavy metals in the marine environment. The use of a suite of biomonitors allows recognition of the presence of relative magnitude of different metal sources (Rainbow, 1995). With the help of bioindicator organisms, biomonitoring can be regarded as a sensitive tool for the evaluation of the biological and ecological significance of aquatic pollution (Prabhakaran et al., 2017).

Moreover, the phytoremediation is an effective technique that uses plants, fungi or algae to degrade or to remove pollutants from soil, atmosphere or aquatic systems (Baghour et al., 2002; Ben chekroun et al., 2013). The phycoremediation is a cost-effective, eco-friendly, and comparatively safe process. It can effectively reduce the nutrient load of wastewater thereby reducing total dissolved solids (Sriram and Seenivasan, 2012).

The seaweeds can eliminate different pollutants either by biodegradation or by bioaccumulation. The latter occurs when an organism absorbs a toxic substance at a higher rate. Bioaccumulation is a process that allows for binding toxic metals or organic substances inside a cell structure (Zabochnicka-Świątek and Krzywonos, 2014). Several process including uptake, storage and elimination are involved during bioaccumulation (Zhou et al., 2008). Seaweeds are able to accumulate trace metals, reaching concentration values that are thousands of times higher than the corresponding concentrations in seawater (Bryan and Langston, 1992; Föster, 1976; Rai et al., 1981). Seaweeds have been commonly employed to detect the biologically available fraction of trace metals in marine environments (Malea and Haritonidis, 2000; Søndergaard et al., 2014; Bonanno and Bonaca, 2018). The by-products of marine phaeophyceae are even more cost-effective heavy metal biosorbers (Sandau et al., 1996).

On the other hand, seaweed is an abundant biomass with high photosynthetic efficiency, high reproduction rate and strong adaptation ability (Wang et al., 2017), which is an advantage of using seaweeds for accumulation of organic and inorganic pollutants as well as subsequent application of this by-product for the production of renewable energy. Seaweeds are capable of producing lipids and hydrocarbons quickly, and their photosynthetic abilities make them a promising candidate for an alternative energy source (Sivakumar et al., 2012). Studies have demonstrated that seaweed and its spent biomass obtained after pigment and phycocolloid extraction found to be a novel and renewable substrate for bioethanol production (Sudhakar et al., 2017).

An alternative source of biomass is from the aquaculture of seaweed which has seen annual average increases in biomass production of 7.5 % since 2000, with production exceeding 15 million in 2010 (FAO, 2012). Furthermore, global seaweed aquaculture

production occupies approximately 20% of the total world marine aquaculture production by weight, with an annual value of US \$6.7 billion in 2013 (Kim et al. 2017; FAO 2017).

Finally, it is important to note that seaweed aquaculture provides ecosystem services, which improve conditions of the coastal waters for the benefit of other living organisms and the environment. Seaweed by-products can be economically valorized in the form of functional ingredients for finfish aquaculture (Wan et al., 2018).

The seaweed biomass offers a novel and added-value dietary ingredient in formulated diets for fish. The seaweed by-products contain a number of pigments and defensive compounds, and secondary metabolites that could have beneficial effects on farmed fish (Wan et al. 2018).

This chapter highlights the significant progress that is achieved in valorization of seaweeds by-products for bioremediation and fish feeds (aquafeeds).

## **2. SEAWEED BIOMASS AND BY-PRODUCTS FOR BIOMONITORING AND BIOREMEDIATION**

*Recently*, there has been growing interest in the use of seaweed biomass for bioremediation and as bioindicators for environmental assessment. Biological indicators or bioindicators are living organisms such as plants, planktons, animals, and microbes, which are utilized to screen the health of the natural ecosystem in the environment (Baghour et al., 2002; Parmar et al., 2016). Biological indicators can provide information on the long-term effects of metal contamination as well as an indication of the potential for impacts at higher levels as a result of trophic interactions (Farias et al., 2018). Due to their fast growth and high biomass production, s*eaweeds are also considered as* promising candidates for bioremediation of aquatic systems contaminated with organic or inorganic pollutants. The seaweeds are used as an alternative to the direct determination of heavy metals in seawater because of their distribution, size, longevity, presence at pollution sites, ability to accumulate metals to a satisfactory degree and ease of identification (Whitton, 1984; Conti and Cocchetti, 2003; Stengel et al., 2004). Wan Maznah (2010) suggests that algae are ideally suited for water quality assessment because they have rapid reproduction rates and very short life cycles, which make them valuable indicators of short-term impacts.

#### **2.1. Seaweeds as Bioindicators**

Marine organisms (e.g., macroalgae, fish, crustaceans and mussels) have been used as bioindicators in order to provide information about concentrations of pollutants in the surrounding environment and to evaluate the status of chemical contamination of aquatic ecosystems and as an alternative to the analysis of water or sediment (Phillips, 1990; Zhou et al., 2008; Azizi et al., 2018). Seaweeds are recognized as accurate bioindicators, as biochemical and physiological changes allied to the response intensities within a population, community, or ecosystem will vary with time and the nature of the disturbance, serving as signals of environmental degradation (Ortega, 2000; Orfanidis et al., 2011, 2014).

Studying the capacity of Mediterranean macroalgae to accumulate and tolerate macroand micro-elements present in seawater and sediments, Bonanno and Orlando (2018) reveal that seaweeds can accumulate and tolerate high concentrations of chemical elements such as Pb, Cd, Zn and Cu, which allow them to be exploited as bioindicators for biomonitoring of aquatic pollution by heavy metals and organic pollutants. Several species of the green algae *Enteromorpha* and *Cladophora* (Figure 1), occurring in fresh water, brackish and/or marine conditions, have been utilized to measure heavy metals in many parts of the world (Al-Homaidan et al., 2011).

In other study, Akcali and Kucuksezgin (2011) reported that the brown algae *Cystoseira* sp., the green algae *Ulva* sp., and *Enteromorpha* sp. possess high potential as cosmopolitan biomonitors for trace metals in the Aegean Sea (Figure 1).

Figure 1. (a) *Cladophora glomerata* (Safari et al., 2016), (b) *Enteromorpha intestinalis* (Ibrahim et al., 2014) and (c) *Ulva* sp. (Baghour, 2017).

More recently, Squadrone et al. (2018) show that Al, Be, Pb and Zn levels in seaweeds from Giglio Island were found to be significantly higher than in macroalgae from other islands of the Tuscany archipelago. These authors reported that the removal operation realized by these seaweeds confirmed the suitability of these marine organisms in signaling an environmental perturbation due to anthropogenic activities. Seaweeds by-products are considered bioindicators of water pollution due to their ability to accumulate metals at several orders of magnitude higher than in the environment in which they live.

#### **2.2. Seaweeds By-Products for Bioremediation**

Bioremediation is the use of living organisms such as bacteria, algae and other organism to remove or degrade pollutants and toxins from soil and aquatic ecosystems. Biomass byproducts demonstrated specific binding abilities, allowing them to be potential adsorbents for the treatment of aquatic ecosystems contaminated with heavy metals (Schneegurt et al., 2001).

Seaweeds and other benthic organisms such as sponges and gastropods were shown to accumulate high level of heavy metals from seawater and, can therefore, serve as biological materials for decontaminating polluted sites (Ben Chekroun and Baghour, 2013; Azizi et al., 2018; Ferrante el al., 2018).

Recently, Fazal et al., (2018) suggests that algae can be effectively employed to bioremediate environmental pollutants and to produce biodiesel. This process of integration (bioremediation-Energy production) can potentially improve biodiesel production and wastewater treatment.

The metal ion uptake by living and dead cells can consist of two different modes. The mechanisms of uptake by living materials (bioaccumulation) and removal by dead ones (biosorption) are entirely different. Biosorption is a physiochemical process that occurs naturally in certain biomass, which allows it to passively concentrate and bind contaminants onto its cellular structure (Volesky, 1990). Biosorption that use living organisms have long been reported as an alternative technology for combating the water pollution caused by heavy metals.

Recent biosorption experiments have focused attention on waste materials, which are byproducts or the waste materials from large-scale industrial operations (Abbas et al., 2014). However, this biosorption could be affected by many parameters such as cell size and morphology, pH, ions concentrations in the external media and temperature (Wase and Forster, 1997). Mohan et al. (2007) showed that by-product chars from bio-oil production can be explored as cost effective adsorbents for arsenic removal from contaminated water system.

The by-products of marine seaweeds are even more cost-effective heavy metal biosorbers. To optimize the heavy metal biosorption by seaweed by-products, Sandau et al. (1996) found that under optimum conditions seaweed by-products, which is cheap and easily available, show high sorption capacities and efficiencies of heavy metal cations, as well as favorable sorption kinetics (Table 1). Sandau et al. (1995) reported that the algal by-products, obtained for example in the preparation of valuable biomaterials: which are practically free of cost, have a biosorption capacity, which is only negligibly lower than the capacity of the original biomasses. Since viability is not necessary for biosorption, dried algae or even algal extraction residues (by-products from the high-pressure extraction of valuable algal components) can be used as biosorptive material (Sandau et al., 1996; Soltmann et al., 2010).

Figure 3. Structures of the main polysaccharides typical of brown algae: (a) alginate; (b) sulphated fucan from Fucales; (c) sulphated fucan from Ectocarpales. (d) Hypothetical model of the biochemical organization of cell walls of brown algae.

Roberts et al. (2015) reported that the potential use of *Gracilaria* waste is as a biosorbent for the removal of metalloids waste effluents (Table 1). *Gracilaria* spp. (Figure 2) by-product is a sustainable substrate for iron-based sorbents (IBS) production and can be used to treat a costly waste problem. The IBS can be produced from waste biomass that remains after the commercial extraction of agar from farmed seaweed.

The cell wall of red macroalgae species contains high concentrations of sulfated polysaccharides such as agar, which are characterized by negatively charged functional groups such as carboxyl. This gives red macroalgae a high affinity for dissolved metals (Davis et al. 2003). The brown seaweeds contained the greatest number of acidic functionalities on the seaweed surface (Figure 3). These carboxylic groups are thought to be responsible for metal absorption (Murphy et al., 2007).

Figure 4. (a) *Palmaria palmata* (Mouritsen et al., 2012)*,* (b) *Polysiphonia lanosa and*  (c) *Ulva reticulate* (Kumar et al., 2018).

Murphy et al. (2007) studied the biosorption performance of Cu (II) by the dried biomass of the two red seaweeds *Palmaria palmata* and *Polysiphonia lanosa*, and they found that carboxyl and sulphonate functionalities involved in binding Cu(II) in both species (Figure 4). However, the amino and hydroxyl groups took part in Cu(II) binding in *P. lanosa*.

Vijayaraghavan et al. (2005) showed that the marine green alga *Ulva reticulate* was found to be an effective biosorbent for the removal of copper (Figure 4), cobalt and nickel from aqueous solutions, because the cell wall composition of green algae provides binding sites such as carboxyl hydroxyl amino and sulphate for metal ions (Deng et al., 2007; He and Chen, 2014; Neori et al., 2003).

# **3. SEAWEED BIOMASS FOR FEEDING FISH AND BIOREMEDIATION IN INTEGRATED AQUA CULTURE SYSTEMS**

Recently, there has been a growing interest in the use of seaweed biomass in formulated diets for fish, in addition to their use for the direct determination of heavy metals in seawater (among other applications). Protein and lipid derived from fishmeal and fish oil respectively are the most expensive ingredients in fish feeds (aquafeeds). Any reduction and replacement of these ingredients by a less expensive protein and lipid sources which will produce the same growth performances will contribute significantly to the reduction of fish production cost.

One of these ingredients is seaweed by-products that contain high valuable protein, lipid and carbohydrate contents. However, like terrestrial plants, nutritional content in macroalgae can vary greatly amongst species. Seasonality and geographic locality can also play an important role in influencing the nutritional composition found in the algal species. In addition to their basic nutritional value (protein and lipid of high quality), seaweeds contain a number of pigments and defensive compounds, and secondary metabolites that could have beneficial effects on farmed fish (Wan et al. 2018). With such promising attributes, seaweeds may fill not only a nutritional role in aquafeeds, but also they may promote fish health and fish welfare. Shpigel et al. (2017) suggested that replacing 100% of the fishmeal by poultry meal and algae (*Ulva lactuca*), while keeping the level of all other ingredients constant, *Sparus aurata* performances were similar to those of fish fed the control feed containing fishmeal.

An Integrated Multi-Trophic Aquaculture (IMTA) system is a practice in which excretions of one or more organisms are utilized by other cultured organisms from different trophic levels. Seaweeds are frequently used in IMTA systems as biofilters of fishpond effluents (Shpigel and Neori 1996; Neori et al. 2004), saving the cost of water treatment while being at the same time a reliable feed source throughout the year. Shpigel et al. (2017) suggested that protein-rich *Ulva lactuca* used as biofilter in an IMTA system was evaluated as a dietary ingredient for gilthead seabream (*Sparus aurata*), at up to 30% replacement ratio of fishmeal enhancing growth performance of fish and reducing nitrogen loads from the effluents by Ulva biofilter, saving on water treatment costs, an additional advantage of integrated multi-trophic aquaculture (IMTA) system. Several studies have reported the beneficial qualities of these macroalgae compounds and their potential for exploitation in commercial finfish feeds.

#### **3.1. Seaweeds as a Sustainable and Functional Aquafeed Ingredient**

Commercially formulated diets represent more than 60% of the production costs in finfish aquaculture (Naylor et al. 2009; Shpigel et al. 2017). A continuous stagnation in the production of fish meal (FM) and fish oil (FO) from fisheries and a rising demand for finfish diets has led to an overall increase in feed costs (Shepherd and Jackson 2013). As result, both feed manufacturers and research institutions are seeking novel economically and environmentally sustainable sources of feed ingredients as replacements for FM and FO. In this context, restrictions on diets based on farmed animal tissue, issues of source availability and low-cost production have seen plants as the principal alternative to FM and FO use in aquafeeds (Gatlin et al. 2007). More recently, processing plant based meals, such as soybean and lupin, through applying exogenous enzymes, chemicals and physical treatments, have allowed manufacturers to overcome the effects of antinutritional factors (ANF) and digestibility issues, which are commonly present in plant-derived ingredients. Unfortunately, an increasing global demand for food (FAO 2009) together with of the use of plants to produce biofuel (Rathmann et al. 2010; Harvey and Pilgrim 2011) will probably increase the price of plant meals and oils in the future, making it less attractive as an alternative to FM and FO into aquafeeds.

Seaweeds by-products offer a novel and added-value dietary ingredient in formulated diets for fish and shellfish aquaculture. Production of biomass can be achieved without dependence on expensive arable land, since seaweed may be collected from coastal regions (in the intertidal, subtidal coastal zones and estuarine habitats) or farmed (Macroalgae aquaculture). The beneficial qualities of the macroalgae compounds and their potential for exploitation in commercial finfish feeds were reported in various studies, with enhancing trends in fish growth, physiology, stress resistance, immune system and fillet muscle quality (Wan et al. 2018).

In an early study, Nakagawa et al. (1984) showed that the inclusion of 10% of *Ulva pertusa* into formulated diet for black sea bream *(Acanthopagrus schlegeli)* produced elevated protein efficiency; while other measured growth performance remained in variable*.* After that, a numerous studies have been performed testing a wide range of fish and seaweeds species. Many of these studies have focused on fish species of high commercial interest, such as rainbow trout, salmon, seabream and sea bass; and centered on several genera of macroalgae,

such as *Ulva*, *Gracilaria* and *Porphyra* species. This was the case of Wassef et al. (2013) who suggested that the inclusion of 5% of *Pterocladia capillacea* in the diet for European seabass (*Dicentrarchus labrax*) resulted in an increase in body weight and weight gain. In the same way, 5% *Pyropiayezoensis* inclusion in diet for red seabream (*Pagrus major)* resulted in increase in fish final weight, weight gain, specific growth rate (SGR) and protein efficiency ratio (PER) Kalla et al. (2008).

Valente et al. (2006) recommended that macroalgae such as *Gracilaria* and *Ulva* can be incorporated up to 10 % in European sea bass feeds without affecting the performance of fish.

In addition, *Gracilaria cornea* and *Gracilaria bursa-pastoris* (Valente et al. 2006), *Porphyra* (Soler-Vila et al. 2009), and *Ulva lactuca* (Wassef et al. 2001) were added to the feed as partial substitutes for dietary fishmeal and increased the fish growth rate and improved protein assimilation.

Other studies using seaweed have suggested that kelp meal works as an excellent additive (attractant, agglutinant and binder) in pelleted feeds for penaeid shrimps and thus improved feed utilization efficiency in this slow feeding species (Cruz-Suarez et al. 2009; Silva-Neto et al. 2012).

### **3.2. Seaweeds Biomass for Bioremediation in Integrated Aquaculture Systems**

In the last years, intensive fed aquaculture (e.g., finfish and shrimp) throughout the world has developed rapidly; making aquaculture the fastest growing global food production sector (Figure 5). Nevertheless, this increase in the aquaculture activities is associated with concerns about the environmental impacts of such often mono-specific practices (Chithambaran, 2016). One of the main environmental impacts is the direct discharge of significant nutrient loads into coastal waters from open-water systems and with the effluents from land-based systems. For this, the aquaculture industry should develop adequate and responsible practices that ensure the remediation of the consequences of its activities in order to maintain the health of coastal waters.

The integrated aquaculture is proved to be potentially more sustainable than monoculture practices, because of the reutilization of waste products of one species by another (Neori et al., 2004). Canada has been a leader in developing seaweed culture techniques as a part of integrated multi-trophic aquaculture (IMTA), where aquatic organisms (fish and shellfish), and seaweed are all grown together in an ecologically-based aquaculture farm design.

The IMTA-produced *U. lactuca* represents multiple advantages for the aquaculture sector by considerably reducing nitrogen loads in the effluents (a significant source of environmental pollution), saving water treatment costs, and turning into an additional valuable crop (Bunting and Shpigel 2009; Holdt and Edwards, 2014).

Various strategies for integrating seaweed into fish culture have been proposed. Buschmann et al. (1994) find that the effluents from intensive tank culture of salmon in Chile favor the production of *Genypterus chilensis* in tank culture. Similarly, Haglund and Pedersen (1993) found that *Gracilaria tenuistipitata* shows a better growth performance in cocultivation with rainbow trout, especially in warm months of the year.

Figure 5. Evolution of the world production resulting from the aquaculture activity (FAO, 2016).

Results indicated that the seaweed is suitable as a good candidate for seaweed/fish integrated mariculture for bioremediation and economic diversification. The integration can benefit economy and environment in a sustainable manner in warm seasons in coastal waters of north China.

From the above-mentioned studies, it seems that the seaweed compounds might show the beneficial qualities, being potential for exploitation in commercial finfish feeds and act as biofilter. As such, these functional compounds could present an attractive incentive to feed manufacturers and fish farmers.

#### **CONCLUSION**

Seaweeds play a significant role in marine ecosystems. They are an important renewable source in marine environments and have received great attention for their high bioremediation capabilities. By-products from seaweeds are currently being used as an alternative adsorbent in removal of heavy metal ions from polluted aquatic ecosystems. Seaweed contains various biologically active components, after the extraction of these molecules; the by-product can be used in formulated diets for fish.

# **ETHANOLAND MACRO ALGAE: WHERE TO NEXT?**

# *Stefan Kraan\**

The Seaweed Company Blue Turtle Ltd.

# **ABSTRACT**

An overview on the ethanol production using macro algae is presented including future developments needed to develop the Industry. The potential of algae blooms, species and production, cultivation systems and bottlenecks, as well as processing and fermetation of macroalgae biomass are dealt with. Some representative examples for the biotheanol production are evaluated.

**Keywords**: biorefinery, bioethanol, macro algae

# **INTRODUCTION**

Seaweeds or macroalgae and ethanol production have somewhat followed a similar pathway as microalgae and biodiesel. Over the last 10 years a lot of effort, funding (EU projects such as Macrocascade, Biomara and Macrofuels), subsidies and investment have gone into this area of research. The current bottleneck for seaweed for biofuel production is adequate upscaling methodologies of seaweed production and mechanisation of seeding, harvesting and processing as at the current level seaweed cultivation for bioethanol is not economically feasible yet (Soleymani and Rosentrater, 2017). These cultivation upscaling technologies are needed in order to establish a seaweed aquaculture industry in Europe. In Western Europe this hasn't happened yet in respect of seaweeds for biofuel production although has happened and is starting to happen at a much smaller scale for food and value added products. Nevertheless in the Western world even for food production there is still a bottleneck which is caused not only by a lack of upscaling cultivation techniques, but also

<sup>\*</sup> Corresponding Author's Email: stefan.kraan@theseaweedcompany.com.

Marine licensing issues, multi-user bay management issues, environmental issues and processing issues (van Oirschot et al., 2017; Hasselström et al., 2018).

Bioethanol has attracted attention for many years as a possible alternative to hydrocarbon fuels. Seaweeds have been often proposed as some of the most promising raw materials for bioethanol production because they do not contain lignocellulose. Seaweeds are a feedstock which is abundant and carbohydrate-rich. It is a crop that can be grown sustainable, uses no agricultural inputs (pesticides, fertilizer, land, water), and is in general not part of the human or animal food chain (Kraan, 2011; 2012; 2013; Obata et al., 2016). One of the most critical aspects of biofuel sustainability from land plants such as corn stand in the way in which biofuel's raw materials are produced, especially with respect to their  $CO<sub>2</sub>$  balance and to the competition with food agriculture areas that they create (Kraan, 2011; Obata et al., 2016). Macroalgae and aquatic fresh water biomass represent major progress in obtaining a feedstock that has high carbohydrate levels and biomass yields. These resources are widespread and available, do not compete with food or agricultural surfaces, produce high quality by-products, can be used as a means to capture  $CO<sub>2</sub>$  and are suitable for integrating in wastewater treatments to reduce pollution. This makes marine aquatic resources one of the most attractive renewable sources for a sustainable energy production (Wargacki et al., 2012).

Rapid growth rates also mean seaweed absorb significant amounts of  $CO<sub>2</sub>$ . One hectare of seaweed can fix about 66t of  $CO<sub>2</sub>$  from the atmosphere. Depending on the species, it will take between  $10-100$  years before the  $CO<sub>2</sub>$  contained in a combusted tree is recaptured in regrowth. For seaweed, taking about six months to mature, it absorbs  $CO<sub>2</sub>$  at a much quicker rate and the carbon released from its combustion is thereby sooner reabsorbed (Obata et al., 2016; Andersen 2017).

Several species of the brown and red algae are used for industrial applications, such as extraction of alginate, and agar or for food e.g., Kombu, Wakame and Nori. Global industrial production of seaweeds is about 25 million tonnes wet weight representing a value of 6 billion dollars (FAO, 2018).

Bioethanol could be produced from seaweeds that are not used for these applications or from the waste generated by the food Industries such as the holdfasts from Wakame processing which are the main waste in farming sites and account for 40-60% of annual production (Jung et al., 2016). Cultivated seaweeds and seaweeds that are not utilized in the marine ecosystem would be suitable for use as raw materials for bioethanol production. Large scale bioethanol production needs highly productive seaweed biomass that either grows fast or can form blooms, Macrocystis pyrifera (Linnaeus) C. Agardh (Rassweiler et al., 2018) and Ulva Linnaeus (Yanagisawa et al., 2013) respectively. Experiments on small-scale cultivation of green seaweeds such as Ulva, Chaetomorpha Kützing and Cladophora Kützing have suggested around 50 tons volatile solids ha/y (Hansson 1983). Habig et al., (1984) have determined that the volatile-solid contents of Ulva spp. are approximately 70% on a dryweight basis indicating about 7 kg dryweight/m2/y. According to Gao and McKinley (1994) the productivity of brown seaweeds such as kelp (Macrocystis C. Agardh, Laminaria J. V. Lamouroux, Ecklonia Hornemann) or Sargassum C. Agardh ranges from 3,3-11,3 dry  $\text{kg/m}^2$ /y with red seaweeds exhibiting a similar range.

# **ALGAE BLOOMS**

Productivity is generally a factor 2-3 higher in Aquatic biomass compared to land biomass. Besides seaweed waste from the processing industries, other sources like Ulva from green tides seems to be a good target for bioethanol production (Yanagisawa et al., 2013). Green tides pose a nuisance for tourism, causes anoxic zones and produces sulphur emissions when washed up and rotting (Shimada et al., 2003; Charlier et al., 2007). It has been estimated that in China, around 2 million wet tonnes of green Ulva seaweeds were produced as a result of a green tide along the shores of Qingdao in 2008 and 2015, and every year with a minimum of 90,000 tonnes in 2012 (Hu et al., 2017). The introduced species Gracilaria salicornia (C. Agardh) E. Y. Dawson in Hawaii in the 1970s to research its potential for an agar industry has now become invasive (Smith et al., 2004). Large decomposing piles of this seaweed have drawn complaints from residents and has driven tourists away (Wang et al., 2011). The adequate disposal of these seaweed wastes, which are regarded as a nuisance, most probably involves high energy input and costs. The production of bioethanol from these seaweed wastes could lead to their effective disposal in addition to their economically advantageous use. Moreover, large Sargassum blooms in the Atlantic Caribbean have become a huge problem (Louime et al., 2017). The genus Sargassum includes many species that are often attached with a holdfast. Those common in the Gulf and western Atlantic are *Sargassum natans* (Linnaeus) Gaillon and *Sargassum fluitans* (Børgesen) Børgesen which are free floating. Huge Sargassum blooms occurred in 2011, 2014, 2015 and as recently as 2018 (Laoime et al., 2017; Putman et al., 2018). When waves of Sargassum washed up on Eastern Caribbean shores seven years ago, people hoped it was a one-off as piles swamped coastlines from Tobago to Anguilla. Nevertheless remote sensing in the summer of 2018 detected more than 323km<sup>2</sup> of Sargassum in the Caribbean basin, which is about three times larger than the previous record bloom in 2015 (Putman et al., 2018).

The reason for this alga to bloom remains unclear but possible causes include ocean pollution and the effects of climate change (Wang et al., 2018). As the alga reproduce asexually by fragmentation; when wind, waves, animals or boats break up the floating mats, small pieces grow into larger ones. Normally floating Sargassum form mats that provide food, refuge, breeding grounds and nursery habitat for an array of marine life from fish to sea turtles and birds. Its role as a nursery for commercially important fish such as mahi-mahi and amberjacks earned Sargassum designation as essential fish habitat. After a few years, mats lose their buoyancy and sink to the bottom of the ocean, becoming food for creatures in the deep Ocean. Washed ashore by wind and currents, the algae add nutrients to the beach ecosystem and help build and strengthen dunes (Putman et al., 2018). Blooms, however, can trap sea turtle hatchlings and thicker-than-normal rafts of it on the water can block needed sunlight for coral reefs. Caribbean fishermen report local flying fish disappearing from affected areas. Thick accumulations can entangle fishing gear and block water intake on fishing boat motors (Louime et al., 2017).

Monthly mean integrated Sargassum biomass in the Caribbean Sea and Central West Atlantic reached at least 4.4 million tons in July 2015. The average % C, % N, and % P per dry‐weight are 27.16, 1.06, and 0.10, respectively (Wang et al., 2018).

The month of October 2018 showed a total Sargassum coverage of 323 km2 as compared with a historical mean of 103 km2 between 2011 and 2017, for the area bounded by  $8 - 23°N$ 

and 89 -  $58^{\circ}$ W. This indicates that there was approx. 12 million tonnes of free floating Sargassum available. The bloom extent in 2018 is still the highest during 2011-2018 for the Caribbean and the central West Atlantic (Wang et al., 2018).

Using algae blooms and waste material from the seaweed industry would make the food versus fuel debate redundant and macroalgae defacto provide the third generation biofuels (Graham-Rowe, 2011; Anderson, 2017). Moreover seaweeds (including Sargassum sp.) can ecologically play an important role as a biosequester that utilizes the atmospheric carbon dioxide for the assimilation as effectively as ligno-cellulosic biomass (Widyaningrum et al., 2016). Perez et al., (2018), demonstrated that with the aid of bacterial laminarinase ethanol can be produced from Sargassum using halotolerant yeast (without pre-treatment).

# **SPECIES AND PRODUCTION**

Several species of macroalgae accumulate high levels of carbohydrates (Holdt and Kraan, 2011), which are all suitable as substrate for direct conversion into ethanol (Li et al., 2014; Ji et al., 2016; El-Sayed et al., 2016). In Western Europe kelp is the species of choice although the fast growing brown alga *Saccharina latissima* (Linnaeus) C. E. Lane, C. Mayes, L. Druehl & G. W. Saunders, has become the species of choice (Forbord et al., 2012). The ability to release spores by controlling light and temperature in tandem with a wellestablished protocol for gametophyte cultivation has made continuous cultivation a possibility (Forbord et al., 2012). Biomass productivity converted to carbon ranges from 1 to 3.4 kg carbon m-2 year-1 (Gao & McKinley, 1994; Mann, 1982; Mohammed & Fredriksen, 2004) and is in line with annual productivity of approximately 2 kg C per m2 for seaweed communities of the European coasts (Lüning & Pang, 2003; Mohammed & Fredrikson, 2004), and 2.8 times higher than for example sugar cane (Gao & McKinley, 1994). There are many different numbers on seaweed production, but worldwide commercial production today is widely recognised to be 12-14Mt dry matter per hectare per year (Chen et al., 2015). For the North Atlantic, cultivation experiments with sugar kelp predict production potentials in the range 170-340t wet weight per hectare (Skjermo et al., 2014). The completed BioMara research programme estimated a seaweed bioethanol production potential of 18927.5 litres per hectare per year (Biomara, 2018).

Sugar kelp (*S. latissima*) is the fastest-growing macroalgal species of the kelp species in the European Atlantic Ocean. This species is similar to S. japonica (Areschoug) C. E. Lane, C. Mayes, L. Druehl & G. W. Saunders of which 3 million ton fresh weight is harvested annually from aquaculture in northern China, and 1 million ton fresh weight additionally in Japan (Wu & Pang, 2006; Ohno & Largo, 2006). Saccharina Stackhouse has as a rule approximately 40-50% carbohydrates of the dry weight (Adams, 2009). Laminaran (a glucose polymer) and mannitol are energy storage compounds, resembling starch in land plants, while alginates are structural compounds and correspond to cellulose and lignin in land plants. The seasonal variations of the carbohydrate composition are considerable (Schiener et al., 2015). The content of storage carbohydrates has a maximum in autumn. During the winter season, with nutrients in excess, the stored carbohydrates are utilized as energy source for protein synthesis reproduction and growth. Growth conditions and harvesting time may therefore strongly affect the quality of the seaweed biomass as substrate for microbial production

processes. As a general rule the highest yields of laminarin and mannitol coincided with the lowest yields in ash, protein, moisture and polyphenols (Schiener et al., 2015).

# **CULTIVATION SYSTEM BOTTLENECK**

Over the last couple of decades different cultivation systems for seaweeds have been developed and improved ranging from intertidal fixed and floating bottom farms for Eucheuma J. Ahardh, Kappaphycus Doty and Gracilaria Greville (e.g., Philippines, Vietnam and Thailand) to elaborate floating net structures for Porphyra C. Agardh and long-line systems for kelp in China, Korea and Japan (Critchly et al., 2006). Modifications of long-line systems have been tested at small scale in Europe (Buck & Buchholz, 2004). These cultivation systems show that there is potential to develop large-scale ocean cultivation of seaweeds. However, existing cultivation and harvesting technology is labour intensive and need to be optimised to reduce costs and energy demand (Troell et al., 2009). Several EU funded initiatives have researched production and new structures e.g., the "Atsea project" (AtSea, 2015) has demonstrated a complete novel approach by using textiles in various forms and shapes creating a secondary seafloor. Using this approach seeding and harvesting could be mechanised and production increased up to 15 kg wet weight per m2. Nevertheless, seaweed cultivation has not become a mainstream activity yet due to cost and lack of mechanisation even with the knowledge to manipulate conditions to produce year-round sorus induction in *S. latissima* by applying short-day treatment of adult sporophytes throughout the year, and by the removal of the basal blade meristem (Forbord et al., 2012). The artificially induced and released zoospores formed viable sporelings at all seasons. This is of huge importance in order to develop a commercial mass scale cultivation and industrial scale-up and continuous production of kelp biomass (Forbord et al., 2012). This indicates that funding and EU initiatives should be directed at up scaling technologies.

# **PROCESSING AND FERMENTATION OF MACROALGAE BIOMASS**

The water content of macroalgae is higher than for terrestrial biomass (80-85%; Holdt and Kraan, 2011), making seaweeds more suited for microbial conversion than for direct combustion or thermo-chemical conversion processes, which is an alternative for land-based biomass (Horn et al., 2000; Ross et al, 2007). The carbohydrates from seaweeds can be used for microbial conversion into a wide range of fuels and chemicals although ethanol seems to be a very straightforward approach (Kraan, 2013).

Ethanol production from hexose sugars, derived from e.g., corn stover or sugar cane, is a well-known process (USDA, 2006). However, hexose-based polysaccharides constitute only about 30-40% of the carbohydrates in kelp. The remaining fraction is composed of C-5 sugars that until now have not been applied as substrates for microbial production processes. However, recent breakthroughs have been made in C5 sugar fermentation technology allowing up to over 80% of the available carbohydrates to be fermented (Takeda et al., 2011; Wargacki et al., 2012; Ji et al., 2016). The potential ethanol production from seaweeds can be calculated and is based on the following assumptions: A carbohydrate content of 50% of the

dry weight and an 80% conversion ratio to ethanol. Through fermentation one gram of sugar can yield 0.4 g ethanol. This will yield 0.2 kg or 0.24 l ethanol from 1 kg dry weight seaweed biomass, corresponding to approximately 0.05 l ethanol per kg wet weight. Nevertheless if we take complex seaweed polysaccharides, levels of 25-40 gram ethanol per litre are achievable using bioengineered microorganisms (Kawai and Murata, 2016). Nevertheless Ji et al., 2016 managed to obtain 0.25 kg ethanol per kg of none pre-treated kelp biomass using a thermophilic bacteria. Moreover, high ethanol yields of 0.44, 0.47, and 0.3  $g/g$  of sugars were obtained by fermenting glucose, mannitol, and alginate at 60°C, respectively (Ji et al., 2016).

# **SEAWEED POLYSACCHARIDES FOR BIOETHANOL PRODUCTION**

Macroalgae are made up of several polysaccharides such as laminarin, mannitol, cellulose, fucoidan, agar, Carragenan and alginate (Holdt and Kraan, 2011). Except for cellulose and laminarin, all other polysaccharides have been utilized industrially. Mannitol, a sugar alcohol, has wide medical applications such as in osmotherapy and in food products where it is used as a sweetener for individuals suffering from diabetes due to its low glycemic index. Fucoidan, a sulfated polysaccharide, is widely used as dietary supplement. Alginate has the most industrial importance. Its utilization ranges from textile printing to pharmaceutical, medical, and food applications (Kraan, 2012).

# **ETHANOL PRODUCTION**

Macroalgae are good candidates for the conversion of polysaccharides into sugars which can then be converted into ethanol (Goh and Lee, 2010; Table 1). However, it is often difficult for one microorganism to convert all components of brown algae with different oxidoreduction potentials to ethanol (Ji et al., 2016; Jung et al., 2013).

The conversion of biomass to bioethanol usually requires different stages (Harun et al., 2014; Widyaningrum et al., 2016):

- Pretreatment of feedstock to release complex carbohydrates
- Hydrolysis of polysaccharides to monosaccharides
- **Fermentation**
- Product recovery

Nevertheless, Ji et al., (2016) demonstrated that the thermophilic bacterium *Defluviitalea phaphyphila* sp. nov.is the first characterized thermophilic bacterium capable of direct utilization of brown algae. It can simultaneously utilize mannitol, glucose, and alginate to produce ethanol.

### **PRETREATMENT**

Several pretreatments consist of hydrothermal pretreatment, wet oxidation, steam explosion, plasma-assisted pretreatment and ball milling (Schultz-Jensen et al., 2013; Harun et al., 2014; Table 1). Wet oxidation of *Chaetomorpha linum* (O. F. Müller) Kützing caused more than 50% biomass loss (Schultz-Jensen et al., 2013) which indicate the need for an appropriate pre-treatment. Acidic pretreatment at high temperature is widely used, but requires certain chemicals which are difficult to recover and can generate non-sugar byproducts, with inhibitory potential on further biological conversion. Alternatively, gamma irradiation is an effective method for the depolymerization of complex polysaccharides and structural breakage of the seaweed cell wall (Yoon et al., 2012). Other pretreatments proposed for altering enzymatic digestibility and ethanol potential for the green macroalgae are ethanol organosolvents and liquid hot water, causing more drastic structural changes than pretreatments with alkaline media and ionic liquids (Jmel et al., 2018).

# **HYDROLYSIS**

Dilute-acid hydrolysis is a typical physicochemical method to treat raw macroalgal biomass (Yanagisawa et al., 2011; Meinita et al., 2012a; Lee et al., 2013; El-Sayed et al., 2016; Soliman et al., 2018), and is highly influenced by acid concentration and hydrolysis time which need to be optimized to maximize concentrations of mono-sugars and ethanol (Meinita et al., 2012a; Soliman et al., 2018). Combination with ionic liquid pretreatment increased the enzymatic saccharification of seaweed waste pretreated (Uju et al., 2015). The decomposition of sugars caused by acid treatment at elevated temperatures can lead to the formation of degraded products, susceptible of causing inhibition of fermenting microorganisms or inducing a prolonged lag phase, i.e., furfural, 5-hydroxymethylfurfural and levulinic acid. Other inhibitory substances could be the metals in macroalgae, which show a higher content  $(1-1.5\%$  wt.) than for terrestrial biomass  $(0.5-1.1\%$  wt.; Jung et al., 2013; Fakhrudin et al., 2014). Degraded products in pretreated hydrolyzate can be removed prior to fermentation, and activated charcoal and calcium hydroxide have been frequently proposed (Meinita et al., 2012b; Ra et al., 2015 and 2017), as for example is done in the detoxification of hydrolyzates from lignocelullosic biomass (Soto et al., 2011). Less often used is the alkaline treatment, i.e., for galactan extraction (strong alkaline solution, 70–90°C, 5 h), but the major advantages are the low polysaccharide yields and generation of waste streams (Goh and Lee, 2010). The efficient hydrolysis to monosaccharides or polysaccharides without a fermentation inhibitor was reported using an integrated pretreatment with hydroxyl radicals and hot water (Gao et al., 2015). Alternatively, the production of platform-chemicals and sugar production by dilute-acid-catalyzed hydrothermal reaction was proposed. *Kappaphycus alvarezii* was used for the production of glucose, galactose, levulinic acid and 5-hydroxymethylfurfural (Lee et al., 2016a).

# **ENZYMATIC HYDROLYSIS**

This is a milder saccharification tool for both whole seaweeds or for residual fractions, but the lack of specific enzyme activities for seaweed polysaccharides limits this approach and the contribution of molecular bioengineering would be interesting since new microorganisms would be required (Wargacki et al., 2012; Jung et al., 2013; Kim et al., 2015; Shukla et al., 2016; Obata et al., 2016; Kawai and Murata, 2016).

The hydrolytic enzymes used for lignocellulosics (cellulase and cellobiase) and other multienzyme complexes are frequently proposed for seaweeds (Yanagisawa et al., 2011; Trivedi et al., 2013). Other specific enzymes for the degradation of brown algal polysaccharides, are alginate lyases, laminarinases or β-glucanases, isolated from marine microorganisms (Wargacki et al., 2012; Jung et al., 2013; Kim et al., 2013; Ji et al., 2016; Obata et al., 2016), seaweed compost (Tang et al., 2009) or sandbar substratum (Kang and Kim, 2015), and could be suitable to saccharify macroalgae, although they showed low hydrolysis efficiency, requiring additional pretreatment (Schaumann and Weide, 1990; Adams et al., 2011; Jung et al., 2013). The enzymes represent an important cost of the process, therefore reutilization is encouraged (Trivedi et al., 2013). Combinations of treatments can be successful, such as mechano-enzymatic (Amamou et al., 2018) or chemical and enzymatic hydrolytic treatments (Ge et al., 2011; Jung et al., 2013; Ra et al., 2015; Sunwoo et al., 2016). The absence of pretreatment prior to fermentation yielded lower ethanol values, but the direct application reduces the product cost.

# **FERMENTATION**

Fermentation to ethanol is generally performed by Saccharomyces cerevisiae, commonly used for industrial fermentation of glucose, but also can ferment galactose (Goh and Lee, 2010; El-Sayed et al., 2016; Renita and Utharalakshmi, 2017), however, macroalgae contain specific carbohydrates with different degree of utilization, i.e., mannitol and laminaran (Horn et al., 2000; Lee and Lee, 2012), and in some cases, specific adaptation of bacterial strains to these specific sugars and to high salinity was required (Cho et al., 2013; Sunwoo et al., 2016). Furthermore the utilization of seaweed mixtures and different microorganisms has been reported, i.e., a mixture of red, brown, and green seaweed wastes treated with acid, saccharified with enzymes and further fermented with a co-culture of adapted S. cerevisiae and Pichia angophorae (Sunwoo et al., 2017). A novel approach consists of the use of metabolically modified bacteria (Takeda et al., 2011). Conditions for hydrolysis and fermentation in studies published from 2000 till 2015 can be found (Fernand et al., 2017) and are summarized and updated in Table 1. The bioconversion strategies widely used are separate hydrolysis and fermentation (SHF) and simultaneous saccharification and fermentation (SSF). Furthermore, consolidated bioprocessing, consisting of performing enzyme production, hydrolysis, and fermentation in a single unit (Harun et al., 2014; Fernand et al., 2017). Most processes were successfully scaled up (Shukla et al., 2016). After the biomass is converted to ethanol, the solid protein residue could be used as an ingredient for fish feed or other protein applications (Seghetta et al., 2016a).

*Defluviitalea phaphyphila* sp. Nov. is the first characterized thermophilic bacterium capable of direct utilization of brown algae (Ji et al., 2016) and can simultaneously utilize mannitol, glucose, and alginate to produce ethanol. Ethanol yields of 0.47  $g/g$ -mannitol, 0.44  $g/g$ -glucose, and 0.3  $g/g$ -alginate were obtained. A rational redoxbalance system under obligate anaerobic condition in fermenting brown algae was revealed in *D. phaphyphila* Alga l strain through genome and redox analysis. The excess reducing equivalents produced from mannitol metabolism were equilibrated by oxidizing forces from alginate assimilation. Furthermore, *D. phaphyphila* Alg1 strain can directly utilize untreated kelp powder, and 10  $g/L$  of ethanol was accumulated within 72 h with an ethanol yield of 0.25  $g/g$ -kelp. Microscopic observation further demonstrated the deconstruction process of brown algae cell by *D. phaphyphila* Alg1 strain (Ji et al., 2016).

### **CONCLUSION**

The growing importance of seaweeds for the production of alcohol as fossil fuel replacement to abate global issues in respect of global warming,  $CO<sub>2</sub>$  reduction and climate change are obvious. The integrated biomass deconstruction system of *D. phaphyphila* Alg 1 strain, as well as its high ethanol yield, provides an excellent alternative for brown algae bioconversion at elevated temperature (Ji et al., 2016). Currently seaweed production from longline systems is not economically feasible. The lowest production level of dry seaweed to meet 0.93(\$/L) for ethanol fuel and 0.07\$/kW-h for electricity was found to be 0.68 and 3.7 million tons (drybasis), respectively (Soleymani and Rosentrater, 2017). However looking at the volume of algae blooms with 2 million tonnes of Ulva and 4.4 million tons of *Sargassum* (Hu et al., 2017; Wang et al., 2018) ethanol production or electricity generation is a reality. Achieving economic cultivation may be possible by lowering production costs and increasing the area under cultivation. Logically society should tap into the availability of massive algae blooms as a feed stock to make seaweed bio-refineries a reality. Seaweed bio-refineries should be supplemented with cultivated seaweeds and it is recommended that time and effort are focused on R&D of seaweed farming in Europe in parallel with exploiting algae blooms. Solving specific bottlenecks in upscaling and mechanical harvesting technologies in order to mechanise large seaweed cultivation at a European level has priority in order to fulfill the promise of macroalgae seaweed bioethanol.

# **ABSTRACT**

At present two native lamprey species occur in the Czech Republic, namely the brook lamprey (*Lampetra planeri*) and the Ukrainian lamprey (*Eudontomyzon mariae*). Both species are listed under Annex II to the EU Habitats Directive (Directive 92/43/EEC), thereby requiring Member States to designate Special Areas of Conservation (SACs) for their conservation. The paper summarizes knowledge about biology, ecology, distribution, monitoring of occurrence and action plans/recovery programmes for the mentioned species.

# **1.INTRODUCTION**

The Czech Republic is situated in the very heart of Europe, and it is sometimes called the ", roof of Europe", as this region is wholly dependent upon precipitation coming in the form of rainfall or snowfall. The Czech Republic´s territory was historically inhabited by four

 $\overline{a}$

lamprey species belonging to the family Petromyzontidae: the sea lamprey (*Petromyzon marinus*), the river lamprey (*Lampetra fluviatilis*), the brook lamprey (*Lampetra planeri*) and the Ukrainian lamprey (*Eudontomyzon mariae*). The occurrence of the first two mentioned species has been historical. The last sea lamprey specimen was caught in Bohemia in 1902 and the river lamprey was reported there for the last time in 1897 (Hanel and Andreska 2016). Nevertheless, both of the lamprey species could appear again in the Czech Republic, as there have been recent reports of their findings in the German reaches of the Labe/Elbe River, not far from the Czech border. Systematic monitoring of the brook lamprey and Ukrainian lamprey in the Czech Republic has been carried out within the Lampetra project implemented by many mappers since the 1990s (Hanel 1994a). Therefore, current knowledge of the topic is presented in this chapter. The taxonomic position of the Ukrainian lamprey in the Czech Republic has been unclear (some authors synonymized it with *Eudontomyzon vladykovi*, others believe that both the species are valid taxons and *Eudontomyzon mariae* does not inhabit the Danube basin, see Hanel et al. (2015), Levin et al. (2016)). For the purpose of this chapter, the lamprey population in the Račí potok/Crayfish Brook (the Danube River basin) in the Czech Republic is classified within the species *Eudontomyzon mariae* (Hanel and Lusk 2005, 2006, Hanel and Andreska 2016).

# **2. RESULTS**

### **2.1. Lamprey Population Monitoring**

Distribution data on both of the lamprey species (i.e., *Lampetra planeri, Eudontomyzon mariae*) are principally based on various sources from the past with some new additions. The former data was gathered from literature (scientific/technical articles, regional contributions, local chronicles), data based on materials kept at museums and universities were also used for the study (Hanel 1994a, c, 1996). The following methods were applied in gathering the new data:

- living adult specimens seen with a naked eye during the spawning period (e.g., Hanel et al. 2015);
- $\bullet$  digging the larvae out of the suitable sediments using a shovel (e.g., Hanel 1994a);
- electrofishing (e.g., Hanel et al. 2015);
- searching for dead adults after spawning (e.g., Hanel and Jankovský 1996);
- searching for the remnants of lampreys´ bodies in the digestive tract of piscivorous vertebrates (e.g., the black stork - Pojer and Hanel 1996, european eel - Bílý 2000, common kingfisher - Čech 2017);
- detection of dead ammocoetes (when the stream bed dries out, e.g. Hanel 2000);

Electrical fishing is the preferred technique used for juvenile lampreys (also called ammocoetes) sampling in waters less than 1 m in depth (APEM 2004, Harwey and Cowx 2003, Dunhama et al. 2013, Hanel et al. 2015). The dual wave operation "on-off" sequence is used to irritate ammocoetes out of the substrate. While the gear is operated, the anode is slowly pulled backwards in the water to cause lampreys to emerge from burrows as a result of electro-taxis. This procedure is repeated throughout each operation. The time sequence for "on" and "off" states during electrofishing can be variable under different natural conditions (water temperature, conductivity, sediment depth). For quantitative surveys, some authors use a delimiting framework (equivalent to a quadrat base area  $1m^2$ ), see e.g. Harvey and Cowx (2003), Persat and Copp (1990). Two basic methods for quantitative sampling are used in the Czech Republic: Point Abundance Sampling or continuous electrofishing in the selected brook/river sections. Matěnová (2003) and Matěnová and Matěna (2003) compared both mentioned methods in the Malše River (Southern Bohemia). Using continual electrofishing the reached estimate was  $2.5$ -17 ammocoetes of the brook lamprey per  $100 \text{ m}^2$ , whereas up to 10,000 ammocoetes per 100  $m<sup>2</sup>$  were found using the PAS method. The total ammocoetes estimation in delimited section of the brook/river is variable due to heterogeneous sediments.

Successive removal method in brook lamprey electrofishing is usually used for quantity estimation. The study for accuracy verification of quantitative estimation was carried out on a smaller lowland trout brook in Central Bohemia (the Losinský potok Brook) in 1996 (Hanel and Müller 1997) and 2015. Characteristics of the Losinský potok Brook are as follows: coordinates [49°50′44,15″](https://tools.wmflabs.org/geohack/geohack.php?language=cs&pagename=Losinsk%C3%BD_potok_(p%C5%99%C3%ADtok_S%C3%A1zavy)¶ms=49.8455983_N_15.1304725_E_type:landmark) N, 15°7′49,7″ E, length 14.3 km, watershed area 40.5 km<sup>2</sup> , average discharge at opening  $0.23 \text{ m}^3 \text{.} \text{s}^{-1}$ , water conductivity approx. 330  $\mu \text{S} \cdot \text{cm}^{-1}$ . The selected stretch was 60 m long, its mean width was 4.0 m, the water column depth 30-40 cm. Pools up to 1 m deep were present in the area of study. The brook bed was not artificially modified, ground was sandy to gravely, with some large stones. Both riversides were vegetated with shrubs and trees. A belt of fine sediments, about 1 m wide, was found along riversides, in depths up to 20 cm. The first test (in 1996) was conducted using electric aggregate IG200/2 (made by Hans Grassl, Germany, direct current, 130-250 V, to 2.5 A, to 250 W), the second one in 2015 was carried out using electric aggregate SEN (made by Radomír Bednář, the Czech Republic, direct current,  $180-220$  V,  $1.2-1.7$  A, to 95 Hz). It was used as a method of energising the electrode for 3-5 seconds bursts of pulsing direct alternative current. A brief 2-3 second pause was made between the bursts, allowing lampreys to emerge when the power stopped.

Figure 1. Result of a successive removal electrofishing exercise on lamprey capture in the Losinský potok Brook (the Labe/Elbe River basin, Central Bohemia) in March 1996. Catch at each fishing (below curve), cumulative catch (upper curve),  $n = 101$ . The theoretical total number of larvae calculated by linear regression was to be 131 (see Hanel and Müller 1997).

Figure 2. Result of a successive removal electrofishing exercise on lamprey capture in the Losinský potok Brook (the Labe/Elbe River basin, Central Bohemia) in May 2015. Catch at each fishing (below curve), cumulative catch (upper curve),  $n = 336$ . The theoretical total number of larvae calculated by linear regression was estimated to be 417.

The goal of the experiment was to estimate how many times hunting by electric aggregate should be repeated before no more larvae are found at the given site. A hunting period lasted 30 minutes, followed by a 15 minute long pause. Hence, the next hunt started 45 minutes after the beginning of the foregoing hunt. Once in the water column, further bursts of electricity immobilised the ammocoetes and allowed them to be netted and removed for subsequent analysis. Immobilized lamprey were captured by a fine-mesh net, and transferred to a waterfilled container on the brook bank. Only larvae longer than 50 mm were recorded. The sampling process was repeated several times until there were no more larvae.

The experiment showed that lamprey abundance can be significantly underestimated if catching is not repeated several times at the same site (see Figures 1 and 2). The large number of electrofishing operations required confirms the difficulty of obtaining quantitative data by lamprey larvae electrofishing. Our results correspond with the data cited by Igoe et al. (2004). After using successive removal electrofishing in the Irish Black River (monitored area of the bottom as for 20 x 2 m) there were no brook lamprey larvae caught, except for the seventh catch (but only 8 individuals were caught in total).

To estimate the number of brook lamprey larvae, Visible Implant Elastomer Tags in the river Ostružná (tributary of the Vltava River, the Labe/Elbe River basin) were also tested, see Křížek (2003). Based on the tagged and nontagged larvae ratio the abundance was estimated to range between 5.9 and 6 ind.m-2 of the examined sediments.

A laboratory experiment in aquarium with known number of ammocoetes was also carried out. In total 20 larvae  $(8-12 \text{ cm in length})$  were placed in a glass aquarium 100 x 50 x 50 cm and with a 10 cm depth of fine sediment from the Losinský potok Brook. After the first hunt using electric aggregate (type SEN) 4 larvae appeared on the sediment surface.

Moreover, an estimate of the size of the lamprey population by electrofishing alone is difficult from another point of view. Small juvenile lampreys (smaller than about 5 cm) are only rarely caught during electrofishing (Igoe et al. 2004, Hanel et al. 2015).

Using continual electrofishing, numbers of the brook lamprey usually varied between 1– 24 ind.m<sup>-2</sup> in brooks and river sediments in the Czech Republic. Big floods can cause exceptional conditions for lampreys. After a flood in the Štěpánovský potok Brook (a tributary of the Sázava River, Labe/Elbe River basin) Hanel and Pešout (1989) found a site with 47 larvae per  $m^2$  in the depth of the silt reaching 30 cm (70-120 mm in length). The ammocoete number ranged between 311 and 7,067 individuals per hectar (calculated from the total surfaces of the bottom of the flowing waters which were studied) in the Czech Republic (Hanel and Lusk 2005).

Based on all the data about brook lamprey larvae numbers in the Czech Republic the following categories can be established: above average abundance – more than 5 ind.m<sup>-2</sup>, average abundance  $0.5{\text -}5$  ind.m<sup>-2</sup>, below average abundance – less than  $0.5$  ind.m<sup>-2</sup> in sediments with optimal structure (Hanel et al. 2015).

Figure 3. Length composition of brook lamprey dead larvae collected in a mill-race of the Padrťský potok Brook on July 1998 (Labe/Elbe River Basin, Western Bohemia), n = 782, see Hanel (2000).

Figure 4. Length composition of electrofished sample of the brook lamprey larvae in the Losinský potok Brook (Labe River basin, Central Bohemia) in May 2015, n = 331.

# **2.2. Growth of Larvae and Population Structure of the Brook Lamprey Population**

Ranges in length/weight growth of brook larvae from various Czech sites were presented by Kux (1985): age 0+ (25–80 mm, 0.03–1.2 g), age 1+ (39–125 mm, 0.25–2.5 g), age 2+

(69–160 mm, 1.0–5.5 g), age 3+ (100–190 mm, 1.5–10.6 g), age 4+ (126–185 mm). In Figure 3 the length structure of the brook lamprey dead larvae collected in the mill-race of the Padrťský potok Brook is depicted. Figure 4 shows the length structure in living ammocoetes of the same species collected in the Losinský potok Brook.

### **2.3. Habitat Selection by Lampreys and Food of Ammocoetes**

Poulíčková (1996, 1998) found over hundred diatoms in total in sediments of 40 running waters with the occurrence of the brook lamprey in the Czech Republic. The following taxa are among the most common species: *Achnanthes lanceolata, A. minutissima, Cymbella silesiana, Fragillaria* sp., *Gomphonema parvulum, Meridion circulare, Navicula avenacea, N. gregaria, N. lanceolata, Nitzschia* sp., *Surirella ovata*. It is interesting that sometimes diatoms can survive passage through lamprey digestive tract. The proportion of surviving diatoms depends on the season (it is higher in winter than in summer) and length of lamprey. The lowest value was found in the genus *Achnanthes* (10-20%), on the contrary the highest surviving share for the genera *Cyclotella* a *Amphora* (65 % and more), see Špačková and Jasenská (1985) and Špačková and Poulíčková-Jasenská (1987). Diatoms as long as 380 μm were observed in the intestinal content, in the genus *Closteria* even 610 μm (with a width of 60 to 70 μm). Fragments of plant vessel bundles reached a length of 350 to 580 μm and width of 40 to 120 μm. The longest organic fragments were 700 to 3960 μm long and 2 to 4 μm wide. The size of sand grains was about 400 μm (Poulíčková 1994).

Poulíčková et al. (2000) studied microphytozoobenthos and macrozoobenthos in 14 brooks with the occurrence of the brook lamprey larvae in the Šumava/Bohemian Forest Mts. region (Southern Bohemia). A total of 69 diatom taxa have been found, the most frequent species being *Achnanthes lanceolata*, *A. minutissima*, *Diatoma mesodon*, *Gomphonema parvulum* and *Meridion circulare*. A total of 31 macrozoobenthos taxa were found, the most frequent species being *Ancylus fluviatlis*, *Drusus* sp., *Limnephilus* sp. and *Rhyacophila* sp. The gut in the larvae of the brook lamprey can also contain small nematodes (Hanel and Pešout, 1989, Poulíčková 1994). Poulíčková and Merta (1998) presented variability of water quality in the whole Račí potok/Crayfish Brook, the only site of occurrence of the Ukrainian lamprey in the Czech Republic (from the spring to the month of September 1995) as follows: water temperature 9.7-12°C, pH 6.97-7.44, dissolved oxygen level 10.2-11.0 mg.l<sup>-1</sup>, conductivity  $168-235 \mu S.cm^{-1}$ , total nitrogen content  $0.5-1.2 \text{ mg.l}^{-1}$ .

Merta et al. (2000) analyzed silts in the Račí potok/Crayfish Brook and in the main stream of the Morava/Moravia River (a stretch between the villages of Postřelmov and Bludov), see Table 1. With the habitat requirements of lamprey larvae in mind, a rapid decrease in the oxygen dissolved in the water in various silt depths should be mentioned. Average protein proportion in dry silt substance in the depth 0-20 cm was 13.7 % in the Račí potok/Crayfish Brook and in the Morava/Moravia River only 8.04 %. Average silt particle in the Račí potok/crayfish Brook was 3.049 mm while in the Morava/Moravia River it was 0.438 mm. Brook lamprey larvae were found in the waters of the Czech Republic, mostly in sediments with particle sizes between 0.1–0.7 mm (Merta et al. 2000; Hanel et al. 2015).

**Table 1. Physical and chemical characteristics of sediment with the occurrence of the Ukrainian lamprey larvae (Račí potok/Crayfish Brook, November 20, 1998) and the brook lamprey larvae (Morava/Moravia River, June 1, 1999), see Merta et al. (2000)** 

Average values of water quality from three brooks with the Brook lamprey occurrence (Štěpánovský potok Brook, Polánecký potok Brook, Částrovický potok Brook, Central Bohemia, Labe/Elbe River basin) are as follows (the values are in mg. $1<sup>-1</sup>$  unless stated otherwise): calcium 54.9-63.7, magnesium 16.2-19.5, iron 0.19-0.26, ammonia 0.34-0.68, chloride 39.2-45.4, sulphate 84.9-94.2, nitrite 0.03-0.089, nitrate 33.3-53.28, o-phosphate 0.042-0.12, pH = 7.32-7.50, conductivity 438-507  $\mu$ S.cm<sup>-1</sup>, total hardness 2.02-2.26 mmol.l<sup>-1</sup>, BOD5 2.67-4.03, total suspended solids 11.7-13, total dissolved solids 307-357.6. The level of heavy metals in sediments (range of average values from the sites with larvae occurrence within the brooks studied) was as follows (in mg.kg<sup>-1</sup> of dry sediment): Cd 0.09-0.21, Cr 1.4-3.2, Cu 1.9-9.6, Zn 8.9-65.1, Pb 4.5-14.6, Ni 2.5-10.1, Hg 0.005-0.021 (Hanel 1994b).

In a study by Slavík et al. (1996) season preference of microhabitat in brook lamprey ammocoetes in the Vltava River was reported. Using Physical Habitat Simulation they found that the larvae migration to offshore sand zones with slow water flow happens in June.

### **2.4. Breeding**

The brook lamprey typical breeding site is a small stream with water 10-20 cm deep over the nests, the redds were usually just upstream from rapids or riffles, often under bridges but also in sunlit areas (author's data). During mating, the oral disc in males usually attaches to the head or branchial region, and the male´s tail almost immediately coils around the female, bringing the urinogenital papilla toward the cloaca of the female. Moreover, Dyk (1949) described atypical breeding, during which the male was not attached to the female.

Our data shows that the most frequent spawning group consisted of a single female with 2 or 3 males. Lohniský (1975) reported that the spawning act was repeated every ½ to 2 minutes, and for individual females, the spawning cycle lasted for 0.5 to 1 hour. Dyk (1949) and Lohniský  $(1966)$  described  $\alpha$  aggressive behaviour in which a male may appear to remove a rival from the nest.

According to Lohniský (1975), the whole spawning period from the beginning of the upstream migration to the spawning grounds to the end of spawning lasts about 23 days at water temperature of  $14-15^{\circ}$ C, 15 days at  $11-17^{\circ}$ C, and 8 days at  $12.0-19.5^{\circ}$ C. The death of spent individuals occurred within 33 days of the completion of spawning. For the record, the first author mentioned observed a solitary female, which spontaneously spawned 438 eggs

using convulsive body movement (water temperature was  $8^{\circ}$ C) after attaching itself on an aquarium wall. The maximum number of eggs per female was 2,696 in an individual with the length of 158 mm, originating from the Mastník Brook (the tributary of the Slapy water reservoir, Central Bohemia), see Hanel and Pešout 1989.

### **2.5. Metamorphosis**

Metamorphosis begins in native waters during the end of the summer. According to the authors observations, complete transformation in the brook lamprey was confirmed in an individual caught on October 23, 2001 in the Štěpánovský potok Brook (the Labe/Elbe River basin), in two males caught in the Losinský potok Brook on November 11, 2016 and in a male and a female captured on November 30, 2001 in the Strašický potok Brook (the Labe/Elbe River basin).

### **2.6. Bioindication by Lampreys**

The saprobity index of the brook lamprey reaches oligosaprobity  $(Si = 1.1)$  at a high significance level  $(I = 4)$ , Sládeček (1976). Morever, Poulíčková et al. (1998) clearly showed that only half of the sites studied matched the expected level, i.e., oligosaprobity. Other localities were found to be within the range of beta-mesosaprobity. The lamprey larvae seem to be able to tolerate a higher organic pollutant level than expected. The saprobity index based on calibration of the sediment diatoms was in good agreement with the results obtained by zoobenthos analysis. The actualized saprobic index (Si), i.e., the indication of an organic pollution level was calculated using analyses of diatoms and benthos from water streams inhabited by the brook lamprey. The values found were  $Si = 1.3$  (indicator weight = 4, oligosaprobic zone - 7, beta-mezosaprobic zone - 3), for more details see Hanel (1997). The results show that the brook lamprey is not fixed to only oligosaprobic zones but it tolerates the beta-mesosaprobic conditions. They can also tolerate the wide ranges in the trophic state, pH and oxygen content (Poulíčková et al. 1998).

The brook lamprey can be found in running waters from trout to barbel fish zones (mostly in trout and grayling ones). The fish zones correspond with better/worse oligosaprobity and better beta-mesosaprobity (BOD<sub>5</sub> to 4 mg.<sup>1-1</sup>) – the extreme value is related to brook lamprey populations. Brook lamprey are specific bioindicators of water quality and environmental conditions. The well balanced length and age structure of larvae confirm long-term high quality in environmental conditions. The observed abundance of ammocoetes in Czech waters varied between 311-7,067 individuals per hectare. These relatively broad ranges may be influenced by various electrofishing methods, anthropogenic factors or various study sites (optimal or sub-optimal muddy sediment habitats). Low number in ammocoetes or total absence of some age groups indicate influence of some negative factors during the past breeding period. Annual observations of breeding population and comparison of adult specimen numbers between years can be a good and helpful bioindicative parameter. Absence of breeding adult specimens or their remarkable low number indicate the influence of some negative factor in the past. Blind larvae are found on the bottom of muddy sediments and due to their specific life strategy they are not suitable bioindicator of short-time

deterioration of water quality. The life strategy of larvae during contamination of their habitats is limited to the lower parts of the substrate and it is necessary for the larvae to withstand these adverse conditions. It is known that the brook lamprey population in the Polánecký potok Brook (Central Bohemia) survived the pollution of the brook with diesel oil which lasted for several weeks. It turned out that the lamprey larvae can survive even a water pollution accident when other ichtyofauna become extinct. Such an event was studied in the Polánka Brook (Central Bohemia, Sázava/Elbe River basin, 49° 41′ 51″N, 14° 51′ 14″ E) in 1992. At that time the quantity of oil substances in the water reached  $0.3 \text{ mg}$ .  $\text{m}^1$  and the level in the upper layers of bottom sediments ranged between 155 to 363 mg.l<sup>-1</sup> (Hanel 2004). Ammocoetes survived because of their underground way of life, as they are continuously buried in soft sediments in the brook bed during their larval stage. The lamprey has been occurring in the Polánka Brook (ammocoetes were confirmed there in 2014 as well). The strategy of larvae during water pollution is therefore to remain in the substrate as long as possible. Only if toxicants penetrate into the substrate, the larvae leave it and tend to get in more suitable sites (author's observations). Therefore, the brook lamprey seem to be a good bioindicator of long-term good quality of the water environment, but its larvae can sometimes survive short-term pollution.

### **2.7. Occurrence of Lampreys**

In the Czech Republic the mapping method for evidence of wild animal findings is the most used. Grid size is 10 degrees East longitude and 6 degrees North latitude. The grid is coded by four digits, for example 6670, where "66" is the row and "70" is the column of the map (see Figure 5).

#### *2.7.1. Lampetra planeri*

Hanel and Lusk (2005) gathered more than 400 brook lamprey samples in the Czech Republic in 1961-2005. Thus, it was confirmed that the species is the most common lamprey there. The species can be found in the Labe/Elbe and Odra rivers basins (98% of the known localities). Only a few isolated populations are found in the Morava/Moravia River basin (the Danube River system), see Merta (2000). All the findings in 1949-2017 are presented in Figure 5, where 301 mapping grids display the occurrence (i.e., 45% from the total number of the mapping grid).

This lamprey inhabits brooks and rivulets in trout and grayling zones at the elevation of 130-900 m above sea level, but most of the findings come from 300-600 m a.s.l. Most findings were made in short streams less than 40 km in length. In total 2/3 of the findings were recorded in natural streams, the rest in streams modified to a various extent. The stream gradient was mostly about 1.5-2 m.km<sup>-1</sup>, the prevalent annual average flow rate in the river mouth of the analysed watercourses was lower than  $1 \text{ m}^3$ . In the Czech Republic, both sexes participate in the nest building usually in shady stream parts about 1-8 m in width and 0.8 m in depth. The spawning occurs usually in May/June in water temperatures of 9-19.5°C (Hanel 1997, 2004).

Figure 5. Occurrence of the brook lamprey (*Lampetra planeri*) and the Ukrainian lamprey (*Eudontomyzon mariae*) in the Czech Republic in 1949-2017. Black dots are *Lampetra planeri*, the yellow dot is *Eudontomyzon mariae*.

Based on surveys carried out in 33 brooks, rivulets and rivers in the Czech Republic were found, together with the brook lamprey, the brook trout (*Salmo trutta*) at 83% of the localities studied, bullhed (*Cottus gobio*) at 53%, stone loach (*Barbatula barbatula*) at 37%, gralying (*Thymallus thymallus*) at 24%, minnow (*Phoxinus phoxinus*) at 28%, gudgeon (*Gobio gobio*) at 19%, chub (*Squalius cephalus*) at 17% and dace (*Leuciscus leuciscus*) at 14%. Ammocoetes were found in those brook sections where the fish number (particularly salmonids) on average was  $13,084$  ind.ha<sup>-1</sup> and the biomass on average was  $234 \text{ kg.ha}^{-1}$ (Hanel 1996). Together the Ukrainian lamprey, the brook trout and the bullhead were reported from the Račí potok/Crayfish Brook (Hanel and Lusk 2006).

#### *2.7.2. Eudontomyzon mariae*

The occurrence of the Ukrainian lamprey in the Račí potok/Crayfish Brook at Velké Losiny (District of Šumperk, Northern Moravia) has been known for almost half a century. This is the only known population of the species in the Czech Republic found in 1968 (Kux 1969). At that time, it inhabited the brook section of about 1.5-2.0 km: the author found 2.5-  $3.2$  ind.m<sup>-2</sup> in suitable sediments there. The status of the site and population size was monitored in 1997-2010 (Hanel and Lusk 1998, 2000, 2002, 2004, 2006, Merta and Křesina 2017).

Since its discovery (1968), the section of the brook inhabited by lampreys has gradually been reduced due to a number of negative factors. These include channel modification and fragmentation, water pollution and high predation. In July 1997, extreme floods occurred in streams of the Morava/Moravia River basin, i.e., in the Račí potok/Crayfish Brook. Thus, in a lower part of the reach where the larvae had occurred, sediment deposits were drifted away by extreme high flows. In this way, the reach containing the larvae was shortened by about 250 m (Hanel and Lusk 1998).

The restoration measures taken in 2005-2006 (wooden dams and artifitial damage to banks causing suitable meandering and new deposits of fine detritus) appeared to be insufficient for the population survival. In order to save the Ukrainian lamprey population, it is necessary to formulate and implement a recovery programme. Purposeful measures must be taken to create, in the adjacent waterlogged meadow, a new meandering brook bed approx. 250 m in length, to provide stabilised drift sedimentation. As a part of monitoring the population, the larval lampreys should be transferred from the lower part into parts harbouring stabilised sediments until the migration barrier is removed. Every year, brown trout should be removed from the brook section in which the larvae occur. Additional modifications in the brook bed should be carried out in order to improve the conditions for the presence of larval lampreys. Perspectively, it is necessary to consider strengthening the Ukrainian lamprey population under study by translocation of larvae gathered from populations living in Slovakia. The donor population should be selected on the basis of assessing the extent of genetic identity with that in the Račí potok/Crayfish Brook population.

Křesina and Hradecký (2009) estimated that about 750 Ukrainian lampreys can live in the restored stretch of the Račí potok/Crayfish Brook (river km 0.62-2.81). The lampreys has become completely extinct from all the historically known sections of the brook by 2013 at the latest. However, in the same year, the presence of ammocoetes was discovered on the previously unexplored lower section of the Račí potok/Crayfish Brook. Between 2014 and 2016, many activities were carried out in order to save the lampreys, particularly reintroduction and recovery transfers of the ammocoetes to the historically inhabited sections in the brook. At present, the population size is estimated at 450–600 individuals of all ages (Merta and Křesina 2017).

### **2.8. Main Threats to Lampreys and Their Conservation and Management**

Lampreys prefer natural and seminatural channels with sites of fine sediments within the suitable qualities (lamprey sites), but also flowing stretches with coarse-grained sand or with gravel (spawning grounds). Lampreys can sometimes survive in the stream even after its modification. The larvae can be threatened by sand exploitation when muddy sediments are taken with the sand. Upstream spawning migration becomes more difficult by various barriers in the channel (e.g. wires, steps etc.) which often are insurpassable for lampreys. Further important factors limiting or preventing the occurrence of the brook lamprey are the following: water pollution (particularly long-term), inappropriate stream modifications, e.g. building of firm sides, removing mud, water loss in parts of the stream due to small hydropower plants, etc., excessive fish stock and, to some extent, predation by some piscivorous birds or mammals (Hanel and Andreska 2006, Hanel at al. 2015). The occurrence of Ukrainian lamprey in the Račí potok/Crayfish Brook is threatened not only by numerous bigger trout (*Salmo trutta*) but by terrestrial ichtyophagous predators occurring there: the black stork (*Ciconia nigra*), the grey heron (*Ardea cinerea*), the Eurasian otter (*Lutra lutra*) and as of recently the American mink (*Mustela vison*). Their imprints and excrements were often found near the fine-grained sediments and potential spawning sites.

The lamprey numbers may also be influenced by extreme water drainage**.** Minimum summer flows, or the incorrect operation of a hydroelectrical power station, can cause the channel to dry which can have lethal effects on larvae because they cannot temporarily survive during a decreased water drainage in bottom depressions, where sufficiently wet mud is maintained. Likewise, extremely increased water flows caused by heavy impact rains

during or after the lampreys´ spawning can damage spawning grounds and drift eggs to unsuitable sites. According to Lusk et al. (1998) significant shifts downstream in the species associated with bottom sediments have been found. These bottom materials are regularly shifted during spates, consequently causing significant shift downstream in the brook lamprey.

The Nature Conservation Agency of the Czech Republic coordinates monitoring habitats and species under the EU Habitats Directive. Both species are listed under Annex II to the EU Habitats Directive (Directive 92/43/EEC), thereby requiring EU Member States to designate Special Areas of Conservation (SACs) for their protection. SACs for the brook lamprey and Ukrainian lamprey were established based on the present knowledge of sites preferred by the viable populations. Altogether 21 sites (sections) of running water were identified for the brook lamprey (17 of them belonging to the Labe/Elbe River basin, 3 sites to the Odra River basin and one site located in the Morava/Moravia (Danube) River basin. The single locality with the occurrence of the Ukrainian lamprey (the Račí potok/Crayfish Brook) was also included into the SACs.

Fundamental principles to protect, conserve and manage habitats inhabited by the brook lamprey in the Czech Republic are as follows:

- maintaining naturally meandering brooks and rivulets, bank and bottom diversity with alternating gravel-sand bottom (breeding sites) and fine deposits (occurrence of larvae)
- continuous water discharge
- preservation of longitudinal migration permeability in streams for adult specimens (elimination of migrating barriers restraining upstream breeding migrations).
- optimal water quality is distinguished by the oligosaprobic level with the maximum limits typical for better beta-mesosaprobity which corresponds with unpolluted water (surface water that has not been substantially affected by human activities, water quality characteristics do not exceed the standard values in surface waters) or slightly polluted waters (surface water having been affected by human activities, however, water quality has been supporting diverse assemblages/communities in a viable ecosystem)
- admissible values of water quality for long-term viable brook lamprey populations are the following: saprobity of macrozoobenthos lower than 2.2, biological oxygen demand, five days (BOD<sub>5</sub>): lower than  $4 \text{ mg.l}^{-1}$ .
- in the Special Areas of Conservation (SAC) proposed for conservation of the brook lamprey and managed for fish it is necessary that the fish stock should be in accordance with natural feeding grounds (elimination of big salmonid or other predatory fishes specimens is recommended to reduce predation on breeding adult brook lamprey specimens).
- rescue transfers of the lampreys with respect to restoration of fishponds, brooks and rivers can be applied (Dušek et al. 2003).

In the most recent edition of the Red List of Threatened Species in the Czech Republic, the Ukrainian lamprey has again been classified as Critically Endangered (CR) while the brook lamprey has been listed as Endangered (Lusk et al. 2017). In accordance with Ministry

of the Environment of the Czech Republic Decree No. 395/1992, as amended later, both the species are classified as critically endangered. Nowadays, the brook lamprey is more widely distributed in the Czech Republic than it has previously been assumed.

### **ACKNOWLEDGMENTS**

The authors express their great gratitude to Pavel Moravec from the Nature Conservation Agency of the Czech Republic for electrofishing. The authors would like to thank Jessica and Michal Kocum for English language revision. The study was supported by the grant scheme PROGRES at the Faculty of Education, Department of Biology and Environmental Education, Charles University, Prague, the Czech Republic.

# **LAMPREY BLOOD CLOTTING: A 60-YEAR JOURNEY FROM FIELD WORK TO GENOMICS**

# *Russell F. Doolittle\* , PhD*

Departments of Molecular Biology and Chemistry and Biochemistry, University of California, San Diego, La Jolla, California, US

# **ABSTRACT**

Mammalian blood clotting is an extremely complex phenomenon involving more than two dozen proteins interacting in a series of limited proteolytic events partitioned into two calcium-dependent pathways, one *intrinsic* to the blood alone and another initiated by a tissue component (*extrinsic pathway*). The two pathways converge and culminate in the thrombin-catalyzed polymerization of a large molecular weight protein called fibrinogen, yielding a space-filling gel ("clot") called fibrin. A long-term study on blood clotting in lampreys has revealed a simpler system in which the extrinsic scheme dominates the process. An evolutionary scenario based on a series of gene duplications accounts for the differences that have arisen since the divergence of cyclostomes from other vertebrates. The earliest of those studies, begun six decades ago, were limited to simple methods dependent on fresh blood plasma, suitable chemical agents to bind calcium to arrest the process, and a stop-watch for measuring clotting times upon the restoration of calcium. Gradually these studies became more sophisticated with the introduction of technological advances like amino acid sequencing, SDS polyacrylamide gels, cloning and DNA sequencing. Even so, some clotting proteins in mammals are present in only trace amounts, and proving their absence or presence in lampreys was not possible until the era of whole genome sequencing. This chapter retraces some of this development from a personal standpoint, beginning with having to capture lampreys by hand and bleeding them at streamside and continuing over the decades to the bioinformatic analysis of complete genomes.

#### **INTRODUCTION**

My interest in the evolution of blood clotting, and the important role lampreys played in unraveling the process, began in the late 1950's. At the time I was a graduate student in a laboratory mainly devoted to the study of blood proteins, including certain aspects of blood clotting in humans. It was an era when not all graduate students were supported by year-round fellowships, and in the summer after my first year of graduate study I found outside employment working for an ophthalmologist conducting a summer project at the Marine Biological Laboratory in Woods Hole, Massachusetts. My job was to measure the chemical composition of eye fluids and blood plasmas from various fish. One perplexing problem I encountered was that in some fish the blood clotted very readily, even before I could get it out of the syringe, whereas in some others, I had no difficulty at all.

I did a lot of reading to find what was known about clotting in fish, and, although there were a few scattered but outdated articles (e.g., Zunz, 1933), in the end there were enough unanswered questions that I decided to center my PhD research on the evolution of clotting (Doolittle, 1961). My plan was to find representative creatures in each of the major vertebrate classes, get blood from them, and see how complex or not the process was compared with humans. In particular, it seemed that no one had ever studied blood clotting in the jawless fish, although I did find one off-hand comment in a report about hagfish hemoglobin that "no anticoagulant was needed since the blood of this animal has little clotting ability" (Manwell, 1958).

So the jawless fish – hagfish and lamprey – were an obvious place to begin except for one problem: obtaining fresh blood from live specimens to work on. Through good fortune I learned that one of my recent instructors, an anatomist named Will Roth, worked on the neuro-anatomy of the lamprey "third eye" and its relationship to the pineal gland. Roth generously offered to give me a lesson in lamprey collection. In New England, it turns out, this is an operation that can only be undertaken for a few months in the Spring. Unfortunately, when I first became aware of this sporadic availability, the season had just passed, and I had to bide my time in the summer of 1959 working with available cartilaginous and bony fish, the eye fluids of both of which I had studied for the ophthalmologist. I froze away blood plasmas so that I'd have something to work on in the fall and winter, periods during which I also read a great deal. These first faltering steps were useful in that I became more adept at handling blood and performing assays, and when the next spring finally came around, I was prepared.

#### **Catching Lampreys**

One rainy day late in April, 1960, Will Roth and I drove north from Boston to one of the many small rivers that drain into the Atlantic Ocean near Exeter, New Hampshire. The equipment we had was decidedly "low tech": two pairs of waders to keep us dry, a few old pillowcases, some simple cloth garden gloves, and a plastic barrel in which to store any lampreys we might catch. The secret, Roth confided, was to understand lampreys and their life style.

As is doubtless detailed elsewhere in this book, sea lampreys, *Petromyzon marinus*, live most of their lives in the open ocean, but they are anadromous and return to the fresh water breeding grounds of their birth to spawn. Adults, which are about two feet long, are not great swimmers against the current, and they need to stop and rest a good deal. They do this by fastening their round mouth – the "sucker" – on to a rock or some other firm object in the stream $1$ 

A good place for collecting is any small dam across one of these streams where the lampreys tend to get stuck temporarily. Most often there are "fish ladders" around these dams, and the lampreys and other migrating fish eventually find their way into those boxy stairs filled with water that allow them to get by the dam.

Usually, all we had to do was grope our way along the bottom of the dam itself, trying not to get too wet from the water spilling over its top. The cloth gloves were needed because lampreys are slippery (but not nearly as slimy as hagfish!). We would simply grab a lamprey behind the head region and guide it into a pillowcase. When enough of them were in the pillowcase, we would waddle back to shore and transfer the specimens into the barrel.

As an anatomist, Will Roth didn't really have to worry about keeping the creatures alive; he could simply cut off their heads and drop them into a suitable fixative. But in order to study blood clotting I needed to get the blood out of the creature while it was still alive, and that took some learning on my part. In the long run, I became very adept and have bled – without exaggeration – well more than a thousand lampreys since that first trip.

#### **Bleeding Lampreys**

 $\overline{a}$ 

There were several little tricks that mattered. First, it was best accomplished as a twoperson operation, one to hold the lamprey and one to do the bleeding (Figure 1). This was true even though we would anesthetize the creatures by putting an anesthetic (e.g., tricaine) in the barrel water. The holder would grasp the animal using disposable diapers to get a good grip.

Figure 1. A 1962 photo of the author preparing to collect blood from a sea lamprey.

<sup>&</sup>lt;sup>1</sup> The word "lamprey" is from the Latin "sucking stone" (LaBonte (1991).

A single-edged razor blade was then used to cut off the tail a few centimeters behind the cloaca, exposing the main caudal vein and artery in cross-section. A large syringe fitted with a big-bore needle with the bevel cut off was pushed gently into the vein. If the bevel were left on, the vein wall would be pulled down on it and close off the system. The syringe had been rinsed well with sodium citrate solution for binding up calcium ions. On my very first attempt, red blood began to fill the syringe as I pulled back slowly on the plunger, and I knew I had a fool-proof method.

The next challenge was to separate the cells from the plasma. Running a centrifuge at streamside is neither convenient nor safe, and whenever possible I'd take the animals back to the lab in Boston and do the bleeding there. The alternative was to do the bleeding in the field, keep the blood cold and well decalcified for the journey back to Boston, and then centrifuge it to separate the plasma from the cells.

# **BLOOD CLOTTING IN MAMMALS**

At this point we need to take a detour from the lamprey experiments to describe, however briefly, what was known at the time about mammalian blood clotting, even then acknowledged to be an exceedingly complex process involving numerous blood plasma proteins, blood platelets, and tissue components. Under ordinary physiological conditions there was an obvious need to strike a balance between keeping the blood fluid in the circulation while at the same time maintaining the potential for rapid gelation in response to injury, the balance being struck by a host of forward and backward compensating reactions. It had long been recognized that a plasma protein called fibrinogen can be converted into a gelatinous material called fibrin by the action of an enzyme called thrombin. Thrombin itself was known to exist in a precursor form called prothrombin, changed into its activated form by two different processes referred to as the *intrinsic* and *extrinsic* systems. The activating complexes – called *thromboplastins* – were calcium-dependent. As such, it was a simple matter to conduct clotting assays in the laboratory if calcium were removed from blood when it was drawn, the simple re-addition to either blood or cell-free plasma leading to the formation of fibrin clots.

The intrinsic scheme involved what were then a set of still unidentified plasma proteins, as well as prothrombin, fibrinogen and calcium. The extrinsic system needed a tissue extract – lung and brain were especially effective – and a somewhat different set of plasma proteins and prothrombin, fibrinogen and calcium.

*Extrinsic system*:

tissue extract + Ca++ + plasma ------ $\rightarrow$  tissue thromboplastin

*Intrinsic system*:

platelets + Ca++ + plasma--------- plasma thromboplastin

thromboplastin

prothrombin ----------------------- thrombin thrombin fibrinogen --------------------- fibrin

Most of the evidence for distinguishing the two pathways was based on simple clotting time assays after the restoration of calcium ions to different mixtures of the various components.

#### **Nomenclature of Clotting Factors**

By mid-century more than a dozen additional clotting "factors" had been identified in human blood plasma, largely protease precursors, protease substrates and protease inhibitors. Because of the confusion that arose with the casual nomenclature of the day, a commission was charged with assigning each a Roman numeral, as in "factor V" or "factor XIII." The previously known reactants were given numerals I-IV: fibrinogen designated factor I, prothrombin as factor II, tissue factor-thromboplastin as factor III, and calcium as factor IV.

What emerged was that, depending on the nature of an injury, either or both of two parallel series of *limited proteolysis* could be initiated, one for the intrinsic scheme and the other for the extrinsic. As depicted above, the two pathways converge and culminate in the thrombin-catalyzed polymerization of fibrinogen. A third pathway, also involving limited proteolysis, led to the subsequent destruction of fibrin. Notably, thrombin activated several factors besides fibrinogen, and the overall process was further regulated by an antithrombin and some other protease inhibitors.

All this was becoming known during an exciting period in molecular biology when the concept of "one gene-one polypeptide" had just become firmly established, and the question presenting itself was, how could such a complicated process with its numerous forward and backward components ever have evolved?

# **BACK TO LAMPREYS**

My first laboratory experiments on lamprey plasma were performed in early May, 1960. As it happened, simple re-calcification of the decalcified plasma resulted in very long clotting times, of the order of 30-40 minutes instead of the two or three minutes needed for human plasma to clot, suggesting a diminished if not absent intrinsic pathway. The obvious way to speed the system up was to add tissue extract to activate the extrinsic system. The commercial tissue factor ("thromboplastin") used in most clotting labs at the time was prepared from rabbit brains, and because it was already recognized that there is a "species specificity" associated with the reaction (Dorst & Mills, 1923; Mann & Hurn, 1952)), I wasn't awfully surprised when addition of the rabbit brain extract had no significant effect in speeding up lamprey clotting. It was obvious that I needed lamprey tissue extract. Lamprey brains are beebee-sized, however, and it was impractical to even think about using them as a source. Instead, I used a mortar and pestle to grind up a few grams of lamprey skin with some sand and water. I poured off the soluble fraction and mixed a small amount of it with the calcium to be added to the plasma. On my first try the clotting time dropped to 27 seconds, more than 50-fold faster than without the extract. I repeated the observation numerous times and ran all sorts of controls. As I write this I still have that laboratory notebook of 58 years ago beside me, and I can remember the pleasure of the moment.

The first impulse was to think that lampreys didn't have an intrinsic clotting system at all, but I realized that there had to be more to the story. Lampreys, like all infra-mammalian vertebrates, do not have platelets or the platelet precursor called the megakaryocyte. Instead they have a class of nucleated white blood cells called *thrombocytes*. The long clotting times may simply have been because the thrombocytes were removed when the blood was centrifuged to obtain the plasma. In the case of humans and other mammals, platelets are less dense than blood cells and do not sediment readily, usually remaining suspended in the plasma. Accordingly, in an effort to keep the lamprey thrombocytes from sedimenting with the denser red cells, I layered lamprey blood on to various concentrations of sucrose solutions and spun them gently. A concentration of sucrose was readily found with a density between that of lamprey red cells and white cells (which include thrombocytes), allowing the latter to be cleanly separated and easily removed (Doolittle & Surgenor, 1962). When an extract of those white cells was added during the re-calcification of lamprey plasma, the clotting times were almost faster than I could measure: of the order of 10 seconds, even better than skin extract on the basis of estimated protein content. Did this imply there was an intrinsic scheme after all? Or did the thrombocytes contain the equivalent of a tissue factor? The answer remains murky to this day.

Nonetheless, it was certain that jawless fish have clotting systems that are basically similar to those found in other vertebrates. The question remained, did they have all the many components that make up the human clotting apparatus? Certainly they had fibrinogen, because the clot had all the characteristics of fibrin. And they must have a calcium-dependent thrombin generating system because calcium removal completely blocked the system, and certainly they had a tissue factor and/or a thrombocyte component. How was I to find out about all the other factors?

Working backwards, I began by purifying the most abundant protein in the system, fibrinogen, and showing that it had the same physical and chemical properties as mammalian fibrinogen, including its sedimentation and diffusion constants. More important, mammalian thrombins clotted the purified lamprey fibrinogen and removed peptide material (fibrinopeptides) proteolytically, just as was known to occur in mammals (Doolittle, 1965).

The next step was to purify lamprey prothrombin, the second most abundant protein in the system. To that end, I treated lamprey plasma with barium sulfate, an insoluble substance known to adsorb mammalian prothrombins and, as we shall see, other vitamin-K dependent clotting factors. Anything that stuck could be eluted by simply changing the solvent conditions. When the eluted material from lamprey plasma was mixed with lamprey thrombocyte extract, to my delight, a powerful thrombin activity was rapidly generated.

# **SPECIES SPECIFICITY**

At this point I had at my disposal purified lamprey and human fibrinogens and very active lamprey and human thrombin preparations. Knowing that calcium was not required for the thrombin-catalyzed conversion to fibrin, I could simply prepare the two fibrinogens at the same concentrations and adjust thrombin dilutions to the point where the homo-specific clotting times were the same in both systems:

The reciprocal experiments with lamprey thrombin clotting human fibrinogen and human thrombin clotting lamprey fibrinogen gave the following clotting times:

Although the lack of exact reciprocity in clotting times was puzzling at first, the general phenomenon of species specificity, whereby thrombin from a given species clotted fibrinogen from the same species faster than it did fibrinogens from another species, was certainly clear.

In 1962, when revelations about mutations and amino acid replacement were on everyone's mind, the following explanation was offered as a model of how species specificity develops in general between any set of interacting proteins:

"Mutations can result in amino acid substitutions in either of the protein reactants which may be (a) helpful, (b) without effect, (c) slightly harmful, or (d) harmful. All of these judgments are made in terms of the rate of reaction between the two proteins. Substitutions of the last type would not persist, but the fact that slightly harmful point mutations must persist long enough for selection pressures to realize complementary (helpful) mutations in the other protein reactant is the crux of 'species specificity' based on a rate of reaction criteria. Category (b) embraces those mutations which result in amino acid changes which do not distort the steric or electronic conditions involved in the protein-protein interactions under study. Such changes result in what might be called a 'secondary species specificity,' one which might be detected physically or chemically but which does not influence the rate of physiological rate of reaction." (Doolittle et al.., 1962)

It was possible to describe this sequence of events pictorially with a model I called "make a hole and fill it." As shown in Figure 2, a mutation may occur that gave rise to a small "hole" on one side of the interface between the two interacting proteins, the loss of interaction energy being quite small. Subsequently, however, a compensatory mutation could occur that allowed the other protein to "fill the hole," restoring the full binding force. However, if one now tries to interact the two mutant forms (in the test tube), the effectiveness of the interaction will be greatly compromised by the clashing residues.

It was quite gratifying when a few years later population biologists brought forward the notion of "neutral evolution" on the one hand (Kimura, 1968), and the advantage and impact of "slightly deleterious" mutations, on the other (Ohta, 1973), in complete accord with the diagrammatic depiction of the kinds of mutational events that lead to "species specificity" (Figure 2).

Figure 2. Diagrammatic depiction of how "species specificity" arises for the interaction of a pair of proteins. Initially, the two proteins  $(A_0 \text{ and } B_0)$  share a fully complementary interface. Different mutations along divergent lineages lead to small losses in complementarity, often by replacement of an amino acid by one with a smaller side chain. Subsequent mutations in the gene for the other protein can fill the gap and restore the full interface. As a result of different patterns of mutation along different lineages, later versions of A and B lose their effectiveness of interaction. Note the lack of reciprocity in the simple example offered:  $A_2$  and  $B_1$  are badly compromised but  $A_1$  and  $B_2$  are less so (from Doolittle, 2013).

# **IDENTIFYING THE LESS ABUNDANT CLOTTING FACTORS**

The downside of "species specificity" was that it precluded the use of simple complementation assays with genetically defective human plasmas. For example, the clotting activity of blood from persons with hemophilia can be restored, not only by the addition of small amounts of normal human plasma but also some other mammalian plasmas, thereby showing that the non-human plasma contained the active factor. But the more distant the nonhuman relationship, the less effective was the correction, to the point where none would occur at all.

Accordingly, even though panels of defective human plasmas were becoming available for virtually all the known human clotting factors, assessing the occurrence of those same factors in a wide range of species by this approach wasn't at all feasible. It was also out of the question to think one could find mutant lampreys with bleeding diseases.

On the other hand, a few factors could be identified in lamprey plasma simply by what they did. As noted above, tissue factor in skin was relatively easy to demonstrate for the extrinsic system, and the presence of insoluble cross-linked fibrin under appropriate conditions indicated that the transglutaminase designated factor XIII was present in lamprey plasma. Beyond that, a simple thrombin generation test showed that an anti-thrombin was also present, although the relative activity was weaker than in the case of humans (Doolittle  $\&$ Surgenor, 1962). The fact that fibrinolysis occurred when clots were left to stand showed that

the precursor protein plasminogen was being converted to plasmin. But determining the presence or absence of the majority of the more than two dozen clotting factors of interest would have to be postponed for several decades.

During that long interval my lab continued to focus on lamprey fibrinogen, comparing it with those from other vertebrates. In this regard, the introduction of SDS gel electrophoresis (Shapiro et al., 1967) provided an elegantly simple method for determining the subunit structure of human and other mammalian fibrinogens, fibrin and cross-linked fibrin (McKee et al., 1970), and we followed the same course with lamprey fibrinogen (Doolittle  $\&$ Wooding, 1974). These studies led to some unexpected differences, including one of the subunits having a significantly larger size, for one, and the finding that the fibrinopeptide B was a glycopeptide, for another (Doolittle & Cottrell, 1974). On the whole, however, lamprey fibrinogen had the same unique structure found in other vertebrates, namely, a dimer of three disulfide-linked polypeptide chains that gave rise to an extended structure with terminal globular regions connected by three-stranded coiled coils to a central region.

By this time I had re-located to Southern California where I found lamprey collecting to be not nearly as rewarding as it had been in New England. Accordingly, I began making annual three-day expeditions back to my old collecting places, flying out to Boston on a Friday, renting a car and driving up to the University of New Hampshire (UNH) in Durham where I could stay at their pleasant New England Center, collect specimens on Saturday, use a centrifuge at their Biochemistry Department, freeze the plasma and ship it back to California, before returning on Sunday. By good fortune one of my former graduate students, Andy Laudano, joined the faculty at UNH and not only helped me collect the lampreys, but became so proficient at every stage that I no longer needed to go myself; Andy did it all.

There was a period after cDNA cloning became available when it was only necessary to ship frozen livers from which we could prepare mRNA. During the 1980's we managed the cDNA sequences of the three homologous chains of lamprey fibrinogen (Strong et al., 1985; Bohonus et al., 1986; Wang et al., 1989), as well as a number of other proteins. More than a decade later we were even able to determine the crystal structures of some important fibrinogen and fibrin fragments (Yang et al., 2002a, Yang et al., 2002b).

Although the similarities and differences found were interesting and informative, they didn't really shed much light on the original question: to wit, how did vertebrate blood clotting ever become so complicated? From the start, the most likely course of events depended on a series of gene duplications, similar to what had recently been shown for the  $\alpha$ and  $\beta$  chains of human hemoglobin (Ingram, 1961). When a full set of those serine proteases that are clotting factors in humans became available, it was possible to reconstruct the history of duplicative events by the construction of phylogenetic trees (Doolittle  $&$  Feng, 1987), but this approach on its own could not provide direct information on *when* the various gene duplications occurred.

# **DOMAIN SHUFFLING**

It became clear during the 1970's that a level of organization exists in proteins beyond the simple concept of primary-secondary-tertiary, sets of consecutive amino acid residues folding into discrete *domains* or folds. Domains are often eponymously named for the protein

in which they were first observed, such as "fibronectin type 1 domain" (Fn1, Fn2 or Fn3)), or "epidermal growth factor domain" (EGF), and so forth. Although some proteins are completely embodied in a single domain, many others are made up of combinations that reflect a heritage of having been shuffled about during evolution. Certainly that is a feature of many of the blood clotting proteins. In this regard, several of the clotting factors are made up of a serine protease domain with various other domains occurring at their amino-terminals, including, for example, EGF or kringle domains. In many cases, these domains serve as good signposts for identifying homologous factors.

Among them is an important domain responsible for the tight calcium-binding and nonbiological absorption on to substances like barium sulfate mentioned earlier. The sequence motif characterizing these domains involves a skein of uncommon  $\gamma$ -carboxyglutamic acid residues – often shortened to "GLA" – and the domains dubbed "GLA-domains." The biosynthesis of GLA residues is the result of post-translational modification promoted by vitamin K, and GLA-domain-containing proteins are often referred to as vitamin-K dependent. A phylogenetic tree of an assortment of clotting factor proteases with aminoterminal GLA-domains from a variety of species – including seven from lamprey – is depicted in Figure 3. It is reassuring that the assignments based on domain arrangement are completely borne out, even though only the serine protease sequence data were used to calculate the tree.

Figure 3. Phylogenetic tree (unrooted) of 18 vitamin K-dependent clotting factor sequences (serine protease domains only) from lamprey (*P. marinus* and/or *L. japonicum*), elephant shark (*Callorrhincus milii*) (only factor IX), pufferfish (*Takifugu rubripes*) and human. The seven lamprey entries include three factors VII, two factors X and one each for thrombin and protein C (from Doolittle, 2015).

Another important domain in some non-protease clotting proteins is the ferroxidase domain, a founding version of which occurs in an intestinal transport protein called hephaestin, as well as a copper-transporting protein found in vertebrate blood plasma called ceruloplasmin (Vulpe et al., 1999). In mammals and other later diverging vertebrates these domains also occur in factors V and VIII. Invariably these domains occur in sets of three, the structures of which form tripods. Hephaestin is readily distinguished from the others because it has a membrane-spanning segment at its carboxy-terminal, whereas factors V and VIII both have a pair of discoidin domains at their carboxy-terminals. Ceruloplasmin has no other domain at its carboxy-terminus and circulates freely in the blood plasma. Also, in factors V and VIII the second and third ferroxidase domains are separated by non-descript segments that are removed by thrombin during an activation process that allows the third leg of the tripod to fall into place.

Ferroxidase domains, like GLA domains, are in keeping with the bulk of the protein remaining on a membrane localized at the site of injury. Similarly, tissue factor, the activation of which ignites the clotting process, is made up of a pair of fibronectin type-3 domains (Fn3) and a membrane-spanning domain. Just as is the case for the serine protease factors, a phylogenetic tree based only on the ferroxidase domain sequences is in perfect accord with the assignment of hephaestins, ceruloplasmins and clotting factors V and VIII (Figure 4).

Figure 4. Unrooted phylogenetic tree of 13 ferroxidase family proteins (coagulation factors V and VIII, hephaestins and ceruloplasmins) from human (5 entries), lamprey (4 entries), pufferfish (3 entries), and zebrafish (1 entry). Each entry depicts three consecutive ferroxidase domains. (from Doolittle, 2015).

#### **BIOINFORMATICS**

As the decades slipped by, the number of fully characterized clotting factors in lamprey slowly grew (Kimura et al., 2009; Ragg et al., 2009), but not to the extent observed in other vertebrates. They *appeared* to have a simpler clotting system (Doolittle et al., 2008), but how could it be proven beyond a doubt? It is much more difficult to prove the absence of a gene than to document its presence. It was the era of complete genome sequencing ushered in at the millennium that provided the means to that end.

Or did it? Whereas complete genome sequences for a variety of vertebrates were soon available, lamprey and hagfish seemed lost in a backwater. Part of the reason was that much of their genomes are highly repetitive, greatly impeding efforts directed at full genome assembly (Smith et al., 2013). There was an alternative strategy, however; one could use complementary data from partially assembled genomes in combination with the all-inclusive trace sequence archive maintained by the National Center for Biotechnology Information (NCBI), and indeed this approach allowed a complete inventory of the lamprey clotting factors that at the very least confirmed the absence of genes for factors VIII and IX (Doolittle, 2015).

# **LAMPREY CLOTTING AND THE 2R HYPOTHESIS**

The fact that vertebrate genomes were typically much larger than the genomes of protochordates from which they had descended led Susumo Ohno to propose that the enlargement was the result of at least two rounds of whole genome duplication (Ohno, 1970). He based this idea on the fact that polyploidy is common not only in plants but also occurs frequently in fish. This bold proposal became known as the 2R hypothesis. The lamprey data bear on the matter because it was thought likely that one of these duplications occurred before the divergence of cyclostomes and the other after. In passing, it can be noted that it has been suggested – without any consideration of lampreys – that the duplications responsible for clotting factor genes may have been linked to 2R whole genome duplication events (Davidson et al., 2003).

Figure 5. Scheme showing how a putative single block duplication event after the divergence of lampreys from other vertebrates gave rise to a more complex clotting scheme. Colors emphasize sets arising through concerted gene duplication. Note that thrombin (T) interacts with other proteins besides fibrinogen. TF = tissue factor. (adapted from Doolittle et al., 2008).

The 2R hypothesis has been much debated over the years, and two recent lamprey genome assemblies seem to have yielded two different interpretations (Mehta et al., 2013; Smith and Keinath, 2015); the most recent comments on the subject seem to favor replacing the second "R" with several large-scale duplications (Smith et al., 2018).

Even so, the blood clotting data remain in full accord with a second round of whole genome duplication occurring after the divergence of cyclostomes from the main line of vertebrates (Figure 5). The distinction between a full genome duplication and a number of partial duplications is difficult to make, however (Escriva et al., 2002), and the matter is hardly settled. In the wake of that divergence the lineage leading to jawed vertebrates must have experienced a large scale block duplication – even if less than genome wide – that simultaneously gave rise to genes that were destined to encode factors VIII and IX, quite apart from several independent duplications that would give rise to additional genes for factors VII and X on the lineage leading to lampreys.

# **FIBRIN CLOTS PRE-DATE LAMPREYS**

Up to this point I have tried to emphasize the prominent role played by lampreys in our understanding of how vertebrate blood clotting evolved. Its importance stems from its having diverged from the main line leading to other vertebrate groups at an early stage when the blood clotting scheme was simpler. Lampreys lack genes for coagulation factors VIII and IX, both of which are critical for the "intrinsic" clotting system and defects in which are responsible for hemophilia in humans. On the other hand, lampreys have three each of the genes for factors VII and X, participants in the "extrinsic" clotting system.

Even though the clotting system leading to fibrin clots in lampreys--and likely hagfish (Banfield & MacGillvray, 1992)-- is less complex than what exists in other vertebrates, it is hardly simple (Figure 5). It is important to note, also, that fibrin clots have never been observed in any protochordate, although in ascidians circulating white cells are known to clump in response to injury. It is notable that these same creatures have a protein that is remarkably similar to vertebrate fibrinogen but which lacks a thrombin-vulnerable site of the sort that leads to fibrin formation, i.e., the elongated molecules have holes, but there are no knobs to fit in them that would allow polymerization (Doolittle, 2012).

These same protochordates have other proteins that have similar domain arrangements as some key vertebrate clotting factors, including proteases with amino-terminal kringle domains, but none of them has a GLA domain or any arrangement similar to that of prothrombin. Intriguingly, there is also a hephaestin-like protein with a set of three consecutive ferroxidase domains and a pair of discoidin domains at the carboxy-terminus, just like the activated configuration found in vertebrate factors V and VIII (Doolittle, 2015). In any case, it wouldn't have taken much in the way of domain shuffling during the interval between the divergence of protochordates and cyclostomes to give rise to the first thrombincatalyzed fibrin clots.

#### **AFTERTHOUGHTS**

Interest in lamprey blood clotting remains high even today as evidenced by a recent article on how the allosteric activation of factor VII by tissue factor is the same in lampreys as in all other vertebrates (Biller et al., 2018). Doubtless, future studies will explore the detailed mechanism of other parts of the clotting scheme as well.

For my own part, there are a number of experiments I would like to have done myself if time and resources had allowed. For example, I have wondered if the three different factors VII that occur in lampreys interact preferentially with one or the other of the two factors X, as might be expected if the same kinds of change occur that lead to the "species specificity" shown in Figure 2? And, if so, how much "cross-talk" exists among them? It would also be of interest to know whether the different versions of those factors are differentially expressed at different stages of lamprey development; does the larval stage express these factors differently from the mature adults?

There is also the matter of the powerful clotting activity associated with lamprey white blood cells (thrombocytes). Is it only because these cells are rich in tissue factor? Or, is it because factor V is bound to these cells and accelerates the process more than occurs in free solution? There are simple experiments I could have done to find this out, but now that it is too late for me, I'm hoping other clotting enthusiasts will take up the challenge and find themselves some lampreys.

# **ABSTRACT**

The occurrence of lampreys of the genus *Lethenteron* (Cephalaspidomorphi, Petromyzontida, Petromyzontiformes, Petromyzontidae) in nineteen rivers and one lake in Sakhalin Island is documented in the chapter. Morphometric parameters in larvae and adult specimens from the selected areas are compared using statistically significant differences. Sex differences in adults in respect to morphometric parameters are also presented.

#### **ABBREVIATIONS**

# **1. MATERIAL AND METHODS**

Archive specimens of caught lampreys and our unpublished data, as well as data from the Sakhalin State University and Sakhalin Research Institute of Fisheries and Oceanography (Sakhalin, Russia) covering the period of 1998-2005 were used for the study. Material caught by electrofishing was preserved in 70% alcohol and later in 2-3% formalin solution. Methods published by Pravdin (1966), Holčík (1986) and Renaud (2011), were used for morphometrical studies. For the morphometrical analysis common statistical evaluation was used (mean, standard error of the mean /S.E.M./, Student's test, level of significance  $P \ge 0.95$ , see Matsueva, 2003).

In total 1228 individulas of lampreys of the genus *Lethenteron* from Sakhalin waters (adults: Nitui River – 245 individuals, Kopilka River – 31, Novikovka River– 33, Pugachovka River – 24, Bol'shoi Garomai River - 153; larvae: Nabil' River - 6 specimens, Yasinge River - 28, Bol'shaya Aleksandrovka River - 25, Bol'shoi Matchi River - 13, Moguchi River - 85, Malyi Garomai River - 74, Kura River - 49, Ol´chovka River - 10, Taranai River - 113, Krasnodonka River - 16, Fevralevka River - 29, Bol´shaya River - 23, Bol'shoy Chibisan Lake - 54, Pugachovka River - 29, Nitui River - 89, Ostrovka River - 48, Novikovka River – 51) were studied , see Figure 1.

Figure 1. Studied rivers of Sakhalin Island where occurrence of larvae and adult lampreys of the genus *Lethenteron* were confirmed.

# **2. TAXONOMIC NOTES**

As of now the taxonomic list includes seven species in the genus *Lethenteron* (Renaud 2011), but the relationships among them has been controversial. Renaud (2011) recognized one parasitic species, *Lethenteron camtschaticum* (Tilesius, 1811) (i.e., the stem species) and six nonparasitic species, *Lethenteron alaskense* Vladykov & Kott,1978, *L. appendix* (DeKay,1842), *L. kessleri* (Anikin, 1905), *L. ninae* Naseka, Tuniyev & Renaud, 2009, *L. reissneri* (Dybowski, 1869), and *L. zanandreai* (Vladykov, 1955) (i.e., the satellite species) in the genus, along with two additional undescribed nonparasitic species from Japan, and noted that the taxonomic limits of the nonparasitic *Lethenteron reissneri* were unclear. Authors have either treated these satellites of *Lethenteron camtschaticum* as distinct species (e.g., Potter et al. 2015) or as synonyms of the species. For example, Artamonova et al. (2011) and Makhrov et al. (2013) have suggested that *Lethenteron ninae, L. reissneri*, and *L. kessleri* are synonyms for *Lethenteron camtschaticum* and that life strategy (i.e., parasitism versus nonparasitism) is not a valid criterion for specific distinctiveness. Li (2014) summarized data on taxonomy of *Lethenteron camtschaticum.*

The original description of the Far Eastern brook lamprey *Petromyzon reissneri* Dybowski,1869 was very short, incomplete and based on material from the upper Amur River basin, Russia (type locality: Onon and Ingoda rivers). In the following years a number of authors conducted morphological studies on what they referred to as the species *Lampetra reissneri* and anadromous *Lethenteron japonica* (= *Lethenteron camtschaticum*) from the lower Amur River basin (Berg 1931, 1948; Abakumov 1960, Hensel 1963). Mina et al. (2006) mentioned that the *Lethenteron japonicum* and *L. camtchaticum* being synonyms is in accordance with the International Code of Zoological Nomenclature (ICZN).

The Siberian brook lamprey *Lethentheron kessleri* was described by Anikin (1905) based on 16 specimens (160-210 mm TL) collected in the vicinity of Tomsk, mostly in the Tom River, including its basin in the Kirgizka River of Western Siberia. According to Holčík (1986) the external morphology, including the dentition of the oral disc, is the same as that of *L. japonicum*. According to the original description of Anikin (1905) the tip of the caudal fin is darkly pigmented, and the top of the second dorsal fin bears a typical dark blotch, a "fine ashy-grey color." The area of distribution according to Reshetnikov et al. (1997) stretches throughout Siberia to the Anadyr and Sakhalin. The species was reassigned to the subspecies category (Berg 1948). Poltorykhina (1979) suggested that the taxon must be classified within the species category (see also Chereschnev 1996; Safronov and Nikiforov 2003). According Yamazaki and Goto (2016) *L. reissneri* and *L. kessleri* were recognized as being conspecific, the name *L. reissneri* taking priority of the ICZN.

The Arctic lamprey *Lethenteron camtschaticum* (Tilesius, 1811) is an anadromous parasitic lamprey species, widely distributed in the Arctic and the North Pacific. Now, its distribution range covers waters of the seas of the Arctic Ocean*.* In the North Pacific, it includes areas from the Bering Strait to the eastern part of the southern Korean Peninsula (the Sea of Japan), as well as those from the central part of Honshu Island (Japan) in the Pacific waters along the Asian coastline to the Kenai Peninsula in the Gulf of Alaska along the United States coastline (Orlov et al. 2014). Several studies focused on the genetic population structure in *L. camtschaticum.* Yamazaki et al. (2011) described establishing a fluvial nonparasitic population of *Lethenteron camtschaticum* as the first step in petromyzontid speciation. Landlocked fluvial non-parasitic populations in the upper region of water reservoirs dams were genetically divergent from anadromous parasitic ones. Yamazaki and Nagai (2013) found discrepancies in allelic frequencies of Lspn013 as being remarkable between anadromous and landlocked-fluvial populations of *L. camtschaticum*, leading to high population genetic divergence between them. Based on a homology search, Lspn013 was estimated to be located near the vasotocin precursor gene, which plays an important role in osmoregulation. Life history differences in lampreys have resulted from habitat difference in the adult phase, which have probably led to recent natural selection on the gene responsible for osmoregulatory functions. Yamazaki et al. (2014) studied migration ecology, genetic population structure and gene flow pattern in anadromous Arctic lamprey (*L. camtschaticum*) by analyzing polymorphic microsatellite loci. Their results suggest that *L. camtschaticum* has considerable ability to migrate long distances in the sea and has lower homing abilities. For resource management of *L. camtschaticum*, unconstrained gene flow across all populations should be maintained.

Currently, there have been conflicting opinions on the validity of the so-called "landlocked" lamprey forms of lampreys. This, according to the opinion of some authors (Bugaev 2007; etc.), is based on their joint spawning in the rivers of Kamchatka. *L. reissneri*  is only a freshwater (landlocked) form of the anadromous species *L. camtschaticum*. At the same time, Gritsenko (1990, 2002) pointed out that the joint spawning of *L. camtschaticum*  and *L. reissneri* within the same spawning area does not violate the reproductive isolation of these forms. Other authors, on the basis of genetic similarity of *L. kessleri* and *L. reissneri*  according to the Principle of Priority of ICZN, consider it possible to regard *L. kessleri* as a junior synonym of *L. reissneri* (Shed'ko 2001, 2002; Yamazaki et al. 2006; Gritsenko 2002). There are also other points of view. Thus, recent results of genetic studies have shown that freshwater forms of *L. reissneri* from the waters of Kamchatka are identical to *L. camtschaticum* (Artamonova et al. 2011; Nazarov et al. 2011) or that *L. reissneri* is synonymous with *L. camtschaticum* (Artamonova et al. 2015). However, these conclusions have not been accepted by a number of other researchers (Renaud 2011; Gritsenko 2012; Renaud and Naseka 2015). Molecular genetics methods have shown a great similarity between the Far Eastern brook (*Lethenteron reissneri*) and the Siberian lamprey (*L. kessleri*), see Yamazaki et al. (2006), Yamazaki and Goto (2016), but Romanov et al. (2017) accepted *L. camtschaticum* and *L. kessleri* as valid species. Acording to Freyhof and Kottelat (2008), lampreys identified as *L. kessleri* from the Arctic basin are *L. reissneri* and a part of those from Sakhalin, Japan and rivers of the Sea of Japan belong to *L. reissneri* and two unnamed species. Two species (*L. camtschaticum, L. reissneri*) are classified under "Least concern" in the IUCN Red List (Freyhof and Kottelat 2008; NatureServe 2013).

This chapter deals with lampreys of the genus *Lethenteron* inhabiting rivers on the island of Sakhalin. Berg (1948) recognized in Sakhalin three lamprey taxa: *Lethenteron* (*Lampetra*) *japonicum* (Martens, 1868), *Lethenteron* (*Lampetra*) *reissneri* (Dybowski, 1869) and *Lethenteron* (*Lampetra*) *kessleri* (Anikin, 1905). Abakumov (1960) and Poltorykhina (1971, 1974) also recognized here three species, but Voronov (1982) only two species: *Lethenteron japonicum* and *Lethenteron reissneri*. Safronov and Nikiforov (2003), Bogutskaya and Naseka (2004) and authors of the Atlas of Freshwater Fishes of Russia (2003) distinguish three species there, namely *Lethenteron japonicum*, *L. reissneri* and *L. kessleri*. Efremova (2006) distinguished three lampreys species (*L. camtschaticum, L. kessleri, L. reissneri*) in Sakhalin rivers. According to Dyldin and Orlov (2016) the Arctic lamprey (*L. camtschaticum*) can be found along the whole coast of Sakhalin in marine waters (in almost all bays), where it swims in many rivers for spawning, including the largest of them, such as Tym', Poronai, and Lyutoga (see also Berg 1948; Taranetz 1937). The occurrence of the species in Sakhalin was reported by Gritsenko (1990, 2002), Nikiforov (2001); Safronov and Nikiforov (2003), Safronov et al. (2008), Pietsch et al. (2012).

The Far Eastern brook lamprey (*L. reissneri*) can be found mainly in southern and central parts of Sakhalin Island, including the Tym' River basins, the Pil'tun Bay, and the Nevskoe and Tunaicha lakes (Berg 1948; Lindberg and Legeza 1959; Gritsenko 1990, 2002). Some authors report its occurrence, as *Lethenteron kessleri,* e.g., Pietsch et al. (2001), Nikiforov (2001), Safronov and Nikiforov (2003) Safronov et al. 2008). Gritsenko (1990, 2002) suggests that there are three lamprey forms on Sakhalin Island: *Lethenteron camtschaticum*, *L. reissneri*, and, possibly, a landlocked form of *L. camtschaticum*. Furthermore, it should be noted that, instead of *L. camtschaticum* and *L. reissneri*, he specified *L. japonicum* and *L. kessleri*, which is due to the views of lamprey taxonomy of the time (see, Gritsenko, 2012). Zhivoglyadov (2014) mentioned from Sakhalin only the genus *Lethenteron* without specific determination. Dyldin and Orlov (2016) distinguished two species in the genus *Lethenteron* (*L. camtschaticum* and *L. reissneri*) in Sakhalin rivers. The occurrence of *L. reissneri* is

supposed in Sakhalin rivers of Novikovka, Yasynge, Krasnaya, Pugachovka, Mereya, Taranai, Ostrovka and B. Chibisan Lake, and *L. kessleri* in the Melkaya and Bol'shoi Garomai rivers and *L. camtschaticum* in the Nitui River (Efremova, 2006).

# **3. RESULTS AND DISCUSSION**

From the above mentioned data it is unclear whether the species position within the genus *Lethenteron* in Sakhalin waters is evident. Therefore we present our results based on the samples studied without specific species determination (as *Lethentheron* sp.). In the next text morphometric and meristic parameters in the lamprey samples examined from various areas are analysed. Berg (1948) found in *L. camtschaticum* the following dentition: supraoral lamina – 2 teeth, infraoral lamina - usually 6, sometimes 7, bicuspid lateral teeth, single row of posterial teeth. Safronov (2000) analyzed dentition in 25 individuals (as *L. camtschaticum*) from the Lazovaya River in Sakhalin: supraoral lamina  $-2$  teeth, infraoral lamina  $-6-7$ , rarely 5 teeth, endoratelal formula – 2-2-2, total number of anterials, 18-22, total number of posterials, 19-23, number of trunk myomeres 70-76. Matsueva (2003) analyzed dentition in 30 specimens (as *L. camtschaticum*, total length 154-183 mm) from the Sakhalin river of Nitui: supraoral lamina – 2 teeth, infraoral lamina – 6, rarely 7 teeth, endolateral formula - 2-2-2, number of trunk myomeres - 68-75. The occurrence of the species was supposed in the Nitui River (see Efremova 2006). Meristic data in lampreys (as the Siberian brook lamprey, *L. kessleri*) based on 140 adults taken mainly from the Ob' River and its tributary, the Irtysh (Anikin 1905, Ioganzen 1935, Poltorykhina (1966, 1971, 1974) are as follows: the supraoral lamina bears two teeth on its edges, the infraoral lamina usually has 6 to 8 teeth, of which the marginals are bicuspid, endolaterals bicuspid, three on each side of the disc, anterial range from 17 to 27, their size decreases towards the disc margin, one row of unicuspid posterials contains 16 to 25 teeth. The dentition of the tongue is known from the original description by Anikin (1905): transerse lingual lamina has one large, sharp tooth flanked by 8 to 9 small cusps, the size of which decreases towards the lamina margin. Longitudinal lingual laminae have minute cusps. The number of trunk myomeres counted by Poltorykhina (1966, 1971, 1974) ranges from 67 to 72. Altogether 121 adults were examined in respect to morphometrical characteristics (Ioganzen 1935, Poltorykhina 1966, 1974). The following are expressed as % of TL: prebranchial length 8.6-14.6, branchial length 8.3-11.1, trunk length 47.4-47.7, tail length 25.5-33.3, disc length 4.4-6.8, diameter of eye 1.5-3.0 (see also Holčík 1986). According to Renaud (2011) ranges of trunk myomeres in the species was 65-73, for resident *L. camtschaticum* form *sensu* Kucheryavyi et al. (2007) as 57-78. Berg (1931, 1948) stated that the key character to distinguish *L. reissneri* and *L. kessleri* is the lack of posterials or their weak development in the former and their presence in the latter. Posterial teeth were not mentioned in the original description, but Berg (1931) reported that they were sometimes absent, which he later (Berg 1948) changed to usually absent, based on material (some of which were re-identified as parasitic *Lethenteron camtschaticum*) from far outside of the type locality. The latter view has been widely accepted by subsequent authors. Unfortunately, the poor condition of the two adult syntypes did not permit verification of the character. However, a row of posterials was clearly visible in six of the seven topotypic metamorphosing ammocoetes and indicates their usual presence in the species (Renaud and Naseka 2015). In view of the fact that they are not unabiguous morphometric and metric differences among the supposed lamprey species (see Tables) all samples of larvae and adults examined are in this chapter designated as *Lethenteron* sp. The occurrence of the Siberian lamprey is supposed in Sakhalin River Melkaya (Efremova 2006). Dentition and morphometric characters according to A. Safronov were as folllows (9 individuals, 158-220 mm) from the Melkaya River: supraoral lamina – 2 teeth, infraoral lamina – 5-7 teeth, endoratelal formula – 2-2-2, total number of anterials, 14-21, total number of posterials, 15- 24, number of trunk myomeres 68-72. Matsueva (2003) studied dentition in 49 individuals from the Bol'shoy Garomai River (120-148 mm): supraoral lamina – 2, infraoral lamina – 6- 7, endoratelal formula – 2-2-2, total number of anterials, 12-20, total number of posterials, 10-16. A number of trunk myomeres in adult lampreys from the above river Bol´shoy Garomay was determined as 67-74 (mean 70.6), see Table 1. Morphometric characters in lampreys from the Bol'shoy Garomai River are presented in the Table 2. The occurrence of the Far Eastern brook lamprey, *Lethenteron reissneri,* is supposed in the following Sakhalin Rivers: Bol'shoi Garomai, Yasinge, Krasnaya, Fevralevka, Pugachovka, Taranai, Mereya, Ostrovka, Novikovka and Bol'shoi Chibisan Lake. Safronov (see Matsueva 2003) studied 9 specimens from the Tym' River with the following results: supraoral lamina – 2 teeth, infraoral lamina – 5-7 teeth, endoratelal formula – 2-2-2, total number of anterials 17-20, total number of posterials 19-21, number of trunk myomeres 57-67. Ioganzen (1935) also mentioned occurrence of the species in Sakhalin Island. The lowest average number of myomeres in ammocoetes within the genus *Lethenteron* was counted in the Ol´chovka as 66.5, the highest in Moguchi (as 69.1), Pugachovka (as 69.9) and Novikovka (as 69.4) rivers.

River/Lake	Larvae			Adults		
	$\mathbf n$	ranges	$M \pm S.E.M.$	$\mathbf n$	ranges	$M \pm S.E.M.$
Pugachovka R.	29	68-72	$69.9 \pm 0.15$	24	68-73	$70.7 \pm 0.23$

**Table 1. Number of myomeres in larvae and adult lampreys of the genus Lethenteron from Sakhalin waters by Matsueva (2003)**

# **Table 2. Morphometric parameters found in larvae of the genus Lethenteron from four Sakhalin rivers (Taranai, n = 30, 130-165 mm TL; Fevralevka, n = 25, 133-187 mm TL; Nitui, n = 30, 132-197 mm TL; Pugachovka, n = 29, 96-162 mm TL; Novikovka n = 20, 76-162 mm TL (Efremova, 2006)**

# **3.1. Larvae**

Differences in morphometric parameters among larvae samples of the *Lethenteron* lampreys in five Sakhalin rivers are presented in Table 3. The smallest frequency differences among samples (statistically significant difference /SSD/ in ten morphometric parameters) was found between the Taranai and Fevralevka rivers, as well as between the Taranai and Nitui rivers. On the contrary, the biggest frequency difference (SSD in 22 morphometric parameters) was confirmed between the Taranai and Novikovka rivers).

# **Table 3. Differences in morphometric parameters among larvae samples of the Lethenteron lampreys in Sakhalin waters. Abbreviations: 1 - Taranai, 2 - Fevralevka, 3 - Nitui, 4 - Pugachovka, 5 - Novikovka), + statistically significant difference (Efremova, 2006)**

Matsueva (2003) studied total length/body weight (W) relationship in the sample of lampreys caught in the Nitui River during 1999-2002 (larvae: total length 14-21.5 cm, ave.  $17.9 \pm 0.15$ , n = 161; adults: total length 12.5-20 cm, ave.  $17.1 \pm 0.12$ , n = 245). Formulated equations have the following form:

 $W = 0.0031 T L^{2.725}$  (larvae)  $W = 0.0026TL^{2.794}$  (adults)

### **3.2. Adults**

Sex differences in adult lampreys from the Bol'shoi Garomai river are presented in Table 4. From the 26 morphometric parameters studied, 18 had statistically significant differences. Females had (in % of the total length) longer maximum body depth, body width, internasal distance, maximum body perimeter, head depth, prebranchial length, snout length, longitudinal diameter of closed mouth slit, prebranchial  $+$  branchial length, first dorsal fin length, first dorsal fin height, second dorsal fin height, caudal fin length and total length. At the same time, males had (in  $%$  of the total length) longer branchial + postbranchial length, postbranchial length, distance between eye and first gill opening.

## **Table 4. Sex differences in adult lampreys of the genus Lethenteron from the river Bol'shoi Garomai (females, n = 25, 123-140 mm TL; males, n = 24, 120-148 mm TL), + statistically significant difference (Efremova, 2006)**

Tables 5 and 6 present the differences between morphometrical parameters in adults from four Sakhalin rivers. There were 25 morphometric parameters (in % of total length) examined in total. When samples were mutually compared, the smallest frequency of differences among the samples (statistically significant difference /SSD/ in 16 morphometric parmeters) was found between the samples from the Pugachovka and Bol'shoi Garomai rivers. On the contrary, the biggest frequency difference (SSD in 24 morphometric parameters) was confirmed between the Novikovka and Bol'shoi Garomai rivers.

#### **Table 5. Morphometric characters in adult lampreys (Lethenteron sp.) from four Sakhalin rivers (Nitui, n = 30, 156-220 mm TL; Pugachovka n = 24, 116-150 mm TL; Novikovka n = 20, 133-179 mm TL; Bol'shoy Garomai n = 49, 120-148 mm TL), Efremova (2006)**

# **Table 6. Differences in morphometric parameters among adult lamprey (Lethentheron sp.) samples in Sakhalin waters. Abbreviations: 1 – Nitui River, n = 30; 2 - Pugachovka River, = 24; 3 – Novikovka River, n = 20; 4 – Bol'shoi Garomai River, n = 49; + statistically significant difference (after Efremova, 2006)**

Sex differences in adults from the Novikovka and Pugachovka rivers are presented in the Table 7. From the 26 studied morphometric parameters, 9 had statistically significant differences. Females had (in % of the total length) longer maximum body depth, internasal distance, maximum body perimeter, head depth, prebranchial length, prebranchial + branchial length, second dorsal fin height, total length. On the other hand, males had (in % of the total length) longer predorsal length.

### **Table 7. Differences in morphometric parameters between sex in the lamprey (Lethenteron sp.) samples originating from the Novikovka and Pugachovka rivers (females, n = 19, 123-179 mm TL; males n = 27, 116-162 mm TL). Abbreviation: M – mean, S.E.M – standard error of the mean, + statistically significant difference, Efremova (2006)**

Comparison of the anadromous and resident lampreys (*L. camtschaticum*) shows that there are no morphologic differences between these forms (Makhrov et al. 2013). *L. kessleri*  is distinguished from *L. reissneri* by the presence of distinct posterial teeth, by the pointed supraoral lamina, by the larger eye diameter, and by the larger number of trunk myomeres (Iwata et al. 1985). *Lethenteron reissneri* differs from *L. kessleri* by reaching a number of 57- 65 (ave. 60.4) myomeres versus 65-73 (ave. 69.0), *L. reissneri* and *L. kessleri* showed an overlap in all body measurements. The number of myomeres in *L. camtschaticum* (as *L. japonicum*) ranges from 68-77 (ave.72.1), see Iwata et al. (1985).

Renaud (2011) elaborated on the determination key for all lamprey species, including the genus *Lethenteron*. Gular region unpigmented (this characteristic requires verification in *Lethenteron kessleri* but the region is definitely unpigmented in the other species referred to below as *L. camtschaticum*, and *L. reissneri*). The second dorsal fin unpigmented; trunk myomeres, 57–65; 38–44 anterials in *Lethenteron reissneri*. The second dorsal fin usually with a dark blotch; trunk myomeres, 65–77; 15–38 anterials are in *L. camtschaticum* (total length, 110–625 mm; parasitic) and *L. kessleri* (total length 112–230 mm; nonparasitic, 15–28 anterials). The key is not suitable to identify the lamprey samples from Sakhalin Island studied in the chapter because of overlapping ranges in the metric parameters.

In the supraoral lamina adults were always found with 2 teeth (the Lazovaya River, 25 species, Safronov 2000; the Nitui River, 30, Matsueva 2003; the Melkaya River, 9, Safronov 2000; the Bol'shoi Garomai River, 49, the Tym´ River, 9, Safronov 2000). Infraoral lamina bears mostly 5-7 teeth (the Lazovaya, Melkaya, Tym´ rivers), and in the Nitui and Bol'shoi Garomai rivers 6-7 teeth. The endorateral row formulae is identical (2-2-2) in the Lazovaya, Nitui, Bol'shoi Garomai and Tym´ rivers. Ranges in the number of anterior teeth (anterials) is overlapping in the Lazovaya (18-22), Melkaya (14-21), Bol'shoi Garomay (12-20) and Tym´ (17-20) rivers. Posterior disc teeth (posterials) range from 19-23 (the Lazovaya River), 15-24 (the Melkaya River), 10-16 (the Bol'shoi Garomai River), 19-21 (the Tym´ River). The number of myomeres varies between 70-76 (the Lazovaya River), 68-75 (the Nitui River), 68- 72 (the Melkaya River), 67-72 (the Bol'shoi Garomai River), 55-67 (the Tym´ River).

The dentition in lampreys from the above mentioned Sakhalin rivers is analogous to the data on *L. camtschaticum* (the Eurasian Arctic) published by Makhrov et al. (2013) exept for the Bol'shoi Garomay river, where the posterial number range is evidently lower (10-16/the Bol'shoi Garomai river/compared to 15-24/data by Makhrov et al. 2013/).

#### **CONCLUSION**

Samples of larvae and adult lampreys of the genus *Lethenteron* from 19 Sakhalin rivers and one lake were studied in respect to meristic and morhometric parameters and evaluated by the standard statistical methods. We confirm statistically significant differences in many morphometric parameters among the samples studied and between sexes, the ranges of trunk myomeres in all samples varied between 63-75. Based on our own results, it is not possible at present to classify the studied samples to definite species within the genus *Lethenteron*  without doubts (see also Khusainova and Karpenko 2017)*.* This question requires further research based on numerous materials from various areas focused on examining clinal variability in meristic and morphometric parameters, ecology and completion of genetic characteristics. Genetic studies are needed to better define the differences among populations inhabiting Sakhalin rivers. Results could also be applied in protecting, conserving and managing the particular species or populations with individual genetic differences originating from various catchment areas in Sakhalin Island (see also Futuyma and Kirkpatrick 2017).

#### **ACKNOWLEDGMENTS**

The authors would like to thank Jessica and Michal Kocum for English language revision.

## **ABSTRACT**

Common carp (*Cyprinus carpio* L.) is an important food fish in many Asian and European countries, where it is considered as an important aquaculture species. Common carp account for approximately 4.1% of the total global aquaculture production and 9% of the global freshwater aquaculture production. The bulk of world's common carp production (97%) comes from aquaculture. It is the most cultured fish species in Central and Eastern Europe, with production levels reaching more than 80% of total fish production in some countries. Aquaculture of this species is not observed in North America, New Zealand and Australia, where it is considered as a potential invasive and noxious aquatic species. Common carp belongs to the largest family (Cyprinidae) of freshwater fishes in the world. Their high adaptive capacity in a wide range of conditions and habitats accounts for their widespread distribution in most countries of the world. Presently, two subspecies exist in the world: the Asian (*C. carpio haematopterus*) and the European subspecies (*C. carpio carpio*). Common carp live in lakes, ponds, reservoirs, natural depressions and rivers. They are bottom dwellers, generally preferring to live near the soft vegetated sediments. They prefer benthic organisms particularly chironomids, oligochaetes, gastropods and other larval insects available in and on the sediment of natural habitats. When preferred foods become depleted, they shift their food habits, feeding niche and behavior. The behavior of common carp is consistent with classical optimal foraging theory. They readily adapt when inter- and intra-specific competition are pronounced. Common carp significantly influence the behavior of other species (e.g., *Labeo rorita*) without showing any aggressive interactions. This article reviews the

origin, habitats, distribution, growth, production, food habit, spawning, maturation, fecundity and behaviour of common carp focusing through a global lens.

**Keywords**: common carp, origin, distribution, habitat, growth, production, food habit, reproduction, fecundity, behavior, b–value, sexual maturity

## **INTRODUCTION**

Common carp can dominate in any freshwater body due to their fast growth, early maturity, high fecundity and high adaptive capacity. These characteristics have enabled them to persist and proliferate in a wide array of environments, making them one of the major exotic species to have spread throughout the world. In some countries, particularly North America, New Zealand and Australia, common carp is considered as an invasive and destructive aquatic pest due to a combination of their potential to be invasive and their ecological impacts on ecosystems (Koehn 2004; Oyugi et al. 2011). In natural habitats, carp is considered a pest fish because of its tendency to destroy aquatic macrophytes (through uprooting of aquatic macrophytes, direct consumption of tubers and young shoots), increase water turbidity and alter ecosystem function for local species. It is one of eight fish on the IUCN list of the World's worst 100 invaders (Lowe et al. 2000).

Many countries consider the management of common carp as a key target for mitigating detrimental impacts on freshwater ecosystems (Britton et al. 2011a). In natural habitats, particularly in lakes, river and reservoirs in Asia, the population of this species is decreasing rapidly due to overexploitation of water resources, climate change and various anthropogenic activities. In Asia and Europe, common carp is an important food fish and is accepted as a naturalized species that poses little or no threat to the environment (Britton et al. 2011b). Due to the high importance of common carp as food fish, aquaculture of this species is a common practice in many Asian and European countries, where it is an important candidate for continued research.

Considering its local importance, most of the research conducted in Europe and Asia has focused on the development of common carp aquaculture, while most of the research in North America, New Zealand and Australia has focused on management of common carp in natural habitats particularly how to mitigate various detrimental impacts of common carp on local fish species (Koehn 2004). However, there has been a limited focus on the global aspects of common carp literature. Consequently, this chapter reviews the origin, habitats, distribution, growth, production, food habit, spawning, maturation, fecundity and behaviour of common carp with a global focus.

# **ORIGIN, HABITATS AND DISTRIBUTION**

Common carp has a high DNA content and about 52% of its enzymes have shown a pattern consistent with duplication (Ohno et al. 1967). These findings support the hypothesis that common carp is an evolutionary tetraploid species that may have originated through species hybridization. Recent genetic evidence (sequence analyses of duplicate loci) indicates that the tetraploidization in common carp occurred around 16–19 million years ago (Larhammar and Risinger 1994). David et al. (2003) determined the time of occurrence of this tetraploidization to around 12 million years ago using microsatellites analysis. According to Berg (1964), modern common carp came from a Caspian Sea ancestor and initially spread into the Black and Aral Sea basins. Under favorable conditions of the postglacial thermal increase they dispersed as far as the Danube and the East Asia (Balon 1995). Common carp appeared in the River Danube about 8,000 to 10,000 years ago and, therefore, it is unlikely that the carp occurred naturally in waters of Central and Western Europe outside the River Danube at the beginning of the Christian era (Balon 1995). Wild carp then reached the delta of the Rhine, somewhat later, probably in  $12<sup>th</sup>$  century.

Assuming the long cultivation history of common carp in Asia, some scientists consider that the ancestor of the European domestic common carp came from Asia during the periods of ancient Greece and Rome (Vooren 1972; Chistiakov and Voronova, 2009). Others scientists believe that a German domestic strain of common carp to be the first improved carp, which appeared after the domestication of a wild common carp collected from the Danube River during the 17<sup>th</sup> and 18<sup>th</sup> centuries (Kirpichnikov 1981, Chistiakov and Voronova 2009). However, recent molecular genetics of wild common carp in some Turkish lakes supports the hypothesis of a single origin of present European domesticated and wild carp to have been from a common ancestor of Central Asian carp (Memis and Kohlmann 2006).

According to Kirpitchnikov (1967), there are at least four subspecies of wild common carp in the world: (i) the European and Transcaucasian *Cyprinus carpio carpio,* (ii) the Middle East *C. carpio aralensis,* (iii) east Asian C. *carpio haematopterus* and (iv) the south Chinese and Vietnamese *C. carpio uiridiviolaceus.* However, according to Balon (1995), two subspecies are present worldwide: *C. carpio carpio* and *C. carpio haematopterus. Cyprinus carpio carpio* is known as the European wild common carp, which originated from the western dispersant. *Cyprinus carpio haematopterus* is known as the Asian wild common carp, which originated from the eastern dispersant. In the duration of a long history of domestication, common carp has been subjected to various kinds of adaptation and genetic interventions particularly chromosome manipulations, selective breeding, sex reversal, and transgenesis (Chistiakov and Voronova 2009). Therefore, many common carp researchers believe that presently all common carp populations in the world may be hybrids. The pure breed of the wild common carp is presently faced with extinction resulting from various genetic interventions, serial domestication, and habitat modifications (Chistiakov and Voronova 2009; Oyugi 2012). In many countries, particularly those in Asia, studies on genetic distances among common carp populations are rare. There is a common belief in a number of Asian countries that wild populations are now dominated by hatchery common carp. Presently, introduction of hatchery–reared common carp is a serious threat for the conservation of wild carp, particularly in Asia and Europe, where common carp are domesticated as an important food fish. In several areas of Europe, the wild carp populations particularly the Danubian wild form is rare or may even be extinct (Piria et al. 2016).

Common carp belong to the Cyprinidae (minnow and carp family), which is the largest family of freshwater fishes in the world. The family Cyprinidae has nearly 2.5 thousands species. Common carp can be easily recognized by its small eyes, thick lips with two barbels at each corner of the mouth. The color of common carp is variable based on the environment, geographical distribution and genetics. However, their color is often olive–green to silvery– grey dorsally, fading to silvery yellow on the belly. Based on the arrangement of scales on the body, common carp has four varieties throughout the world: scaly common carp, mirror carp, linear carp and leather carp. Two genes, S (scaly) and N (nude) present on two chromosomes are responsible for the arrangement of scales on the body. The arrangements of scales are dependent on the character of these genes, whether recessive  $(S, N)$  or dominant  $(s, n)$ . Common carp that are coved with scales are called scaly carp (genes: SSnn, Ssnn). Mirror carp (ssnn) are partially scaled along their sides. Some common carp have no scales and are called leather carp (ssNn). Scales arrangement of linear carp (SSNn, SsNn) is along the lateral line. The genotypes SSNN, SsNN and ssNN do not exist in common carp.

When reared under unfavorable conditions, mirror carp are generally less resistant and achieve lower growth rates compared to scaly carp but both have similar viability (Kirpitchnikov 1999). Leather and linear carp are less viable even under favorable conditions. When common carp become mature, the operculum and the pectoral fin's upper surface of male common carp develop tubercles and turn rough compared to the female common carp. Mature males often release white milt, which oozes out from its genital opening on slight pressure on the abdomen. The belly of mature female are swollen compared to males (Oyugi 2012). Wild common carp has a typical life span of about 17 to 24 years but their lifespan can be up to 47 years in captivity (Froese and Pauly 2002).

The common carp is native to Europe and Asia. The natural distribution of this fish is very wide. Their high adaptive capacity in a wide range of conditions and habitats distribute them almost in all countries in the world. The ecological spectrum of carp is very wide. It normally lives in a temperature range of around  $15-32$ °C, but are able to survive in a wide range of temperatures  $(2-40^{\circ}C)$ . They can easily survive winter in an ice–covered lake, reservoir or river if some free water remains below the ice. Therefore, it is considered a eurythermal fish species. Common carp can also live in water with low dissolved oxygen. They may be found in waters with dissolved oxygen concentrations less than 2.0 mg/L and able to survive in water with dissolved oxygen concentrations levels as low as 0.5 mg/L for several days (Panek 1987; Zhou et al. 2000; Butler and Wahl 2010). They take atmospheric oxygen by gulping at the water surface at very low dissolved oxygen concentrations in the water.

Lakes, ponds, natural depression and rivers are natural habitats of common carp (Barus et al. 2001; Rahman 2015a). Common carp are mainly bottom dwellers, generally preferring to live near the soft vegetated sediments. In rivers, they are generally found in standing water or moderately flowing water. According to Butler and Wahl (2010), common carp prefer littoral zones with low current velocity compared to lotic areas with high current velocities in rivers. During the colder months, common carp, particularly adults, stay in the deeper areas of lakes and river channels and during the warmer months they migrate toward shallow, heavily vegetated floodplain areas (Bajer et al. 2011; Taylor et al. 2012). The optimal pH for common carp is 6.5–9.0. Water pH of <5.0 and >10.5 are harmful or lethal to common carp. Common carp can tolerate salinity up to about 5‰. However, sometimes they are found in brackish– water estuaries and bays, where their growth and production are normally very low.

## **GROWTH AND PRODUCTION**

Common carp is one of the most important food fish in many Asian and European countries. In 2015, it contributed over 4.4 million metric tons to fish production worldwide (FAO 2017). The bulk of the world's common carp production (97%) comes from aquaculture (Figure 1). Asia contributes the majority of world's common carp production. In 2015, Asia contributed 92% of the world's aquaculture production and half of the world's capture production (Figure 2). Among all countries, Mexico contributed the highest common carp capture production and China contributed the highest common carp aquaculture production (Table 1). Common carp account for approximately 4.1% of total global aquaculture production and 9% of the global freshwater aquaculture production. The common carp also accounts for the world's third highest farmed fish production, mainly from polyculture. It is the most cultured fish species in Central and Eastern Europe, with production levels reaching more than 80% of total fish production in some countries (Woynarovich et al. 2010; Adamek et al. 2012; FAO 2017).

Figure 1. Global capture and aquaculture production of common carp (data source: FAO 2017).

Common carp is well recognized as one of the oldest domesticated fish species. In Asia, domestication of common carp first commenced in China in the 5<sup>th</sup> century BC, whereas their domestication in Europe started during the period of the Roman Empire (Balon 2006). Common carp is normally cultured in various grow–out systems, which include conventional pond culture, large–scale commercial farms, duck cum fish, cage culture, irrigated area culture and rice field culture. In many Asian countries, common carp is most commonly cultured as a bottom–dwelling fish in polyculture ponds. For example, in south Asian countries, the traditional pond polyculture mostly includes a bottom dwelling fish like common carp with a surface (e.g., catla, *Catla catla*) and a column dwelling fish (e.g., rohu, *Labeo rohita*). As in Asia, common carp is also cultured in earthen ponds in Europe, applying extensive and semi–intensive management regimes, thereby allowing use of natural food resources for growth (Anton–Pardo et al. 2014).

Figure 2. Continent-wise capture (a) and aquaculture (b) production of common carp (data source: FAO 2017). The production of common carp in Australia is very low compared to other continent and therefore, it has been ignored.

### **Table 1. Top 15 capture and aquaculture producing countries and their production (tons) in 2015**

Source of raw data: FAO (2017).

A typically semi–intensive production system generally utilizes a combination of supplementary feeding and occasional fertilization with animal manure to increase natural food availability, particularly phytoplankton, zooplankton and various aquatic invertebrates. In Asian semi–intensive polyculture systems, a larger fraction of the natural food available in the pond is used by various species. In some cases, common carp enhance the food available for other species, as a consequence of nutrients re–suspension from their feeding activities, thus increasing further the total fish yield per unit area. The supplementary feed applied in semi–intensive systems usually varies from a high protein containing diet (Rahman et al. 2006) to cheap and locally available raw ingredients such as wheat, triticale or rye (Markovic et al. 2009; Anton–Pardo et al. 2014). The specific growth rate (SGR) of common carp can be 0.3 to 2 percent of body weight per day (Table 2). Carp generally reach 0.5 to 1.0 kg body weight within 6 months in the polyculture fish ponds in tropical and subtropical areas, particularly in Asia. Growth is much slower in ponds in the temperate zone (Europe), where the fish reach the 1 to 2 kg body weight in a three–year cycle. The growth of common carp is greatly dependent on culture location and management strategies particularly density of fish, and the quality and quantity of supplementary feed (Table 2). However, a strong understanding of growth and condition, food habit, stocking density, and environmental effects of common carp is essential for a sustainable and cost–effective semi–intensive aquaculture of this fish.

\*,% body weight day–1 ; S, stocking density; A, artificial feed; L, location reach the 1 to 2 kg body weight in a three–year cycle. The growth of common carp is greatly dependent on culture location and management strategies particularly density of fish, and the quality and quantity of supplementary feed (Table 2). However, a strong understanding of growth and condition, food habit, stocking density, and environmental effects of common carp is essential for a sustainable and cost–effective semi–intensive aquaculture of common carp.

# **LENGTH–WEIGHT RELATIONSHIP AND CONDITION FACTORS**

Published information on length–weight relationships indicates that common carp have negative allometric growth  $(b < 3.0)$  in most natural habitats and aquaculture ponds (Table 3). This indicates that length increment of common carp is higher than weight increment. Common carp do not show any habitat–wise distinct growth coefficient (b value) and condition factor (Table 4).

M, male; F, female.

## **FOOD HABIT**

Various research on food habit of common carp (e.g., Khan 2003; Adamek et al. 2003; Rahman et al. 2006; Rahman et al. 2008a; Saikia and Das 2009; Anton–Pardo et al. 2014) indicates that adult common carp prefer benthic organisms particularly chironomids, oligochaetes, gastropods and other larval insects associated with the benthos of natural habitats. In most cases, a variety of foods are identified in their stomachs. Therefore, they are omnivorous, with a tendency towards the consumption of animal foods, such as chironomid larvae, gastropods, oligochaetes, water insects, larvae of insects, worms, mollusks, and zooplankton (Table 5). Additionally, the common carp consume various plant–originated foods such as fresh and decayed seeds, leaves and stems of various aquatic and terrestrial plants. Phytoplankton is also found rarely in the stomachs of common carp.

Among a wide variety of factors that can influence the diet of common carp, the most important factors are age/size, availability of natural food resources, season and food competition (Rahman et al. 2009; Kloskowski 2011). Like many other fishes, common carp food preferences differ across their different age and /or size structures (Table 5). This ontogenetic food habit of common carp is greatly dependent on anatomical structures, behavior, physiological demands, habitat and food supply. Changes in the size of the mouth and oral anatomy may also correspond to ontogenetic dietary shifts (Rahman et al. 2009; Rahman 2015a). Various studies on food habit of common carp indicate that common carp prefer zooplankton when they are small, whereas larger fish prefer benthic macroinvertebrates over zooplankton (Adamek et al. 2003; Rahman et al. 2009). There is also some evidence of zooplankton avoidance by large common carp. For example, Rahman et al. (2009) observed that common carp of up to 15.4 cm total length preferentially selected zooplankton, but those larger than 18.9 cm total length avoided them. Phytoplankton ingestion by common carp is likely accidental given common carp of all sizes tend to avoid its direct consumption (Rahman et al. 2009). According to Al–Lamy and Taher (2016), common carp do feed directly upon phytoplankton in their larval and juvenile stages.

Common carp consume different food organisms in different amounts depending on their availability in the surrounding environment (Rahman et al. 2009). When preferred foods become depleted, common carp shift their food habits. For these fish, both availability of preferred food items and the presence of competitors are equally important. When low abundance of preferred food items (benthic macroinvertebrates) or density of common carp is high, they switch to their next most–preferred food items (zooplankton) (Rahman et al. 2009; Rahman 2015a). Zooplankton can be a very dominant dietary item in the absence of benthic macroinvertebrates. Zooplankton consumption can be particularly dominant in fish ponds where the stocking density of common carp is high. However, in the absence of preferred food, common carp follows the classical optimal foraging theory, whereby they broaden their feeding niche to maximize their food intake (Rahman and Meyer 2009). The results of various research indicates, however, that common carp has excellent adaptive capabilities in the presence of low food availability. For example, at high density, when there are insufficient natural foods, common carp eat the fry of other fish (Weber and Brown 2011; Rahman 2015b). In ponds supplied with artificial feed, common carp shifts its preference from zooplankton and benthic macroinvertebrates to artificial foods (Rahman et al. 2006; Rahman and Meyer 2009; Jurajda et al. 2016). Common carp grow better in ponds supplied with pelleted artificial feed than with cereals. Pelleted artificial feed acts as a source of nutrients for common carp growth, but it also indirectly maintains ecological stability of the surrounding environment due to less disturbance from carp feeding on natural foods (Rahman 2015b).

## **SPAWNING, MATURATION AND FECUNDITY**

Among a variety of factors that influence the reproductive biology of common carp, strain of fish, water temperature and habitat are the most important. Fish of the Asian strain mature faster than the European strain. In tropical and subtropical environments, this fish is able to mature around 6 months of age, whereas it takes more than 3 years age for common carp to reach maturity in temperate systems, particularly in northern Europe or North America. For example, in pond culture in India, males matured at 6 months of age and females at 8 months, whereas in Canada, in the wild, male common carp matured at age 3–4 years (35.6 cm fork length), and females at age 4–5 (43.2 cm fork length) (Parneswaran et al. 1972; Tempero et al. 2006). The size at first sexual maturity typically is around 30 cm in natural environments but they can be mature as small as 11 cm (Table 6). Water temperature and sexual maturity are highly correlated and geographical location (latitudes) of habitats, therefore, play an important role into at age of maturity of common carp (Fernandez–Delgado 1990; Tempero et al. 2006). Males also generally mature earlier than their female counterparts.

Apart from influencing maturation, temperature also has a large influence on the carp spawning period. The spawning season of Asian common carp populations may start when the water temperature is  $>15^{\circ}$ C, although they generally spawn between 18 and 26 $^{\circ}$ C. The spawning activity of this fish generally decreases above  $26^{\circ}$ C and ceases entirely above  $28^{\circ}$ C (McCrimmon 1968; Fernandez–Delgado 1990). The European carp start their spawning when water temperatures reach 17–18°C. According to Horvath (1985), under pond conditions the optimum spawning temperature for common carp in Europe is between 18°C and 22°C, although spawning of this fish may take place as low as  $14^{\circ}$ C. In Canada, carp spawned

between 16.5°C and 28°C, with a peak of spawning activity between 17°C and 23°C (McCrimmon 1968). In USA particularly in Minnesota, common carp spawns when water temperatures exceed 16–20°C (Bajer and Sorensen 2010; Chizinski et al. 2016).

**Table 6. Size at first sexual maturity of male (M) and female (F) common carp in various habitats, globally**

\*Fork length.

Common carp are able to adapt their reproductive strategies with local environmental conditions. Therefore, spawning seasons of common carp are generally longer in tropical and sub–tropical regions compared to temperate regions. In temperate regions, they normally spawn in spring or early summer (Table 7). For example, in the UK, spawning period of carp is between May and June. In tropical and sub–tropical regions, common carp may spawn almost across the entire year if sufficient food is available under suitable water temperatures. For example, carp spawn throughout the year in south Asian countries like Bangladesh and India, with two spawning peaks in January–March and July–August. Hailu (2013) observed year round spawning of common carp in Amerti Reservoir, Ethiopia at 18.9 to 23.1°C. Common carp were observed to extend their spawning from September to April (8 months) in northern New Zealand (Tempero et al. 2006). Sometimes they exhibit more than one reproductive cycle per year in tropical and sub–tropical regions. For example, Guha and Mukherjee (1991) reported two clear reproductive cycles of common carp per year in west Bengal, India. In temperate regions, common carp generally spawn once in a year.

Carp typically spawn in weedy shallow areas (about 0.5–1.0 m deep) in natural environments such as lakes and rivers. They prefer to spawn during flooding periods when the level of water is rising. Some scientists believe that common carp, particularly Asian strains start to spawn when the ion concentration in the water decreases abruptly at the beginning of the rainy season. In lakes, common carp generally live in deep water but they move to vegetated shallow areas for breeding. Balon (1995) reported that common carp of the Volga and Danube rivers spawn when water temperature reaches 18°C and large schools of this fish enter recently flooded grass flats within the inundation areas. Chizinski et al. (2016) observed that the adult common carp migrate to Lake Susan and Lake Riley wetlands for spawning over relatively short time periods that last just a few days between April and June, and whose specific timing varies but always occurs after water temperature rose to 10ºC and usually coincided with rain. Adult fish return from wetlands to their original habitats after spawning during summer (Bajer and Sorensen 2010). The young fish stay in wetlands for up to two years (Bajer et al. 2015).

Common carp are a highly fecund fish. This fecundity varies largely on their age, size, health, habitats and the number of times a carp has produced eggs. Their fecundity may vary between 100,000 to 250,000 oocytes per kg body weight (Table 8). A typical 45 cm long female can produce from 0.3 to 1 million mature oocytes over a breeding season (Froese and Pauly 2002). Almost similar information was also provided by Sivakumaran et al. (2003), who stated that a ripe female of 5 kg weight may produce up to 1 million mature oocytes. During breeding, male and female carp spawn by swimming side by side. The male carp are more active than the female, and they generally nudge the female with their fins and head to stimulate spawning. However, finding a mate during spawning is not difficult in natural environments as the ratio of male to female for all sizes is 1:1 in natural (Table 9).

# **BEHAVIOR**

Study on common carp behaviour in natural environments is difficult due to high turbidity and, in consequence, low visibility. Therefore, bbehavioral studies on common carp through direct observation have largely been restricted under natural conditions particularly in lakes, reservoirs and rivers. Nevertheless, direct observation can provide important information on grazing and swimming behaviour and inter and intra–specific social interactions. These can provide more insight on feeding niches occupied by various species in presence of common carp in natural ecosystems. A very limited number of studies on common carp behavior (e.g., Rahman et al. 2008b; Rahman et al. 2008c; Rahman and Meyer 2009; Rahman et al. 2010) were undertaken under semi–natural conditions and therefore, knowledge regarding their behaviors under semi-intensive pond aquaculture is extremely scarce.

Rahman et al. (2008a) observed the behavior of common carp in tanks in which seminatural conditions were simulated and which had a large glass wall allowing to observe various behaviors including inter and intra–specific social interactions. They stocked common carp with various combinations of water column dweller fish rohu (*Labeo rohita*) and studied the behaviors of both fishes under different species combination and natural/supplemental food situations. They concluded that the common carp is a benthic feeder as it grazed 63–68% of its total grazing time on the bottom. Common carp did not show any intra- or inter–specific aggressive behavior but the behavior of other species (rohu) was significantly influenced by the presence of common carp. However, both common carp density and supplemental feeding significantly influenced inter and intra-specific social interactions, and the time spent for grazing natural food by common carp. Common carp grazed during both day and night but primarily by day (Rahman et al. 2008c; Rahman and Meyer 2009).

As mentioned earlier, common carp is an omnivorous fish that primarily feeds on benthic macroinvertebrates (chironomids, tubificids) and zooplankton, but the bulk of its diet consists of detritus (Rahman et al. 2009). When common carp had access to both their preferred prey of benthic macroinvertebrates and zooplankton, they grazed on the bottom, whereas fish with access to only zooplankton grazed in the water column. The dependency on zooplankton shifts the common carp's feeding niche from the benthic zone to the water column. In this case, common carp spends the majority of its grazing and swimming time in the water column (Rahman and Meyer 2009; Rahman et al. 2010). Common carp increased their grazing time when food availability was very low in the environment (Rahman and Meyer 2009). However, the behavior of common carp is consistent with classical optimal foraging theory, whereby they selected their preferred prey (benthic macroinvertebrates) when available but switched to less preferred prey (zooplankton) when the preferred prey were not avail able (Rahman and Meyer 2009; Rahman et al. 2010). Behavioral observations are particularly very useful to clarify species interactions and feeding ecology in polyculture ponds and can also provide some insight into such interactions in their natural environments.

# **ASSESSING THE EFFECTIVENESS OF CONTROLLED REPRODUCTION OF THE COMMON CARP FROM 16 BREEDING LINES**

# *Elżbieta Brzuska\**

Institute of Ichthyobiology and Aquaculture in Gołysz, Polish Academy of Sciences, Zaborze, Poland

## **ABSTRACT**

The effectiveness of reproduction of the common carp (*Cyprinus carpio* L.) from sixteen breeding lines (four Polish lines: 2,3,6, K; five Hungarian lines: 7,8,W,0,T; two Lithuanian lines: B and BVP; Israeli line D; French line F; Yugoslavian line J; German line N; Ukrainian line UR) after ovulation stimulated with Ovopel  $[$ (D-Ala<sup>6, Pro9</sup>NEtmGnRH-a) + metoclopramide] was examined. The following parameters of reproduction effectiveness were investigated: the weight of eggs in grams and expressed as a percentage of the female's body weight, the percentage of fertilized eggs after 12-h incubation, the percentage of living embryos (24 and 36 h), the number of eggs, the number of living embryos 36h and the percentage of spawning females after hormonal stimulation. Considering the traits investigated, it can be concluded that the best reproduction effect was obtained in lines B, BVP and 8, while the least successful breeding was noted in lines N, J and 3. The highest number of living embryos after 36-h incubation was obtained in fish from lines B, T, BVP and UR (757.9; 692.9; 685.5; 656.1 and 655.6 thousand, respectively), and the lowest in lines N, 3, 2 and J (343.7; 404.5; 446.1; 459.3 thousand, respectively). The highest number of living embryos (36h) is to be expected from fish aged 14, 13 and 9 years (976.1; 879.5 and 826.6 thousand, respectively), whereas the lowest was from fish aged 15 and 11 years (259.5 and 279.9 6 thousand).

### **INTRODUCTION**

Research on the effectiveness, of controlled reproduction of various breeding lines of the common carp (*Cyprinus carpio* L.) after stimulation with natural and synthetic preparations has been conducted at the Institute of Ichthyobiology and Aquaculture in Gołysz (Polish Academy of Sciences) (PAN ZIGR Gołysz) since the 1970s. The scope of the studies conducted in the years 1978-2014 has been described by Brzuska (2006a, 2012a, 2016). This type of research is possible thanks to a genetically varied herd of the common carp developed after decades of genetic studies and husbandry work at the Institute. The herd is comprised of 17 breeding lines, constituting a "living gene bank", unique on the European scale. The breeding lines of carp in Gołysz are of different origins: Hungarian (line 7, line 8, line W, line 0, line T), Polish (line 2, line 3, line 6, line K), Lithuanian (line B, line BVP), Ukrainian (line UR, fully scaled line Up), French (line F), German (line N), Yugoslavian (line J), and Israeli (line D) (Białowąs et al. 2008).

Being so genetically valuable, this material is the basis for not only genetic, immunological (e.g., Rakus et al. 2003; Jurecka et al. 2009; Napora-Rutkowski et al. 2017) and breeding studies, but also for genetic improvements to the common carp population in Poland and national programs of preserving genetic reserves of the species, which is extremely important for the economy. It needs to be emphasized that several of these lines (line 3, line 6, line W, line 7, line 8, line 0, line F) comprise material for important crossbreeds (Guziur et al. 2003).

Research into the effectiveness of controlled reproduction of different breeding lines of the common carp conducted in Gołysz has made use of various natural preparations to induce ovulation, such as carp pituitary homogenate CPH (e.g., Brzuska 1991, 1997, 2000, 2003, 2006b; Cejko and Brzuska 2015, 2017), bream pituitary homogenate (Brzuska 2017), human chorionic gonadotropin hCG (Brzuska 2017) and pregnant mare serum gonadotropin PMSG (Brzuska and Ryszka 1990). Synthetic preparations, that is GnRH analogues, such as: [D-Tle<sup>6</sup>, Pro<sup>9</sup>NHEt<sup>9</sup>] GnRH-a *Lecirelin* (Brzuska 2004, 2006b) and DesGly<sup>10</sup>[D-Ala<sup>6</sup>] GnRHethylamide *Kobarelin* (Brzuska 2000) and complex preparations, containing both GnRH analogue and a dopamine receptor antagonist, have been used as well. Complex preparations applied to this species in Gołysz include Ovaprim (Syndel, Canada), containing salmon analogue D-Arg<sup>6</sup>, Pro<sup>9</sup>Net-sGnRH and domperidone (Brzuska and Adamek 1997), and Israeli agent Dagin, which contains a super active GnRH salmon analogue D-Arg<sup>6</sup>, Pro<sup>9</sup>Net-sGnRH and a dopamine receptor antagonist, metoclopramide (Brzuska 2005, 2006c). In other experiments, common carp were also stimulated with Aquaspawn (Spawnrite, Republic of South Africa), which consists of D-Lys<sup>6</sup>Trp<sup>7</sup>Tys8-mGnRH and domperidone (Brzuska 2001a).

The largest number of experiments on common carp of different origin have been conducted at PAN ZIGR Gołysz with the use of spawning agent Ovopel (e.g., Brzuska 2003, 2005, 2006b,c, 2011, 2012b, 2014; Brzuska and Grzywaczewski, 1999; Brzuska and Białowąs 2002; Cejko and Brzuska 2015, 2017). This complex preparation produced in Hungary contains a mammalian analogue GnRH (D-Ala<sup>6</sup>, Pro<sup>9</sup>NEt) mGnRH and metoclopramide (Horváth et al. 1997). It has been used in Gołysz since 1998 to induce ovulation and spermation in the common carp, not only in experimental spawning, but also in commercial reproduction. It should be emphasized that Ovopel has also been used with other

species of fish, not exclusively from the *Cyprinidae* family, yielding satisfactory results in propagation (Kłodzińska and Okoniewski 1998; Brzuska 2001b, 2012c; Kucharczyk et al. 2001; Szmyt et al. 2012).

Most studies conducted at the Gołysz Institute on common carp of different origins aimed to establish whether reproduction effectiveness after ovulation induced with Ovopel differs from the results of treatment with carp pituitary homogenate (CPH) (e.g., Brzuska 2003, 2005, 2010a; Brzuska and Grzywaczewski, 1999; Brzuska and Białowąs 2002; Cejko and Brzuska 2015, 2017). Three studies investigated the effectiveness of reproduction in several breeding lines of *Cyprinus carpio* after ovulation stimulated with Ovopel (Brzuska 2011, 2012b, 2014). However, there has been no comprehensive study that would report breeding results of more than ten lines of common carp available at the Institute after Ovopel-induced stimulation. This study presents the effects of propagation in 16 lines. The full-scaled Ukrainian line (Up) and 5-year-old females could not be included in the analysis due to incomplete data on its controlled reproduction.

Both the current and previous (e.g., Brzuska 1991, 2010b; Cejko 2007) research addresses the key issue of a potential association between the effectiveness of reproduction and the origin and age of females, as well as the spawning agent used. This is of particular importance in view of the fact that the results could be used to decide whether it is profitable to keep old females with a high body mass and use them in spawning. For example, maintaining and breeding such females is labor-intensive and is very costly, because of expensive agents inducing ovulation and spermation.

A crucial practical question that needs to be addressed in long-term studies on the effectiveness of the controlled reproduction of common carp originating from different breeding lines is whether it is possible to accurately predict the effectiveness of reproduction (expressed in the weight of eggs obtained, the percentage of living embryos, the total number of eggs and the number of living embryos) on the basis of easily measurable parameters (age and body weight of females, the weight of eggs obtained). Research questions concerning regression predictions of traits affecting the effectiveness of common carp reproduction have been the subject of previous studies (e.g., Brzuska 1997, 2011, 2012b, 2014; Brzuska and Grzywaczewski 1999).

The aim of the present study was to assess the effectiveness of controlled reproduction in 16 breeding lines of the common carp of different origin, to establish whether the age of females significantly determines the investigated effectiveness parameters and to make regression predictions of the weight of eggs  $(g)$ , the percentage of living embryos after 36h incubation, the total number of eggs and the number of living embryos (36h).

## **MATERIAL AND METHODS**

The data for statistical analysis was obtained from artificial spawning of the common carp conducted at PAN ZIGR Gołysz, in 12 breeding seasons (1998, 1999, 2001, 2002, 2004, 2005, 2008, 2009, 2010, 2011, 2012, 2013). The 323 females used for reproduction were 4 and 6-16 years old and weighed 3.40-15.30 kg. The females came from 16 breeding lines (2, 3, 6, K, 7, 8, W, 0, T, B, BVP, D, F, J, N, UR). The agent used for stimulating ovulation was the Hungarian preparation Ovopel [(D-Ala<sup>6</sup>, Pro<sup>9</sup>NEt-mGnRH-a) + metoclopramide] (Unic-

trade, Hungary), applied in two doses (1/5 pelletkg<sup>-1</sup>, and after 12 h 1 pelletkg<sup>-1</sup>; Horváth et al. 1997). The eggs were obtained from each female by stripping, and were fertilized separately with pooled milt of 3-4 males from the same line as the female. Hormonal stimulation was also conducted on males, which were treated with Ovopel applied in a single dose of 1 pellet kg<sup>-1</sup>. The fertilized eggs were treated in accordance with the Institute's procedures (Cejko 2007, Cejko and Brzuska 2017). Eggs from every female were incubated in a separate 7-L Weiss glass in water whose temperature was  $21 \pm 1^{\circ}$ C. The percentage of fertilized eggs was calculated after 12 h incubation, and the percentage of living embryos after 24- and 36-h incubation.

The parameters of reproduction effectiveness investigated for each of the breeding lines were: the weight of eggs (in grams and as % of female BW), the percentage of fertilized eggs (after 12-h incubation), the percentage of living embryos (after 24 and 36 h), the total number of eggs and the number of living embryos after 36 h incubation. The number of eggs and the number of living embryos (36 h) were calculated for the mean egg weight attributed to each female body weight class following a five-class categorization (Cejko and Brzuska 2015). The mean egg weight for class I ( $> 3 \le 5$  kg) was 1.27 mg; for class II ( $> 5 \le 7$  kg) 1.29 mg; for class III ( $> 7 \le 9$  kg) 1.38 mg; for class IV ( $> 9 \le 11$  kg) 1.48 mg and for class V ( $> 11$  kg) 1.56 mg.

The data was verified using the least squares analysis of variance (Harvey 1987), with the breeding line as the main classification factor. The linear model (1) used in the analysis included regression on female body weight and on age of females. The analysis determined the least square constants (LSC) and the least square means (LSM) for the parameters investigated in each breeding line (Tables 1, 2, 3).

$$
Y_{ij} = \alpha + a_i + bW_{ij} + dG_{ij} + e_{ij}
$$
 (1)

where:

 $Y_{ii}$  – observation j within line i  $\alpha$  – the theoretical general mean with the assumption that  $W_{ij} = 0$  and  $G_{ij} = 0$  $a_i$  – the effect of the breeding line i i = 1…….16 b – regression on the age of the female  $W_{ii}$  – the age of the female d – regression on the female body weight  $G_{ii}$  – female body weight  $e_{ii}$  – random error associated with observation j

In order to establish whether the age of females significantly determined the effectiveness of reproduction in the breeding lines of different origin, least squares analysis of variance was performed according to the following linear model (2).

$$
Y_{ijk} = \alpha + a_i + w_j + dG_{ijk} + e_{ijk}
$$
 (2)

where:

The breeding line was introduced into model (2) in order to bind the variability regarding this effect, reduce the error and increase the precision of estimating the effect of the age of females on the traits studied. The least square constants (LSC) and the least square means (LSM) estimated in the analysis of variance conducted according to model (2) are presented in Tables 8, 9, 10. The F-test was used to check the significance of the main classification factors (line and age of females) on the reproduction effectiveness parameters (Tables 1, 2, 3, 8, 9, 10). The significance of differences between mean values calculated for each breeding line and age group were verified for these parameters using the Duncan test with Kramer's modification (Harvey 1987) (Tables 4, 5, 6, 7, 11, 12, 13).

The percentage of ovulating females after hormonal stimulation was also calculated for each breeding line and each female age group (Figures 1, 2). Multiple regression analysis was used in order to predict the weight of eggs  $(g)$ , the percentage of living embryos after 36h incubation, the total number of eggs and the number of living embryos after 36-h incubation for each breeding line. In the equations where the dependent variable was the weight of eggs in grams, the independent variables were age and body weight of the females. In the equations where the dependent variable was the percentage of living embryos (36 h), the number of eggs or the number of living embryos (36 h), the independent variables were age, body weight of the females and also the weight of eggs (g). For predicting the number of living embryos after 36-h incubation for each female age group regression equations were derived with the independent variable being the body weight of females and weight of eggs in grams. The precision of estimation and adequacy of the constructed equations for a given set of data was characterized with the coefficient of determination  $(R^2)$ , describing the degree of variance explained by the model. The degree of correlation between the dependent variable and independent variables was estimated with multiple correlation R, describing the proportion between the dependent variable and the combined effect of the other variables. The results of regression predictions are presented in Tables 14, 15, 16.

### **RESULTS**

### **Female Ovulation after Ovopel Treatment**

Eggs were obtained from all females in line 3, K, 0 and BVP, from 94.44% of females in line B and from 90% of females in line T. The lowest percentage of ovulating females was for line J  $(46.66\%)$  and line 2  $(66.67\%)$ . In three lines  $(7, W, W)$  the percentage of ovulating females fell within the range of 76.47-79.48%, while for five lines  $(6, 8, D, F, U_R)$ , the range was 83.87 - 89.47% (Figure 1). Eggs were produced by all females aged 11, 12 and 16 and from 90.78% of the 8-year-old fish. The lowest percentage of ovulating females was observed for fish aged 4, 6 and 15 (68.75%, 75.75% and 77.17%, respectively). For fish aged 10, 13, 7, 14 and 9 the percentage of ovulating females fell within the range of 79.31-84.09% (Figure 2).

Figure 2. The percentage of ovulating female common carp aged 4 and 6-16 years after Ovopel treatment.

## **The Effect of the Origin of Females on the Weight, Quality and Total Number of Eggs and the Number of Living Embryos after 36 h Incubation**

The results of the analysis of variance and the F test show that the origin of females significantly determined all the traits investigated pertaining to the effectiveness of reproduction (Tables 1, 2, 3). Based on the least squares means that were calculated, it can be concluded that the highest weight of eggs (g) was obtained from females in lines T and B (1363.83 and 1248.73g, respectively). The mean scores showed positive deviation from the overall mean by as much as 347.43 and 232.34g (Table 1). High means (over 1100g) were

also noted for this trait in lines 6, F, BVP and  $U_R$  (Table 1). The lowest LSM scores for the weight of eggs  $(g)$  were obtained for lines N, 3 and 2 (664.48, 765.24 and 773.25g, respectively), with deviations from the overall mean of  $-351.91$ ,  $-251.15$  and  $-243.13g$ , respectively (Table 1).

The mean scores calculated for the weight of eggs expressed as the percentage of the body weight of females in the lines studied showed the lowest weight of eggs for females in lines N, 2 and 3 (8.77%, 9.70% and 10.45%; Table 1), and the highest weight for females in lines T, B, 7 and F (18.29%, 15.26%, 14.48% and 14.37%; Table 1). The least squares means calculated for lines  $6$ , F, D and  $U_R$  also showed positive deviation from the overall mean. However, the scores were lower than those for lines T, B, 7 and F (Table 1).

The percentage of fertilized eggs was the highest for eggs obtained from females from lines B and BVP (97.03 and 96.17%). The means calculated for this trait showed positive deviation from the overall mean by as much as  $\sim$  5% (Table 1). An exceptionally high percentage, over 90%, was also noted for lines 2, 3, K, 8, 0 and J. The lowest mean scores for the percentage of fertilized eggs were observed in lines T, D and N (81.87, 85.06 and 86.11%), while the means for lines 6, 7, UR, F and W also showed a negative deviation from the overall mean (Table 1).

**Table 1. Constants (LSC) and least-squares means (LSM) estimated for the weight of eggs (in grams and as % of female BW) and fertilized eggs (12 h) in 16 breeding lines of common carp and results of F-test**

b,  $P \le 0.01$ ; a,  $P \le 0.05$ ;  $\alpha$ , theoretical general mean

The highest least squares means for the percentage of living embryos after 24-h incubation were noted for lines B and BVP and lines 3 and 8 (93.79 and 92.54%; 91.47 and 90.93%; Table 2). During the next 12 h of incubation, the high percentage of living embryos continued in three lines: B, BVP and 8 (Table 2). Importantly, there was a significant decrease in the quality of eggs obtained from females from line 3 between the 24 h and 36 h hour of incubation (the percentage of living embryos after 24 h was 91.47, and after 36-h only 82.32). The lowest percentage of living embryos after 24- and 36-h incubation was noted for lines T, D and N (73.33 and 72.79%; 82.37 and 78.02%; 82.73 and 80.83%; Table 2).

### **Table 2. Constants (LSC) and least-squares means (LSM) estimated for percentage of viable embryos after 24 h and 36 h of incubation in 16 breeding lines of common carp and results of F-test**

b,  $P \le 0.01$ ; a,  $P \le 0.05$ ;  $\alpha$ , theoretical general mean

The analysis of the least squares means for the total number of eggs obtained from females in the lines studied has demonstrated that the highest number of eggs was produced by fish in lines T (909,200) and B (832,400). The means for these lines deviated from the overall mean by +231,600 and +154,800 (Table 3). Mean scores higher than 700,000 were calculated for seven lines (6, 7, 8, BVP, D, F and UR; Table 3). The lowest mean number of eggs was noted in lines N, 3, 2, J and 0 (442,900; 510,200; 515,500; 546,800 and 583,800), and the mean calculated for line N deviated from the overall mean by more than 200,000 (Table 3).

The highest number of living embryos after 36-h incubation was produced by fish from lines B, T and BVP (757,900; 692,900 and 685,500, respectively). The means for this trait deviated from the overall mean by  $+ 182,000, + 117,000$  and  $+ 109,600$  in the respective lines. A high number of living embryos (36 h) was also observed in lines 6, 8, F and UR (638,000; 630,600; 656,100 and 655,600 (Table 3). The lowest number of living embryos (36 h) (343,700), was noted in line N, and the mean deviated from the overall mean by as much as - 232,100. A relatively low mean score for the trait was also observed in lines 3, 2 and J (404,500; 446,100 and 459,300; Table 3).

### **Table 3. Constants (LSC) and least-squares means (LSM) estimated for total number of eggs and number of living embryos (36 h) in 16 breeding lines of common carp and results of F-test**

b,  $P \le 0.01$ ; a,  $P \le 0.05$ ;  $\alpha$ , theoretical general mean

Regression on the age of females included in the model was significant only for the weight of eggs (g), while regression on the body weight of females was significant for the weight of eggs  $(g)$ , for the number of eggs and the number of living embryos after 36 h incubation (Tables 1, 2, 3). The result of the Duncan test, showing the significance of differences between the mean values calculated for the traits studied within the breeding lines, are presented in Tables 4, 5, 6, 7.

## **The Effect of Female Age on the Weight, Quality and Total Number of Eggs and the Number of Living Embryos after 36 h Incubation**

The age of females significantly determined all the parameters investigated pertaining to the effectiveness of reproduction, except for the percentage of living embryos after 36-h incubation (Tables 8, 9, 10). The least squares means calculated for the weight of eggs expressed both in grams and the % of female BW showed the highest weight of eggs for females aged 14, 13, 9 and 10 years (1563.28g and 18.95%; 1412.35g and 16.53%; 1302.46g and 16.56%; 1078.94g and 13.79%) and the lowest weight of eggs for fish aged 15, 11 and 16 years (502.29g and 6.99%; 708.80g and 9.03%; 763.85g and 10.74% (Table 8).

**Table 8. Constants (LSC) and least-squares means (LSM) estimated for the weight of eggs (in grams and as % of female BW) and fertilized eggs (12 h) for 12 female age classes of common carp and results of F-test**

b,  $P \le 0.01$ ; a,  $P \le 0.05$ ;  $\alpha$ , theoretical general mean

The lowest means for the percentage of fertilized eggs and the percentage of living embryos after 24-h incubation were noted in the 11 years of age group (81.83% and 71.16%). A relatively low percentage of living embryos (24h) was observed for females aged 15 and 16 years (78.86% and 79.16%, respectively) and the highest for those aged 12, 6, 4, and 13 years (95.91%, 94.79%, 94.57% and 94.46%) (Table 9). As shown by the least squares means estimated for the age groups, the quality of eggs expressed in the percentage of living embryos after 36-h incubation was the highest for females aged 12 and 13 (93.29% and 92.27%, respectively), and the lowest for those aged 11 and 15 years (71.00% and 78.86%). (Table 9).

The highest number of eggs and the highest number of living embryos (36 h) was noted for females aged 14, 13 and 9 years (1092,200 and 976,100; 975,000 and 879,500; 946,300 and 826,600; Table 10). Within the twelve age groups, the least squares mean scores for the number of living embryos (36 h) fell within the range of 505,100-664,300 in as many as six
groups (4, 6, 7, 8, 10 and 12 years; Table 10). The lowest mean scores calculated for the total weight of eggs and the number of living embryos (36h) were noted for 15 and 11-year-old females (355,200 and 259,500; 495,900 and 297,900; Table 10).

Regression on the body weight of females included in model 2 was statistically significant for the weight of eggs expressed in grams and as % of females BW, and for the number of eggs and the number of living embryos after 36-h incubation (Tables 8, 9, 10). The results of the Duncan test, showing the significance of differences between mean values calculated for the investigated traits within female age groups, are presented in Tables 11, 12, 13.

#### **Regression Predictions**

Table 14 shows multiple regression equations for the weight of eggs (g) in the 16 breeding lines and values of the coefficient of determination  $(R^2)$ . The adequacy of the equations to the existing conditions of individual variability and also to environmental and genetic factors indicates that predicting the weight of eggs (g) only on the basis of the age and female body weight cannot be considered satisfactory. By comparing the  $\mathbb{R}^2$  values for the lines studied, it can be seen that in comparison with other lines, the coefficient of determination was relatively high for lines D, T and W (0.63, 0.61 and 0.60). The highest  $\mathbb{R}^2$ was noted in line UR (0.93) (Table 14).

Breeding lines	Equations of multiple regression	$\mathbb{R}^2$
2	$Y_1 = -1709.32 + 383.78_{x1} - 72.30_{x2}$	0.38
3	$Y_1 = 542.86 - 19.23_{x1} + 48.12_{x2}$	0.13
6	$Y_1 = 281.06 - 2.11_{x1} + 103.53_{x2}$	0.39
K	$Y_1 = -857.49 + 151.10_{x1} + 81.36_{x2}$	0.53
7	$Y_1 = 0.4883 + 117.04_{x1} + 5.13_{x2}$	0.02
8	$Y_1 = 59.56 + 68.33_{x1} + 44.12_{x2}$	0.05
$\Omega$	$Y_1 = 3278.44 - 314_{x1} + 71.48_{x2}$	0.22
W	$Y_1 = -215.02 - 3.32_{x1} + 144.17_{x2}$	0.60
T	$Y_1 = 521.58 - 151.67_{x1} + 22.47_{y2}$	0.61
B	$Y_1 = 3613.64 - 283.36_{x1} + 46.91_{x2}$	0.18
<b>BVP</b>	$Y_1 = -1695.07 + 245.33_{x1} + 119.98_{x2}$	0.31
D	$Y_1 = -1657.44 + 346.80_{x1} + 11.78_{x2}$	0.63
$\mathbf{F}$	$Y_1 = -281.76 + 47.48_{x1} + 120.81_{x2}$	0.37
J	$Y_1 = 1128.45 - 48.96_{x1} + 28.12_{x2}$	0.32
N	$Y_1 = -68.56 + 66.12_{x1} + 27.86_{x2}$	0.03
<b>UR</b>	$Y_1 = -12680 + 1175_{x1} + 246.60_{x2}$	0.93

**Table 14. Regression predictions for weight of eggs in grams within 16 breeding lines of common carp. R<sup>2</sup>– Coefficient of determination**

Dependent variable: weight of eggs in grams  $(Y_1)$ ; Independent variables: body weight of females  $(x_1)$ , age of females  $(x_2)$ .

#### **Table 15. Regression predictions for percentage of living embryos (36 h), number of eggs and number of living embryos (36h) within 16 breeding lines of common carp. R<sup>2</sup>– Coefficient of determination**

Dependent variables: percentage of living embryos 36 h (Y<sub>2</sub>), number of eggs (Y<sub>3</sub>), number of living embryos 36 h (Y<sub>4</sub>); Independent variables: age of females  $(x_1)$ , body weight of females  $(x_2)$ , weight of eggs in grams  $(x_3)$ .

Table 15 shows multiple regression equations, where the percentage of living embryos (36 h), the number of eggs and the number of living embryos (36 h) constituted the dependent variables, while the independent variables were: age, body weight of the females and the

weight of eggs (g). Predictions for the percentage of living embryos after 36-h incubation made on the basis of the age and body weight of females and the weight of eggs obtained (g) were most precise for lines U<sub>R</sub>, BVP and N (0.95; 0.95 and 0.81, respectively; Table 15). The coefficient of determination ( $\mathbb{R}^2$ values fell within the range of 0.45 - 0.66 in five lines (3, W, T, B and F). The prediction rate for the number of eggs can be considered satisfactory for all the breeding lines. The  $\mathbb{R}^2$  for the respective lines was high, falling within the range of 0.93 -0.99 (Table 15). The reliability of prediction for the number of living embryos after 36-h incubation was satisfactory for all the breeding lines and the highest  $\mathbb{R}^2$  values were noted for lines  $U_R$ , BVP, 2, N, K and W (0.99; 0.99; 0.97; 0.96, and 0.96), and the lowest for lines T and 3 (0.68 and 0.77) (Table 15).

Table 16 shows multiple regression equations for the twelve age groups of females, where the dependent variable was the number of living embryos after 36 h incubation, while the independent variables were the body weight of females and the weight of eggs in grams. Taking into consideration the coefficient of determination, it can be concluded that the reliability of prediction of the number of living embryos (36 h) was very high for as many as nine age groups, that is, females aged 4, 7, 8, 9, 10, 12, 13, 14 and 15. The prediction was not reliable for 11-year-old females only  $(R^2 = 0.05)$ .

Dependent variable: number of living embryos after 36 h incubation  $(Y_1)$ ;

Independent variables: body weight of females  $(x_1)$ , weight of eggs in grams  $(x_2)$ 

### **SUMMARY**

On the basis of the results presented it can be summarized that considering the rate of ovulating females and the least squares means estimated for the traits investigated, the best breeding effects were obtained for two Lithuanian breeding lines, that is, line B and BVP, and the Hungarian line 8.

The number of living embryos (36 h) estimated for line B was higher than the number of living embryos (36 h) calculated for the other lines studied and the reliability of prediction of this trait can be considered high.

Regarding line BVP, eggs were obtained from all females and the quality of the eggs after 36 h incubation was the highest. Moreover, in the Hungarian line 8, the percentage of ovulating females and the number of living embryos (36 h) was high. The reliability of prediction of both the number of living embryos (36 h) and the number of eggs can be considered high.

The Hungarian line T was characterized by the highest mean weight of eggs and the highest number of eggs obtained. However, attention should be paid to the fact that the percentage of fertilized eggs and living embryos (24 and 36 h) estimated for line T was significantly lower in comparison with the other lines studied. The lowest percentage of ovulating females was noted for the Yugoslavian line J and Polish line 2. It cannot remain unnoticed that the very high quality of eggs for line J 12 h after incubation was drastically lower in the subsequent incubation stages.

The percentage of ovulating females in Polish line 3 and the mean weight of eggs were relatively low, while the percentage of living embryos was significantly lower after 36-h incubation in comparison with the percentage of living embryos calculated after 24 h. The reliability of prediction for percentage of living embryos (36 h) can be considered not very high for line 3. The females of the German line N produced eggs of the lowest mean weight, and thus these eggs should be considered to be of low quality. The number of living embryos for this line was also the lowest and the prediction rate for these parameters was very high.

Low quality of eggs (24 and 36 h) was also noted for the Israeli line D, however, the mean number of living embryos (36 h) estimated for this line was close to the overall mean. The Ukrainian line UR can be considered highly effective in reproduction due to the significant percentage of ovulating females and the high number of eggs and living embryos.

The highest mean weight of eggs was obtained from females aged 14, 13 and 9 years. The quality of eggs obtained from 9-year old females was lower in comparison with the quality of eggs produced by 13 – and 14 year old fish. The highest number of living embryos (36 h) was noted for 14 – year old females. A relatively high weight of eggs was also obtained from 7- and 8 – year old females, but the percentage of ovulating fish was higher in the  $8 -$  year old group. The study show higher number of living embryos (36 h) for  $7 -$  year old females.

Following the Ovopel treatment all the  $11 -$  and  $12 -$  year old females produced eggs but the mean weight estimated for these age groups deviated negatively from the overall mean. The number of living embryos  $(36 h)$  for  $11 -$  year old fish was very low, although the reliability of prediction for this parameter was very low. The 16 – year old females treated with Ovopel ovulated as well, but the number of living embryos (36 h) for this age group was lower than the overall mean. Only the  $4 -$  and  $6 -$  year old group percentage of ovulating females was lower than the 15- year old group. Females from the 15 – year old group produced the lowest number of living embryos (36 h).

#### **CONCLUSION**

For economic reasons and breeding effectiveness, artificial reproduction should involve females which produce the highest possible number of offspring. The present study shows that the best female age range for breeding is 13-14 years and 9 years. However, it needs to be noted that the cost of maintaining fish that age with a large body weight is high. Moreover, ovulation stimulating agents administered per 1 kg of body weight are also expensive. When using 4- and 6-year old females for reproduction, one needs to remember that the share of ovulating fish in the total number of the treated fish will (most likely) not exceed 75%, and the number of living embryos after 36 h incubation will be about 500000. By estimating the effectiveness of reproduction in various breeding lines of the common carp and different age groups of females one may make decisions that will ensure the best possible results of spawning under controlled conditions. Such conditions make it possible to precisely monitor the percentage of ovulating females after hormonal stimulation (one of the most important parameters describing the effectiveness of reproduction), the weight of the eggs obtained and their quality throughout the incubation period.

#### **ACKNOWLEDGMENTS**

I would like to express my deep gratitude to the former head of the Institute of Ichthyobiology and Aquaculture of the Polish Academy of Sciences in Gołysz, Professor A. Pilarczyk, and the present head of this Institute, Dr. I. Irnazarow, for enabling me to conduct the study presented in this paper. I would like to thank everyone involved in performing the controlled reproduction in the hatchery at this Institute (Dr. J. Adamek, Dr. B. Cejko, R. Ronchetti MSc, U. Czudek, D. Rajba-Nikiel, J. Krzempek, R. Wrzecionko and S. Chucher). I also cordially thank Mrs. U. Karosek for her careful technical preparation of the manuscript. I would also like to thank Ms. A. Rybacka for translating the text into English. I would also like to thanks the anonymous reviewers for valuable suggestions and remarks that allowed me to improve the MS.

### **ABSTRACT**

Carp (*Cyprinus carpio* L.) in both Central and Eastern Europe and Asia are mainly reared in shallow earth ponds that allow a large proportion of their diet to be provided insitu via pond zooplankton and zoobenthos. Fish farmers generally consider natural foods superior to artificial diets (especially for younger fish) due to their high digestibility, high water content and rapid growth rate, which ensures high fish densities. Further, such a diet has significant benefits for fish growth and survival and reduces the fish farmer's outlay considerably. However, while the production costs of carp farmed using natural production only are low, stocking densities and yields are also low in comparison to more intensive production systems. Following a period of increasingly intensive management up to the late 1980s, most carp pond farmers now employ a semi-intensive management system characterised by the combination of natural food items (the abundance of which is increased by the addition of animal manure and lime) with supplementary feed that provides the missing nutritional elements, prolongs the growing season and increases growth rates and yield-per-unit volume. In this chapter, we briefly examine the role of zooplankton and zoobenthos in carp diet and nutrition, summarise present semi-intensive management systems and the role of manure and lime in promoting zoobenthos and zooplankton availability, and assess the impact of supplementary feeding on natural food uptake by carp. Finally, we highlight a number of suggestions for better balancing the uptake of natural and supplementary feed resources, thereby reducing overall costs, increasing production intensity and efficiency and reducing environmental impact.

### **INTRODUCTION**

The common carp (*Cyprinus carpio*) is an omnivorous, benthivorous cyprinid fish that has been cultivated by humans in Europe and Asia for hundreds of years as a source of food, not least as it is highly adaptable in relation to habitat and diet (Soltani et al. 2010; Manjappa et al. 2011; Rahman 2015a). Indeed, carp are now the third most widely cultivated freshwater fish species in the world (Table 1; FAO 2013), with production levels in some Central and Eastern European countries now representing over 80% of total fish production (Woynarovich et al. 2010; Anton-Pardo et al. 2014). To this day, carp in both Central and Eastern Europe and Asia are mainly reared in shallow, extensively or semi-intensively managed earth ponds, with the advantage that a large proportion of their food can be provided in the form of naturally occurring dietary items such as zooplankton and zoobenthos (Woynarovich et al. 2010; Adámek et al. 2012). As such, carp pond farming is usually seen as an efficient, stabilising and environmentally friendly form of farming (Szucs et al. 2015). Indeed, its ability to effectively utilise natural food resources and its low impact on the surrounding environment makes carp an ideal candidate for organic farming (Adámek et al. 2015). However, the ever growing need to increase production levels and efficiency has led to changes in pond management aimed at lengthening the carp growing season and increasing stock levels. As such, most farms now use a system that tries to balance use of autochthonous (natural) and allochthonous (imported) food sources.

**Table 1. World production of the top ten aquacultural fish species in 2015 (data based on statistics from FAO 2017b)**

Here, we provide a short overview of the role natural food resources play in the diet of carp, how carp affect zooplankton and zoobenthos communities and how modern pond management methods seek to increase pond productivity by increasing food supply (e.g., by use of fertilisers and supplementary feeds). In general, we concentrate on examples from Central Europe (and especially the Czech Republic); however, both the management methods used and the resulting dietary preferences are generally applicable elsewhere.

# **THE CHANGING ROLE OF NATURAL FOOD RESOURCES IN CENTRAL EUROPEAN CARP FARMING**

#### **A Short History**

Fishponds of up to several hundreds of hectares have been constructed in Central Europe for the rearing of mainly common carp since at least the  $11<sup>th</sup>$  century (Pechar et al. 2002). Most were (and still are) no more than 1-2 m deep and were constructed by damming marshes, swamps or small river floodplains (Pokorný and Hauser 2002). In what is now the Czech Republic (and elsewhere in Central and Eastern Europe), a particularly intense period of building took place at the end of the  $15<sup>th</sup>$  and beginning of the  $16<sup>th</sup>$  centuries, during which the methods employed in carp aquaculture were greatly improved (Hoffmann 1996). In particular, a more systematic approach was employed, with carp categorised and separated into individual age groups (Hartman et al. 2015). Following a period of decline, resurgence in pond building took place during the 19<sup>th</sup> century when a number of management practices aimed at increasing productivity were introduced, e.g., summer drainage, supplementary feeding, liming and fertilisation (Šusta 1898). This was followed by a second period of intensification in the second half of the  $20<sup>th</sup>$  century when more intensive pond management measures were introduced, including high levels of supplementary feeding (mainly cereals), use of solid and liquid manure, fertilising with inorganic fertilisers and intensive liming (Figure 1). All such measures aim to increase the production of natural food resources (zooplankton/zoobenthos) in the pond in order to increase the biomass of carp (and other fish) that could be harvested. Many duck farms were also established on ponds at this time in order to diversify production (Pokorný et al. 2015). This era of highly intensive management reached its peak in the 1980s, at which time most ponds in Central Europe were highly eutrophic (Pechar 2000; Vsetickova et al. 2012), being subject to extreme algal blooms and disease outbreaks, including botulism, which has been linked to duck production (IUCN 1997; Babinszky 2009). Aside from an excess of nutrients in the water, high densities of fish stock meant that larger *Daphnia* sp. became overgrazed and smaller zooplankton species, which are unable to check phytoplankton growth (especially cyanobacteria), proliferated (Potužák et al. 2007).

Since then, pond farming has shifted to a more semi-intensive management system, with the majority of food based on natural zooplankton and zoobenthos production supplemented by processed or artificial feeds. Today, use of organic and inorganic fertilisers is controlled to prevent the eutrophication and algal blooms, increased turbidity and low oxygen concentrations associated with high nutrient concentrations, while lime is mainly used to counter the negative effects of fertilisation (Adámek et al. 2012; FAO 2017c). Central and

Eastern European and Central Asian semi-intensive carp ponds generally have relatively high stocking densities, with fish yields generally ranging between several hundred to several thousand kilograms per hectare (Kestemont 1995). The ponds are usually harvested over a three- to four-year production cycle utilising three to four main fishpond types: (a) an optional pre-nursery pond for production of advanced fry  $(C_a, 0.3-1.5, g)$ , (b) nursery ponds for production of one-year carp  $(C_1, 20-70 \text{ g})$ , (c) on-growing ponds for production of two-year carp  $(C_2, 100-350)$  g) and (d) marketing ponds for production of three- to four-year marketable fish  $(C_3, 600-1750 \text{ g}; C_4, >2 \text{ kg})$  (Horváth et al. 1992). As the majority of marketable fish are not sold during or directly after the pond harvest, the fish will be kept in storage ponds until transported or sold (Stibranyiová and Adámek 1998).

### **NATURAL FOOD RESOURCES IN CARP DIET**

#### **The Role of Natural Food Resources in Carp Diet**

Carp larvae and fry feed mainly on zooplankton (e.g., rotifers, copepod nauplii); however, they switch to larger prey (e.g., copepods, cladocerans) as they grow (Osse et al. 1997; Chakrabarti and Sharma 1998; Nunn et al. 2010; Woynarovich et al. 2010; Dulić et al. 2011; Anton-Pardo and Adámek 2015; Füllner 2015). As adults, carp switch to a mainly benthic feeding style, their large, accordion-like mouths and barbels (one pair each on the upper and lower lips) enabling them to dig, sift and filter bottom muds and sediments for food (Froese and Pauly 2011). The size at which this shift occurs will vary in relation to a range of factors, including the density and ratio of both food types (Anton-Pardo and Adámek 2015). Osse et al. (1997) suggested that carp shifted from planktivorous to benthivorous feeding at around 8-18 mm total body length. Studies on functional morphological traits, however, suggest a somewhat later shift, the carp's mouth position shifting from 'terminal' to downward projecting (reflecting the shift to benthic feeding) at around 20-25 mm (Vilizzi and Walker 1999). Crustaceans remain the dominant dietary item until around 100-150 mm (Khan

2003; Britton et al. 2007), though some studies have noted the change to a primarily benthic diet as early as 30-50 mm (Kloskowski 2011).

From the juvenile stage onward, carp are able to utilise a wide range of natural food types, though animal prey usually represents 75% or more of the prey taken (Michel and Oberdorff 1995). Prey types most often taken include plankton, crustaceans and insects (including larvae and pupae), especially chironomids and other benthic invertebrates (Michel and Oberdorff 1995; Colautti and Remes Lenicov 2001; Khan 2003; Rahman et al. 2008; Anton-Pardo et al. 2014). In addition, they will also take the softer parts of aquatic plants and their seeds, along with fish eggs and larvae and even smaller fish or crayfish larvae (Hinojosa-Garro and Zambrano 2004; Weber and Brown 2011; FAO 2017a). Zooplankton may persist as an important part of the adult diet, however, with the percentage taken varying between 0% and 90+% (Adámek et al. 2003; Khan 2003; Rahman et al. 2006; Marković et al. 2009; Woynarovich et al. 2010; Kloskowski 2011; Anton-Pardo and Adámek 2015), depending on food availability and spatial and temporal variation (Garcia-Berthou 2001; Saikia and Das 2009; Rahman et al. 2010). As the branchial sieve of the adult carp is incapable of retaining organisms smaller than 0.25 mm (Sibbing et al. 1986; Colautti and Remes Lenicov 2001; Dulić et al. 2011), large cladocerans tend to be the main zooplankton ingested. As carp are visual predators, such large zooplankton are easier to see and catch, not least as they are more highly pigmented than copepods and have a slower escape speed (Drenner et al. 1978; Dulić et al. 2011).

In general, the proportion of different prey classes in the diet will vary through the seasons, with zooplankton more important in spring and early summer, molluscs and copepods in winter, and chironomids from the end of spring to autumn (Michel and Oberdorff 1995; Bauer and Schlott 2004; Kloskowski 2011). Such shifts in feeding preference will usually be matched by a shift in feeding niche from the benthic zone to the water column and back (Rahman et al. 2010; Rahman 2015b). Overall, common carp are flexible and opportunistic feeders that can switch between preferred and alternative dietary items, depending on availability (Anton-Pardo et al. 2014; Hoole et al. 2001).

Figure 2. Schematic depiction of fingerling biomass development during the first growing season in a typical Central European fishpond, showing the changing importance of natural and supplementary food over time. X-axis = ten day period (decade) during the growing season;  $M = May$ ,  $O = October$ (adapted from Füllner 2015).

Theoretically, carp can be farmed using the natural production of the pond only (e.g., zooplankton, benthos and aquatic plant material); however, while this type of pond production is characterised by low production costs it is also limited to low stocking densities and low yields (Stanković et al. 2011), not least as carp growth is highly dependent on the seasonal availability of zooplankton/benthos. In most temperate regions, for example, while peak production of zooplankton and zoobenthos occurs in spring, water temperatures are optimal for carp growth around mid-summer, when natural food levels have started to drop (Dulić 2007; Dulić et al. 2009; Füllner 2015; see Figure 2). Further, while natural dietary items are an important source of lipid and protein in carp diet, they are poor in carbohydrates, containing just 3 to 4.8% dry matter (Mitra et al. 2007). For these reasons, supplementary (mainly cereals) or commercial feeds (along with fertilisers) are commonly used in carp aquaculture (Kibria et al. 1997; Woynarovich et al. 2010).

#### **Natural Food Resources and Carp Nutrition**

As stated above, carp larvae and fry feed mainly on zooplankton but switch to larger prey and zoobenthos as they grow. Zooplankton may remain an important dietary component well into adulthood; however, this depends on their relative abundance and season. Albrecht and Breitsprecher (1969), who undertook a large-scale review of literature concerning fish food in ponds, provided average composition values as follows (% dry matter in parentheses; see Table 2 for a more detailed breakdown by prey class): water 85.8%, protein 7.4% (52.1), carbohydrate 3.8% (27.3), lipids  $1.1\%$  (7.7) and ash 1.1% (7.7). The nutritional value of zooplankton and zoobenthos varies greatly, however, depending on the group analysed and environment factors such as water temperature (Anton-Pardo and Adámek 2015). While there have been fewer studies on the nutritional content of zoobenthos, values tend to be similar to those for zooplankton (Tables  $2 \& 3$ ), especially regarding the two species most often taken by carp, chironomids and daphniids (Michel and Oberdorff 1995; Colautti and Remes Lenicov 2001; Khan 2003; Rahman et al. 2008; Epler et al. 2010; Anton-Pardo et al. 2014). Again, lipid and amino acid content vary both seasonally and with developmental stage, especially in copepods (Kibria et al. 1999; Brucet et al. 2005). Protein content can reach more than 50% in some genera (e.g., Daphnia, Cyclops), though content in rotifers is usually somewhat less at between 25-50% dry wt. (Conceicao et al. 2010; Jeeja et al. 2011; Yin et al. 2013). Protein levels in chironomids are also estimated at around 50% and lipid content at 10% (Habib et al. 1997). For most cladocerans and copepods, total amino acid content generally lies above 50% (Kibria et al. 1997; Mitra et al. 2007). Bogut et al. (2007) estimated protein content in *Chironomus plumosus* at 55% dry wt. (7% wet wt.), mineral content at 8% dry wt. (1% wet wt.), crude fat at 1% wet wt., nitrogen-free extractive substances at 28% dry wt. and water content at 88%. For *Daphnia magna*, Bogut et al. (2010) estimated protein levels at 39% wet wt. (1% dry wt.), raw fat at 5% dry wt., fibre at 4% dry wt and water content at 97%. Aside from methionine and phenylalanine, levels of essential amino acids are found in "adequate" quantities for carp (Bogut et al. 2010).

Unlike protein and amino acid levels, which are generally genetically determined, lipid content tends to reflect levels in the fish's diet (DeMott and Muller-Navarra 1997). Fatty acids are essential for fish larval growth and development and a deficiency in juvenile and adult fish has been linked with poor fecundity, fertilisation rates and viability (Rainuzzo et al.

1997), along with fatty liver degeneration, myocarditis, low erythrocyte haemoglobin concentrations, changes in cell membrane permeability, fast breathing, poor food utilisation, lowered growth rates and increased susceptibility to stress (Bogut 1996). Carp, in particular, require omega-3 fatty acids (Watanabe et al. 1975; Csengeri 1993), their deficiency being reflected in a lowered growth rate and synthesis and accumulation of non-essential omega-9 fatty acids in muscle tissue. In general, zooplankton tend to have a high proportion of highly unsaturated fatty acids (HUFA), such as docosahexaenoic acid (DHA), eicosapentaenoic acid (EPA) and total conjugated linoleic acids (CLAs), all omega-3 fatty acids. It has been estimated that carp require between 0.5 and 1.0% HUFA and polyunsaturated fatty acids (PUFA) for optimal growth (Bogut 1995; Robinson 1984; Takeuchi 1996). While fatty acid content will vary with species, temperature and season (Kibria et al. 1999; Persson and Vrede 2006; Mitra et al. 2007); lipid content in zooplankton tends to be around 10% dry wt., usually with more unsaturated than saturated fats (Kibria et al. 1997; Bogut et al. 2010; Lei et al. 2013). In *D. magna*, for example, Bogut et al. (2010) recorded 19% saturated fatty acids and 66% unsaturated fats, with 27% of unsaturated fats comprising omega-3 fatty acids. Lipid levels in rotifers tend to be relatively high at approx. 20% dry wt., though they tend to be low in HUFAs (Yin et al. 2013). Copepods, on the other hand, have only moderate levels (predominantly unsaturated DHA), while cladocerans have higher proportions of monounsaturated fatty acids (MFA) and EPA (Persson and Vreded 2006; Guo et al. 2008; Smyntek et al. 2008; Mraz et al. 2012). (For a full description of the nutritional requirements of carp, see FAO 2017a and references therein).

#### **Table 2. Nutrient composition of dominant carp prey items (mean + range; adapted from Albrecht and Breitsprecher 1969)**

\*Nitrogen free extracts (carbohydrates consisting almost entirely of indigestible chitin).

#### **Table 3. Nutrient composition of benthic carp prey items (adapted from Epler et al. 2010)**

\*Nitrogen free extracts (almost entirely indigestible chitin).Benefits of Utilising Natural Food Resources

The nutritional value (as human food) of carp is highly dependent on the quality and composition of the fish's diet. Fish farmers generally consider natural foods superior to artificial and supplementary diets (especially for younger fish) due to their high digestibility (particularly proteins); high water content (85-95%); soft structure (allowing deformation soon after digestion) and motility, which attracts fish to the food ensuring high take-up (Bogut et al. 2007. Indeed, there is considerable evidence that a natural diet has significant benefits for fish growth and survival (Anton-Pardo and Adámek 2015). The content of dry matter in zooplankton, for example, is relatively low at around 10%. As such, they are easier to break down than dry feed and are more palatable for larvae and juveniles (Lie et al. 1997; Kolkovski 2001; Mitra et al. 2007; Conceicao et al. 2010). Further, it is thought that exogenous enzymes in natural live foods play a fundamental role in the breakdown of organisms in the larval digestive tract as the larvae themselves naturally have low levels of digestive enzymes (Govoni et al. 1986). A number of studies have noted increased growth rates (and weight gain) in carp as the amount of available zooplankton increases (Jana and Chakrabarti 1990; Chakrabarti and Jana 1992). Further, both yield and survival rate, especially in carp larvae and fry, have been shown to increase as the proportion of zooplankton in the diet increases (Chakrabarti and Sharma 1998; Sharma and Chakrabarti 1999; Markovic et al. 2009). More indirectly, live prey remain active (e.g., edible and available) if uneaten, while supplementary and artificial feeds (which may contain up to 10x more dry matter than natural food) fall to the pond bottom and contribute to nutrient enrichment and eutrophication (Breukelaar et al. 1994; Conceicao et al. 2010; Anton-Pardo and Adámek 2015; see also Torres and Adámek 2013 and references therein as regards remobilisation of nutrients through bioturbation caused by carp feeding). Finally, use of natural foods reduces the fish farmer's costs considerably and the rapid growth rate of zooplankton ensures high densities shortly after the pond is filled (Kibria et al. 1997; Lubzens et al. 2001).

## **SUMMARISING CARP IMPACT ON ZOOPLANKTON AND ZOOBENTHOS ASSEMBLAGES UNDER EXTENSIVE CONDITIONS**

As a result of their feeding habits, carp can have a significant impact on the quantitative and qualitative composition of extensive pond zooplankton and zoobenthos assemblages. As outlined earlier, for example, the removal of large cladocerans by planktivorous carp can result in cyanobacterial blooms as smaller zooplankton species, which are unable to check phytoplankton growth (especially cyanobacteria), then proliferate unchecked (Potužák et al. 2007). Further, Tátrai et al. (1998) demonstrated that carp tend to avoid eating smaller zooplankton following a decline in cladoceran biomass; instead, they switch to intensive feeding on zoobenthos. Tátrai et al. (1997) were also able to show that the intensity at which zoobenthos (mainly chironomids and *Chaoborus*) are reduced by benthivorous feeding cyprinids (including carp) was significantly correlated with pond stock biomass. By digesting these benthic macroinvertebrates, carp also transfer nutrients from the benthic zone to the pelagic zone, thus enhancing internal nutrient loading (Andersson et al. 1988). Season, age and size (correlated with age) have all been shown to influence the composition of zooplankton and zoobenthos taken in the diet (Nieoczym and Kloskowski 2014). While

copepods and small bodied cladocerans tend to be least abundant in the presence of small carp (0+), for example, large cladoceran grazers appear to be most suppressed in ponds with medium sized fish  $(1+)$ . On the other hand, the density of small dipteran (mainly chironomid) larvae tends not to differ across fish sizes, though larger larvae are usually more abundant in ponds stocked with small carp, as larger carp  $(2+)$  are known to penetrate deeper into the substrate than smaller fish (Panek 1987).

Surprisingly, after summarising current knowledge on the impact of carp on aquatic ecosystems based on 129 laboratory and "natural" field experiments, Vilizzi et al. (2015) concluded that there was no clear evidence for a decrease in zooplankton. The majority of impacts on benthic invertebrates were negative (decreased abundance), however, both under laboratory and field conditions. An absence of any direct impact on zooplankton community structure was also noted by Lougheed et al. (1998), though total zooplankton biomass was reduced by increased turbidity and nutrient loading. Other studies have noted a positive (increased abundance) relationship between carp presence and zooplankton biomass (Parkos et al. 2003), and a negative relationship on macroinvertebrate abundance (Parkos et al. 2003), zoobenthos biomass (Wahl et al. 2011) and zoobenthos diversity (Wilcox and Hornbach 1991). This suggests that there is, as yet, no overall unifying pattern to the impacts of carp on the natural food community. In general, however, under extensive conditions, benthic foraging will tend to impact phytoplankton abundance and diversity through bottom-up processes, such as increased nutrient concentrations and turbidity, while zooplankton and benthic invertebrates will be affected by top-down processes, such as predation and reduced foraging efficiency (Weber and Brown 2009).

The impacts of carp on natural food populations will be somewhat different under semiintensive and intensive pond management, with quantitative and, especially, qualitative factors largely influenced through the addition of allochthonous foods and fertilisers that artificially raise productivity and extend the growing season. The impacts of modern semiintensive management techniques on the zooplankton and zoobenthos community are discussed in more detail below.

# **PRESENT POND MANAGEMENT PRACTICE AND PRODUCTION OF NATURAL FOOD**

In most parts of Central and Eastern Europe and Central Asia, carp are now farmed using a semi-intensive, three-stage polyculture approach. Briefly, following artificial spawning, larvae are grown on in special ponds that have previously been kept dry to remove pathogens, surviving fish and predatory insects. About 15-30 days are required for feeding larvae to grow into 'advanced fry', and a further 45-85 days to reach the 'fingerling' stage (FAO 2017a). In the past, pesticides/insecticides were usually added at this point to prevent development of crustaceans (cladocerans and copepods); thereby promoting development of rotifers, the preferred food of larval carp (Adámek et al. 2014). As use of pesticides has now been banned in most countries, rotifer development may be promoted by rapid inundation and immediate manuring. The addition of animal manure (or artificial fertiliser) ensures sufficient food (mainly phytoplankton) for the successful development of zooplankton, especially during the later stages of carp rearing (Li et al. 1996; Jana and Chakrabarti 1997; Kaur and Ansal 2010;

Füllner 2015). The addition of straw or hay bundles will further increase the numbers of small zooplankton such as ciliates, infusoria and rotifers. Liming may also take place at this stage to control water pH and disinfect the pond bottom (Füllner 2015). In most cases, the pond will have first been refilled gradually to around 50-60 cm. After stocking the larvae, the pond will then be fully filled over a further five to ten days. This also helps ensure a high initial concentration of rotifers. A number of studies have shown that the ideal sustainable zooplankton density at the point of larval stocking ranges from 8.5 to 40 rotifers  $ml^{-1}$ (Valdenberg et al. 2006) or 20 to 40 mg  $L^{-1}$  biomass (Li et al., 1996). After one summer, the fingerlings are stocked in growing or rearing ponds, with 25-50 gram fingerlings grown on to table size over a three-year cycle and 100 gram fingerlings over a two-year cycle (Füllner 2015). The size of table fish varies from country to country but generally varies between 1 and 3 kg. The two-step process tends to be more common, with fish stocked at a higher density in the first step and grown on to 0.25–0.50 kg, while in the second step the fish reach between 1–3 kg. Both steps last around 120–170 days (FAO 2017a). The rearing ponds will also have been kept dry prior to stocking, in order to improve substrate structure and remove pathogens and surviving fish, following which unwanted vegetation is removed and organic manure spread on the surface, adding essential mineral nutrients and carbon that are generally lacking in fish ponds. The most important of the minerals essential for fish pond primary production are nitrogen (N) and phosphorus (P). In general, the recommended total quantity of soluble N and P available in ponds should be around 100 to 200 kg/ha/season, with an ideal proportion of N to P of around 6:1 (Pócsi 1982; see also Figure 1). Over winter, the carp will be left in the rearing pond until they are harvested in spring, moved to special overwintering ponds or harvested in autumn and moved to a different rearing pond where they will be kept over the next season. Finally, carp ready for sale (usually at 3-4 years) may then be moved to storage ponds fed with clean water to ready them for the table.

Generally speaking, both fish and zooplankton production are improved when multiple fish species differing in feeding style (and other biological features) are farmed together in a balanced manner (polyculture). Not only are the natural food resources utilised more efficiently but intensive consumption can actually stimulate zooplankton production further (Rahman 2015). Furthermore, as monocultures utilise natural fish foods less effectively than polycultures, such systems also tend to be highly dependent on the addition of supplementary feeds (e.g., grain) and fertilisers, unless stocked at very low densities (Woynarovich et al. 2010; Rahman 2015). When planktivorous fish are kept together with common carp, for example, ponds generally require between 20 and 40% less fertiliser to maintain adequate natural food levels (Rahman 2015).

# **USE OF MANURE AND LIME FOR INCREASING NATURAL FOOD AVAILABILITY**

Farmyard manure, together with the bacteria that develop on its surface, serves as an ideal protein-rich food for zooplankton as they are able to consume the organic materials either directly or through a very short food chain. Spreading manure on the pond bottom prior to inundation can save time, manpower and costs. Manure will often be added to the pond after inundation, however, as well as through the production season, thereby ensuring a more

effective result. The manure is normally applied as a relatively large first treatment, followed by repeated smaller doses at regular intervals (e.g., daily, weekly, biweekly or monthly), thus ensuring that the pond ecosystem is not overloaded and all organisms are kept in an active production phase for as long as possible (Woynarovich 1963; Woynarovich et al. 2010). Growth of natural food resources can also be supported through the addition of inorganic fertilisers, which, while lacking carbon (essential for photosynthesis), provide essential minerals through an alternative route. One advantage of inorganic fertilisers is that the contents can be standardised, unlike farmyard manures whose contents vary depending on how the animals were kept. It should be noted here that the use of fertilisers and farmyard manures is now strictly limited in many countries due to eutrophication and algal blooms in ponds and receiving waterbodies caused by high nutrient loading and the proliferation of bacteria and pathogens (Kestemont 1995). As a result, supplementary feeding is now the main tool used for intensifying fish (and supporting zooplankton) production in most Central European countries.

The addition of lime is an important part of modern pond management. Prior to filling, lime helps disinfect the pond bottom and, after filling, helps stabilise ecological processes and control phytoplankton blooms. As most fish do best in water with a pH of between 7.0 and 8.5, for example, lime is usually added to raise the pond's pH (McLarney 1984). Lime also reduces extremes in daily pH fluctuations and supports chemical processes such as decomposition and mineralisation of organic materials (Ribianszky and Woynarovich 1962; McLarney 1984; Woynarovich et al. 2010).

Zooplankton enter the pond either externally, along with feed water (e.g., allochthonous), or internally, after hatching from viable resting eggs (ephippia) deposited in pond sediments. Many zooplankton are able to survive dry periods by forming resistant stages that remain in diapause in the sediment and hatch when conditions improve, e.g., when the pond is refilled with water (Hairston et al. 1995). Disturbance of the sediment, e.g., by carp feeding, can also promote zooplankton development by releasing ephippia, which hatch once they reach more suitable aerobic conditions in the surface layers (Hairston et al. 1995). Both temperature and light are also important factors affecting when zooplankton eggs hatch and when peak biomass of zooplankton becomes available (Li et al. 1996). To ensure optimal growth rate in carp, it is important that fish are stocked during the peak period of natural food abundance in the spring (Valdenberg et al. 2006; see Figure 2).

# **SUPPLEMENTARY FEEDING AND ITS IMPACT ON NATURAL FOOD UTILISATION**

Semi-intensive carp production is characterised by use of natural foods produced within the pond supplemented with additional feed that provides missing nutritional elements (e.g., dry matter, minerals, carbohydrates), prolongs the growing season, increases growth rate and increases yield-per-unit volume. In addition to their direct influence on fish growth (Billard 1999), supplemental feeds also benefit fish indirectly by providing nutrients that stimulate production of zooplankton and benthos (Hepher et al. 1989; Milstein 1999).

In general, as carp grow, use of supplementary feeds increases, with the result that carp often significantly reduce their intake of natural foods (Rahman et al. 2008b, 2010). As stated previously, however, most fish farmers now recognise the benefits of naturally produced food in carp diet and much effort is now spent on balancing the input of allochthonous and autochthonous food sources and on improving the formulation of such feeds. Most commercial feeds now aim to mimic the composition of natural food, for example, with around 25-50% protein (including essential amino acids), 10-15% carbohydrates and 12-15% lipids (Jirásek and Mareš 2001a,b). Generally speaking, fish farmers now aim to achieve around 70–75% of carp growth through consumption of natural foods such as zooplankton and zoobenthos, and around 25-30% from supplementary feeding with (mainly) raw whole cereals such as wheat or barley (Adámek et al. 2012). More protein-rich artificial feeds may be provided near the end of the production season, before winter sets in (Woynarovich et al. 2010; FAO 2017a).

In recent years, significant progress has been made in fish nutrition through the use of pelleted and extruded feeds, their higher digestibility resulting in a lower feed conversion ratio and a reduction in excessive nutrients released into the pond system (Hardy and Barrows 2000). Such feeds (especially pellets) have been shown to provide an increase in weight gain (Cirić et al. 2013, 2015), improve meat quality (Zivić et al. 2014) and increase the abundance of zooplankton (especially Cladocera and Copepoda) and benthic macroinvertebrates while lowering the abundance of cyanobacteria (Cirić et al. 2013 2015). Surprisingly, Hlaváč et al. (2015, 2016) observed no difference in zooplankton abundance between ponds with and without supplementary feeding or between different feed types, though they suggested this may have been due to increased turbidity from bottom-feeding adult carp inhibiting zooplankton ingestion of phytoplankton and masking any potential change. On the other hand, some studies have documented an effect on zooplankton composition when wheat, corn and barley are used as supplementary feed, with rotifers (e.g., *Keratella*), a species of no importance in adult carp diet, often coming to dominate the community (e.g., Adámek et al. 2004). While some copepods are known to predate on rotifers, *Keratella* sp. are resistant to such predation (Plassmann et al. 1997); hence, their dominance was most likely the result of high carp predation pressure on cladocerans, which are superior competitors than rotifers (Gilbert 1988; Christoffersen et al. 1993). According to Másílko (2014), the density, biomass and species diversity of zooplankton and zoobenthos were richer when carp were fed a mixture of mechanically treated and raw cereals.

In Central and Eastern Europe, supplementary feed is usually spread from a barge moving along a linear route, three to six days a week. The actual amount of food delivered will vary depending on water temperature and oxygen concentration, fish size and periodic analysis of zooplankton quality and quantity accompanied by *in vivo* evaluation of carp gut content (Faina 1983; Adámek et al. 2014). In late summer and autumn, as food requirements increase and availability of natural food begins to decline (see Figure 2), the amount of supplementary food provided will increase and may be spread over a wider area (FAO 2017a). While supplementary feeding has been in use for some time now, there is a surprising lack of information available on how carp actually respond to this feeding style. Anecdotal information, for example, suggests that carp quickly learn where food is easily available (e.g., at repeatedly used supplemental feeding sites) and reduce their ranges accordingly. Two recent studies (Adámek et al. 2016; Jurajda et al. 2016) have confirmed that concentrated and repeated supplementary feeding at one main site does indeed result in heavy aggregations of carp.

general pattern of activity was very similar across fish, with carp utilising the whole pond area (regardless of size or age) but with the greatest proportion of readings for almost all fish centred on the supplementary feeding area during the feeding period (Figure 3). Those fish excluded from such sites (e.g., through poorer competitive ability) relied more heavily on natural foods and, as a result, showed lowered growth rates and fat content, resulting in poorer individual 'quality' and uneven stock size composition (Jurajda et al. 2016). There was also an increased likelihood of water quality issues near the feeding area as turbidity was increased through heavy bottom stirring and overcrowding, potentially leading to eutrophication, pH and oxygen peaks/troughs and reduced photosynthesis. Feeding sites also showed significantly lower dissolved oxygen values, which dropped below the physiological optimum for carp  $(3 \text{ mgl}^{-1} \text{ O}_2)$  on hot summer days shortly after feed application (Adámek et al. 2016).

Figure 3. Concentration of carp activity (telemetry with kernel analysis; 10 carp; numbers in parentheses represent positive readings; dark areas represent concentrated activity) in a Czech semi-intensively managed pond. The dashed line indicates the main supplementary feeding route. Note there was no supplementary feeding in winter; all winter readings are from deeper water under the outlet (adapted from Jurajda et al. 2016).

Overall, zooplankton appeared to be underutilised, with biovolume varying only slightly between feeding and non-feeding sites. Macrozoobenthos density and biomass, on the other hand, were significantly lower at feeding sites; presumably as carp concentrating at such sites

were ingesting cereal and macrozoobenthos from the bottom without distinguishing between them. The only exception to this pattern was in June, when there was no significant difference between feeding and non-feeding sites due to a considerable increase in chironomid numbers prior to emergence (Matěna 1990). In general, carp activity was more concentrated at the feeding area in spring and more evenly spread over the pond in summer and autumn, when feed tended to be spread more widely (Adámek et al. 2016; FAO 2017a).

Diet analysis showed that grain represented between 69 and 99% of ingested food at the feeding sites, with no grain found in fish from the non-feeding sites. Interestingly, a similar trend was observed after four days with no supplemental feeding (September), with grain still making up 36% of the diet in carp collected close to feeding sites and no grain found in fish at non-feeding sites, suggest that there was still an excess of grain available to carp. Natural food, represented mainly by zooplankton, always made up a greater proportion of the diet at non-feeding sites (61–53%) during those periods when supplemental food was being supplied, though fish at the feeding sites still included between 11 and 29% zooplankton in the diet. In general, fish at the non-feeding sites also had a wider diet (e.g., benthos, etc.), bringing the proportion of natural foods up to 57–82% overall at non-feeding sites. When grain was spread more evenly (summer/autumn), however, zooplankton consumption dropped dramatically at both feeding and non-feeding sites, not exceeding 0.5% by proportion in either area. After a period of no supplemental feeding, the proportion of zooplankton remained relatively stable at non-feeding sites but rose considerably at feeding sites (up to 29%). During the summer and autumn, grain comprised around 93% of the diet at both feeding and non-feeding sites, indicating a clear preference for grain over natural foods when available and when competitive exclusion was reduced (Adámek et al. 2016; Jurajda et al. 2016; Table 4).

#### **Table 4. Diet composition of carp sampled by electrofishing from supplemental and natural feeding areas in a Czech semi-intensive fishpond. SFA = supplemental feeding area, NFA = natural feeding area (Table adapted from Adámek et al. 2016)**

While the two studies reported above (Adámek et al. 2016; Jurajda et al. 2016) examined a series of semi-intensive ponds in the Czech Republic, the dietary patterns and impacts reported are likely to be common to all carp ponds managed in a similar manner elsewhere. In general, these studies showed that concentrated and repeated supplementary feeding with grain or artificial feed in one small area results in aggregations of carp, potentially leading to uneven population growth, body condition and flesh quality, uneven utilisation of natural food resources and reduced water quality from turbidity, increased nutrient input and localised reductions in dissolved oxygen.

As the financial sustainability of fish farming depends mainly on market prices and production efficiency (Bosma and Verdegem 2011), future sustainability requires a reduction in costs, along with an increase in production intensity and efficiency, without harming the aquatic environment. Up until now, it has generally been assumed that up to 75% of carp growth under semi-intensive conditions is provided by natural food items (Adámek et al. 2012), and carp farmers have tended to base their management decisions on such figures. The studies outlined above, however, indicate that this is not necessarily true, at least not for all carp in the pond. As a means of ensuring the future sustainability of carp pond farming, therefore, Adámek et al. (2016) and Jurajda et al. (2016) suggested that both water quality and carp quality could be improved by spreading less supplemental feed over a greater area at wider time intervals. This would ensure full utilisation of supplementary feed (reducing economic costs and increasing water quality) and a more homogenous spread of fish over the pond, thereby ensuring more efficient use of natural food (further reducing the amount of supplemental feed needed), reduced turbidity from concentrated feeding (further improving water quality) and more homogenous size/weight distribution and improved meat quality.

#### **ACKNOWLEDGMENTS**

The study was financially supported by the Ministry of Education, Youth and Sports of the Czech Republic through projects CENAKVA (CZ.1.05/2.1.00/ 01.0024), CENAKVA II (LO1205 under the NPU I program) and OP Fisheries Project No. CZ 1.25/3.4.00/13.00451.

### **ABSTRACT**

Common carp (*Cyprinus carpio* L.) aquaculture is performed almost exclusively in earth ponds to benefit from the natural resources for fish growth and development. Since zooplankton organisms are important

components in these freshwater aquatic habitats, the aim of this chapter is to present a review about the relevance of zooplankton and its interactions with cultured carp and the carp pond environment. Zooplankton constitute one of the major protein sources in carp diet with varying importance depending on the availability (density, biomass, composition and size structure), fish age, season and environmental variables. On the other hand, as carp are size-selective predators, they can strongly modify composition and structure of zooplankton communities, impeding the presence of vulnerable taxa which leads to increasing abundance of zooplankton taxa that can avoid predation. The strength of the predation pressure is also related to pond management measures, depending on parameters such as fish density, supplementary feeding or fertilization (manuring). In addition, zooplankton community dynamics vary along the whole growing season as a result of carp body size and total biomass increase. Zooplankton and its resting stages may also be affected by bioturbation caused by carp searching for benthic food organisms in pond sediments. Finally, the position of zooplankton organisms in intermediate levels of pond food chain predestines them to act as good indicators of water

quality, especially with respect to eutrophication processes that are becoming steadily more common in carp ponds.

**Keywords**: common carp, stocking density, copepods, cladocerans, freshwater habitats, natural resources, supplementary feeding, water quality

#### **INTRODUCTION**

Common carp (*Cyprinus carpio* L.) aquaculture is performed almost exclusively in earth ponds to benefit from the natural resources for fish growth and development (Figure 1). It is a traditional aquaculture widely extended in Central and Eastern Europe and Asia.

Zooplankton are important inhabitants of carp ponds. They play a key role in aquatic ecosystems, holding the central position between primary producers and higher trophic levels. They have an essential function in transferring carbon and energy from phytoplankton to fish, contributing to the recycling of nutrients through food chains in freshwater and marine water bodies (Attayde and Hansson 1999; Harris et al. 2000). Due to a high dispersal capacity, through wind, rain, birds and even reaching long distances (e.g., 1000 km) through humans (Bilton et al. 2001; De Meester et al. 2002), zooplankton can readily colonize a wide variety of habitats. Therefore, zooplankton communities are found in most freshwater bodies, ranging in size, productivity, type of fish community and geographical location (Dodson 1992; Hessen et al. 2006).

Compared to marine populations, freshwater zooplankton is less diverse in terms of phylogeny. Freshwater zooplankton comprises organisms with limited swimming ability and ranging from 0.2 to 2 mm (meso-zooplankton; Harris et al. 2000). The main taxa included are from the phyllum Rotifera, and the sub-phyllum Crustacea (sub-class Copepoda and infraorder Cladocera). Most species are filter-feeders, feeding on small algae, bacteria and detritus, but some copepods are either selective feeders, selecting small algae or bacteria, or predators, preying upon small rotifers and cladocerans, or even other copepod species (Fryer 1957b). Cladocerans and rotifers reproduce through cyclical parthenogenesis (Gliwicz 2004): after a period of propagation through parthenogenesis, a type of successful asexual reproduction mode (Decaestecker et al. 2009), they can reproduce sexually when females produce fertilized eggs (Harris et al. 2000). This allows these species to reach high-density values in a short time through parthenogenesis; but also to restore genetic variation through sexual reproduction (De Meester et al. 2006). On the contrary, copepods only have sexual reproduction (Gyllström and Hansson 2004). During their life cycle, many species of zooplankton have a period of diapause, or a state of dormancy by producing dormant stages that provide survival when unfavorable external conditions arise, e.g., drought, low temperature and oxygen, predation, food limitation etc. (Brendonck and De Meester 2003). In fish ponds, which are usually dried for longer periods, this diapause period is especially relevant, since it will allow the rapid colonization of the pond once it is filled again the next growing season. Apart from this autochthonous source of zooplankton, most of the ponds are filled with water coming from other ponds or other water sources, with the subsequent associated organisms (allochthonous source). The combination of these two sources of zooplankton populations results in the rapid development of zooplankton assemblages in carp ponds, and influences the abundance, biomass and zooplankton species composition. Thus, it
is recommended to monitor inlet water variables to ensure that it has the appropriate parameters for zooplankton development, since certain conditions, such as high conductivity and low hardness that can arise in water coming from deep tube wells, can result in a significant decrease in the size of the zooplankton community (Dulić et al. 2014).

Figure 1. Pictures of a variety of carp ponds: a) pond Belo jezero at Ečka fish farm, Serbia (photo by Z. Dulić) b) pond Horak in Třebon, Czech Republic (photo by M. Anton-Pardo); c) Experimental carp pond at faculty of Agriculture School Estate, University of Belgrade (photo by Z. Dulić); d) Secchi disk measuring water transparency in a carp pond at faculty of Agriculture School Estate, University of Belgrade (photo by Z. Dulić).

The aim of this chapter is to provide a review about the ecology of zooplankton in common carp ponds. Firstly, the interaction of zooplankton with carp stock will be reported, highlighting the importance of zooplankton as natural food for carp growth, but also how carp stock and pond management influence zooplankton ecology. Other interactions such as predation of copepods upon carp fry or parasitic interactions will be also described. Secondly, the interaction of zooplankton with the environment in carp ponds will be reviewed: how zooplankton can modify the ecosystem variables, and how the variation in environmental variables affects them.

## **INTERACTIONS ZOOPLANKTON-CARP**

### **Zooplankton as Food for Carp**

Common carp is considered omnivorous, with a high proportion of animal food in its diet (Michel and Oberdorff 1975). Many studies point out that adult carp feed on benthic organisms, mainly chironomids (Michel and Oberdorff 1975; Rahman 2008a), but at different life stages, zooplankton of different size may be an important part of the diet of carp, depending on their availability in a given fish pond (Adámek et al. 2003; Rahman et al. 2006; Kloskowski 2011; Anton-Pardo et al. 2014).

In carp larvae, the yolk sac consumption period is relatively short (3-5 days), so the beginning of feeding on external sources of nutrients is much earlier compared to other fish species. This is usually related to the diameter of fish eggs, so larger eggs determine a bigger and longer lasting yolk sac that provides fish larvae with endogenous nutrients up to three weeks after hatching (Lavens and Sergeoloos 1996). Additionally, the dimension of the eggs also reflects the mouth gape size at first feeding of larvae. As in most teleost fish, common carp larvae are quite small (around 5 mm in length after hatching; Jones and Houde 1981), and have a small mouth gape  $(0.3 - 0.4 \text{ mm})$ ; Dabrowski et al. 1983) preventing them from ingesting large prey. Thus, they can feed only on the smallest zooplankton organisms, such as rotifers and copepod nauplii (Nunn et al. 2012). The development of the gill rakers (size and interraker spaces) is usually related to the increase of the mouth gape, so they gradually modify the retention of prey of certain size. The gill raker slits in early carp larvae are less than 0.21 mm, while in older carp they are at a minimum of around 0.78 mm (Dabrowski and Bardega 1984). This increased gill raker-slit size enables adult carp to retain zooplankton organisms such as large cladocerans, with body size length around 0.500 mm, mainly *Daphnia* species, while smaller forms pass through the raker slits (Dabrowski and Bardega 1984).

Different authors (Osse et al. 1997; Vilizzi and Walker 1999 and references therein; Nunn et al. 2007) investigated the onset of carp feeding on bottom fauna and reported ranges from 8 to 25 mm total body length. This shift in feeding preference is significantly related to changes in the position of the mouth from terminal in larvae to downwardly projected in older carp (Vilizzi 1998). This is also understood to be a transitional period from larval to juvenile carp. However, the preference towards different prey in carp juveniles and adults depends largely on their availability in the environment and other variables, such as the use of different microhabitats for feeding or physiological changes (Nunn et al. 2012; Anton-Pardo et al. 2014). For instance, in new fish ponds with poorly developed sediment, zoobenthos is scarcely present, thereby carp feed mainly on microcrustaceans (Dulić et al. 2011).

Regarding nutritional content, for early larvae of *Cyprinus carpio*, which are characterized by an underdeveloped digestive system, zooplankton play an important role as a source of exogenous enzymes, improving the digestion of complex molecules in larval gut (Delbare and Dhert 1996; Kolkovski 2001). Several authors (Dabrowski and Glogowski 1977; Lauff and Hofer 1984; Pedersen et al. 1987; Munilla-Moran et al. 1990) investigated digestion processes in larvae of different fish species and found between 40 and 80% of enzymatic activity was provided by live food organisms. Additionally, zooplankton organisms have gut neuropeptides and nutritional 'growth' factors, which also improve fish digestion (Kolkovski 2001).

Zooplankton is also a valuable source of amino acids, especially for early life stages of common carp, but it is also a significant provider of highly unsaturated fatty acids (HUFA) that are pivotal for the survival and growth of larvae (Olsen 1999; Sargent et al. 1999; Brett et al. 2009; Anton-Pardo and Adamek 2015). Some authors reported that the essential and nonessential amino acid content of zooplankton can meet the general requirements of farmed fish (Delbare and Dhert 1996; Kibria et al. 1999; Ovie and Ovie 2006; Mitra et al. 2007). Mitra et al. (2007) found that methionine was only slightly lower in mixed zooplankton from earth carp ponds compared to the amino acid requirements of common carp (NRC 1993). Furthermore, since amino acid content is species specific (Guisande 2006), and, generally, not influenced by food (Mitra et al. 2007), feeding on a greater variety of zooplankton species could provide a more balanced protein nourishment for fish in ponds.

In contrast to amino acids, lipid content in zooplankton and fish reflects the lipid profile of their diet (Sekino et al. 1997; Steffens and Wirth 2007; Bauer and Schlott 2009; Burns et al. 2011). For zooplankton, the accumulation of highly unsaturated fatty acids is strongly influenced by both, the quality of phytoplankton ingested and the taxonomic group. Several studies have found that cladocerans are rich in eicosapentaenoic acid (EPA) and arachidonic acid (ARA), while copepods have a higher content of docosahexaenoic acid (DHA) (Persson and Vrede 2006; Smyntek et al. 2008; Burns et al. 2011). Additionally, both zooplankton groups accumulate a similar level of  $\alpha$ -linolenic acid (ALA; Smyntek et al. 2008; Kainz et al. 2009) which is significant for carp nutrition since they can convert ALA to n-3 HUFA's (Tocher 2003). Trbović et al. (2017) reported that at the end of the growing season in earth ponds, when zooplankton increased its proportion in the feed bulk, there was a strong positive influence on the level of n-3 HUFA in the dorsal muscle of farmed carp. Thus, even a small increase in natural food availability compared to supplemental feed can significantly result in improved carp meat quality.

### **Influence of Pond Management on Zooplankton Ecology**

### *Fish Stock Density and Biomass*

The density and composition of fish stock is a crucial factor influencing the quantitative and, especially, the qualitative composition of zooplankton assemblages in aquatic environments (Jepessen et al. 2011), including carp ponds. Composition of the pond zooplankton community is highly influenced by fish predation pressure, affecting not only its biomass (Figure 2), but also the density and species composition (Figure 3). At the beginning of the growing season when carp food intake is limited by water temperature, larger species of cladocerans, such as Daphnia magna, D. pulicaria or *Simocephalus vetulus*, are abundant (Potužák 2009). Cladocerans of the genus Daphnia are exceptionally efficient in reducing food resources (phytoplankton and bacterioplankton) and out-competing smaller zooplankton species (Brooks and Dodson 1965). Generally, adult common carp reduce the abundance of large-bodied zooplankton either directly (Lewkowicz and Zurek 1991; Rahman et al. 2006) or indirectly through increased nutrient load and increased turbidity which inhibits phytoplankton development and its ingestion by filter-feeders (Lougheed 1997). In contrast, smaller planktivorous carp commonly reduce large-bodied zooplankton density directly

through predation (Chumchal et al. 2005; Weber and Brown 2009; Carey and Wahl 2010). Fott et al. (1980) documented the changes in the development of zooplankton assemblages in a carp pond during two years. The first year, though the carp stock was abundant (800 – 1000 individuals ha-1), its biomass was low  $\sim$  100 kg ha-1) and large daphniids prevailed. In the second year, carp stock density declined due to natural mortality (associated with winter temperatures), but its biomass was higher due to growth. As a consequence, the strong predation pressure led to the elimination of large crustaceans and its replacement by smaller zooplankton taxa (*Daphnia galeata*, *Ceriodaphnia spp.*, *Bosmina spp.*, Copepoda and Rotifera). Exceptionally, Parkos et al. (2003) recorded higher values of zooplankton biomass in experimental enclosures with carp compared to fishless control. However, the carp used for the experiments were between 2 and 2.5 kg, and thus too big to provide effective top-down control of zooplankton development.

Figure 2. Main features of development of a pond ecosystem with high (a) and low (b) fish stock predation pressure (Adámek et al. 2014). Note: small zooplankton < 2 mm; large zooplankton –  $cladocerans > 2 mm$ ).

The crucial role of common carp in pond ecosystem functioning was proved by experimental three-year exclusion of carp from a hypertrophic pond (Pechar et al. 2017). In general, common carp exclusion resulted in the dominance of large filtering zooplankton (genus Daphnia) keeping the pond ecosystem in a "clear water" state. In the second growing season, a rapid onset of submerged macrophytes (mainly *Ceratophyllum demersum*) was observed. However, pond stability was threatened by oxygen deficiencies, and especially, by the invasion of the omnivorous r-strategist topmouth gudgeon (*Pseudorasbora parva*), which led to zooplankton disappearance, cyanobacterial blooms of *Anabaena sp.*, and macrophytes disappearance. The experiment clearly demonstrated how vulnerable the carp pond ecosystem can be, if stocking is not appropriately managed.

However, in lower trophic states, which are generally very rare in carp ponds, the response of zooplankton community to fish density is quite different, as shown by Christoffersen et al. (1993). In fishless enclosures, total zooplankton density was significantly higher, except for rotifer density, which was lower, probably as a combined effect of mechanical interference with Daphnia and food competition (Gilbert 1988), but also as a result of copepod predation (Plassman et al. 1997). In contrast, cyanobacteria (Microcystis, Aphanizomenon and Anabaena species) bloomed in enclosures with fish.

Increased biomass of planktonic cyanobacteria is often a consequence of increased fish predation pressure on cladocerans, impacting nutrient concentrations and zooplankton food resources ("edible" phytoplankton) and food selectivity (Gragnani et al. 1999; Gasiunaite and Olenina 1998). Cyanobacterial water blooms, however, may enter also into the carp pond trophic chains with negative impacts on zooplankters, such as cladocerans, as shown by Hietala et al. (1997), Lauren-Maatta et al. (1997) or Claska and Gilbert (1998). Nevertheless, Nandini and Rao (1998) have demonstrated the tolerance of cladocerans to high Microcystis biomass resulting from genetically increased resistance to cyanotoxins and increased digestibility of Microcystis.

Despite all these documented results, a review of 119 studies by Vilizzi et al. (2015) revealed inconsistent evidence for impacts of carp on zooplankton, showing the high variability on zooplankton dynamics in particular.

Figure 3. Relationship between percentage representation of Daphnia pulicaria in zooplankton and a stock biomass in a carp pond (adapted from Potužák, 2009).

As the changes in zooplankton community structure and biomass invoked by carp grazing pressure are very relevant, the analyses of zooplankton quality and quantity is necessary for the implementation of appropriate management steps in supplementary feeding on carp pond. The in vivo evaluation of carp gut content is often used for the support of proper subsequent decision (Faina 1983).

Increased ingestion of zooplankton by carp can also be associated with limited benthic food resources, since carp have been shown to shift their feeding niche from the bottom to the water column and feed principally on zooplankton in the absence of benthic macroinvertebrates (Rahman et al. 2010).

In general for zooplankton diversity, the highest values are found in ponds with a low to medium level of intensification (Přikryl 1996). In such ponds, sufficient extent of aquatic vegetation is often maintained and there is also a sufficient food on offer for filtering zooplankton. Due to high species richness and diversity of littoral zooplankton, reflecting the development and extent of submersed and emerged vegetation, community structure in littoral areas is often a better indicator of the biological value of a pond than the structure of pelagic zooplankton.

To summarize the available knowledge about common carp–zooplankton interactions, it is evident that the response of pond zooplankton assemblages is essentially influenced by carp density. This is seemingly in a certain contradiction with the conclusions of Vilizzi (2015); however, his conclusions (see above) have been acquired by the analysis of the results from both natural (mostly) and pond farming conditions. Thus, the effect of carp stock is poor and unpredictable under natural conditions and low stocking densities, while strong and apparent effects are noticeable under pond farming conditions (e.g., Potužak et al. 2007, Potužak 2009).

### *Supplementary Feeding*

Although basic fish nutrition in earth ponds remains based on natural food resources, supplementary feeding is also commonly provided, with the aim of supplementing nourishment to farmed fish. The density of carp stock can be doubled if supplementary feed is provided (Rahman 2015). Regular supplementary feeding in designated feeding places often reduces feeding activities of carp, so they concentrate on feeding places, which reduces the use of natural food resources including zooplankton, across the entire area of the pond (Adámek et al. 2014, 2016; Jurajda et al. 2015). Several studies confirmed that the sufficient amount of artificial feed in pond environment shifts the feeding behavior of carp (Rahman et al. 2006, 2008b, 2010) reducing the predation pressure on the biggest zooplankton. A recent study by Ćirić et al. (2015) reported a significant increase in the abundance of large-sized cladocerans and a decrease in the density of phytoplankton in ponds receiving high protein pelleted feed stocked with intermediate densities of common carp. However, the trend towards the intensification of semi-intensive carp production through favoring supplementary feeding regimes have negative implication on the exploitation of natural food - zooplankton by older carp (Anton-Pardo and Adámek 2015).

From the hydrobiological point of view, supplementary feeding also represents a certain nutrient loading to the pond ecosystem (mainly phosphorus to consider the needs of the carp individuals; Figure 4, Adámek et al. 1997). Therefore, zooplankton abundance may be also increased by nutrient input leading to a rise in phytoplankton growth (Moriarty 1997; Milstein et al. 2002). It is not clear, however, whether this impact is stronger than the effects of fish predation on zooplankton (Schindler 1992; Khan et al. 2003). Hlaváč et al. (2016) reported that the addition of nutrients through supplementary feeding may stimulate algal growth, though this response may have been masked by high zooplankton predation pressure or by increasing turbidity caused by carp benthic feeding.

### *Fertilization*

The objective of pond fertilization is to supply macro- and micro-nutrients necessary for natural primary production, and thus, increase invertebrate development. Strong influence of artificial fertilization on zooplankton in ponds may, however, confound cascade effects (Havens 1993; Khan et al. 2003). As a result, the undesirable high trophic level is manifested mainly in the summer period when cyanobacteria often dominate phytoplankton. This results in instability and low efficiency of productive processes due to poor transfer of nutrients and energy in pond food chain, since cyanobacteria dominance represents a source of primary production which cannot be effectively used in higher trophic levels. As a consequence of inappropriate phytoplankton food resources on one side, and heavy predation pressure by fish on large species on the other side, zooplankton usually have an unsuitable structure (dominated by small species) as carp food. Nutrient input can also benefit the so-called microbial loop, since organic substances produced in the system are decomposed by bacteria, which are consumed by live heterotrophic flagellates and ciliates consumable by large cladocerans. Nevertheless, it causes a considerable increase in overall heterotrophic activity and risks of oxygen deficits (Pechar et al. 2002; Adámek et al. 2014).

### **Zooplankton Succession in Carp Ponds**

The successional patterns of zooplankton populations in different habitats are influenced by a combination of abiotic (temperature, oxygen concentration, nutrients etc.) and biotic factors (competition and predation; Sommer 1989). In artificial water bodies with a considerable level of management, such as earth carp ponds, zooplankton community is shaped by several factors such as stocking density, age of carp, water quality, pond management and supplementary feeding (Sommer et al. 1986).

As size-selective predators, carp significantly modify zooplankton communities in these habitats. The most vulnerable taxa to predation are large cladocerans such as individuals of the genera *Daphnia* or *Simocephalus*, that are more conspicuous, especially females carrying eggs (Gliwicz 1994; Gliwicz 2004) or those with ephippia (cladoceran resting eggs) due to the intense pigmentation (Lazzaro 1997). These larger taxa develop at the beginning of the growing season, when water temperatures are still low and predation pressure by carp is not high. When temperature rises, a rapid depletion of large herbivorous cladocerans in nursery and on-growing ponds (for one- and two-year-old carp, respectively) releases the competition for zooplankton food resources (phytoplankton), leading to the domination of small-sized

cladocerans, e.g., *Bosmina* (Figure 5a), *Ceriodaphnia*, and *Daphnia longispina* and *D. galeata*, a variety of rotifers, small cyclopoid copepods and their larval stages -nauplii and copepodites- in particular (Figure 5b). The eutrophic conditions in carp ponds favor the midsummer shift towards blooms of large and inedible phytoplankton, mostly cyanobacteria, and unstable levels of oxygen concentration and pH (Potužak et al. 2007).

With knowledge of size and species composition of zooplankton community, it is thus easy to estimate fish stock density, its health status and/or composition. So occurrence of large planktonic filtrators (*Daphnia magna*, *D. pulicaria*, *D. pulex*, *D. longispina*), together with high water transparency, indicates weak predation pressure by carp stock due to low biomass, high mortality, incidence of diseases, or poor environmental conditions. On the other hand, it is possible to predict a high stock biomass or mass occurrence of small cyprinid fish, from great occurrence of small zooplankton (nauplii, small cladocerans and rotifers) together with low water transparency, which it usually occurs in ponds at the end of the growing season (Potužák 2007; Adámek et al. 2014).

Figure 5. Regression between fish stock biomass and the percentage of the cladoceran *Bosmina longirostris* (a) and copepod nauplii (b) (Potužák, 2009).

In carp nursery ponds, natural succession of zooplankton is usually manipulated in order to achieve the desirable development with regard to their size and density. The early larvae are vulnerable to predators and diseases present in the pond environment (Section 2.4). Additionally, small carp larvae can ingest only the smallest zooplankton organisms, such as rotifers, at the beginning of feeding. Different pond management practices as fertilization and specific zooplankton inoculation are used to couple fry feeding needs and zooplankton size (Ludwig 1999; Morris and Mischke 1999). The right timing between the larval developmental stages and zooplankton of matching size is crucial for the success of the rearing process (Valdenberg et al. 2006; Antón-Pardo and Adámek 2015). The best results, in terms of good larval growth and development, are obtained by the gradual succession of zooplankton starting with rotifers and copepod nauplii, followed by small cladocerans and copepods, and larger cladocerans, mainly daphnids, thereafter. A carefully monitored fertilization regime will provide enough nutrients for phytoplankton development and it will increase zooplankton densities (Jana and Chakrabarti 1997; Kaur and Ansal 2010). However, the abundance and composition of zooplankton emerging from both pond sources, internal (dormant stages in the

sediment) and external (water input), during the pond inundation cycle (filling of the ponds with water), are quite unpredictable. A common practice among fish farmers, to ensure a large production of rotifers in nursery ponds and the elimination or reduction of crustacean competitors for food resources (cladocerans and copepods) and potential predators of carp larvae, is the application of agricultural insecticides a week before stocking the larvae (Woynarovich et al. 2010). However, application of pesticides and other chemicals should follow the regulations for each country and it should be applied in the correct dosages and time, to avoid undesirable side-effects upon non-target aquatic organisms. Specific zooplankton inoculation or reseeding can also be applied if the density of required zooplankton is not obtained by the above-mentioned measures (Billard 1999).

## **Other Interactions**

### *Predation of Copepods on Carp Juveniles*

One of the negative effects of zooplankton on common carp populations is represented by predation on fish larvae. Many studies point out the predatory behavior of adult copepods belonging to certain genera, such as *Eudiaptomus*, *Mesocyclops*, *Acanthocyclops*, *Cyclops* or *Diacyclops* (Fryer 1957a; Brandl 2005). These are widespread genera commonly found in freshwaters, and specifically, in carp ponds (Dulić et al. 2009; Adámek et al. 2014). A few number of studies report predation of copepods upon age-0 fish of several species (Hartig and Jude 1984; Cooper 1996; Brandl 1998; Fregadolli 2003), with copepods attacking prey much larger than the attacker itself (up to 15 times larger; Cooper 1996). The damage caused to the fish is more significant when copepod densities are high (Fabian 1960; Frimpong and Lochmann 2005). In addition, copepod attacks are a factor of stress for fish fry, which can negatively affect larval growth (Fregadolli 2003). This could be one of the causes of serious mortality in fish early stages, since in experimental studies, a mortality of fry caused by copepods between 25 and 50% has been found (Fabian 1960; Brandl 1998; Fregadolli 2003).

Regarding common carp, there are just a few studies reporting copepod predation on larvae. In an experiment with the cyclopoid copepod *Acanthocyclops robustus* and 10 individuals of 1-day-old common carp, an average of 2.2 individuals were dead in 5 days (Piasecki 2000). This same study reports that cyclopoids were able to prey upon larvae up to six days. Additionally, the presence of alternative preys influenced the larval mortality: in the presence of *Daphnia magna* and rotifers, the predation effect on carp larvae was lower (average reduction of 1.7 larvae in 5 days; Piasecki 2000). Therefore, predatory copepods may strongly affect the survival of cultured common carp, especially in spawning and nursery ponds, despite that the density of rotifer and small cladoceran (as alternative prey) could be high in these ponds.

Management strategies to avoid high copepod predation rates on small carp larvae include the pond bottom drying, disking and liming; monitoring the species composition and abundance of zooplankton in the input water; and stocking of fish prior to the development of large zooplankton populations [\(Fregadolli 2003;](#page-1750-0) [Piasecki et al. 2004\)](#page-3886-0).

#### *Zooplankton as Parasites and Disease Vector*

Freshwater copepod species of the genus *Lernaea*, *Lamproglena* (Lernaeidae, Cyclopida) and the families Lernaeopodidae (Siphonosto-matoida) and Ergasilidae (Poecilostomatoida) are known fish ectoparasites, and some of these species can be found in common carp (Hudson and Bowen 2002; Piasecki et al. 2004; Gutiérrez-Galindo and Lacasa-Millán 2005; Boane et al. 2008; Davydov et al. 2011). Parasitic cyclopoids show modifications of the second antennae to facilitate the attachment on fish gills, skin and/or fins (Tedla and Fernando 1969).

Lernaeid copepods are cosmopolitan and they occur in all the continents (Piasecki et al. 2004). They are common ectoparasites, which cause lethargy, but they can also penetrate into fish tissues, resulting in heavy mortality and morbidity, especially in young fish, with subsequent economic losses [\(Hemaprasanth et al. 2008\)](#page-1751-0). The occurrence of these parasites can be high in common carp in different parts of the world [\(Gutierrez-Galindo and Lacasa-](#page-1751-1)[Millan 2005;](#page-1751-1) [Davydov et al. 2011\)](#page-1474-0). Nevertheless, Hemaprasanth et al. [\(2011\)](#page-1751-2) studied the susceptibility of common carp fingerlings to this parasite and they concluded that in monoculture, they were completely resistant, while in polyculture, all the individuals were infected. However, 25-35 days post infection parasites started to disintegrate and the fish were completely recovered.

Some copepods can also act as intermediate hosts of fish parasites, which penetrate into fish organisms via their food [\(Cooper 1996,](#page-1474-1) Piasecki et al. 2004). However, the infection rate is usually very low: between 0.01 and 1.0% [\(Marcogliese 1995\)](#page-3885-0). On the contrary, cladocerans rarely are intermediate host for parasites [\(Marcogliese 1995\)](#page-3885-0).

Some of the parasite taxa using copepods (Cyclopidae and Diaptomidae) as intermediate hosts, can cause strong damage in common carp, such as the tapeworm of the genus *Bothriocephalus*, which can cause an inflammation of digestive tract, a reduction in feeding rates and growth, and even mortality in carps (e.g., Brandt et al. 1981). Other examples are the tapeworm *Ligula intestinalis* and the nematode species which cause philometrosis (*Philometra* spp. and *Philometroides* spp.[; Piasecki et al. 2004;](#page-3886-0) [Moravec and Cervinka 2005\)](#page-3885-1)

Finally, possible negative impacts of zooplankton may also include the transmission of viral diseases to fish, although studies on this subject are scarce [\(Overstreet et al. 2009\)](#page-3886-1), and to our knowledge, absent in common carp.

# **INTERACTIONS ZOOPLANKTON-ENVIRONMENT**

### **Impact of Zooplankton on Pond Ecosystem Health**

Zooplankton can themselves modify the environmental conditions in the ponds, which can then lead to negative effects on carp growth. These effects would be detrimental when zooplankton density is extremely high, so their impacts are amplified.

For example, oxygen consumption by zooplankton increases at higher temperatures and with organism sizes (Blazka et al. 1982). The oxygen availability also decreases in eutrophic waters, which is the case for many carp ponds (Lampert and Sommer 2007). These facts, together with lower solubility of oxygen at higher temperatures and increased oxygen

consumption in high fish densities, could have consequences in oxygen availability in fish ponds, especially in the summer months (Blazka et al. 1982).

The excretion of nutrients by zooplankton can also modify the nutrient balance in fish ponds (Andersson et al. 1998). Ammonium and phosphorus excretion is positively correlated with temperature and negatively with body weight (Ejsmont-Karabin 1983; Gulati et al. 1989). In the case of fish ponds, the contribution to nutrient regeneration by zooplankton can be considerable, especially with high temperatures and when the community is dominated by small size organisms (Gulati et al. 1989). However, an excess in ammonium excretion could result in toxicity to common carp fry and adults, especially when pH is high, so the concentration of toxic ammonia (NH3) increases. Despite this, common carp does not seem to be highly sensitive to this pollutant and it has physiological mechanisms to avoid its toxicity (Hasan and Macintosh 1986; Liew et al. 2013).

### **Zooplankton Organisms and Pond Water Quality**

As ecosystem engineers, carp can widely modify the environmental characteristics of the aquatic habitats where they live (Matsuzaki et al. 2009). The strength of this influence depends on fish density and biomass (carp biomass above 50 kg ha-1 can produce impacts on water quality; Parkos et al. 2003; Mehner et al. 2004), but also on fish age, since carp larvae and fry are planktivorous organisms with a minor effect on nutrient concentration (Weber and Brown 2009). Bioturbation (Section 3.3) and carp excretion are other activities that release a considerable amount of nutrients, sediment, detritus and other organic matter to the water column. The increase in nutrients and the rise of chlorophyll concentration leads many carp ponds to eutrophic and hypertrophic states (Roozen et al. 2007; Rahman et al. 2008c; Matsuzaki et al. 2009).

Figure 6. Relationship between the *Daphnia* index and chlorophyll concentration (A) and transparency (B) (from Potužák, 2009).

Traditionally, some fish species have been used to control the eutrophication and to prevent the appearance of toxic algae, such as tilapia or silver carp (Jancula et al. 2008; Ke et al. 2009). Recently, the use of zooplankton organisms for such purposes has been also proposed, since the capacity of zooplankton to filter great amounts of phytoplankton and bacteria has been widely demonstrated when organism densities are adequate (Fukushima et al. 1999; Nandini et al. 2004). Integrated plankton-fish systems have been applied using recycling aquaculture systems where the wastes of fish tanks are used to grow algae for zooplankton consumption, which in turn, is used for rearing fish (van Rijn 1996, Gilles et al. 2013).

Zooplankton density is a good estimator of the pond productivity, since good production results are obtained when zooplankton and zoobenthos remain high throughout the whole production cycle (Woynarovich et al. 2010). Some studies use zooplankton community to assess water quality in carp ponds, using different metrics: e.g., species richness, zooplankton abundance, taxonomic composition, ecological functioning, diversity index or saprobic index (Dulić et al. 2009; Dulić et al. 2010).

In general, zooplankton abundance is positively correlated with increasing eutrophication, because the increase in abundance is mainly caused by the rise of rotifers and small zooplankton taxa (Haberman and Haldna 2014; Azevedo et al. 2015). Rotifers and copepod nauplii are normally less affected by algal blooms (common in nutrient-rich habitats) than large crustaceans, since they seem to be less susceptible to the toxicity of some cyanobacteria (Gilbert 1990; Ceirans 2007). Additionally, larger zooplankton taxa are more sensitive to water pollution, such as pesticides or heavy metals (Fleeger et al. 2003), so their absence in aquatic habitats may be used as indicator of water quality deterioration. Therefore, large cladocerans are one of the most widely group used as indicator of changes in water variables (Jeppesen et al. 2011). Suppressed abundances or absences of cladocerans in fish ponds have often been the result of increased pond eutrophication (Potužák et al. 2007), along with the gradual increase of fish stock in the last decades (Komarkova et al. 1986; Pechar 1995). These modifications involve changes in zooplankton community composition and abundance, increasing the abundance of cladoceran competitors. Thus, with a relative abundance of *Daphnia* spp. below 40%, the average body length of zooplankton decreases, caused by the dominance of rotifers, copepods and small cladocerans as Bosmina (Pechar 1995). In relation to algal community, when less efficient filter-feeding zooplankters dominate, the frequency of large colonial forms of algae and the trophic level of the ponds increase (Sipauba-Tavares et al. 2011). In contrast, when the abundance of *Daphnia* species is high, their filter-feeding efficiency results in the control of phytoplankton development, thereby increasing water transparency (Pechar 1995). Based on this fact, Potužák (2009) defined the so-called *Daphnia* index that expresses the relationship between the *Daphnia* size and its relative percentage in relation with total zooplankton, so it also defines their filtering capacity, largely dependent on their size. The *Daphnia* index demonstrates well the ability of zooplankton to control development of pond phytoplankton (Figure 6), with the exception of situations in hypertrophic ponds with high biomass of non-consumable cyanobacteria. Additionally, in some situations in fish ponds, large *Daphnia* can be recorded even with high fish stocks. This fact could be explained by the decreased predation pressure upon zooplankton when high protein supplementary feeding is used in the fish ponds (Rahman et al. 2006; Rahman et al. 2008b; Ćirić et al. 2015), together with a reduction in the visibility of carp in turbid waters (Potužák et al. 2007, 2008).

### **Influence of Bioturbation**

Bioturbation is a common process in earth carp ponds. It is a result of the burrowing activity of benthivorous fish and/or different sediment-dwelling invertebrates that physically disturb and mix the sediments (Brönmark and Hansson 2005; Matsuzaki et al. 2007 and references therein; Adámek and Maršálek, 2013). Bioturbation initiates resuspension of sediments as well as aeration of the pond sediment, whereas it increases the turbidity of fish ponds and releases a substantial amount of nutrients and particulate organic material accumulated in the sediments to the overlaying water. To a lesser degree, resuspension can be promoted by wind induced wave actions in shallow waters (Avnimelech et al. 1999). Increased level of nutrients (particularly phosphorus and nitrogen) in the water can positively affect the zooplankton community through bottom-up processes via enhanced production of phytoplankton (Rahman 2015). However, nutrient overload and high turbidity of water can either interfere with large zooplankton filtering activity leading to the increase of smallbodied zooplankton (Kirk 1991), or can decrease the overall phytoplankton production due to the lack of light (Billard 1999).

In recently created earth carp ponds, zooplankton (active and resting stages) are mostly introduced from the adjacent water bodies that are used as a water source for the ponds. In older fishponds, a part of the zooplankton community comes from the internally formed dormant egg depositions in the sediment, usually up to a few centimeters  $(2 - 10 \text{ cm})$  thick. Some studies showed that fishponds that have been used for a long time could have more than 1000 resting eggs  $\text{cm}^2$  of pond sediment (Li et al. 1996). In all groups of zooplankton, e.g., rotifers, cladocerans and copepods, an active egg bank exists, with egg densities in the range of  $103 - 105$  per m<sup>2</sup> of sediment (Brendonck and De Meester 2003). Deposition of dormant eggs happens regularly in natural water bodies that dry out periodically as it is the case of most carp ponds (Geiger 1983; Hairston 1996; Hairston et al. 2000; Brendonck and De Meester 2003; Gyllström and Hansson 2004; Ning and Nielsen 2011). Disturbance of the egg bank in the sediment caused by bioturbation can either bring the eggs towards the surface or can bury them deeper into the sediment (Gyllström and Hansson 2004).

To a lesser extent, benthic fauna can also contribute to the resuspension of particulate matter from the bottom (Adámek and Maršálek 2013), since in older fishponds the sediment layer is usually thick and supports a rich benthic fauna (mainly chironomid larvae, e.g., *Chironomus plumosus* and oligochaets as *Tubifex* sp. and *Limnodrilus* sp.; Dulić et al. 2011; Adámek et al. 2014).

Apart from bioturbation, pond management measures such as disking (harrowing), applied during pond drying in winter prior to filling with water in spring, can contribute to the translocation of zooplankton resting eggs either upward to the surface or deeper into the sediments (Dulić et al. 2014). If not buried deeper than 10 cm, viable dormant eggs of rotifers, cladocerans and copepods will hatch in spring during the fishpond inundation cycle, when triggered by suitable conditions, usually appropriate temperature and photoperiod (Hairston et al. 2000; Brendonck and De Meester 2003).

## **CONCLUSION**

Zooplankton assemblages constitute an important component of aquatic ecosystems, and in particular, of carp ponds. Their interactions with the other inhabitants of these habitats, especially with carp, make zooplankton an essential factor not only for fish performance, but also to help keeping carp pond ecosystems stable and healthy.

Finding the right balance between the availability of zooplankton and the addition of supplemental feed is the biggest challenge in current carp pond aquaculture. Regular monitoring of the zooplankton community in the pond is a good tool for the adjustment of the amount of added feed. This can improve the exploitation of natural resources and at the same time, it can reduce the cost of supplemental feed. Additionally, the daily distribution of supplemental feed that is not restricted to fixed areas in carp ponds can shift the feeding habits of carp resulting in increased search for zooplankton present in other microhabitats of the pond. Adjusting the quantity of external feed provided to carp needs will impose a decrease in nutrient input in the carp ponds. This will lead to a lower trophic level in these habitats, improving the water quality, and ultimately, converting these aquatic ecosystems into biodiversity reservoirs for aquatic and other associated organisms.

# **HEAVY METALS AND MICROELEMENTS CONTENT IN COMMON CARP**

# *Snežana Štrbac\**

Faculty of Environmental Protection, Educons University, Sremska Kamenica, Serbia

## **ABSTRACT**

Over the last few decades there has been a growing interest in determining metals levels in the aquatic environment. Estimating heavy metals and microelements in fish is very important, particularly commonly consumed fish like common carp (*Cyprinus carpio* L.). A study was conducted to assess the level of bioaccumulation of heavy metals and microelements, and to analyze their distribution among different common carp organs from various locations. Bioaccumulation of Al, As, B, Cd, Co, Cr, Cu, Fe, Hg, Mn, Ni, Pb, Se, Sr, and Zn in common carp at four different localities along the Serbian stretch of the Tisa River revealed that their bioaccumulation occurs in different concentrations in various fish organs. Bioaccumulation of heavy metals and microelements are significantly different among various organs with the accumulation of heavy metals and microelements in gills and liver being higher than in the brain. It is noted that the average bioaccumulation was fairly uniform at all sites, with no significant variability for bioaccumulation across sampling locations. The difference among fish species from common carp, silver bream, sterlet and northern pike in relation to content of heavy metals and microelements was significantly different in common carp compared to silver bream, sterlet and northern pike. Based on these results it can be concluded that common carp have an important role in the biomonitoring of heavy metals and microelements levels in river ecosystems.

**Keywords**: common carp, heavy metals, microelements, rivers, biomonitoring

## **INTRODUCTION**

The contamination of aquatic ecosystems with metals has seriously increased worldwide attention into this issue (Karadede and Unlu 2000). Over the last few decades there has been a growing interest in determining metals levels in the aquatic environment.

Fish are one of the best bioindicators for estimating metals pollution and risk potential for human consumption in freshwater systems. They are considered an excellent biological marker of the increasing concentration of heavy metals and microelements in aquatic environments because they are constantly exposed to contaminants and occupy various trophic levels in food chains. Fish are often at the top of the food chain and may accumulate large amounts of metals. Also, given they are exposed immediately to any pollution event they represent an obvious sign that environmental impacts have occurred. They can be used to monitor the concentrations of the polluting substances accumulated over time (Simonović 2001).

Metals enter fish both in food particles and water via the gills and skin. Once in the body, they move into the blood stream and are carried to either a storage point or to the liver where they are transformed or stored. As a result of different mechanisms of adsorption, regulation, storage and excretion of metals, there are differences in the concentration of heavy metals and microelements in certain organs (Rao and Padmaja 2000; Storelli et al. 2006). Variations in the bioaccumulation of metals in various fish tissues are conditioned by a large number of factors: nutrition type, trophic status, source of each specific metal, remoteness of organisms from the contamination sources, presence of other ions (Giesy and Weiner 1997), food access (Chen and Folt 2000), occurrence of metallothionein and other proteins responsible for detoxification in fish tissues (Deb and Fukushima, 1999). Water temperature, transport of metals through the membrane, rate of fish metabolic activity, different mechanisms of adsorption, regulation, depositing and excretion of metals, species, age and size of fish, exposure time (Idodo Umeh 2002), as well as position and organ function (Nussey 2000) are also factors from which conditioned variations in the bioaccumulation of metals in various fish tissues. Numerous studies have analyzed metal accumulation in the muscles since it is the main part of a fish consumed by humans. Has-Schön et al. (2006) claimed that fish muscles are not a good indicator of total contamination, and that it is necessary to include metabolically active organs such as the liver and gills where the accumulations are significantly higher than in muscle tissue due to the existence of metal-binding proteins (Ploetz et al. 2007; Uysal et al. 2009). However, gills and liver are a much better contamination indicators than fish muscle. Gills are the primary organ by which the metals are adopted from the water, thus they reflect the concentration of metals in the water in which the fish live (Heath 1987). On the other hand, the ability of the liver to accumulate metals is a result of the activities of the metаllothionein, a protein which bonds metals and reduces their toxicity (Ekpo et al. 2008; Višnjić Jeftić et al. 2010). The liver is the main site of accumulation, biotransformation and excretion of pollutants in fish (Shinn et al. 2009).

It is very hard to compare the concentration of metals in the same tissue among different species due to species-specific differences in the bioaccumulation patterns of metals. Such differences are a result of highly species-specific membrane permeability and enzyme systems along with differences in fish nutrition, habitat type, fish mobility and other features connected with fish behavior. According to past research, filter-feeding fish species that filter

particles in surface waters and benthivorous fish that feed particularly on mollusks and crustaceans which are known to accumulate high levels of heavy metals in their body accumulate the highest concentrations of heavy metals (Chen et al. 2000; Folt et al. 2002).

This paper assess the level of bioaccumulation of heavy metals and microelements and analyzes their distribution among different common carp (*Cyprinus carpio* L.) organs in different spatial locations. These results were presented to explain whether there are targeted bioaccumulation organs for individual metals and whether heavy metal and microelements concentrations vary across sites using common carp as a bioindicator. Passive biomonitoring was analyzed and autochthonous organisms were collected as bio-monitors from certain sites.

## **MATERIALS AND METHODS**

### **Study Area and Sample Collection**

The Tisa River in Serbia was chosen as a study area. The basin of the Tisa River is one of the largest natural river systems in Southeastern Europe, and is located almost exactly in the geographical centre of Europe. The river originates in the Zakarpatian Mountains in western Ukraine and flows into the Danube near Slankamen in Serbia. With respect to its length of 966 km, the Tisa forms the largest tributary of the Danube River. Anthropogenic activities asociated with communal, industrial and agricultural uses have resulted in permanent pollution of the Tisa River.

This study was performed at four sites on the Tisa River in Serbia. The first fish sampling site was on the border with Hungary where the Tisa River enters the territory of Serbia at the  $153<sup>rd</sup>$  km of the river flow. The second and third sampling points were situated at  $58<sup>th</sup>$  km and  $72<sup>nd</sup>$  km of the river flow. The forth sampling point was at  $3<sup>rd</sup>$  km of the river flow near confluence of the Tisa River at the Danube River (Figure 1). All marks refer to the upstream distance from the confluence with the Danube River.

Figure 1. Map showing different sampling sites (●) in the Tisa river.

A total of 40 fish were caught by professional fishermen during October 2010. On the day of sampling, fish were transported to the laboratory of Faculty of Environmental Protection, Educons University and stored at -20°C. Prior to dissection, fish were thawed at room temperature and their total body (TL), standard (SL) and fork (FL) length, height (H), and total wet weight were measured. The average values and standard deviation for body weight (g), TL (mm), FL (mm) and SL (mm), H (mm) and age are given in the Table 1.

Dissection was performed on a polypropylene base with stainless steel scissors, scalpels and forceps. Gills, liver, and brain were taken from each individual. Dissected organs were packed in plastic bags and stored at -18°C until chemical analysis. The same fish organs from the same site were merged into a composite sample of 10 individuals.

## Table 1. The mean  $(\pm$  standard deviation) body weight  $(g)$ , total length  $(TL, mm)$ , **fork length (FL, mm) and standard length (SL, mm), height (mm) and age (years) of common carp**

N, number of common carp.

### **Sample Preparation**

All samples' portions in amount of about 1 g were digested in a microwave digester (ETHOS 1, Advanced Microwave Digestion System, MILESTONE, Italy) using 8 ml of 65%  $HNO<sub>3</sub>$  and 1 ml of 30%  $H<sub>2</sub>O<sub>2</sub>$  (Carlo Erba, Italy) of analytical reagent grade. The samples were allowed to ramp to 200 °C for 15 min, digest at 200 °C for 20 min, and cool down for 10 min. After cooling to a room temperature, digested samples were diluted with distilled water to a total volume of 25 ml. All the plastics and glassware were washed in nitric acid for 15 min and rinsed with deionized water before use. High purity argon was used as inert gas. The analysis was performed by inductively-coupled plasma optical spectrometry (ICP/OES, Thermo Scientific iCAP 6500 Duo Instrument, Thermo Fisher Scientific, Cambridge, UK), and comprised assessment of concentrations of 15 heavy metals and microelements (Al, As, B, Cd, Co, Cr, Cu, Fe, Hg, Mn, Ni, Pb, Se, Sr and Zn). All element concentrations were expressed in  $\mu$ g g<sup>-1</sup>.

### **Statistical Analysis**

In order to investigate significant differences between the sample means, one–way ANOVA with post hoc test analysis based on the Scheffe and Games-Howell test was applied. Data showed mostly normal distribution or close to normal distribution and therefore no transformations were done for statistical analyses. Statistical confidence was set at  $\alpha =$ 0.05. All data were analysed using software SPSS version 15.0 (SPSS Inc. Chicago, USA).

# **RESULTS AND DISCUSSION**

The contents of heavy metals and microelements in common carp were determined in the liver, gills and brain. The mean values and standard deviations of heavy metals and microelements (expressed in  $\mu$ g g<sup>-1</sup> wet mass) measured in different fish organs from different locations are given in the Tables 2 and 3. Based on the results, Al, Fe and Zn were the elements that were most accumulated in the common carp.

**Table 2. The mean (± standard deviation) heavy metals and microelements (μg g-1 wet mass) in various organ of common carp**

# **Target Organs for Bioaccumulation of Heavy Metals and Microelements in Common Carp**

In total the average values for the content of heavy metals and microelements in the wet mass of particular fish organs across the four sites were as follows: Al  $(116.57 \text{ µg g}^{-1})$ , B (0.31  $\mu$ g g<sup>-1</sup>), Cr (0.41  $\mu$ g g<sup>-1</sup>), Mn (6.27  $\mu$ g g<sup>-1</sup>), Ni (0.13  $\mu$ g g<sup>-1</sup>) and Sr (14.08  $\mu$ g g<sup>-1</sup>) accumulated mostly in the gills; As  $(0.14 \mu g g^{-1})$ , Cd  $(0.78 \mu g g^{-1})$ , Co  $(0.04 \mu g g^{-1})$ , Cu (15.83  $\mu$ g g<sup>-1</sup>) and Pb (1.01  $\mu$ g g<sup>-1</sup>) in the liver; Fe (144.88  $\mu$ g g<sup>-1</sup>; 162.54  $\mu$ g g<sup>-1</sup>) and Zn

(155.01  $\mu$ g g<sup>-1</sup>; 135.91  $\mu$ g g<sup>-1</sup>) in both liver and gills, while Se accumulated most in brain (0.40 μg  $g^{-1}$ ) (Tables 2 and 3). The average values of Hg were about the same in all fish organs (Table 3). The obtained results showed that the bioaccumulations of heavy metals and microelements in the carps' liver (22.49  $\mu$ g g<sup>-1</sup>) and gills (29.36  $\mu$ g g<sup>-1</sup>) were much higher than their bioaccumulation in the brain  $(5.83 \text{ µg g}^{-1})$  (Figure 2). The difference in bioaccumulation between particular carp organs was significant ( $F_{(2, 11)} = 21.477$ , p < 0.0001) and the Games-Howell post hoc test denoted gills and liver as the organs where the bioaccumulation was significantly higher than in the brain.

These studies showed that the liver and gills accumulate heavy metals and microelements more compared to the brain. This result is in agreement with Vinodhini and Narayanan (2008), Khaled (2009) and Jarić et al. (2011). Based on these results, the fish organs were a factor which remarkably impacted the bioaccumulation of heavy metals and microelements (Dural et al. 2007; Yılmaz et al., 2007). Accordingly, bioaccumulation in the liver was the greatest for As, Cd, Co, Cu and Pb, while in gills the bioaccumulation was the greatest for Al, B, Cr, Mn, Ni and Sr, and in both liver and gills bioaccumulation was the greatest for Fe and Zn. Higher concentrations of Cu in the liver, Al and Sr in the gills, Fe and Zn in liver and gills were expected, considering that the liver represented the target organs of Cu (Vapa and Vapa 1997), and gills for Al and Sr bioaccumulation (Schiffman 1961; Handy and Eddy 1989). The greatest concentrations of Fe in the liver and gills were expected as it enters the composition of hemoglobin (Carpene et al., 1994). Liver tissue was assigned as highly active in adopting and depositing heavy metals and microelements (Dural et al. 2007). The ability of the liver to accumulate metals is the result of the activities of metаllothionein, a protein which bonds metals and reduces their toxicity (Ekpo et al. 2008; Oguzie and Izevbigie 2009; Višnjić Jeftić et al. 2010). Depending on the type of metal, its concentration, fish species, length of exposure and other factors, metals on one hand can increase or decrease the activity of hepatic enzymes, and on the other hand they can lead to histopathological changes in the liver (Paris-Palacios et al., 2000). In contrast to the liver, the reasons for the high concentration of metals in the gills are the result of both metal complexes presence in the mucus (which cannot be totally removed from the lamellae prior to analysis), and the absorption of metals on the surface of the gills which is conditioned by the accessibility of the protein with which the metal bonds (Palaniappan and Karthikeyan 2009; Dural et al. 2006; Erdogrul and Erbilir 2007).

The present research confirms that the liver is a good indicator of chronic exposure to heavy metals and microelements because it is the site of metal metabolism. Thus, it is the main indicator of the state of the surrounding aquatic ecosystem due to the fact that the concentrations of metals in the liver are often in proportion to those in the environment (Dural et al. 2007). Unlike the liver, gills are the primary organ by which the heavy metals and microelements are adopted from the water thereby reflecting the concentration of metals in the water in which the fish live (Heath 1987). In the gills, the concentrations of metals are especially greater at the beginning of exposure, before the metals reach the other parts of the organism (Rao and Padmaja 2000).

## **Sampling Sites Variations of Bioaccumulation of Heavy Metals and Microelements in Common Carp**

Based on Figure 3 which shows descriptive statistics of the average values of heavy metals and microelements in carp depending on the site, it is noted that the average bioaccumulation is fairly uniform across site. The largest bioaccumulation was at the site "153 km" (20.44  $\mu$ g g<sup>-1</sup>), and the smallest at the site "72 km" (17.93  $\mu$ g g<sup>-1</sup>). According to the concentrations of each heavy metal and microelement that were found in fish at four different localities of sampling, it seemed that Al, Fe and Zn were the elements that accumulated the most in total average values at all sampling localities in fish, followed by Cu, Mn and Sr that accumulated slightly less (Tables 2 and 3). There was no significant variability for bioaccumulation across sampling localities ( $F_{(3, 11)} = 0.018$ , p > 0.996).

Figure 3. Mean heavy metals and microelements concentrations ( $\mu$ g g<sup>-1</sup>) in common carp in various sampling sites.

# **Species-Specific Differences in the Bioaccumulation of Heavy Metals and Microelements**

In order to determine the importance of common carp in the biomonitoring of aquatic ecosystem loads with heavy metals and microelements, the average content of heavy metals and microelements in the common carp were compared to the average values in the silver bream (*A.brama*), starlet (*A. ruthenus*) and northern pike (*E. lucius*) from the same river. Based on the distribution of heavy metals and microelements concentrations in different fish species for each of the tested elements, it can be noticed that the average bioaccumulation of heavy metals and microelements is the greatest in common carp  $(19.22 \mu g g^{-1})$ , and the smallest in the silver bream  $(6.28 \text{ µg g}^{-1})$  (Figure 4).

Figure 4. Mean heavy metals and microelements concentrations ( $\mu$ g g<sup>-1</sup>) in various fishes.

In order to determine the existence of statistically significant differences in the bioaccumulation of heavy metals and microelements in different fish species one-way ANOVA was conducted. The difference among fish species in concern for the content of heavy metals and microelements was significantly different  $(F(3, 59) = 9.410, p = 0.0001)$ , with a higher content of heavy metals and microelements is in common carp than silver bream, sterlet and northern pike.

The differences in the bioaccumulation obtained in four fish species can be best explained by differences in their feeding behavior. Northern pike are piscivores, silver bream and starlet are benthivores, while common carp are omnivores. Kidwell et al. (1995) and Voigt (2004) noted that predatory species such as pike accumulate the most Hg. The increased concentrations of Hg can be explained in the way that this is the only metal which shows a certain degree of biomagnification, the concentration increasing from the lowest trophic level of the food chain to the highest one. The nutrition of benthivorous fish such as silver bream and sterlet consists of larvae of various groups of insects (Trichoptera, Chironomidae, Ephemeroptera, Plecoptera and Simulidae), small mollusks, articulate worms (Oligochaeta), crayfish and other invertebrates. Several sources reported that increased concentrations of heavy metals in water and sediment coincide with the increase of their concentrations in water insects, relating to the bioaccumulation of heavy metals by the bottom fauna as the main components of the nutrition of benthivorous fish species (Smith et al. 1996).

Given that different species adopt metals in different ways, the exact relationship between metals in the environment and their presence in the bodies of insects can vary in regard to fish taxa and metals (Chen et al. 2000). Woelfl et al. (2006) point to a small bioavailability of heavy metals, as well as a low factor of bioaccumulation for the larvae of chironomids which are highly abundant in the benthic sediment of the Tisa River in the area investigated here. Duquesne et al. (2000) have determined higher concentrations of Cu and Cd in amphipod shrimp species *P. walker* as a result of their increase in the aquatic environment. Unlike the water insects, it has been confirmed that mollusk tissue is not a good indicator of the state of an ecosystem. A number of authors have noted an inconsistency of results and concluded that it is hard to establish the general trend of bioaccumulation on the part of the mollusks (Timmermans et al. 1989; Elder and Collins 1991; Van Hattum et al. 1991; Gundacker 2000). Laua et al. (1998) confirmed that there was no link between the concentration of metals present in tissues or the mollusk shell and the total metal concentrations in the environment. In the nutrition of omnivores, along with the bottom fauna, plant material can also be an important dietary component. Janković (1983) determined that at the age of 2+ and over common carp starts to feed on macrophytes as well as benthic invertebrates. In contrast to the bottom fauna featuring no general trend of bioaccumulation of heavy metals and microelements, water plants can accumulate significant amounts of metal in their tissues, which can be up to as much as  $10<sup>6</sup>$  times more in relation to their concentrations in water habitats (Kovacs et al., 1984). The statistically significant differences determined for the bioaccumulation of heavy metals and microelements between common carp on one and northern pike, sterlet and silver bream on the other side, can be explained by feeding of common carp on aquatic vegetation that accumulates significant amounts of heavy metals and microelements in comparison to other components occurring in the diet of other fish species discussed here. The age of all common carp we investigated was from  $2+$  to  $4+$ , which infers

that macrophytes are likely a significant part of their diet, along with the bottom fauna elements.

## **Ecosystems Variations of Accumulations of Heavy Metals in Common Carp**

This study has established that the concentrations of heavy metals and microelements in fish vary from organ to organ, and from fish species to fish species, but the locality within one ecosystem does not affect them. So, in, order to assess the quality of the Tisa River ecosystem, we also included a comparison of the content of heavy metals and microelements in the common carp from different ecosystems in addition to the Tisa River.

The contents of heavy metals and microelements in the liver and gills of the common carp from the Tisa River were compared to the contents of heavy metals and microelements in the liver and gills of common carp from Kaban Dam Reservoir (Varol and Sünbül, 2017), Peyang Lake (Wei et al., 2014), the Danube River (Subotić et al. 2013), Beyşehir Lake (Altındağ and Yiğit 2005), and the Begej River (Škorić et al. 2012) (Table 4).

**Table 4. Comparison of heavy metal and microelements content (μg g-1 ) in common carp from different ecosystems**

Comparing the content of heavy metals and microelements in the liver and gills of the common carp from the Tisa River, the followings results are observed. In the liver of the common carp from the Tisa Al were higher compared to the Danube River, but lower compared to the Begej; in the gills they were higher compared to the Danube, but lower than the Kaban Dam Reservoir and the Begej River. As in the liver and gills of the common carp from the Tisa River is lower than from Peyang Lake and the Danube. B in the liver and gills of the common carp from the Tisa River were lower than from the Danube. Cd in the liver and gills of the common carp from the Tisa were lower than from Kaban Dam Reservoir, Peyang Lake and Beyşehir Lake. Cr in the liver of the common carp from the Tisa River were higher compared to the Danube, but lower in relation to the Peyang Lake; in gills they were
higher compared to the Danube River and Beycheher Lake, but lower compared to Peyang Lake. Cu in the liver of common carp from the Tisa River were higher compared to the Begej River, but lower in relation to the Peyang Lake and the Danube, in gills were higher compared to the Kaban Dam Reservoir and the Danube. Fe in the gills of the common carp from the Tisa River were lower compared to the Begej River. Hg in the liver of the common carp from the Tisa were lower than from the Danube and the Begej. Mn in the liver and gills of the common carp from the Tisa were lower in relation to the Danube and the Begej. Ni in the liver and gills of the common carp from the Tisa were lower than from Peyang Lake. Pb in the liver of the common carp from the Tisa were higher than from Peyang Lake, but in the gills they were higher than from Peyang and Beycheher Lake, but lower than from Kaban Dam Reservoir. Sr in the gills of the common carp from the Tisa were lower in relation to the Danube and the Begej. Zn in the liver of the common carp from the Tisa were higher compared to the Begej, but lower in relation to Peyang Lake and the Danube, in gills they were higher than from the Kaban Dam Reservoir, but lower than from the Peyang Lake, the Danube and the Begej.

## **CONCLUSION**

Bioaccumulation of certain heavy metals and microelements in common carp at four different localities along the Serbian stretch of the Tisa River revealed that their bioaccumulation occurs in different concentrations in various fish organs. The analyzed elements were accumulated significantly more in the gills and liver compared to brain. The bioaccumulation of the tested elements was significantly greater in common carp compared to silver bream, sterlet and northern pike, which can be explained by omnivore feeding of common carp in age 2+ and over, with the great proportion of aquatic vegetation (which is known to accumulate significant amounts of heavy metals and microelements) in their diet. Fish species also appeared to be a factor which impacts the bioaccumulation of heavy metals and microelements, i.e., there was a difference between four species due to their interactions at an ecosystem level via trophic position and general habitat use. Locality as a factor revealed no impact on the bioaccumulation of heavy metals and microelements in the Tisa River fishes. Based on the results it can be concluded that *Cyprinus carpio* have important role in the biomonitoring of heavy metals and microelements levels in river ecosystems given they are a major bioaccumulator of heavy metals and microelements.

## **ABSTRACT**

Common carp (*Cyprinus carpio* L.) is one of the most important fish species in the world and together with other cyprinid fish species represents an important source of protein and various unsaturated fatty acids. Fish meat has been shown to be an important part of a healthy human diet. This paper reviewed the factors that affect the meat quality of common carp including chemical and fatty acid compositions. It was found that the fat content and fatty acid composition significantly differs among different fish species, even when they belong to the same family. In addition, the same parameters were found to be influenced by different environmental factors, especially by diet. Significant roles of good production technology and appropriate structure of planktonic and benthic organisms, which play a significant role in carp nutrition, meаt quality and desirable chemical and fatty acid composition, have been also discussed. Using properly formulated feed mixtures had a positive effect on fish health, production parameters and meat quality. Both animals and vegetable components as ingredients in formulated carp feed and their effects on production performance and meat quality have been reviewed.

**Keywords:** Cyprinids, chemical composition, fatty acids, culture systems, nutrition

## **INTRODUCTION**

The common carp (*Cyprinus carpio* L.) is one of the most important fish species in the world and together with other cyprinid fish species represents an important source of protein and various unsaturated fatty acids. It is a freshwater fish species which is often reared in

<sup>\*</sup> Corresponding Author's Emails: ljubojevic.ljubojevicd.dragana@gmail.com; dragana@niv.ns.ac.rs.

warm-water fish ponds. It is one of the earliest domesticated fish species which has been cultured for human nutrition. It was reared in China as early as the 500 BC. Today, this species is reared not only in Asia, but throughout the world and is one of the most domesticated fish species. The common carp is a very strong and robust fish species capable of surviving in across a wide array of temperature and water quality. Common carp is abundant across Serbia as well as in many areas worldwide and is a highly important and esteemed fish species. Because of numerous desirable traits, such as high fecundity, good conversion of both natural and high muscle protein content, fast growth-rate, both healthy and tasty meat and resistance to poor environmental conditions and diseases, this fish species is widly domestricated in Europe and Asia. Common is one of the highly preferred fish due to the specific flavors, savory flavors in various recipes, and require a short time for its preparation for cooking. Muscles are the main part of the body of the fish that are used in human nutrition. Common carp is a medium fatty fish and most of its fat stored as adipose tissue in the abdominal wall (Mráz and Pickova 2009).

Meat of common carp is an important nutritional source of protein and monounsaturated fatty acids (MUFA) (Ćirković et al. 2011; Ćirković et al. 2012; Ljubojević et al. 2013a,b,c,d; Ljubojević et al. 2015), and contains n-3 highly unsaturated fatty acids (HUFA), especially eicosapentaenoic (EPA) and docosahexaenoic (DHA) acid (Steffens and Wirth 2007; Ljubojević et al. 2016; Župan et al. 2016), which play an important role in key physiological processes in human health. The fat content and fatty acid composition of cyprinid fish species are influenced by age, season, various environmental factors, culture systems and, especially nutrition.

## **THE SIGNIFICANCE OF FISH IN THE HUMAN NUTRITION**

Consumption of fish meat is encouraged due to high protein content, presence of essential amino acids, minerals and vitamins, and in addition a sufficient amount of polyunsaturated fatty acids (PUFA), such as n-3 PUFA. Fish is the main source of n-3 fatty acids (n-3 HUFA) and it is considered as a healthy food with many positive effects on human health, especially in the prevention of cardiovascular disease (Conor and Conor 2010). PUFA may be important in the reduction of mortality caused by heart diseases (Kris-Ethertonet al. 2002). In addition, n-3 PUFAs decrease the content of low-density lipoproteins (LDL) in human serum, have antiarrhythmic effects, and inhibit lipogenesis in the liver, platelet aggregation and damage of blood vessels. They are very important in the prenatal development of the nervous system (Allen and Harris 2001). Further, the PUFA from n-6 series, and in particular from n-3 series participate in the prevention of diseases of the nervous system, improve learning ability, play an important role in ontogenesis (Arts et al. 2001) and also play anti-inflammatory functions (Dorea 2008). Arachidonic acid (ARA) and DHA are essential for the development and function of the brain and retinas (Lauritzen et al. 2001). The shortage of α-linolenic acid (18:3 n-3, ALA) is responsible for neurological disorders and poor growth (Cundiff et al. 2007). There is strong evidence that dietary docosahexaenoic acid (DHA) lowers the cholesterol level in serum, and other n-3 PUFAs lower triglycerides in the serum, but do not affect serum cholesterol (Balk et al. 2006; Ryan et al. 2009).

Essential polyunsaturated fatty acids such as ALA, EPA and DHA are not synthesized in the human body and effectively synthesized only by aquatic organisms; therefore, humans can receive these essential fatty acids through consumption of marine and freshwater fishes (Jabeen and Chaudhry 2011). There are recommendations from various world organizations related to fish consumption and intake of n-3 fatty acids. The European Food Safety Authority recommends intake values of 250 mg of EPA and DHA per day for healthy people (EFSA 2009), while in the case of people who suffer from some form of heart disease and have elevated triglyceride levels recommends a daily intake of EPA and DHA over 1 and 2 to 4 g, respectively (Kris-Etherton et al. 2002). The recommended optimal n-6/n-3 ratio in food for human consumption, according to numerous studies ranges from 1:1 to 4:1 (Simopoulos 2002) and this ratio is lower than occurs in most fish species. N-6 fatty acids are also essential, but they are present in most feedstuffs. Results from analyses of the most common meat products of domestic animals and poultry have shown that the ratio of n-6/ n-3 fatty acids was in the range of from 6.5 to 43.2 (Sampels et al. 2009). Increased intake of n-6 fatty acids is associated with a global increase in the number of obese people (Strandvik et al. 2008) and inflammatory processes (Calder 2008). Conversely, the intake of n-3 fatty acids decline and numerous scientific publications indicate that this phenomenon is closely related to several health problems (Calder 2008). While fish is a food that is traditionally considered a good source of n-3 fatty acids, measures to improve fat quality of fish are necessary for future human health needs and fish production technologies also need improvement from an economic point of view.

It is very difficult to determine a standard recommended intake of fish when the diversity of various fatty acids composition among various fish species is considered (Ćirković et al. 2012; Ljubojević et al. 2013cd). Further, providing such guidelines is also difficult due to the variation of fatty acid composition in fish. For example, fatty acid composition in common carp can vary significantly depending on their levels and type of nutrition (Mráz and Pickova 2009; Ljubojević et al. 2013a; 2014). When all of the above issues are considered, it can be said that the ability to produce quality fish with a predictable and known content of n-3 HUFA could be very important for producers. There have been some significant studies that covered different culture systems of growing carp and different aspects of its nutrition (Steffens and Wirth 2007; Mráz and Pickova 2009; Ćirković et al. 2011; Ćirković et al. 2012a,b,c; Ljubojević et al. 2016) but there is high uncertainty around them as they have gathered results from highly variable systems ranging from farmed-carp in intensively managed systems (Ljubojević et al. 2015; Župan et al. 2016) to wild-caught in natural river systems (Ljubojević et al. 2013d).

Epidemiological and nutritional studies have shown a link between nutrition and the incidence of heart disease. Therefore, therapy in the form of proper nutrition is considered to be important as a medicinal treatment of cardiovascular disorders. Beneficial effects of fatty acids from fish for human health is highlighted in the text, but it is impossible to explain the beneficial effects of fish meat on the human health only in terms of EPA and DHA, because fish do not only provide fats and fatty acids, but also provides a many other nutritional ingredients, such as proteins. Previous investigations have shown that, in relation to casein, fish protein in the commercial feeds reduce the level of blood cholesterol in laboratory animals (Hosomi et al. 2011). In addition, fish proteins have other beneficial effects such as anti-hypertensive properties. Further, fish proteins also lower low-density lipoprotein (LDL-

C, often known as "bad cholesterol") while increasing high density lipoprotein (HDL-C, often known as "good cholesterol"), and also have a favorable effect against obesity (Boukortt et al. 2004; Oishi and Dohmoto 2009). Many epidemiological and clinical studies have shown that an increase in LDL-C levels, and decrease in HDL-C levels are important factors for the occurrence of cardiovascular diseases (Jacobson et al. 2007). Results of Hosomi et al. (2011) indicate that the fish proteins lower the cholesterol content in the liver and serum by increasing the excretion of cholesterol and bile acid in the faeces as a result of low micellar solubility of cholesterol, and high capacity for binding bile acids.

Content of essential amino acids in fish meat is very high, especially for example tryptophan, an amino acid which is the precursor of serotonin, which is responsible for the state of mind in humans (Gadoth 2008).

## **FACTORS AFFECTING CHANGES IN THE CHEMICAL AND FATTY ACID COMPOSITION OF MEAT OF COMMON CARP**

The chemical composition including fatty acids of common carp is affected by many factors, of which the most important factors are rearing system, diet, genetic factors, gender and sexual maturity, obesity and age of the fish. The aim of this paper is to discuss the effects of these factors on chemical composition including fat quality in common carp.

#### **Chemical Composition of the Fillets of Various Fish Species**

The major differences are established in the content of fat in muscle tissue between different fish species, as well as differences in the fatty acid composition (Fontagné-Dicharry et al. 2010). Ćirković et al. (2012) performed evaluation of meat quality of different fish species reared in polyculture and compared productivity and meat quality of carp (*Cyprinus carpio* L.), silver carp (*Hypophthalmichthys molitrix*), grass carp (*Ctenopharyngodon idella*), catfish (*Silurus glanis*), zander (*Stizostedion lucioperca*) and tench (*Tinca tinca*), which were grown in polyculture on natural food in ponds fertilized with livestock manure. In the above mentioned investigation fish were grown in earthen ponds with a surface area of 1 ha and average depth of 1 m in the polyculture on natural food. The fish pond was stocked in April 2011 and harvested in October 2011. Samples of two-year-old carp, two-year-old silver carp, grass carp, catfish and zander and three-year-old tench were taken during the harvesting. The stocked tench was older in comparison with the other species to avoid the possibility that catfish and zander eat up two-year-old tench. Fish species were reared under variable natural atmospheric conditions and fed natural food. The production of natural food was based on the natural production of benthic and planktonic organisms that were increased by application of agrotechnical measures such as drying of fishponds during winter, soil treatment, fertilization and adding lime. Livestock manure (2000 kg/ha) was applied to the bottom of empty ponds and later bi-weekly over the water surface (4000 kg/ha during growing season). Agricultural limestone was applied to the bottom of empty ponds and over the water surface and fish ponds were aerated. After fish removal, they were weiged, and muscle tissue samples from each breed were taken for further analysis. It was found that the production parameters, chemical composition and quantity of n-3 fatty acids varied widely among different species, even when they belonged to the same family as the majority of the examined fish belonging to the family *Cyprinidae* (Table 1, 2, 3).

#### **Table 1. Production parameters of fish species reared in polyculture (Ćirković et al. 2012)**

Values are presented as means  $(n = 60)$ .

## **Table 2. Proximate composition of fish reared in polyculture (Ćirković et al. 2012)**

SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; USFA, unsaturated fatty acids; PUFA, polyunsaturated fatty acids series n-3 (n-3 PUFA) and n-6 (n-6 PUFA).

The mean stocking weight was the highest for common carp  $(250 \text{ g})$  and the lowest in zander (30 g) and harvesting weight was the highest in silver carp (1450 g) and the lowest in tench (200 g), while the survival rate was the highest in catfish (90%) and the lowest in tench (40%). Total stocking density was 274 kg/ha and harvesting density was 820 kg/ha.

The amount of protein was the highest in the fillets of zander (19.3%) and the lowest in grass carp and tench fillets (15.8%). Fat ranged from 0.38% in the muscles of zander to 5.24% in the muscles of grass carp. The total cholesterol content was highly variable, being the highest in the silver carp fillets  $(62 \text{ mg}/100 \text{ g})$  and the lowest in catfish  $(34 \text{ mg}/100 \text{ g})$ . The total amount of saturated fatty acids (SFA) was the highest in silver carp (33%) and the lowest in catfish (25%). Individiual SFAs were variable by species. Palmitic acid (C16:0) was predominant, whereas lauric acid (C12:0) was the least SFA in samples. The most abundant MUFA was oleic acid (C18:1, n:9), ranging from 22% in silver carp to 18% in tench, followed by palmitoleic acid (C16:1, n:7). The MUFA proportion was the lowest in tench (28%) and greatest in silver carp (37%). Tench had the highest (44%) and silver carp had the lowest (30%) PUFA proportions.

Samples were also highly variable in terms of n-3 and n-6 contents, for instance the n-3/n-6 ratio was the lowest in common carp 0.92, whereas it was the greatest in grass carp (2.28). Similarly, the PUFA:SFA, an indicator of the quality of lipids, was the least favorable in silver carp (0.91) and the most favorable in tench (1.63).

Meat quality of carp is highly variable, and changes depending on age, breeding system, and nutrition. Fat content in carp ranges from 2.3 to 16.8%, protein content lightly varies between 14 and 18% (Vladau et al. 2008; Trbović et al. 2009; Ćirković et al. 2011; Ljubojević et al. 2013ab). Cholesterol content varies by season. Trbović et al. (2009) reported 48.9 mg/100 g fat in one-year-old carp in April and 54.3 mg/100 g fat in the same age samples harvested in June. According to results obtained by Ćirković et al. (2012), cholesterol level was 55.8 mg/100 g fat in two-year-old carp. Cholesterol content of carp varies considerably from 47 to 120 mg/100 g, depending on fish breed and age, husbandry system, and harvest season (Bieniarz et al. 2001; Kopicova and Vavreinova 2007). This variability was very notable in silver carp, grass carp, tench, and catfish (Kopicova and Vavreinova 2007). Fat of terrestrial animals also contain variable amounts of total cholesterol. Williams (2007) reported that cholesterol content in meat of beef, veal, lamb and mutton was 50, 51, 66 and 66 mg/100 g, respectively. Pork meat has been reported to contain 44-98 mg/100 g (Bragagnolo and Rodriguez-Amaya 2002). Further, the average fat content in beef, sheep and pig meat is 3.8-17.3; 6.3-35.0 and 1.6-11.5%, respectively (Vladau et al. 2008).

Organic fertilization with livestock manure is a very cheap and effective method of increasing practically all nutrient components in fish pond ecosystems. Indeed, rearing of fish in polyculture on natural food with fertilization results in satisfactory fish production with a preferrable fatty acid composition as well as enhancing utilization of natural food resources. It could be said that rearing fish in polyculture on natural food with the use of agricultural limestone and livestock manure achieved satisfactory results in terms of the final weight of two-year-old fish and their nutritive composition as presented earlier. It is necessary to take into account the stocking density of fish to grow in pond-polyculture, as well as on the combination of appropriate species for the greatest production outcomes. Furthermore, nutrient composition varies widely among fish breeds. Lipid profiles particularly, appear more strongly variable among fish species than fish feeding habit (i.e., herbivorous, omnivorous or carnivorous).

Ljubojević et al. (2013d) performed a comparative analysis of proximate and fatty acid composition of seven fish species from the Danube River including asp (*Aspius aspius*), common bream (*Abramis brama*), common barbel (*Barbus barbus*), common carp (*Cyprinus carpio*), sterlet (*Acipenser ruthenus*) and northern pike (*Esox lucius*). The chemical composition and quantity of n-3 fatty acids varied largely among fish species. (Тable 4, 5).

Average body weight of experimental fishes: asp (*Aspius aspius*), common bream (*Abramis brama*), common barbel (*Barbus barbus*), common carp (*Cyprinus carpio*), sterlet (*Acipenser ruthenus*) and northern pike (*Esox lucius*) was 1220, 1230, 870, 1420, 1320 and 1480 g, respectively. The amount of protein was the highest in the fillets of barbel (18.61%),

without significant difference with protein content in the flesh of pike and asp ( $p > 0.01$ ), and the lowest in common carp fillets (16.69%). Fat ranged from 1.61% in the muscles of pike to 7.78% in the muscles of barbell and there was significant difference in the fat content among all examined fish ( $p < 0.01$ ). Results of ash content in fish flesh also showed statistically significant difference among species, except for common carp and sterlet. The total cholesterol content was highly variable, being the highest in the sterlet fillets (73.59 mg/100 g) and the lowest in asp (36.26 mg/100g) and variation was statistically significant among fishes ( $p < 0.01$ ).

## **Table 4. Proximate composition of seven freshwater fish species from the Danube (Ljubojević et al. 2013d)**

SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; USFA, unsaturated fatty acids, PUFA, polyunsaturated fatty acids from series n-3 (n-3 PUFA) and n-6 (n-6 PUFA).

A lipid analysis in the paper of Ljubojević et al. (2013d) enabled the classification and quantitative determination of 21 fatty acids and besides that the sum of saturated fatty acids (SFA), monounsaturated fatty acids (MUFA), polyunsaturated fatty acids (PUFA), n-3 acids, n-6 acids, n-3/n-6 ratio, n-6/n-3 ratio and ratio of PUFA/SFA, as well as ratio of USFA/SFA which represent the indicators of lipid quality (Table 5). The total amount of saturated fatty acids (SFA) was the highest in pike (39.9%) and the lowest in bream (27.27%). Individual SFA were variable by species. Palmitic acid (C16:0) was predominant in all species, whereas arachidic acid (C20:0) was the least SFA in samples. Caprylic acid (C8:0) was detected in fat of asp, common bream, and pike and percentage of these fatty acid was higher in this species with regard to pentadecylic acid (C15:0), margaric acid (C17:0) and arachidic acid (C20:0), while, in barbell, carp and sterlet C8:0 was not detected. The most abundant MUFA was oleic acid (C18:1, n-9), ranging from 17.70% in pike to 32.11% in bream, followed by palmitoleic acid (C16:1, n-7) and vaccenic acid, C18:1cis-11The MUFA proportion was the lowest in pike (31.66%) and greatest in bream (56.09%). Pike had the highest (28.15%), while bream had the lowest (17.07%) PUFA proportion. Asp, which is also carnivorous like pike had high PUFA content (27.99%). Samples were also highly variable in terms of n-3 and n-6 contents, for instance the n-3/n-6 ratio was the lowest in common carp  $(0.44)$ , whereas it was the greatest in sterlet (2.9). Similarly, the PUFA/SFA, an indicator of the quality of lipids, was the least favorable in bream (0.63) and the most favorable in barbel (0.92).

The flesh obtained from the experimental fishes by Ljubojević et al. (2013d), was characterized by a variable fat and water content. The same regularity was observed by Żmijewski et al. (2006), Luczynska et al. (2008) and Ćirković et al. (2012), who found a reverse correlation between the fat and water contents, which is common for many fish species. The results of proximate composition of common carp, pike and common bream obtained by Ljubojević et al. (2013d) are quite similar with those of Bud et al. (2008), where fishes were obtained from aquaculture and no data was given about age or body weight of fishes.

It has been reported that under culture conditions, fish muscle contains more lipid than in the wild (Cahu et al. 2004). An interesting fact is that common carp from the free catch had fat content 7.1% (Ljubojević et al. 2013d) which is much higher compared to cultured carp (Ćirković et al. 2012; Ljubojević et al. 2012b). The exception to this is for cultured carp fed with grains with fat content between  $10-15%$  and confirming that proximate composition of common carp is highly dependant on their diet (Steffens and Wirth 2007).

Significant differences in the content of ash, which was the lowest (0.63%) in pike and the highest (1.31%) (Ljubojević et al. 2013d) in barbel may be due to the presence of small bones in fish fillets. Namely, the calcium, which released during bone demineralization, can contribute to a greater mass fraction of ash in the total chemical composition of fish meat.

According to Andrade et al. (1995), the most dominant saturated acids in freshwater fish from south Brazil were palmitic (C16:0) and stearic (C18:0), whereas palmitoleic (C16:1) and oleic (C18:1) acids were the major component among monounsaturated fatty acids. Among saturated and monounsaturated acids in the most fish studied, oleic acid was the highest, followed by palmitic and palmitooleic acid (Ljubojević et al. 2013d).

Almost all freshwater species, with the exception of pike, contained higher amounts of monounsaturated fatty acids (MUFA) than saturated fatty acids (Ljubojević et al. 2013d), in compliance with results found by Luczynska et al. (2008) for bream and pike. The relative contents of n-3 PUFA (10.31-17.66%) was higher than the n-6 polyunsaturated fatty acids containing from 6.76 to 14.11%, except for common carp, which is in a line with results noted by Luczynska et al. (2008) for fresh water fishes.

From a nutrition viewpoint, humans could also consider the relative fatness of fish as for PUFAs expressed per 100 g of fish meat, intake of n-3 PUFAs is larger for fat fish than lean fish (Cahu et al. 2004; Lichtenstein et al. 2006). Wood et al. (2008) have suggested that ratio of PUFA/SFA should be above 0.4 and according that all examined fish species have had favorable (from 0.63 to 0.92) PUFA/SFA ratio. The n-6/n-3 ratio in all examined fishes (Ljubojević et al. 2013d) was in the optimal range of 2/1–4/1 for human health as suggested by Simopoulos (2002).

The knowledge about cholesterol content in food is important, especially in fish meat, because consumption of fish is currently increasing based on the recommendations for healthy nutrition. Cholesterol content in female and male carp fillets was in the range of 69.4 -77.6 mg/100g (Komprda et al. 2003). Trbović et al. (2009) reported that the amount of total cholesterol was 48.9 mg/100 g in one-year-old carp in April and 54.3 mg/100 g in the same age samples harvested in June. In the study implemented by Ćirković et al. (2012), cholesterol level was 55.8 mg/100g in two-year-old carp. Cholesterol content in carp muscle tissue can vary considerably from 38 to 120 mg/100 g, depending on fish breed and age, husbandry system, and harvest season (Bieniarz et al. 2001; Ćirković et al. 2011). Kopicova and Vavreinova (2007) detected the content of total cholesterol in common carp, sterlet, northern pike and asp and it amounted 47, 61, 86 and 45 mg/100g, respectively. The pike used in the study conducted by Kandemir (2012) had an average weight of 1457 g and the amount of cholesterol found in tissue was 146.4 mg/100g. Ćirković et al. (2012) found differences among six freshwater fishes with respect to the amount of cholesterol detected in muscle tissue was significant and detected the level of total cholesterol rangomg from 34.34 mg/100g in catfish to 62.32 mg/100g in silver carp. Research conducted by Moreira et al. (2001) on the cholesterol content of many freshwater fish species showed that the values ranged between 40.99 and 52.79 mg/100g. According to Luzia et al. (2003) the amount of total cholesterol in freshwater fish is lower in comparison with marine fish. The daily intake of cholesterol is currently recommended not to exceed 300 mg (James and Ralph 2000). It can be argued that mentioned freshwater fish in the study conducted by Ljubojević et al. (2013d) are wellfavored sources of cholesterol.

Fish should be included in human diets for at least three reasons: as a general source of nutritional components; as low fat, high protein food; and as source of polyunsaturated fatty acids (Ljubojević et al. 2013d). At the same time, the recommended ratio of polyunsaturated fatty acids (PUFA) to saturated fatty acids (PUFA/SFA) should be increased to above 0.4 (Wood et al. 2008). Since some meats of terrestrial farmed animals naturally have a PUFA/SFA ratio of around 0.1 (Wood et al. 2008), meat has been implicated in causing the imbalanced fatty acid intake of today's consumers. Fish lipids are particularly rich of polyunsaturated fatty acids (PUFA) that are only slowly synthesized in humans which is the major difference between meat of fish and meat of farmed terrestrial animals (Vladau et al. 2008). The n-3/n-6 ratio was found to be generally lower in cultivated than in wild fish (Orban et al. 2003). That is mainly due to nutrition and lowered level of fish meal as a protein source and its completely or partial replacement with cheaper protein sources. The recommended ratio of n-6/n-3 should be less than 4 (Scollan et al. 2006) and this ratio in some meats of terrestrial animals is higher than this (Wood et al. 2008). However, it is difficult to rank the examined fishes from best to worst from the point of view of human nutritive value. The fat content in fish tissue contributes to its organoleptic properties, texture and flavour. Tissue which is rich in fat is juicy, while lean tissue is dry and perceived as thickly fibrous (Żmijewski et al. 2006). On the other hand, there are certain groups of people who require meat with minimal fat and cholesterol content.

The importance of the results obtained by Ljubojević et al. (2013d) lies in the fact that there were no data on meat quality of freshwater fish species from the Danube River in the Serbia region, therefore it can be valuable information to ecologists, environmentalists, nutritionists, food scientist and other scientists. The meat of warm water fish from the Danube River represents a valuable source of healthy nutrition for consumers. Chemical and fatty acid composition varied between different species and among the same species. All examined species have had PUFA/SFA ratio higher than 0.4, and n–6/n–3 ratio was lower than 4 which are the prescribed values recommended from WHO/FAO organization. The potential of exploiting presently insufficiently used freshwater species for developing high-protein foods for market and for introducing as a new species in aquaculture, underscore the need for reliable analytical data.

Ljubojević et al. (2013c) examined the economically most important fish species which are presented on the market for the Republic of Serbia, whereby the attention was not devoted only to differences in the meat quality of studied species caused by the influence of fish species, but also the differences that arise as a consequence of different growing systems and the use of different nutrients and completed feed for carp. The objective of the above study was to assess the chemical and fatty acid compositions of common carp (*Cyprinus carpio*), silver carp (*Hypophthalmichthys molitrix*), bighead carp (*Aristichthys nobilis*), grass carp (*Ctenopharyngodon idella*), сatfish (*Silurus glanis*) and zander (*Stizostedion lucioperca*) which were collected from retail stores in the area of Novi Sad. The samples were taken on 19th December (St. Nicolaus day), when the fish consumption is greatest in the Republic of Serbia and approximately half of the annual sales of fish is reached on that day. Eight samples of each fish species were taken from different retail stores (each sample of fish per species was taken from a different shop) and stored at  $-18^{\circ}$ C till the next day when the analyses were performed. The weight within each fish species (marketable fish) was almost the same (average weight of common carp, silver carp, bighead carp, grass carp, Wels catfish, and zander were 2200, 2740, 2850, 1790, 2610, and 420 g, respectively). All fish were two years old (the end of growing season). All sampled fish were farm-raised (from different fish farms) in the semi-intensive systems of rearing, which is the main type of fish production in Serbia. In addition to natural food, cereals or extruded fish feed were supplemented depending on the feeding technology of the fishpond facilities. The results of the chemical composition determination are shown in Table 6. It was observed that fat content varies most in common carp (6.3–15%), bighead carp (3–10%), silver carp (4–8%), and at the least in zander (1.5– 2.2%). Protein content also varied but less than fat content, and the variation was also the greatest in common carp (14.1–16.9%) and the lowest in silver carp (17.6–18.6%). Variation within the same species was noted in the amount of total cholesterol, which was the highest in common carp (43.2–65 mg/100 g). Interspecific differences of chemical composition were noticeable. Significant variations in the distribution of various fatty acids were noted between and within species. Fatty acid compositions, which are shown in Table 7, were ranged widely especially in the fillets of common carp, thus C16:0 was in the range of 17.3–33.4%. The amount of saturated fatty acids was notably constant in all examined species being around 30%, with palmitic acid being the dominant saturated fatty acid, no significant differences between species were observed  $(p>0.01)$ . The amount of C18:1cis was in a wide range in common carp fillets and the lowest value was observed in silver carp fillets (12.5%). The amount of C22:6n-3 varied between the species and within the same species, and it was the lowest in the fillets of common carp and most favorable in the fillets of zander. The greatest deviation of total SFA was observed in common carp and in the contents of MUFAs and PUFAs in catfish and zander. The lowest n-3/n-6 ratio was found in one sample of common carp (0.12), and the greatest one in one sample of bighead carp (3.7). This ratio also varied between the species, the lowest value having been observed in common carp and the highest in the fillets of bighead carp, with no statistically significant differences between the silver and bighead carps.

#### **Table 6. Chemical composition of seven fish species obtained from retail stores from Serbia (Ljubojević et al. 2013c)**

Values are means  $(n = 8)$ .

Regarding chemical (Table 6) and fatty acid compositions (Table 7) of muscle tissue in the paper of Ljubojević et al. (2013c), it was expected that some major differences would be found within the same species and among different species in percentages of the nutrients monitored between the tested fish species in the present experiment because the fish came from the different environments, different species were included, and they were fed with different diets.

Values are means (n = 8). SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; USFA, unsaturated fatty acids, PUFA, polyunsaturated fatty acids from series n-3 (n-3 PUFA) and n-6 (n-6 PUFA).

High average values in the fat content observed in the fillets of Cyprinids, especially in those of common carp, showed that the energy-protein ratio was not balanced in the diet of these fishes in a number of ponds. Fauconneau et al. (1995) and Romvári et al. (2002) also reported that lipid content of common carp fillets show high variance  $(1-13%)$  in commercial sized fish depending mainly on their previous nutrition.

The total cholesterol content in the carps fillets in the paper of Ljubojević et al. (2013c) is in agreement with the data of Bieniarz et al. (2001) and Kopicova аnd Vavreinova (2007) who reported slightly higher cholesterol content in the most analyzed fish species (49–92 mg/100 g) in comparison with terrestrial animal meats  $(45-84 \text{ mg}/100 \text{ g})$  (Piironen et al. 2002) and it was lower for catfish and zander (33 and 42 mg/100 g, respectively), which is in agreement with our previous results (Ćirković et al. 2012). The total cholesterol content in the animal tissues can be influenced by the composition of the diet (Komprda et al. 2003). That could be the explanation for the variations in cholesterol content because the examined fishes came from different ponds and thus fed with different diet.

The obtained results by Ljubojević et al. (2013c) regarding to the fatty acid composition are in agreement with previous reported results referred to studied fish species (Jankowska et al. 2004; Celik et al. 2005; Steffens and Wirth 2007; Ćirković et al. 2012). The chemical composition including the fatty acid profiles varies widely among different fish species as previously noted by Ćirković et al. (2012).

The reason for the least desirable composition of fatty acid profile in the lipids of common carp can be accounted for by the type of food dominating in the diet. The traditional approach to the rearing of common carp in the Republic of Serbia is based on foods naturally occurring in ponds (zooplankton, benthos). The energy-producing component of their diet is supplemented with untreated cereals (corn and wheat). The feed rich in saccharides leads to an increase in the percentage of oleic acid (C18:1n-9) in the body lipids of the fish. At the same time, a decrease occurs in the percentage of n-3 PUFA (Fajmonová et al. 2003; Buchtová et al. 2007). According to the research conducted by Buchtová et al. (2010) and Ćirković et al. (2012), the carp grown on natural food had a high content of both n-6 and n-3 fatty acids. Ljubojević et al. (2013a) observed that PUFA/SFA ratio was the most favorable in the carp fed completed feed mixtures and the least in that fed with maize and wheat. All species of the warm water fish analyzed contained significant quantities of the n-6 series, particularly C18:2 and C20:4. The presence of these and the other PUFA emphasizes the potential of freshwater fish for use on special low fat diets. Wood et al. (2008) have suggested that the ratio of PUFA/SFA should be above 0.4, and according to that all the fish species examined revealed a favorable (from 0.66 to 1.17) PUFA/SFA ratio. Scollan et al. (2006) suggested that the n-6/n-3 ratio should not exceed 4 for the prevention of cardiovascular, heart, and certain chronic diseases. All studied species meet this suggestion. However, the European Food Safety Authority recommends the intake values: 2 g of n-3 PUFA ALA per day and 250 mg of EPA and DHA per day (EFSA, 2009). The percentage values of fatty acids were transferred to weight in mg/g of fillets according to Exler et al. (1975). A 200 g of edible portion of fillets of common carp, silver carp, bighead carp, grass carp, Wels catfish, and zander contained 436, 1320, 1774, 412, 612, 420 mg of EPA+DHA, respectively; and 1198, 2160, 2780, 1076, 954, 524 mg of n-3 PUFA, respectively.

The elementary prerequisite for the sustainable carp and other fresh water fishes production, with favorable chemical and fatty acid compositions, should be seen in the development of better feeding procedures. Completed formulated feed mixtures are necessary in modern fish farming because they improve the growth performance and chemical and fatty acid compositions in fish (Ljubojević et al. 2013a).

#### **Effects of Diet on the Chemical Composition of Common Carp**

Steffens and Wirth (2007) determined the impact of basic breeding systems and therefore the nutrition on survival rate, the yield per unit of area, chemical composition, the amount of total cholesterol and fatty acid composition of common carp, which was confirmed by Ljubojević et al. (2013a) in an experiment on two-year-old common carp (Table 8). Fish were grown in similar ponds and subjected to 1 of 3 feeding systems: only natural food (extensive system), supplemental grain (semi-intensive system), and extruded formula consisting of soybean, sunflower kernel, wheat flour, corn and brewery yeast (semi-intensive system). The

experimental carp were measured biweekly in order to adjust the daily feed rate that was 3% of the total fish mass. Fish were hand-fed twice daily at 8:00 and 15:00 h. The fishponds were stocked in March and harvested in October. All fish were reared under variable natural atmospheric conditions. Natural production in each pond was increased by application of agrotechnical measures such as drying of fish ponds during winter, soil treatment, fertilization and adding lime as described by Ćirković et al. (2012). The same methods of cultivation and fertilization were applied in each experimental units. The aeration of the fish ponds was continuously secured by using one aerator per pond. The water flow was about  $3.5 \text{ l s}^{-1}$ , that provided that there were no adverse effects of carbon dioxide and ammonia on the carp. Feeding extruded formula doubled production per hectare of pond surface area, compared with feeding supplemental grain and almost thrice compared with feeding only natural food. Chemical composition, fatty acid composition as well as the n-3/n-6 ratio varied widely by the diet (Тable 8, 9). Carp fed extruded formula yielded the most preferable the unsaturated fatty acid: saturated fatty acids and polyunsaturated fatty acids: saturated fatty acids ratios. The conclusion was that properly processed plant nutrients can be important and a good source of protein for common carp and lead to improvements of production parameters in the pond, and the quality of the fish meat as a final product for human consumption. The harvesting weight, survival, harvesting density, and specific growth rate were the greatest in the semi-intensive system with addition of extruded feed mixture and lowest in the extensive system. At the end of the rearing period in October the average final live weight of carp in the group that had been fed on natural food was 462.58 g. Final live weight of carp in the group that had been given grains supplementary feeding was 754.08 g and in the group that had been formula feed feeding was 1188.75 g. Total harvesting density was 994.5 kg/ha in the extensive, 1696.68 kg/ha in the semi-intensive and 2734.12 kg/ha in the intensive system. Feeding extruded formula increased production per hectare of pond surface area almost doubled compared with feeding supplemental grains and almost thrice compared with feeding only natural food.

Supplementary feeding with grains leads to improved growth performance in common carp, and especially feeding with extruded formula. Survival rate in carp that ingested only natural food was lower than that of carp fed grains, as well as those fed formulated feed. In general, in all groups the survival rate was satisfactory and it was within the range considered normal for carp pond production in the Republic of Serbia. Additional feeding with grains almost doubled average final body weight, while carp that received extruded formula showed three fold higher final body weight than carp fed only natural food and that lead to doubled harvesting density in the semi-intensive system and threefold higher harvesting density in the intensive system compared with the extensive system. Consequently, all growth parameters were the highest in the intensive system and lowest in the extensive system. These factsct justified the use of supplemental feed in the rearing of carp and it represents a major opportunity to increase production in carp ponds. The growth parameters and total production of the carp were quite affected by that of the diets. Using adequately prepared extruded formula can further improve growth performance and yield of fish per unit of area. Administered extruded feed results in good growth and feed conversion. Higher temperature influenced the significantly higher growth rate of common carp in region of Republic of Serbia compared with Central Europe (Steffens еt al. 2005). Besides the direct effect of using feed containing high protein indirect effect was achieved through nitrogen and phosphorus, which are released during digestion of formulated feed and increased development of natural food in the pond (Marković and Ćirković 2008). The positive effect is certainly significant in maintaining a better quality of water environment. Carp reared in intensive systems had the greatest protein and moderate lipid, ash, and cholesterol contents. Expectedly, rearing in the extensive system reduced total lipid and cholesterol contents.

In the literature, depending on age, rearing system, and feed, fat content varies from 23 to 168 g kg-1DM and protein content varies from 140 to 180 g kg-1 in carp (Vladau et al. 2008; Trbović et al. 2009; Ćirković et al. 2010). In the present trial nutrient composition was highly dependant on diet. Supplementary feeding with grains leads to enlarged amounts of crude lipid in fish meat and it was doubled higher compared to supplementary feeding with extruded formula and three-fold higher compared to carp which ingested only natural food. The fillets obtained from the experimental fish were characterized by a varied content of fat and water. The same pattern was observed by Ćirković et al. (2012). The varied content of fat was compensated by the content of water, which is in agreement with the results obtained by Żmijewski et al. (2006), who found a reverse correlation between the fat and water contents, which is common for many fish species. Crude protein level was the highest in the fillets of carp from an intensive system, while there were no significant difference in the amount of protein in fillets of carp from extensive and semi-intensive systems. Cholesterol content in fish meat is not correlated with fat content (Piironen et al. 2002). Data about influence of diet and rearing systems on cholesterol content in carp are limited. However, it is known that cholesterol content in lipids of carp varies considerably, within the range of 470 - 1200 mg kg<sup>-1</sup> (Bieniarz et al. 2001; Kopicova and Vavreinova 2007). Total cholesterol content in the research of Ljubojević et al. (2012a) was the highest in semi-intensive system and the lowest in extensive system, but in all groups was favorable and within the previously mentioned (Bieniarz et al. 2001; Kopicova and Vavreinova 2007). This great variability could be related to harvest season and age as well as rearing system. The present results confirms that proximate composition of common carp highly depends of diet (Steffens and Wirth 2007). The fat content in fish meat contributes to its juiciness, tastefulness and texture, as well as organoleptic properties. Lipid content in fillets from the extensive system was very low and such lean tissue is dry and perceived as thickly fibrous. On the other hand, there are certain groups of people who require meat with minimal fat and cholesterol content.

Variable	Extensive (Only	Semi-intensive	Semi-intensive	
	natural Food)	(Grain mixture: 80%)	(Extruded feed	
		$Corn + 20\%$ Wheat)	mixture)	
Moisture $(gkg^{-1})$	814.9	764	783.5	
Crude protein $(gkg^{-1})$	154.8	155.9	171.7	
Crude lipid $(gkg^{-1})$	20.7	68.5	31.9	
Crude ash $(gkg^{-1})$	09.6	11.6	10.3	
Cholesterol $(mgkg^{-1})$	379.4	578	513.1	

**Тable 8. Proximate analysis results of common carp reared in different culture systems (Ljubojević et al. 2013a)**

Rearing in the extensive system resulted in the greatest total SFA level in meat of carp, particularly of palmitic and stearic acids. In the semi-intensive system with addition of cereals, MUFA was the greatest, predominantly of oleic acid. Carp that ingested only natural food had higher n-3 fatty acids in the muscle than carp that received supplemental wheat or

extruded formula. However, common carp reared in the intensive culture system had higher n-6 fatty acids than carp reared other two culture systems. Thus, the total amount of PUFA was higher in muscle triacylglycerol of carp fed with extruded formulated feed compared to carp fed only on natural food. This is reflection of dietary fat being transferred to body tissues. The n-3/n-6 ratio of the fish muscle was the highest in carp fed only on natural food, followed by carp fed extruded formula and the lowest value was observed in carp that received supplemental wheat. The highest level of n-3 fatty acids was found in the muscle of carp that received only natural food and the lowest in carp fed supplemental grains. In two year-old-carp fed extruded formula was observed the best ratio USFA/SFA, PUFA/SFA, the highest content of PUFA, the lowest content of SFA compared with other two groups. Lipids of carp in semi-intensive production with addition of extruded feed contained less MUFA (45%) than carp from the semi-intensive production with addition of cereals (64%).

The preference for a feed rich in saccharides leads to an increase in the percentage of the oleic acid in body lipids of the fish, which is produced in the organism by desaturation and elongation of SFA (Buchtova et al. 2007). At the same time, proportion of PUFA n-3 decreases (Fajmonova et al. 2003; Buchtova et al. 2007). Supplementary feeding with grains leads to reduced amounts of essential fatty acids in fish meat and this is due to the lower proportion of natural food in the diet of the carp which received additional grains. The two fatty acids 18:2n-6 and 18:3n-3 are precusors for synthesis of n-6 and n-3 PUFAs, recpectively (Sargent et al. 2002). According to Ljubojević et al. (2013a) carp that received extruded formula showed high values of n-6 fatty acids in their muscle, based on the high content of linoleic acid in the diets (Table 9). However, although grain mixture contained slightly higher amount of linoleic acid than formulated feed, percentage of this fatty acid was lower than in carp fed formulated feed, as well as than in carp which ingested only natural food, but the absolute content of linoleic acid was 2-3 folds greater in muscle of carp fed grains compared with muscle of carp fed only natural food. In general, in all groups the content of the n-6 fatty acids was higher than the content of n-3 fatty acids. The fatty acid composition of the carp muscle triacylglycerols was quite affected by that of the diets. Diets containing soybean or corn were characterized by high linoleic acid content. High contents of n-6 fatty acids in the grain based and extruded formulated (soybean meal, sunflower cernel, wheat flower and corn) diet resulted in high levels of these fatty acids in the carp meat.

The fatty acid composition of common carp reflects, to a large extent, that of the diet. The n-3/n-6 ratio varies between 0.8 and 2.4 (Steffens et al. 2005). There are reports indicating this ratio is about 0.5 (Kopicova and Vavreinova 2007; Ćirković et al. 2010), even less, about 0.2 (Trbović et al. 2009; Ljubojević et al. 2011). Ackman (2000) reported EPA and DHA acid concentrations in farmed carp as low as 0.35. In the study conducted by Ljubojević et al. (2013a), feeds did not contain highly USFAs. Freshwater fish possess the bioconversion capacity to elongate and desaturate C18 PUFA to n-3 and n-6 fatty acids such as arachidonic acid, EPA and DHA (Bell et al. 1997). Ćirković et al. (2011) have found that breeding system and especialy nutrition affected the fatty acid composition of fish. According to Buchtova et al. (2010) and Ćirković et al. (2012), common carp which was grown exclusively using natural food available in the fish pond had a high content of the n-6 and n-3 fatty acids, аnd Ćirković et al. (2011) noted that the PUFA/SFA ratio was the most favorable in common carp fed completed feed mixtures, and the least favorable in common carp which receiced grains as supplementary feed. The USFA/SFA ratio was also the most favorable in common carp which received completed feed mixtures.

## **Тable 9. The main group of fatty acids of common carp reared in different culture systems (Ljubojević et al. 2013a)**

SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; USFA, unsaturated fatty acids, PUFA – polyunsaturated fatty acids from series n-3 (n-3 PUFA) and n-6 (n-6 PUFA).

Ljubojević et al. (2013a) found that the ratio of  $n-3/n-6$  in common carps varied by feed and/or rearing system. Using adequately processed plant meals as replacement protein sources can further improve productivity and nutritive value of carp, as reflected by n-6 polyunsaturated fatty acids, especially linoleic and arachidonic acids and favorable content of total cholesterol.

## **Effects of Good Production Technology and Appropriate Structure of Planktonic and Benthic Organisms on Chemical and Fatty Acid Composition of Common Carp**

The fatty acid composition of completed feed mixture can change the fatty acid composition of various tissues, including muscle tissue of fish (Pickova and Morkore 2007; Kjaer et al. 2008; Todorčević et al. 2009; Ljubojević et al. 2013a; 2014), and changes in fatty acid composition of tissue will continue to affect many metabolic processes related to the synthesis and catabolism of fatty acid and lipid storage (Tocher 2003). The cost of fishmeal (FM) and fish oil (FO) on the global market increases continuously, rendering their sustainability as questionable components in fish feed (Tacon and Metian 2008). Neither FM nor FO is produced in many countries; the import thereof raises production expenses and poses a serious problem for the fish farming industry. Thus alternative feed components are necessary to meet these requirements. Natural food of common carp is mainly based on zooplankton, zoobenthos and detritus (Adámek et al. 2003). Plankton and benthos contain high levels of n-3 polyunsaturated fatty acids (n-3 PUFA), including EPA and DHA (Mráz et al. 2012; Ljubojević et al. 2014). Therefore, good preparation of fish ponds, and appropriate technology during the growing cycle are necessary for the proper quantities, as well as favorable structure of natural food, which is of great importance regarding improving the fatty acid composition of common carp carp and other cyprinid species. Grains are commonly used as a supplementary feed for carp. Since the grains are rich in carbohydrates and have a very low level of n-3 fatty acids, the meat of carp fed with grains contains a high percentage of oleic acid and low level of n-3 HUFA (Ljubojević et al. 2013a).

Analysis of the natural food disclosed that it was rich in EPA and DHA, with a high n-3/n-6 ratio which was higher than 3 (Ljubojević et al. 2014). In the total lipid of natural food samples the proportion of SFA, MUFA and PUFA ranged from 27.6 to 28.4%, 26.1–27.4, and 45.3–46.8% of total identified fatty acids (FA), respectively. The content of total SFA as well as of palmitic acid, which was the most prevalent SFA in all groups, did not vary considerably among the experimental units. OA was the most prevalent MUFA in all units. Among n-6 PUFA, the most prevalent was arachidonic acid (AA), and relatively high percentages of LA and ALA were also detected.

## **Effects of Formulated Feed Mixtures on Fish Health, Production Parameters and Meat Quality**

Due to the intensification of cyprinid fish species production, industrially produced feed mixtures have become an essential factor in successful rearing of these species. Fish meal and fish oil represent a good source of protein and fat in feed for fish, but because of the growing volume of production and higher consumption and consequently reduced availability and a drastic increase in the price of these components, there is growing interest for the use of components of vegetable origin as a complete or partial replacement for fish meal and fish oil in fish feed. Replacement of fish meal and fish oil with components of vegetable origin in fish feed can have negative effects on meat quality of fish, including cyprinid fish species, since it is known that fish meal is a good source of amino acids, and fish oil is good source of n-3 HUFA, which is not the case for vegetable oils, which contain a high percentage of 18C n-3 fatty acids, while the vegetable oils are usually devoid of n-3 HUFA, and thus may lead to deterioration of the fatty acid composition of fish meat.

The use of components of vegetable origin and their effect on the production performance, as well as on meat quality parameters of produced fish was the aim of research conducted by Ljubojević et al. (2015), where the experiment was carried out on carp in cage rearing system. For the purpose of this trial, triplicate groups of common carp (*Cyprinus carpio* L.), average weight of 400g were distributed in twelve cages of 125 m3, while stocking density was 1000 individuals per cage. The cages, which are normaly used for commercial production of common carp were placed on Tikveš Lake (Republic of Macedonia). Prior to the feeding trial, the fish were aclimatized and fed with commercial extruded feeds (FSH "Komponenta," Ćuprija, Republic of Serbia) according to the recommendations of the manufacturer. The trial lasted 75 days, from April to June 2013. Four isolipidic extruded diets were formulated (FSH Komponenta, Ćuprija, Serbia) to provide 33% of protein [high protein (HP) diets] or 28% of protein [low protein (LP) diets]. Ingredients used for the basic diet were: soybean meal, sunflower meal with 33% of protein, corn, wheat, yeast and mineral and vitamin mix. 6% of fish oil (FO diet) or rapeseed oil (RO diet) was added in a vacuum coater to the basic formulated feed. Thus, four different diets were obtained: ROHP-rapeseed oil-high protein, FOHP-fish oil-high protein; ROLP-rapeseed oillow protein and FOLP- fish oil-low protein. Daily feed amount was given in three sessions at 8.00, 13.00, and 17.00 h; by automatic feeders.

The FOHP diet contained 29.7% saturated fatty acids (SFA) of which approximately two third (19.4%) was palmitic acid and 35.5% MUFA, whereas the content of OA was 28.5%. The FOHP diet contained 14.3% n-6 PUFA, predominantly LA (12.4%) and 20.5% n-3 PUFA, with 5.8% EPA and 11.2% DHA. Lowering protein content resulted in decreased level of SFA, which was 25.3% in the FOLP diet and in slightly increased content of MUFA (39.8%), mainly due to increased content of OA (35.6%). Inclusion of RO in high protein diet result in decreased content of palmitic, eicosanoic, AA, EPA and DHA (approximately for 7.5%; 0.1%; 0.9%; 4.5% and 8.7%, respectively). The n-3/n-6 ratio decreased from 1.4 and 0.9 in diets containing FO (with high and low protein level, respectively) to 0.5 and 0.2 in diets containing RO (with high and low protein level, respectively). The total content of MUFA was the highest in the ROLP diet, mainly due to high content of OA, which is the most abundant fatty acid in RO, but also in corn which was used to replace FM. The content of total MUFA was approximately 1.8 fold higher in diets which contained RO with the same content of protein, and 1.2 fold higher in the FOLP in comparison with the FOHP diet. The total content of n-6 PUFA was increased 1.3 fold in the diets with RO, mainly due to increased content of LA (from 12.2-14% in the diets with FO to 20.2-28.7% in the diets with RO).

There were no significant differences in initial mean weights of the fish. Following 75 days of trial, the mean weight was between 1400 g in FOHP and 1416 g in ROHP group. No statistically significant effect of oil source or protein level or interactions of these factors were observed in final body weight, although the highest body weight was observed in the ROHP group. Moreover, no significant effects of abovementioned factors or their interaction were identified in growth parameters (SGR and WG). Feed conversion ratio (FCR) was satisfactory for all treatments and ranged from 1.58 to 1.67. Two-way ANOVA showed no significant effect of oil source, dietary protein level or their interaction on FCR.

No significant effects of treatments were observed in the content of crude protein and ash in common carp fillets. Moisture content was significantly lower in carp fillets from groups which received diets with lower protein content, which was accompanied by higher content of fat in muscle tissue (Тable 10). Oil source showed no significant effect on proximate composition of carp fillets, but resulted in significant changes in fillet fatty acid compositions (Таble 11).

The proportions of the analyzed fatty acid groups were significantly affected by the diet used. Oil source and protein level significantly affected muscle fatty acid composition. However, significant interactions between oil source and protein level were observed only for a few fatty acids. It was observed that content of OA increased 1.5-fold, total MUFA 1.5-fold, LA increased 1.7-fold, total n-6 PUFA 1.4-fold and ALA 1.9-fold in flesh of common carp from group ROHP compared to flesh of carp from FOHP group. On the other hand, the content of saturated fatty acids (SFA) decreased 1.2-fold, arachidonic acid (ARA) 1.4-fold, EPA 2.8-fold, DHA 1.9-fold and n-3/n-6 ratio 1.4-fold in flesh of carp from ROHP group compared to FOHP group. The content of EPA in muscle tissue decreased more than twofold, while decrease in DHA content was moderate. It is interesting that content of DHA was higher in muscle tissue of carp fed diets supplemented with RO compared to the RO diets. Decreased level of protein in diets, i.e., replacement of FM with corn resulted in increasing content of margarinic acid (17:0), stearic acid (18:0), OA and total MUFA content and in

decreasing of content of ALA, EPA, DHA, total PUFA, total n-3 PUFA, as well as n-3/n-6 in muscle tissue of carp.

Variable (%)	<b>FOHP</b>	<b>ROHP</b>	<b>FOLP</b>	<b>ROLP</b>	Two-way ANOVA p		
					Oil	Protein	Interaction
Moisture	78	78.1	74	74.1	0.93	p<0.001	0.98
Crude protein	16.8	16.9	16.6	16.5	0.93	0.18	0.67
Crude lipid	$\overline{4}$		8.2	8.1	0.86	p<0.001

**Тable 10. Proximate composition (% of wet weight) in fillets of common carp fed the four experimental diets for 75 days (Ljubojević et al. 2015)**

All values are mean  $(n = 3)$ ; FOHP, fish oil-high protein group; ROHP, rapeseed oil-high protein group; FOLP, fish oillow protein group; ROLP, rapeseed oil-low protein group.

## **Таble 11. The main groups of fatty acids (% of the sum of all fatty acids) in fillets of common carp fed the four experimental diets for 75 days (Ljubojević et al. 2015)**

All values are mean  $(n = 3)$ ; SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; n-3 PUFA, polyunsaturated fatty acids from the n-3 family; n-6 PUFA, polyunsaturated fatty acids from the n-6 family. FOHP, fish oil-high protein group; ROHP, rapeseed oil-high protein group; FOLP, fish oil-low protein group; ROLP, rapeseed oil-low protein group.

Several studies have shown that total replacement of FO with vegetable oils, including RO in diets of cyprinid fish species, has no negative effects on fish growth and growth parameters (Turchini et al. 2007; Kukačka et al. 2009; Zakęś et al. 2010). Results obtained by Ljubojević et al. (2015) are in agreement with the previous studies and showed no negative effect of total inclusion of RO instead of FO on production parameters and growth of common carp reared in cages under natural conditions.

Ng et al. (2003) stated that the weight gain in the African sharptooth catfish *Clarias gariepinus* was considerably higher when fed with the addition of palm oil than with fish oil and assumed that a high proportion of n-3 PUFA in feed supplemented with fish oil is responsible for reducing the growth rate in this species. The high level of n-3 PUFA in feed is also associated with retardation of growth of tilapia (Ng et al. 2001) and grass carp (Du et al. 2008). Radunz-Neto et al. (1994) reported that very low content of n-3 fatty acids in feed for the larvae of common carp (peanut oil as a source of fat) did not significantly affect the growth parameters compared to the group which received a diet containing cod liver oil. Fingerlings of common carp which were fed diets supplemented with 10% corn oil, soybean oil, rapeseed oil or fish oil showed no significant differences in the growth parameters and

feed conversion ratio (Steffens et al. 1995). The high survival rate (> 95%) was observed in all experimental groups which were included in the study (Ljubojević et al. 2015), with no significant difference between the experimental treatment, indicating that the experimental feed mixtures did not have negative effects on the health of carp during the trial. Moreover, according to Keshavanath et al. (2002), carp growth in low protein diets compared to high protein diets was not significantly affected, which is in line with the results obtained by Ljubojević et al. (2015). Cho et al. (2001) noted that weight gain of common carp decreased linearly with increasing protein level in feed. In the trial conducted by Satpathy et al. (2003) the same growth parameters were observed in Indian carp (*Cyprinus catla*) fed diets contained 35% or 40% of crude protein. This phenomenon may be related to the optimization of protein level which is used for growth, while the fat or carbohydrate in feed satisfies energy needs (Caballero et al. 2002). The optimal ratio of protein and energy is a key factor for the efficient utilization of protein.

The optimal ratio of protein and energy is a key factor for the effective utilization of protein. The carbon atoms of glucose from feed can be efficiently used by carp as an energy substrate, since replacement of animal proteins with high levels of carbohydrates in feed does not affect growth performance growth. Increasing the amount of digestible starch also leads to an increase in the fat deposition, indicating that most of the carbon atoms of glucose from feed are included in the process of lipogenesis. In addition, increasing the amount of digestible starch significantly improves the retention of proteins which highlights the fact that the increasing of utilization of glucose for energy production leads to the reduction of protein wastage. If proteins are present in greater quantities than optimal in feed it leads to their utilization for energy production, which explains the results obtained by Capilla et al. (2004) that the retention of protein was lower in the group of carp fed with feed rich in proteins compared with the group fed with feed where the fish meal was completely replaced with maize and containing the lower protein content. It should be noted that in the study conducted by (Ljubojević et al. 2015), as well as in previously research, lipids in the experimental diets were not just from the added oil, lipids were also from the used vegetable meal and from fishmeal (fat content originating from the added oil in research Ljubojević et al. (2015) was 73.5% of total fats). Keshavanath et al. (2002) observed no changes in production parameters of carp when total amount of FM in the diet was replaced by corn (diet with 19% protein). It must be taken into account that, in the above mentioned experiment, tanks with fertilized bottoms were used, which corresponds to the production of carp in earthen fish ponds. The authors noted a protein sparing effect with the use of ingredients rich in carbohydrates, and this effect was pronounced when protein level was sub-optimal, compared to optimal protein level in diets for common carp fingerlings. A protein-sparing effect was confirmed in the study conducted by Ljubojević et al. (2015), and similar results regarding production performance were found when diets with 33% and 28% protein were used. Experiments conducted to date indicate that, when nutritional needs for essential fatty acids for omnivore species such as common carp, but also herbivores, such as tilapia and grass carp are fulfilled, the use vegetable oils in feed for these species does not affect growth performance or the feed efficiency. In addition, the need for fatty acids with 20 and 22 carbon atoms (C20 and C22 HUFA) can be met from their precursors in feed.

According to previous research (mainly on salmon and trout) results showed that both factors of protein levels and oil sources have an influence on the chemical composition of the examined fish (Solberg 2004; Torstensen et al. 2004; Ruyter et al. 2006; Trbović et al. 2012).

Nutritional requirements of carp for proteins vary from 25% to 35% (Hossain et al. 1997) and are highly dependent on the age of the fish. Steffens (1996) indicates that the increase in energy content in feed is a possible strategy for saving protein and limiting the production of ammonia in fish ponds. Ljubojević et al. (2015) noted that moisture content was significantly lower in carp fillets from groups which received diets with lower protein content, which was accompanied by higher content of fat in muscle tissue. Thus, an increased level of carbohydrates resulted in increasing deposition of fat, both around visceral organs and in muscle tissue. Similar findings were noticed after the inclusion of carbohydrate-rich grains, in the feed of common carp in a semi-intensive system (Vasha et al. 2007; Ljubojević et al. 2013а). A negative correlation between the fat and water contents in the flesh of the carp was also previously shown (Ljubojević et al. 2013a). The research conducted by Keshavanath et al. (2002) also showed that chemical composition of carp flesh was influenced by the experimental diets, especially contents of fat and ash. They observed progressive increase in fat contents in muscle tissue with increase of carbohydrate content in diets, while the protein content was constant in all dietary treatments. Ljubojević et al. (2015) also indicate that the retention of the protein in the muscle tissue was achieved when the level of dietary protein decrease, which further indicates that the protein sparing effect, was achieved. The content of SFA in common carp fillets was higher than in the RO and LP diets tested, and in the fillets of the carp fed diets supplemented with RO and with lower protein content it increased sufficiently, so that it was comparable to the values noted in the FO and HP groups. Accordingly, the quantitative and qualitative content of SFA in the experimental diets supplemented with RO was sufficient to maintain this group of fatty acids at a level comparable to values noted in the fish from group FO. This is a noteworthy finding since SFA in muscle tissue represent an important component of polar lipids. In several studies conducted on marine fish species during feeding with feed with addition of vegetable oil was found lower levels of SFA in muscle tissue compared to fish fed diets with addition of fish oil (Izquierdo et al. 2003, Montero et al. 2005). This was also confirmed by Molnár et al. (2006), during feeding trial in perch fingerlings with the addition of linseed oil in feed. Fish feeding with feed which comprise oils of vegetable origin which are rich in the C18 fatty acid (OA, LA, ALA), leads to an increase in the content of these fatty acids in tissues (Mourente et al. 2005). It seems that common carp utilize OA well as a source of metabolic energy (Ljubojević et al. 2015). Lowered levels of this FA in the muscle tissue, regardless of the dietary treatment, might mark highly active mitochondrial enzymes oxidizing FA (Torstensen et al. 2000). This can be related to the fact that mitochondrial β-oxidation is of specific importance to muscle tissues (Nanton et al. 2003).

Fatty acid composition of carp meat is heavily influenced by the fatty acid composition of carp feed (Steffens and Wirth 2007; Ljubojević et al. 2013а) and there is a linear correlation between individual fatty acids in the total fat in the tissue and their concentration in lipids from feed according to research conducted by Ljubojević et al. (2014). Oil source and protein level significantly affected muscle fatty acid composition. However, significant interactions between oil source and protein level were observed only for a few fatty acids. It was observed that content of OA increased, as well as total MUFA, LA, total n-6 PUFA and ALA in flesh of common carp from group ROHP compared to flesh of carp from FOHP group. On the other hand, the content of saturated fatty acids (SFA) decreased, as well as arachidonic acid (ARA), EPA, DHA and n-3/n-6 ratio in flesh of carp from ROHP group compared to FOHP

group. The content of EPA in muscle tissue decreased more than twofold, while decrease in DHA content was moderate. It is interesting that content of DHA was higher in muscle tissue of carp fed diets supplemented with RO compared to the RO diets. Decreased level of protein in diets, i.e., replacement of FM with corn resulted in increasing content of margarinic acid (17:0), stearic acid (18:0), OA and total MUFA content and in decreasing of content of ALA, EPA, DHA, total PUFA, total n-3 PUFA, as well as n-3/n-6 in muscle tissue of carp. These data showed that when specific fatty acids are in abundance in the diets that they are selectively utilized for energy production via β-oxidation, and for desaturation and elongation (Bell et al. 2003). In contrast, when FA, and especially n-3 HUFA, are limited in the diet they are retained or deposited in the muscle or in other tissues. Along with the selective deposition and retention of n-3 HUFA, moderate reduction of EPA and DHA may also be affected, albeit to a lesser extent, by desaturation and elongation of alpha-linolenic acid occurring in the liver which can be enhanced by including vegetable oils of vegetable in fish feed (Tocher et al. 2003). On the other hand, EPA is likely to be used and catabolized to generate energy and to a lesser extent, will be deposited in the biomembranes than DHA (Morais et al. 2011). It has been shown that feed containing vegetable oil leads to improved retention of n-3 fatty acids in salmon and in this way makes reserves that will be used in case of need (Bendiksen et al. 2003). In addition, it is known that the presence of vegetable oils activated fatty acid desaturation and elongation in vitro (Tocher et al. 2000; Bell et al. 2001). In study conducted by Ljubojević et al. (2015) trends in levels of docosapentanoic acid (22:5n-3, DPA) and DHA in carp fillets relative to their respective dietary contents (DPA and DHA increased in fillets) suggested the bioconversion of EPA to DHA. A similar trend of the selective deposition was seen in n-6 FA in which improved retention was seen in AA.

The intermediates, gamma-linolenic acid (18:3n-6), eicosadienoic (20:2n-6), dihomo-γlinolenic (20:3n-6) and eiocosatrienoic (20:3n-3) acid were detected in carp fillets in RO groups. Since vegetable oils are deprived of these fatty acids and they are part of the biosynthetic pathways of n-6 and n-3 HUFA, this result features adaptive attempts to moderate HUFA deficiencies. When the content of ALA or LA in the diets was increased, eicosatrienoic acid 20:3n-3 or eicosadienoic acid 20:2n-6 content in muscle tissue was also increased. A similar phenomenon was observed in Atlantic salmon (Tocher et al. 2002). Ghioni et al. (2002) have shown that the ingested stearidonic acid 18: 4n-3 rapidly converted in eicosatrienoic acid 20: 4n-3, and that both of above mentioned fatty acid is further subjected to the process of elongation and desaturation to EPA and 22: 5n-3, but not the 22: 6n-3 in cell culture of salmonids. The high level of LNA and LA in feed mixtures supplemented with rapeseed oil and the content of n-3 HUFA from fishmeal appears to meet the needs for essential fatty acids of common carp in research conducted by Ljubojević et al. (2015). This is probably derived from the ability of common carp to selectively retain DHA and bioconvert LNA to EPA and DHA; EPA to DHA, and LA to AA. Therefore, results obtained by Ljubojević et al. (2015) indicate that the common carp have high tolerance to diets that differ significantly in fatty acid composition. It is also noteworthy that the main consequence of higher DHA and lower LA contents in the fillets of the common carp was the increased value of the n-3/n-6 ratio compared to the levels of this ratio in the diets. However, in the case of the RO and LP groups, value was significantly lower than that in the groups FO and HP. Despite the deficit of C20 and C22 fatty acids in fish feed supplemented with rapeseed oil, a low content of these fatty acids was detected in meat of goldfish (Pozernick and Wiegand 1997), and this phenomenon is explained by the ability of freshwater fish to

produce HUFA from LA and ALA (Buzzi et al. 1996). It is known that MUFA are produced by desaturation of SFA or by synthesis in the body from food rich in energy (Csengeri 1996; Henderson 1996), in a same way as other vertebrates by desaturation of the present compounds by using the  $\Delta$ -9 desaturase or could be produced from external sources and stored directly into adipocytes.

Deposition of EPA and DHA in the muscle tissue of common carp indicating a high potential for the use of rapeseed oil as an ingredient in feed for carp and further research during the whole growing season is necessary, in order to avoid the possibility that the results obtained in a relatively short period of time show no real degree of change in fatty acid composition to the end of the growing cycle. The biggest problem is the high cost of this type of trial. Despite an increase in total world consumption of fish meal and fish oil in aquaculture, the average share of fishmeal and fish oil in feed for particular species is in steadily decline, as is the case with crabs (from 28% to 20%), marine fish species (from 50% to 32%), salmon (from 45% to 30%) and carp (from 10% to 5%) (Tacon and Metian, 2008). The great number of previous studies, which more than two decades is dealing with this problem, certainly contributed to the above mentioned fact, but there is still a need to reduce consumption of these ingredients in order to preserve natural resources and to ensure economically sustainability of fish production.

## **Effects of Age, Sex and Genetic Factors on the Chemical Composition of Fish Meat**

#### *Age*

Results related to meat quality of carp are vary among authors, with differences mostly caused by analysis of different-aged fish. Ljubojević et al. (2011) analyzed the meat quality of one-year-, two-year- and three-year-old common carp and found that age significantly affects the chemical composition of meat, mostly with reduced water content and increased fat content in meat with increasing age, but to a small extent on the fatty acid composition of the fish. The established n-3/n-6 in different categories were in the range from 0.1 to 0.16, and the most favorable ratio was observed in one-year-old carp and the least favorable in threeyear-old carp. Results obtained by Ljubojević et al. (2011) were consistent with studies conducted by Trbović et al. (2009) on the yearling carp, and the ratio was lower than the results obtained by Ćirković et al. (2012) for two-year-old carp which were fed with natural food. Fat and moisture content increased with age, while amount of protein and ash decreased in older common carp. It was found that the age of the fish had a much smaller effect on the fatty acid composition of fish meat compared to effect on the chemical composition of fish meat. Thus, no significant effect of age on n-3/n-6 ratio was observed. Percentage shares of EPA and DHA slightly decreased with age, as well as PUFA/SFA ratio which is an indicator of the quality of fat, PUFA content decreased with age while MUFA content increased.

The fat content was the most favorable in meat of two-year-old carp, while the fat content in meat of three-year-old carp was slightly above 10%, and more than 10% of fat in carp meat could lead to a negative sensory properties of meat. The two year production cycle could be a good way to produce carp with optimal chemical composition of meat.

Low content of n-3 fatty acids in all three age categories is due to nutrition, which is applied to the pond from which the samples were taken, where grains are added as additional feed. The consequence of this type of production and great amount of grains in nutrition is reflected in a large percentage of oleic acid in the fat from all three examined age groups (over 50% of total fatty acids). The meat quality of carp could be improved by introducing completed feed mixtures and improving agro-technical measures, in order to increase production of natural food in the pond.

Fauconneau et al. (1995) found that the increase in body weight of carp is stimulated by increased feed intake, regardless of the age of fish and that is closely associated with an increase in fat content, both in the flesh and in muscle tissue of fish. This fact is very important in breeding of carp, because high energy level in feed for stimulation growth and shortening production time affects the increase in fat content, while the protein content in the meat remains constant (Kaushik 1995).

#### *Genetic Factors*

It has been shown that the fat content in the muscle highly heritable traits in common carp and that there is a relatively high positive genetic correlation between body size (body length and body weight) and fat content in muscle tissue (Kocour et al. 2007). On the other hand, Buchtova et al. (2007) did not note the impact of hybrids on the fatty acid composition in experiment with four different hybrids of common carp. It is obvious that there is a need for further research when it comes to genetic factors.

#### *Sex and Sexual Maturity*

Buchtova et al. (2010) in their research on four hybrids of common carp found only small differences in the fat composition between males and females, which are probably caused by different fat content in muscle tissue. Fajmonova et al. (2003) did not note the difference between the sexes when it comes to fat content and fatty acid composition in three-year-old common carp.

#### **CONCLUSION**

Common carp is one of the most important fish species worldwide and represents an important nutritional source of unsaturated fatty acids. Its meat has been shown to play an important role in human health. It was found that the fat content and fatty acid composition significantly differs in different fish species, even when they belong to the same family. In addition, the same parameters were found to be influenced by different environmental factors, good production technology аnd appropriate structure of planktonic and benthic organisms, especially by diet. Using formulated feed mixtures had a positive effect on fish health, production parameters and meat quality.

#### **ACKNOWLEDGMENTS**

I am thankful to the Ministry of Education, Science and Technological Development of the Republic of Serbia for the financing of the project 'The influence of the quality of the

components in cyprinid fish feed on the meat quality, losses and cost-effectiveness of production' (TP-31011), which enabled the research and obtaining numerous results published in this Chapter.

# **DISEASES OF COMMON CARP AND THEIR CONTROLMEASURES**

*M. M. Rahman1,\* , M. Nur-Nazifah<sup>1</sup> and S. R. Balcombe<sup>2</sup>*

<sup>1</sup>Department of Marine Science, Faculty of Science, International Islamic University Malaysia, Kuantan, Pahang, Malaysia <sup>2</sup>Australian Rivers Institute, Griffith University, Nathan Qld, Australia

# **ABSTRACT**

Common carp (*Cyprinus carpio* L.) contribute significantly to global freshwater fish production but it may also play a significant role in the expansion of various parasitic fish diseases around the globe as many parasites are dispersed locally and internationally due to common carp trade. The production of common carp in natural habitats and in aquaculture farms often become threatened due to various factors including disease outbreaks. Disease increases the management costs as well as decreasing fish production. To prevent and control various diseases, it is important to understand the mechanism of disease outbreak, which generally involves a complex interaction among fish, pathogens and the environment. High stocking density, poor management practises and various environmental problems result in exposure of fishes to stress that often leads to disease. The disease can also be initiated by various biological agents, which can be prevented and controlled by effective management practices. Due to the preference of soft vegetated sediments as habitat, common carp is also susceptible to many pathogens (e.g., viruses, bacteria, fungi, parasites, etc.), which cause various diseases. A severe pathogenic infection may cause high mortality of fish. This paper reviews various diseases of common carp and their control measures.

**Keywords:** disease, common carp, causative agent, sign, prevention, control measure, viruses, bacteria, fungi, ectoparasites, endoparasites, life cycle, host

# **INTRODUCTION**

Common carp (*Cyprinus carpio* L.) perhaps represents the one fish species, freshwater or marine that has attracted the most attention from humans across the globe. It is one of the most widely distributed freshwater fish in the world (Piria et al. 2016). In many countries particularly in Central Asia and Europe, common carp is one of the most popular food fish and is commonly cultured in aquaculture ponds applying extensive or semi-intensive methods. In many countries, common carp is considered as the main aquaculture species. Thus, it contributes significantly to global fish production, particularly global freshwater aquaculture production. In some countries, particularly in Australia and North America, common carp is considered as a destructive invasive alien species as it causes major impacts to habitat and ecosystems including affecting many local species. It is one of the most destructive fish, being among the hundred worst invasive alien species (Zambrano et al. 2006; Khan et al. 2016). It is often believed that common carp play a significant role in the ongoing expansion of various parasitic fish diseases around the globe (Oros et al. 2015). Many parasites have been dispersed locally and internationally due to the common carp trade which are then spread to local fish populations. While there are a multitude of factors that can impact on the production of common carp, in both natural and farmed populations, disease is one of the most important factors (Hoffman 1999). Disease increases the management costs of carp farming and also leads to reduced profits due to diminished fish production. The tentative estimated annual global loss of fish production due to disease is \$1.05 billion to \$9.58 billion (Shinn et al. 2015). To prevent and control various diseases, it is important to understand the mechanism of disease outbreak, which generally involves the complex interaction among fish (host), causative agents of disease (pathogens) and the environment (Snieszko 1974). High stocking density, poor management practices and various environmental drivers result in exposure of fish to stress that often leads to disease (Snieszko 1974; Lavilla 2001). Biological agents (pathogens) particularly viruses, bacteria, fungi and parasites may initiate disease. Their growth and abundance are related to various environmental factors (e.g., temperature, various dissolved gases, pH, and availability of food). However, sound management practices can reduce the growth and abundance of biological agents.

Common carp prefer to live near the soft vegetated sediments, which is generally characterized by poor water quality and high decayed organic matter. Due to this habitat preference, common carp is susceptible to many benthic-associated pathogens, which cause a range of diseases. Commonly encountered diseases of common carp include Saprolegniosis, Branchyo-mycosis, Erythrodermatitis, Columnaris disease, Bacterial gill disease, Mycobacteriosis, Spring viraemia of carp, Carp pox, Koi Herpes Virus Disease, Costiosis, Coccidiosis, Ichthyophthiriosis, Chilodonellosis, Trichodinosis, Myxobolosis, Dactylogyrosis, Gyrodactylosis, Diplostomosis, Phosthodiplostomosis, Sanguinicoliasis, Ligulosis, Bothriocephalosis, Khawiosis, Nematode infestation, Phylometrosis, Fish Leech infestation, Ergasilosis, Lernaeosis and Argulosis. This chapter reviews diseases of common carp and their control measures.

# **SAPROLEGNIASIS**

Saprolegniasis is a fungal disease caused by water molds of the family *Saprolegniaceae*. Many species are responsible for this disease. Most of the species are from the *Saprolegnia, Achyla, Aphanomyces and Dictyuchus* genus. They infect eggs, fry, fingerlings and adult common carp and this disease is, therefore, considered a major problem in common carp aquaculture (Bruno et al. 2010). Saprolegniasis generally occurs more in hatcheries compared to fish farms. The optimum temperature for the causative agents is 15 to  $30^{\circ}$ C but the range of temperature for their growth is 3-33°C (Aly and El Ashram 2000)*.* Sudden changes in temperature can make fish vulnerable to saprolegniasis, due to increased physiological stress (Bruno et al. 2010; Das et al. 2012). In India, Das et al. (2012) observed severe mortality of fingerlings by this disease during the period of early November 2009 to late January 2010 (winter months). They observed that fishes died within 12-15 days from the onset of infection. The causative agents generally attack an existing injury on the fish and gradually spread to healthy tissue. Presence of dead eggs and poor water quality particularly low water circulation, low dissolved oxygen and high ammonia can influence rapid spreading of the disease (Ruthing 2009).

# **Causative Agents**

Species in the genera of *Saprolegnia* (most common)*, Achyla, Aphanomyces and Dictyuchus*. The major etiological agents of saprolegniasis *Saprolegnia parasitic*, *Saprolegnia diclina* and *Achlya hoferi* for freshwater fish and fish eggs.

## **Disease Signs**

White fungal colonies appear on egg surface, body surface, and wounded or ulcerated areas of fish. The first sign of infection is visible red or grey patches of filamentous mycelium. Gradually, the infected area would appear as cotton-like, white to grey growth on the skin, gills, fins and eyes or eggs of fish. An acute infection takes 7-8 days from the beginning of infection (Das et al. 2012). In severe cases, almost the whole body may be covered with fungal growth.

#### **Management and Control**

Malachite green at 5 mg/L for one hour or 5% sodium chloride at 1-2 mg/L or combination of 100 mg/L of formalin and 2.5 mg/L of malachite green for one hour are generally used for the infestation of infected eggs, fry, fingerlings and adult fish (Eli et al. 2011). Repeated doses can be used if necessary, although malachite green and formalin do have an acute impact on the aquatic environment. Immunity of fish frequently treated with these chemicals is suppressed (Prost and Spinska 1989). Das et al. (2012) suggested two steps

at the beginning of infection for a faster recovery: dipping fish with 4g salt per liter of water for 2 minutes followed by with 5 ppm potassium permanganate  $(KMnO<sub>4</sub>)$  for 10 minutes.

# **BRANCHYOMYCOSIS**

Branchyomycosis is a fungal disease and also known as gill-rot disease. This disease is found in fish suffering from an environmental stress particularly low pH and dissolved oxygen (Ramaiah 2006). The main sources of infection are the fungal spores carried in the water and detritus on pond bottoms and it therefore, occurs in the environments in which there is an abundance of decaying vegetation (Jhingran and Pullin 1985). It is an acute infection of the gills that may cause high mortality of common carp due to anoxia through obstructing the flow of blood through the gills (Noga 2010). The tubules of fungus grow into the epithelial cells of the gills, causing inflammation and damaged blood vessels around the epithelial cells. The infected gill can be rotten due to decreased blood supply and gill epithelial cell hyperplasia. It usually occurs at temperatures exceeding 20°C (Jhingran and Pullin 1985). The responsible fungus species can grow best between 25° and 32°C but can still grow at temperatures between 14° and 35°C. Fry and small fingerlings are more susceptible to this disease compared to adult fish.

#### **Causative Agent**

*Branchiomyces sanguinis*

## **Disease Signs**

Fish may appear lethargic. Infected gill filaments become brownish with white or gray streaks. Fish suffer from respiratory distress observed by behaviours such as rapid movement of the operculum. Fish exhibit signs consistent with oxygen deprivation and therefore, gulp air at the water surface. Occurrence of secondary bacterial and viral infection is almost common (NACA 1989). Severely infected fish have typical gill-rot lesions, which may be similar to those associated with other gill infections.

#### **Management and Control**

Good management practices can create environmental conditions unacceptable for fungal growth and therefore, culture systems should be dried and treated with quicklime (calcium oxide, dose: 150-200 kg/ha) and copper sulfate (2-3 kg/ha) before starting the culture cycle. A therapeutic bath with 5% NaCl (salt) for 5-10 minutes can improve the infection. Copper sulfate and formalin are also suggested for treating infected fish. An antibiotic may also be used if secondary bacterial infection occurs (NACA 1989). As the tissue dies and falls off, the spores are released into the water and transmitted to other fish. Therefore, great care must be taken to prevent movement of the disease from infected fish to uninfected fish. Infected fish should be reared separately until recovery from the disease.

# **ERYTHRODERMATITIS**

Erythrodermatitis is commonly known as ulcer disease because it causes inflammatory lesions of the skin and by necrosis leading to ulceration. It is a sub-acute to chronic contagious disease of the skin (Pol et al. 1980). This disease is common all over the world including Europe. In 1987, this disease caused high losses of common carp in Greece (Sioutas et al. 1991). In late 1980, this disease occurred with seriously skin ulcerations in West Java, Indonesia (Jhingran and Pullin1985). Besides common carp, other carp species are also susceptible to this disease. The infection often starts at the site of an injury on the skin and base of fins. The infected area become a red inflammatory zone and gradually raised skin lesions form which then ulcerate exposing the underlying muscles. Bacteria probably release some toxic compounds, which could account for the marked inflammation and the tissue necrosis (Pol et al. 1980). Severe occurrence of this disease generally occurs in the spring when water temperature rise and bacterial growth is increased.

#### **Causative Agents**

This disease is caused by a variety of widespread and common bacterium species, but particularly, *Aeromonas hydrophila, Aeromonas salmonicida, Pseudomonas* spp. are the most common agents.

#### **Disease Signs**

The following signs are common in fish infected by the Erythrodermatitis (NACA 1989).

- Erythema (redness) on the skin and base of fins, often some small spherical nodules on fins
- Hemorrhages and ulcers with jagged rims
- Protruding scales
- Exophthalmia
- Swollen abdomen
- Hemorrhages on gills
- Pinkish fluid in the body cavity
- Secondary *Saprolegnia* infection

Reducing stocking density and stress by applying extensive culture technologies are beneficial to prevent this disease (NACA 1989). A wide range of sulfonamide drugs such as sulfamerazine, sulfaguanadine, sulfadiazine, sulfamethazine and sulfisoxazole can be used to treat this disease. The drug terramycin (antibiotics) can be supplied with feeds at  $5-7$  g/100 kg fish daily for 7-10 days or intra-peritoneal injection can be applied at 25 mg/kg body weight (Jhingran and Pullin1985).

# **COLUMNARIS DISEASE**

Columnaris disease is considered to be an important bacterial disease and was first reported by Davis (1992) in warm water fishes of the Mississippi River. It is distributed worldwide in various wild and cultured freshwater fish species including common carp (Declercq et al. 2013). Fish infected by this disease may display skin lesions, fin erosion and gill necrosis and for those infected there is a high degree of mortality (Figueiredo et al. 2005; Declercq et al. 2013). A recent experiment indicates that common carp die within 12 h after inoculation of the causative agent of this disease. This disease exhibits a diffuse lesion by affecting all gill arches bilaterally (Declercq et al. 2015). Generally, outbreaks of this disease are associated with poor water quality with a high organic load, high temperature and high fish density (Decostere et al. 1999). According to Jhingran and Pullin (1985), the outbreaks of this disease usually occur only at temperatures above 18 to 20°C.

A clinically healthy fish which has survived from a previous outbreak of columnaris disease may act as an infection source for other fish (Suomalainen et al. 2005; Declercq et al. 2013). For example, a rainbow trout (*Oncorhynchus mykiss*) surviving from a columnaris infection can release up to 5 thousand colony forming units/ml/h of viable bacteria into tank water (Fujihara and Nakatani 1971). However, a dead fish release the agent of the disease at a higher rate compared to living fish (Kunttu et al. 2009; Declercq et al. 2013). It is very hard to eradicate this bacterium from an aquatic environment. The bacteria can survive at a high temperature (25°C) up to 16 days in hard, alkaline water with a high organic load (Fijan 1968; Declercq et al. 2013). It can grow on particulate fish feed and can even survive in sterile river mud (Declercq et al. 2013).

#### **Causative Agent**

*Flavobacterium columnare (gram-negative bacterium)*

#### **Disease Signs**

This disease causes serious infections characterized by lesions on the head, back, gill and fins. The lesions may start as small raised whitish plaques, often with a reddish peripheral zone and soon develop into large hemorrhagic ulcers (Jhingran and Pullin 1985).

Both external treatments and oral administration are applied to recover fish from this disease. External treatments are possible when the infection is still superficial. Potassium permanganate, chloramphenicol, copper sulfate, nifurpirinol, nifurprazine and oxolinic acid are used effectively in bath therapies. Oxytetracycline and terramycin are used with feed if the disease is in an advanced stage.

# **BACTERIAL GILL DISEASE**

Bacterial gill disease is caused by a filamentous bacterium, which is highly contagious to fish. It is probably cosmopolitan in its distribution and nearly all freshwater fish are potential hosts. This disease can reside in carrier fish and culture systems. The bacteria can colonize on fish gill tissues in less than one hour after contamination of viable bacterial cell (Ostland et al. 1995). It disturbs gas exchange due to thickening of the epithelial layer. Poor water quality condition (low dissolved oxygen, high unionized ammonia  $(NH<sub>3</sub>)$  and water turbidity) together with high stocking density may influence acute outbreak of this disease. Acute outbreaks of this disease generally cause a daily high mortality per day. Suitable water temperature for the disease outbreak is generally from 5° to 19°C (Bullock et al. 1994).

#### **Causative Agent**

*Flavobacterium branciophyla*

#### **Disease Signs**

Affected fish generally lose appetite and therefore, they become lethargic and are commonly observed gulping near the water surface. They normally gather near the outlet of the culture system. White areas of gill appear as pale and swollen. Necrosis of infected areas may occur but not common. Sometimes opercula become flared. Epithelial hyperplasia may occur due to attachment of large number of filamentous bacteria to the gill.

#### **Management and Control**

Good water quality together with low stocking density is very useful to prevent the disease. Treatment with a salt bath (5%) is also helpful to recover fish from this disease. Adding copper sulfate at 0.5 ppm, and potassium permanganate at 2 to 4 ppm to ponds is also successfully used for recovery of fish from this disease.

# **MYCOBACTERIOSIS**

Mycobacteriosis in fish is caused by mycobacteria, which are abundant in the soil, on the surface of plants, on the skin of vertebrates and in human food (Snieszko 1978; Gauthier and Rhodes 2009). It is one of most common chronic diseases worldwide in cultured and wild fishes (Gauthier and Rhodes 2009). However, fish pathogenic mycobacteria differ from those that cause diseases in other animals. Fish pathogenic mycobacteria belong to the genus *Mycobacterium* under the *mycobacteriaceae* family. All fish, particularly teleost fish are susceptible to this disease. The first case of mycobacteriosis was seen in common carp in a pond in France (Snieszko 1978). However, it is infrequently reported as a problem in wild and cultured common carp. Fish can be susceptible to this when they are in poor condition and also have scale loss, skin ulcers, or a history of reproductive problems (Francis-Floyd et al. 2011). Poor water quality with high organic loads and high fish stocking density can exacerbate the mycobacteriosis infection (Francis-Floyd et al. 2011).

## **Causative Agent**

*Mycobacterium foptuitum*

#### **Disease Signs**

The external signs of mycobacteriosis depend on the species of fish affected and the water temperature. Loss of appetite, sunken abdomens, shallow grayish irregular ulcerations, fin rot, deformities of the vertebral column and mandible, exophthalmos, and loss of one or both eyes are external signs in fish infected by this disease (Snieszko 1978).

#### **Management and Control**

There is no widely accepted treatment for this disease and, therefore, destroying infected populations are recommended to reduce spreading of this disease (Gauthier and Rhodes 2009). This bacterium is very resistant to standard anti-mycobacterial antibiotics including streptomycin, isoniazid, rifampicin, and ethambutol (Bragg et al. 1990; Gauthier and Rhodes 2009). There is an incomplete understanding around the management of this disease and significant effort should be directed into its research.

# **SPRING VIRAEMIA OF CARP (SVC)**

Spring viraemia of carp (SVC) is an infectious viral disease of common carp of all age groups. It is distributed mainly in temperate countries. This disease is generally not observed in tropical or subtropical climates. Although other cyprinid fish (e.g., grass carp *Ctenopharyngodon idella*, silver carp *Hypophthalmichthys molitrix*, crucian carp *Carassius*, goldfish *Carassius auratus*, etc.) are also hosts of this virus, the main host is common carp. It is considered as a notifiable disease as it causes significant mortalities in carp species, particularly common carp. SVCV is bullet-shaped RNA virus. The virion measures approximately 80 to 180 nm in length and 60 to 90 nm in diameter (Ahne et al. 2002).

The disease spreads through blood-sucking parasites and faeces of infected fish. Occurrence of this disease with a high mortality rate usually occurs in spring, when water temperature begins to rise after a cold winter. The suitable temperature for spreading SVC is between  $10^{\circ}$ C and  $17^{\circ}$ C. The virus can remain infective in the water for more than 4 weeks and in mud for about 6 weeks at 4°C to 10°C (Ahne et al. 2002). The first targeted organ of Spring viraemia of carp virus (SVCV) is gills then gradually entering internal organs (liver, kidney, spleen, alimentary tract, etc.) via blood (Ahne et al. 2002). The first observed clinical signs are edematous viscera, peritonitis, enteritis and hemorrhages in different organs after 8 to 11 days of infection and first mortalities appear after 20 days of infection (Ahne et al. 2002). Generally, fish less than one year old are very susceptible to infection with SVCV. Cumulative mortality of young fish infected by the SVC can be up to 90%.

#### **Causative Agent**

*Rhabdovirus carpio*

#### **Disease Signs**

In carp, the external signs of SVC include lethargy, darkened body, hemorrhages of the skin, pale gills, decreased respiration rate, exophthalmia, loss of equilibrium, abdominal distension, and fish congregating near inlet or outlet in enclosed systems, and an inflamed or edematous vent. Internal signs include peritonitis, ascites, catarrhal and hemorrhagic enteritis, edematous viscera and petechial hemorrhages of the internal wall of the swim bladder (Negele 1977; Ahne et al. 2002). The blood vessels can be fully necrotic in the final stage of the disease.

# **Management and Control**

Fish, particularly adult common carp are generally protected from this disease if water temperatures are more than  $20^{\circ}$ C, as at this temperature fish are able to produce protective levels of interferon and antibodies (Ahne et al. 2002). Juvenile fish can be infected at more than 20°C of water temperature. However, elevated water temperature can prevent the outbreaks of SVC. Infected fish should not be transferred to uninfected farms to prevent spreading of SVCV. Fish develop a strong protective immunity against SVCV if they survive from SVC outbreaks. Presently, there is no vaccine against SVC.

# **Carp Pox**

Carp Pox is one of the oldest known fish diseases, which is caused by a herpesvirus infection. This virus is referred as Cyprinus Herpesviris 1 (CyHV-1). It is a contagious disease in overcrowded condition but it does not generally kill fish. Pox-like appearance on the fish body is due to abnormal dermal cell growth and/or neoplasms. This disease is widely distributed in almost all countries of the world and affects usually cyprinids particularly common carp (Haenen et al. 2004; Goodwin 2012). The fish are not distressed if the infection only attacks small areas of the body. However, fish may be distressed if the lesions cover the mouth or gills that impede feeding and/or respiration (Walker and Winton 2010). Fish may susceptible to secondary infections if they become weak due to severe infection.

#### **Causative Agent**

Cyprinid herpesvirus 1 (CyHV-1)

#### **Disease Signs**

Initially, the carp pox appears as milky or grey-white lesions. The lesions first appear as flat, smooth and raised and can develop all over the external surface including fins of the fish. In severe case, the lesions can be thicker on the body, which may weaken the fish. Secondary infection by bacteria may occur if immunity is suppressed.

#### **Management and Control**

Elevated temperature is helpful for recovering the disease and healing the wounds. Fish, previously infected, although recovered are then sources of infection. Therefore, stocking previously infected fish should be avoided.

# **KOI HERPES VIRUS DISEASE (KHV)**

Koi Herpes virus disease (KHV) considered as one of the most important disease of koi and common carp. It is a highly contagious disease that can cause mass mortalities (up to 80 to 100%) in koi and common carp of all ages (Haenen et al. 2004; Ilouze et al. 2006; Michel et al. 2010). This disease cause severe economic losses to the carp culture industry worldwide (Adamek et al. 2014; Boutier et al. 2017). This disease is caused by Cyprinid herpesvirus 3 (CyHV-3), which contains a double-stranded DNA genome. The virus can infect a wide range of species including freshwater mussels and crustaceans but it causes disease only in koi and common carp. This virus can cause disease in hybrids of koi  $\times$  goldfish, koi  $\times$  crucian carp and common carp  $\times$  goldfish with a high mortality rate (Hedrick et al. 2006; Bergmann et al. 2010).

The virus can stay in a latent or carrier state without obvious clinical signs in host fish for some period of time. Movement by such carrier fish via international trade has resulted in the rapid spreading of the disease across the globe (St-Hilaire et al. 2005). Many scientists believe that the worldwide trade in koi and common carp is generally held responsible for the spread of the virus. Piscivorous birds may also be responsible for the rapid spread of this disease (Boutier et al. 2015). Besides koi and common carp, goldfish, tench, vimba, common bream, common roach, European perch, ruffe, gudgeon, rudd, northern pike, Prussian carp, silver carp and grass carp can carry CyHV-3 and transmit it to native carp (Boutier et al. 2015). Although this disease first occurred in koi carp in Europe in 1996, the first severe outbreak of this disease was in koi and common carp farms in Israel in 1998 (Haenen et al. 2004). Most of the European countries have experienced the widespread mass mortality in carp farms. Presently, the disease has been recorded at least 28 different countries including Australia, USA and Canada. Disease occurs generally at water temperatures between 15.5 ºC and 28ºC on common carp and its varieties with an incubation period of 6-21 days depending on water temperature (Hara et al. 2006; Rakus et al. 2013; Haenen et al. 2004). Sometimes fish die within one hour of the first signs appearance (Haenen et al. 2004). Australia is currently considering the introduction of CyHV3 for the biological control of common carp, where they have been implicated in massive degradation of aquatic ecosystems (McColl et al. 2017)

#### **Causative Agent**

Cyprinid herpesvirus 3 (CyHV-3)

#### **Disease Signs**

The clinical signs of KHV vary among individual fish depending on the severity of infection (Boutier et al. 2015). Behavioral signs include lethargy, fatigue, disorientation, neurological symptoms with erratic swimming, loss of equilibrium, increased gill beat rate expressed by gasping at the water surface and gathering near well-aerated areas (Perelberg et al. 2003; McDermott and Palmeiro 2013; Rakus et al. 2013). The consistent clinical signs are moderate to severe gill necrosis with diffuse discoloration. Other common clinical signs are anorexia, sunken eyes, fin erosion, folding of the dorsal fin, sloughing of scales, superficial hemorrhaging at the base of the fins, pale, hemorrhages and ulcers on the skin associated with increased mucus secretion and also decreased production of mucus in the ulcer areas, leaving the epidermis with a sandpaper-like texture, and accumulation of abdominal fluid and abdominal adhesions (Haenen et al. 2004; McDermott and Palmeiro 2013; Perelberg et al. 2003). Histopathological changes generally occur in the gills, skin, gut, liver, kidneys, heart, spleen and brain of infected fish (Miyazaki et al. 2008; Boutier et al. 2015). However, most severe damage is observed on the skin and fins (Miwa et al., 2014). Hepatocytes are the most affected cell in the liver (Miyazaki et al. 2008). In the kidney, a weak peritubular inflammatory infiltrate accompanied by blood vessel congestion and degeneration of the tubular epithelium in many nephrons is observed (Pikarsky et al. 2004; Boutier et al. 2015). The main susceptible cells are the splenocytes in the spleen. According to Miyazaki et al.

(2008), a large numbers of necrotic splenocytes accompanied by hemorrhages are observed in extreme cases. Focal meningeal and parameningeal inflammation is usually observed in the fish brain (Pikarsky et al. 2004). Pathologists face a diagnosis problem as secondary infections are very common. The reported major secondary parasitic infections for fish with KHV include those caused by *Ichthyobodo* sp., *Trichodina* sp., *Ichthyophthirius* sp., *Dactylogyrus* sp., *Chilodonella cyprini* and monogenean parasites (Perelberg et al. 2003; Haenen et al. 2004). The bacterial infections with *Aeromonas* sp., *Pseudomonas* sp. and *Shewanella putrifaciens* are commonly reported (Haenen et al. 2004).

It is difficult to detect this disease in its latent stage, and therefore various preventive measures are recommended to avoid infection. Ronen et al. (2003) developed a protocol to induce a protective adaptive immune response in common carp. According to their protocol, healthy fingerlings are exposed to the virus by cohabitation with sick fish for 3–5 days at permissive temperature (23°C). Then, the fish are transferred to the non-permissive temperature of 30 degrees for 25–30 days.

#### **Costiasis**

Costiasis is a protozoan disease for freshwater fish including common carp (koi) and goldfish. This disease is normally observed in aquaculture ponds. It is also known as ichthyobodoosis, which is caused by two species of Ichthyoboda, *Ichthyobodo necator* and *I. pyrformis*. Both species are obligate parasites with one host cycle. They are characterized as small, bean-shaped, two flagella (stalk), nucleus and contractile vacuoles. They usually attach to the skin, gill and fins of fish with their adhesive disc positioned at the posterior end. Overcrowding of fish, poor water quality and physical injury may cause severe outbreaks of the disease. The suitable temperature for a rapid reproduction of the parasites is between  $10^{\circ}$ C and  $25^{\circ}$ C. The parasites cannot survive at water temperature more than  $30^{\circ}$ C while, they form a cyst like state at water temperatures below 8<sup>o</sup>C.

#### **Causative Agents**

*Ichthyobodo necator, I. pyrformis*

#### **Disease Signs**

The clinical signs include blue-grey films on the skin and gills, red patches on the skin, excess mucous production, respiratory distress, gulping at inlet (areas of high oxygen) and erratic swimming. Fish become weak as they lose appetite. Severely infected fish may die due to oxygen deprivation. Infected fish are usually affected by secondary infection of fungus and bacteria.

Good environmental and nutritional conditions may prevent the disease. Infected fish should be treated rapidly as both *Ichthyobodo necator* and *I. pyrformis* multiply quickly. Water temperature more than  $30^{\circ}$ C is helpful to control the disease as parasites cannot tolerate this temperature. Bath treatments with salt (3% for 10 minutes) or acriflavine (10 mg/l for 10 hours) or formalin (50 parts per million for two hours) are also useful to recover fish from this disease. However, treatment using a high water temperature is safer than the treatment using chemicals.

#### **Coccidiosis**

Common carp fry are often infected with enteritic coccidiosis (Steinhagen et al. 1998). It is caused by protozoan parasites. Infection is most prevalent in common carp fry from July to September (Steinhagen and Hespe 1998). Coccidiosis is a serious disease for carp fry of 1 to 2 months old fry if they are temperature stressed in fall or spring (Steinhagen et al. 1998). According to Novakov et al. (2015), this disease mostly occurs in one year old fingerlings. However, this disease can be widespread in fish of all age classes. Infection of fish occurs via fecal contamination and indirect transmission via tubificid oligochaetes (Steinhagen and Korting 1990; Steinhagen and Hespe 1998). Carp which had recovered from the parasitic infection have been found to be vulnerable to fecal contamination (Steinhagen and Korting 1990). The most common source of contamination is from sediments with high numbers of infective oocysts and infected tubificids (Steinhagen and Hespe 1998; Novakov et al. 2015). This disease primarily occurs in aquaculture ponds but, some severe cases have been reported in natural environments (Novakov et al. 2015).

#### **Causative Agents**

*Goussia carpelli* (enteritis coccidiosis), *Goussia subepithelialis* (nodular coccidiosis)

#### **Disease Signs**

Fish lay on pond bottoms as they become very weak due to pathological changes in the intestine. Other signs of infection include hollow eyes, debilitation, thin body but large head, edema of abdominal membranes and intestinal wall, intestinal wall is dark from swollen intestinal mucosa. Sometimes fish discharge yellowish mucus. Moderate mortalities may occur due to this disease.

The most important prophylactic measure is to disinfect the fish pond bottoms by drying followed by liming. Osarzol, furazolidon, amprolium chloride are effective therapeutics agent against *Goussia* sp. According to Novakov et al. (2013), furan compounds provide the best effect in the coccidiosis treatment in common carp.

#### **Ich (White Spot Disease)**

Ichthyophthiriasis, commonly known as ICH is caused by a common obligate protozoan parasite *Ichthyophthirius multifiliisn* that infects the external surfaces of freshwater fish particularly skin and gill. Sometimes the parasite may be present only on the gills and not on the skin as the gills are the primary site of infection. The parasite is generally spherical shaped, but they can change shape. They have hair like structures called cilia and move like an amoeba. Mature parasites may reach 0.5 to 1.0 mm diameter and can be seen with necked eyes (Jhingran and Pullin 1985). Although most fish species are susceptible to this parasite, this disease is mostly observed in common carp. This disease is more generally known as one of the most common diseases found in commercial fish farms worldwide (Clark and Dickerson 1997; Davis et al. 2002).

After attaching on to a fish body, the parasite gradually penetrates the mucus layer and epithelium in the gills or skin. At this stage, it is very hard to treat the disease as mucus and host cells cover the parasite (Durborow et al. 1998). Therefore, diagnosis and treatment should be done at the early stage to avoid fish mortalities. The outbreak of this disease generally occurs during spring when water temperature is between  $18^{\circ}$  and  $25^{\circ}$ C and cause mortalities of fish in a short time (Davis et al. 2002). Therefore, severe outbreaks are more common in temperate or sub-tropical areas compared to tropical environments. This disease is very infectious particularly in fish farms and hatcheries with a high fish stocking densities. Fish die in cases of severe respiratory problems. Secondary infection of fungi and bacteria are quite common in fish infected with this parasite.

#### **Causative Agent**

*Ichthyophthirius multifiliis*

#### **Disease Signs**

White spots generally appeared on the skin and the fins. Fish may rub or scratch on objects or on the pond bottom, presumably because of irritation. Fish often show violent swimming movements. Gill damage, increased respiratory frequency, gasping at the water surface and gathering near well-aerated areas are common signs of this disease.

In many cases, wild fish were observed to be the carrier of this parasite. Therefore, attempts should be taken to prevent entry of wild fish into the aquaculture ponds. Sometimes, river water is the source for filling aquaculture ponds. In this case, fish should be released into the pond at least 3 days after filling the pond with river water as this period of fishless water will kill any juvenile parasites due to their absence of hosts (Durborow et al. 1998). Water temperature more than  $30^{\circ}$ C is also helpful to stop reproduction and control the parasite. Bath treatments with malachite green (1-2 ppm) plus formalin (167-250 ppm) or acriflavine (10 ppm) or salt (3%) or quinine hydrochloride (0.1 ppm), methyl blue (0.5 ppm) are also useful to recover fish from this disease.

#### **Chilodonellosis**

Chilodonellosis cause major mortalities of at least 16 species of wild and farmed freshwater fishes including common carp (Mitra et al. 2013; Gomes et al. 2017). According to Gomes et al. (2017), this disease has been recorded in 14 countries in the world. This disease is caused by at least two species of ciliated protozoan parasites (*Chilodonella hexasticha* and *C. cyprini*) from the genus *Chilodonella*. Common carp is usually affected by *C. cyprini,*  which attach on gills and skin of fish and graze on mucus, bacteria and algae available in gills and skin of the common carp (Dopheide et al. 2011). The parasite penetrates fish's epithelial cells to uptake cell contents using their specialized mouth organ named cytostome or cytopharynx (Noga 2010; Gomes et al. 2017). *Chilodonella cyprini* is microscopic (length: 30-70 μm, width: 20-60 μm), almost heart shaped and usually reproduced by binary fission. This parasite has a wide thermal tolerance range, between  $4^{\circ}$ C and  $20^{\circ}$ C but the most suitable temperature for reproduction is from  $5^{\circ}$ C to 10 $^{\circ}$ C (Gomes et al. 2017). Their reproduction is slowed down and stopped at water temperatures from  $15^{\circ}$ C then rising to  $20^{\circ}$ C. Therefore, common carp is safe from this disease when they are cultured at high water temperature  $(20^{\circ}$ C or more).

#### **Causative Agent**

*Chilodonella* spp.

#### **Disease Signs**

Fish produce excess mucus on the skin, which is presented as cloudy skin. Fish may hang near the surface due to lethargy or may jump out of water. Gills of fish may become pale in color. Fish condition may be reduced due to loss of appetite. Fish scratch or rub on objects present in the water and may gather at well aerated areas. In severe cases, ulcers may appear on the various places on the body due to epithelial cell necrosis and fish deaths can then occur from respiratory distress.

Good water quality along with low fish stocking density is recommended to prevent the disease. Both bath and pond treatments are used to control the *Chilodonella.* Bath treatment with salt 10 ppt for 1 hour or potassium permanganate  $(KMnO<sub>4</sub>)$  20 ppm for 1 hour, formaldehyde solution 150 ppt for 1 hour or hydrogen peroxide 200 ppm for 30 minutes is effective to control the *Chilodonella.*

# **Trichodiniasis**

Trichodiniasis is one of the important diseases of cultured marine and fresh water fishes including common carp worldwide (Valladao et al. 2016). This disease is caused by several species of protozoan under the genus *Trichodina*, which are peritrichal ciliated obligate parasites but not always associated with disease. The parasites are saucer shaped, microscopic with 40-60 µm diameters and reproduce through binary fission. They generally attach to the external surface of fish particularly skin, gills and fins. The parasites use fish as their home and transportation but feed on bacteria available on the surface of the fish body. Unsuitable water quality (e.g., unsuitable water temperature, pH, carbon dioxide and free ammonia concentrations) and overcrowding influence the severe outbreaks of the disease, which increase stress, reduce immunity of host fish and influence secondary infection of fungi and bacteria (Kugel et al. 1990; Khoshnood and Khoshnood 2014). A severe outbreak of the disease may cause a significant mortality (Maciel et al. 2018).

# **Causative Agent**

*Trichodina* spp.

#### **Disease Signs**

Fish usually become lethargic and exhibit flashing. Appearance of white patches on the skin surface, frayed fins, pale gills, respiratory distress, secretion of excess mucus are common sings of Trichodiniasis. Fish may lose appetite followed by cessation of feeding, gasping near the water surface, and necrosis of epithelial cells followed by skin ulcers can occurred in severe cases.

# **Management and Control**

Maintaining a healthy environment, suitable fish stocking density and good hygienic practices are the best management to prevent the disease. The same medications for treating Ich can be used to control the parasites of Trichodiniasis. A conventional bath treatment using sodium chloride (1%) plus formaldehyde (1ppt) for 15 min is very effective to control Trichodiniasis. Valladao et al. (2016), observed a similar result of 100% effectiveness in the treatment of trichodiniasis when they compared a mixture of 0.5 ppt formaldehyde  $+1\%$ sodium chloride with the conventional treatment.

#### **Myxobolosis**

Myxobolosis in common carp is caused by myxozoan parasites, which are distributed in many countries of the world. Of around 500 species under the genus *Myxobolus*, approximately 30 *Myxobolus* species are well described as pathogens of common carp (Molnar 2002; Eiras et al. 2005). However, some other species, which are the pathogen of other cyprinid fish may also be capable of infecting common carp (Dayoub et al. 2007). Various species are generally described based on the morphological characteristics of spores and typical hosts (Molnar 2002). The size and shape of *Myxobolus* spores are highly variable and identification of species therefore is sometimes difficult. In most cases *Myxobolus* species infect gills, kidney and muscles of fish but they can infect all organs including urinary bladder, brain, heart and gut of fish. In some cases, these parasites enter through muscle cells and become scattered all over the body and are often excreted through the gut. In these cases a large number of spores can be found in the intestinal mucus (Molnar 2002). *Myxobolus* species may cause mild to severe hemorrhage in various infected organs of common carp (Kaur and Katoch 2016).

#### **Causative Agent**

*Myxobolus* spp.

#### **Disease Signs**

Based on the infected organs, edema, loose scales, exophthalmia, white nodules on gills are common signs of this disease. Sometimes, mild to severe hemorrhage may occur in muscle, liver and kidney. Necrosis in the muscles and liver occur in severe cases.

#### **Management and Control**

The followings actions are effective to control Myxobolosis (Wagner 2002).

- Older fish are less susceptible to this disease compared to younger fish and therefore, prevalence rate can be reduced by stocking large fish only.
- Feeding pelleted feed containing 0.1% dicyclohexylamine (Fumagilin) for 3-7 weeks reduces prevalence rate and eliminates morbidity and mortality.
- Calcium Cyanide at 4,000 kg/ha should be applied to infected ponds.

• Chlorine at 5,000 ppm in a 10 minutes exposure or 1,600 ppm in 24 hours exposure for infected ponds.

# **Dactylogyrosis**

Dactylogyrosis in common carp is caused by monogenean parasites from the *Dactylogyrus* genus, which is the largest helminth genus, with more than 900 species (Neary et al. 2012). The parasites are commonly known as gill flukes. *Dactylogyrus* can complete its life cycle within one host and therefore, they can spread quickly and easily. The parasites have two pair of anchors, which are used to attach to the gills of host fish. They have 4 tiny eyespots at the anterior (head) end. The parasites can lay up to 20 eggs per hour if the temperature is suitable. The eggs hatch within 4 days. In a heavy infestation, the parasites can be attached to other parts of the host body. *Dactylogyrus* are serious parasites for wild and cultured freshwater fish including common carp. Fry and fingerlings are more susceptible to the parasites compared to adult fish.

The prevalence of the infection on fish can vary according to season, which influences water temperature oxygen concentrations of water, size of fish host and fish maturity (Ozturk and Altunel 2006; Tekin-Ozan et al. 2008). Different species show different temperature preference and seasonal variations in their infection parameters (Neary et al. 2012). *Dactylogyrus* generally prefer temperatures above 20°C (Jhingran and Pullin 1985). Poor water quality, particularly when contaminated with industrial and urban pollutants generally increase the occurrence of outbreaks of this disease (Borji et al. 2012). Nutritionally weak fish are more easily infected by the *Dactylogyrus* parasites. The presence of parasites may cause weight loss, and reduced fecundity of host fish (Grabda1991). Heavy infection by the parasites can cause high mortalities of fish.

#### **Causative Agents**

*Dactylogyrus* spp.

#### **Disease Signs**

Fish swim to water inlets (or areas of high oxygen); proliferation of gill epidermis; flukes are visible on gills at low (40-60) magnification

#### **Management and Control**

Before culturing fish, ponds should be prepared by drying and subsequently liming to prevent the disease. Bath or pond treatments can be used to control disease outbreak. Several chemicals are generally used for bath and pond treatments. Bath treatment with 1% Masoten or Neguvon (trichlorphon) for 2-3 minutes or 200-250 ppm formalin for 30 minutes or 0.1-0.2 ppm Bromex (dimethyl 1, 2-dibromo-2, 2-dichloroethyl phosphate) for a long period or 2-5% salt is effective to control the disease (Jhingran and Pullin 1985). Pond treatment with the similar dose (0.1-0.2 ppm) of Bromex is generally used to control the parasite. Bath treatment with salt for a prolonged period should be avoided because common carp die after exposure to 3.5% salt for 40 minutes, to 2.5% for 60 minutes and 1% for 24 hours (Jhingran and Pullin 1985).

# **Gyrodactylosis**

Gyrodactylosis in common carp is also caused by monogenean parasites from the *Gyrodactylus* genus, which has more than 350 species (Halvorsen and Ex Hartvigsen 1989). According to Rubio-Godoy and Garcia-Vasquez (2015), nearly 500 species of *Gyrodactylus* are currently known. The parasites are usually known as skin flukes primarily attach on skin and fins of fish. They may occasionally found on the gills of fish. They have prominent hooks for attaching to the host's skin but they do not have eyespots at their anterior end. Adult parasites give birth to live offspring, which become immediately parasitic. *Gyrodactylus* generally feed on the epidermis of the skin of the host fish. They can complete their life cycle on one host. Various species of *Gyrodactylus* are normally identified based on the size and shape of the opisthaptor (adhesive organ). A high fish stocking density and poor environmental conditions characterized particularly by low dissolved oxygen and high organic matter loads may accelerate the infection of this disease. Under aquaculture conditions, *Gyrodactylus* populations can sometimes increase almost exponentially and overwhelm their fish hosts (Rubio-Godoy and Garcia-Vasquez 2015).

#### **Causative Agents**

*Gyrodactylus* spp.

# **Disease Signs**

Fish may become lethargic but sometimes they swim restlessly. They produce excess mucus and therefore, skin becomes cloudy. Fish rub upon hard material present in the system. Infected areas may become red due to hemorrhage. Extended periods of infection may also lead to secondary infections from fungus and bacteria.

#### **Management and Control**

Same for Dactylogyrosis control

# **Diplostomosis**

Diplostomosis is one of the more well-known diseases of freshwater water fish including all varieties of common carp and is reported from more than 125 freshwater species globally (Valtonen et al. 2003; Larsen et al. 2005; Mama and Abdullah 2013). This disease is also recorded in some brackish water fishes and majority of the published information surrounding Diplostomosis is associated with its impacts on rainbow trout. It does not generally occur in indoor aquaculture systems. Diplostomosis is caused by cercariae and metacercariae of species under the genus *Diplostomum.* Metacercariae of *Diplostomum* species attack fish eye lenses and *Diplostomum* species are, therefore also referred to as eye-flukes. In severe cases, the parasites in the lens can cause cataracts and blindness in fish (Shariff et al. 1980; Behrmann-Godel 2015).

*Diplostomum* species are digenean trematodes that have complex three-host life cycle involved piscivorous birds (definitive host), snails (first-intermediate host) and fish (secondintermediate host). The piscivorous birds release eggs of *Diplostomum* through their faeces. After embryonic development in the egg, a free-swimming miracidium comes out in the water in 21 days (Palmieri et al. 1976). The miracidium penetrate snails and move to the hepatopancreas of snails, in which they reproduce asexually releasing large numbers of cercariae into the water column. An individual snail may release tens of thousands of cercariae per day (Karvonen et al. 2006). The production of cercariae is season-specific, which is strongly influenced by water temperature. Cercariae of *Diplostomum* generally enter small blood vessels through the gills and fins of fish and reach to the fish eyes within 30 minutes (Palmieri et al. 1976; Karvonen et al. 2006). In the lenses of the fish eyes, cercariae become infective metacercariae in 45-120 days. When a fish-eating bird eats the infected fish, the worm becomes adult within the intestine in 3-5 days (Palmieri et al. 1976).

#### **Causative Agents**

*Diplostomum* spp.

#### **Disease Signs**

Infection in the eye generally reduces fish vision, food intake and growth are impacted with altered fish behavior, particularly swimming and grazing behavior. Development of inflammation, hemorrhage, exophthalmia and cataracts in eyes are also commonly observed signs of this disease.

# **Management and Control**

Diplostomosis is usually prevented by disrupting the *Diplostomum* their life cycle, which can be achieved by keeping piscivorous birds away from the pond area, or by eradicating the first-intermediate host (snail) in ponds. Drying and subsequent liming improves pond health and eradicates snail populations. When common carp are cultured in tanks or raceways, increasing water current is also effective to reduce infections (Field and Irwin 1994). Bath treatment with formalin (10 mg/L for 16 hours) or sodium percarbonate (minimum 40 mg/L for 16 hours) is effective in eradicating the parasites (Larsen et al. 2005). Szekely and Molnar (1991) fed droncit (330 mg per kg body mass) for treating metacercariae parasitizing grass carp with l00% efficacy. They also treated infected grass carp and silver carp with l00% efficacy by exposing to a droncit solution  $(1 \text{ mg/L})$  for 90 hours. However, droncit treatment as applied by Szekely and Molnar (1991) may also be effective to treat infected common carp.

#### **Phosthodiplostomosis**

Phosthodiplostomosis are primarily reported in wide range of Cyprinid fish including common carp but it may occur in other fishes particularly fishes in the Perciforme and Channiformes families (Nguyen et al. 2012; Athokpam and Tandon 2014; Ozturk and Ozer 2014). It is caused by metacercariae of species of the *Posthodiplostomum* genus and is distributed globally (Niewiadomska 2002) with around 30 species of *Posthodiplostomum* known to cause the disease. Metacercariae of *P. cuticola* cause numerous tiny black spots (cysts metacercariae) on the skin, muscle, and in the fins of fish (Rolbiecki 2004). Therefore, infection with *P. cuticola* is also called black spot disease, which is often harmful for fish, particularly fry. A mild infection generally causes little harm to affected fish but a strong infection may cause weight loss and several changes in the blood chemistry of host fish (Rolbiecki 2004). Accumulated blood hemoglobin and chromatophore around the matacercaria are decomposed and produce hemomelanin appearing as dark back pigments (Markovic and Krsmanovic 2008).

*Posthodiplostomum* species are digenean trematodes and therefore, the life cycle of *P. cuticola* is almost similar to *Diplostomum* species, which have a complex three-host life cycle involved piscivorous birds (e.g., herons) as the definitive host, snails as the first-intermediate host and fish as the second-intermediate host. The main difference is observed during metacercarial stage. At this stage, *P. cuticola* form a cyst and reside on the skin, muscle, and in the fins of fish.

#### **Causative Agent**

*Phosthodiplostomum cuticola*

#### **Disease Signs**

Black spots generally appear on the skin, muscle, and in the fins. Infected common carp fry may be deformed. Mild infection is generally not very devastating to fish but in a severe case, fish may have increased physiological stress, reduced feed intake and weight loss, necrosis of skin and muscle fibers, increased erythrocyte sedimentation rate and leukocyte count, reduced hemoglobin content and erythrocyte count (Williams and Jones 1994). Severely infected juvenile fish and fry may experience vertebral column deformation, heavy blood loss, and even death (NACA 1989; Williams and Jones 1994).

#### **Management and Control**

Same treatments for Diplostomosis

#### **Sanguinicoliasis**

Sanguinicoliasis is a serious disease of cultured common carp caused by digenean blood flukes and has been reported with mass mortalities in many countries of the world (Sommerville and Iqbal 2006). The parasites live and reproduce within the circulatory system of fish, where their presence may result in the obstruction of blood flow (Lee 1990). Most of the flukes are host-specific. The common life cycle of digenean blood flukes is described by Kirk and Lewis (1993) and Bullard and Overstreet (2002). According to these authors, adult flukes deposit thin-shelled, pliable eggs in the circulatory system of the specific fish. Some eggs travel to and lodge in the host's gill, where the embryonic development and hatching usually occur. After hatching, the first free-swimming form of the fluke, the miracidium, emigrates through the gill epithelium and looks for a suitable intermediate host, which can be a snail, bivalve or polychaete. After reaching the intermediate host, the parasite reproduces asexually, producing the second free-swimming cercaria, which leave the intermediate host. Some cercaria die and other infect fish through gills, skin, eyes, fins, or alimentary tracts. Sometimes, the flukes mature, copulate, and releases eggs in the heart or branchial vessels. The cercaria penetrates the fish host through its gill, skin, eye, fin, or alimentary tract and develops through the juvenile stage as a schistosomule before ending up in a specific site in the circulatory system of the host. They often settle in the heart or branchial vessels where the fluke ultimately matures, copulates, and releases eggs. Both lightly and heavily infected fish have poor growth rates and low food utilization (Iqbal and Sommerville 1986).

#### **Causative Agents**

*Sanguinicola* spp.

#### **Disease Signs**

Lethargy; swimming in spiral movement; reduced feed intake; fish spend more time at the water surface; exophthalmia on some occasions; gill inflammation

Controlling blood flukes is easier than controlling parasites, which have direct life cycle or intermediate host. Blood flukes can be controlled by eradicating snails and bivalves by applying copper sulfate when there is no fish in the culture system. Before culturing fish, ponds should be dried and subsequently limed which then can destroy eggs and larvae of snails, bivalves and polychaetes from the ponds. Before stocking in ponds, tanks or raceways, fingerlings should be examined carefully for the presence of either blood fluke eggs or adults or other parasites. Some scientists recommend bath treatment with Praziquantel to treat fish infected by blood flukes (NACA 1989).

# **Ligulosis**

Ligulosis in fish is caused by the plerocercoid stage of *Ligula intestinalis,* which is a pseudophyllidean cestode inhabiting the intestine of piscivorous birds. This disease mostly occurs in freshwater cyprinid fish including common carp, which ingest zooplankton. *Ligula intestinalis* is distributed throughout the northern hemisphere particularly Europe and Russia (Dubinina 1980). It has a complex three-host life cycle: a copepod as the first intermediate host, a cyprinid fish as the second intermediate host and a piscivorous bird (e.g., herons, gulls, ducks, cormorants, etc.) as the final host. The ichthyophagous birds discharge unembryonated eggs into water with their faeces. In the water, ciliated free-swimming coracidiums emerge from egg shells after the embryonic development. Coracidiums are eaten by crustacean copepods, in which coracidiums develop into procercoids within 2-3 weeks (Loot et al. 2001; Sohn et al. 2016). When copepodes with procercoids are eaten by the fish, procercoids develop into plerocercoids in the abdominal cavity of the fish. The plerocercoid larvae stay more than 10 months in the fish host (Dubinina 1980; Sohn et al. 2016). The larvae become adult in the intestine of piscivorous birds (Ogambq-Ongoma 1975). Plerocercoids squeeze the internal organs of the fish and cause disruption of their functions. Severely infected fish die due to their stomachs rupturing.

#### **Causative Agent**

*Ligula intestinalis*

# **Disease Signs**

Infected fish usually accumulate in shallow waters and swim on their sides or belly up. Fish stomachs generally become distended. Parasites can be visible in infected fish. Infected fish show abnormal swimming behavior including slow swimming. Fish usually stop eating, lose body weight and are anemic.

The disease can be controlled by targeting the intermediate hosts, particularly controlling copepod populations in ponds. Masoten (25 ppm) or Dipterex (25 ppm) is commonly used to reduce copepod populations in ponds. Drained, wet ponds can be treated with calcium chloride (about 70 kg/ha) or calcium hydroxide (about 2 tons/acre) or calcium hypochlorite to eradicate eggs and larvae of copepods. The life cycle of the parasite can also be disturbed by expelling birds. Infected fish can be treated with Droncit  $(5 \text{ mg/kg})$ , which can be incorporated into feed pellets.

#### **Bothriocephalosis**

The parasitic disease, Bothriocephalosis in common carp is caused by a pseudophyllidean tapeworm *Bothriocephalus acheilognathi*, which is one of the most dangerous helminth parasites of cultured common carp (Nie and Hoole 2000; Sofi et al. 2016). The parasite has several synonymous scientific names including *B. fluviatilis, B. gowkongensis, B. opsariichthydis, B. phoxini, B. kivuensis*, *B. aegyptiacus* and *Schyzocotyle fluviatilis*. Besides common carp, this parasite infects approximately 200 species of freshwater fish with most suitability for cyprinid fish (Salgado-Maldonado and Pineda-Lopez 2003; Sofi et al. 2016). The original distribution of this parasite is the East Asia, however, it spread rapidly in many countries in the world via fish trade. The parasite has a simple, short and two-host life cycle. The parasite requires common copepod species (e.g., species fprm *Acantocyclops*, *Macrocyclops*, *Mesocyclops*, *Tropocyclops* and *Diacyclops* genera as intermediate hosts for around two weeks (Korting 1975; Scholz et al. 2012). Eggs come into the water with the faeces of the host fish and mobile coracidia emerge from the eggs after embryonation. Copepods become the host when they consume Coracidia. The parasites complete their life cycle in the fish when fish ingest infected copepods. Water temperature plays an important role in rapid development of all stages of the parasite life cycle. For example, larval development is completed within 21- 23 days at water temperature 28-29°C, but water temperature at15-22°C it takes 1.5-2 months (Scholz et al. 2012). Bothriocephalosis can have pronounced detrimental effects on fish including negative effects on health, growth and production of fish. Sometimes, it causes mass mortality in fish farms particularly in hatchery ponds.

# **Causative Agent**

*Bothriocephalus acheilognathi*

#### **Disease Signs**

Infected fish generally show the following signs.

- Sluggish movement
- Swimming at the surface
- Enlarged abdomen
- Severe damage to the intestinal tract
- Reduced growth
- Death

Bothriocephaliasis can be controlled by drying fish ponds annually or treating drained wet ponds with calcium chloride (about 70 kg/ha) or calcium hydroxide (about 2 tons/acre) or calcium hypochlorite to kill copepods. Insecticides include Masoten (25 ppm) or Dipterex (25 ppm) can be used to reduce copepod populations in ponds (Hoffman 1983). Infected fish can be treated with anthelmintics, such as Chlorinated salicylanalid or Droncit (5 mg/kg) in feed.

# **Khawiosis**

Khawiosis is the intestinal infection of fish including common carp caused by several species of Caryophyllidean tapeworms from the genus *Khawia*. Among several species, only *Khawia japonensis* and *K. sinensis* are observed to be intestinal parasites of common carp and *K. sinensis* has more potential parasitic effects on common carp compared to *K. japonensis*. *K. sinensis* has two synonymous scientific names (*Tsengia neimongkuensis* and *T. xiamenensis*)*,* while *Khawia japonensis* has four synonymous scientific names (*K. iowensis, K. cyprini Caryophyllaeus japonensis, Bothrioscolex japonensis*) (Scholz et al. 2011). *K. sinensis* was described by Hsu (1935) from the vicinity of Beijing, China while *K. japonensis*  was originally described by Yamaguti (1934) from Lake Biwa in Japan (Oros et al. 2015). Both parasites dispersed from Asia to many European countries and the USA with common carp and other fish particularly grass carp (Scholz et al. 2011). *K. japonensis* is larger (length: 19.5–24.5 mm; width: maximum 1.2 mm) compared to *K. sinensis* (length: 41–112 mm; width: 1.3–2.3 mm) (Oros et al. 2009).

*Khawia* need aquatic tubificids (Annelida: Oligochaeta) as their intermediate hosts. Eggs are laid unembryonated into water and the oncosphere infective for intermediate hosts is formed after a few weeks (e.g., 2–4 weeks in the case of *K. sinensis*) of embryonation within the egg shell. Generally, 30-65 days old oncosphere infects tubificds, in which it stays for around 54 days for the procercoid development (infective larvae) (Scholz 1991). Temperature significantly influences oncosphere and procercoid developments. *Khawia* has some negative impacts on the health and production of the common carp (Williams and Jones 1994). In severe case, *Khawia* infection causes mortalities of common carp.

#### **Causative Agents**

*Khawia sinensis* and *K. japonensis*

## **Disease Signs**

Loss of appetite; sluggish movement; serious inflammations of the intestine and destructions intestinal epithelium of the host; anemia as a consequence decreasing erythrocyte number and leukocyte activity; slow growth; worms may protrude from anus.

#### **Management and Control**

The disease outbreak can be prevented by eradicating tubificids (intermediate host) by drying and liming the pond. It is very difficult to kill tapeworms in the fish intestine. However, praziquantel, benzimidazoles and niclosamides can be used for oral treatment (Treves-Brown 2000). Sudova et al. (2010) recommended orally administered praziquantel at a dose of 50 mg/kg for an effective control of *K. sinensis* in the common carp intestine.

# **Nematode Infestation**

Nematodes of the genus *Contracaecum* have a worldwide distribution, with their larvae recorded in many marine and freshwater fish species including common carp (Klimpel and Palm 2011; Tavakol et al. 2015). *Contracaecum* has a complicated life cycle, which involves a variety of hosts that are transferred through the food chain. It has four larval stages (L1–L4) and an adult stage (Anderson 2000; Valles-Vega et al. 2017). According to Huizinga (1967), the parasite generally spends their first and second larval stages in the eggs. Copepods ingest the fee-swimming second larval stage after it hatches from the egg into the water. The second larval stage grows without molting in the coelom of copepod. When a fish eats the infected copepod, L2 grows, molts and become L3 in the abdominal cavity of fish. When this fish is eaten by a suitable piscivorous host, L3 stays in the proventriculus where it grows and molts twice to become the adult stage (Valles-Vega et al. 2017).

# **Causative Agents**

*Contracaecum* spp.

#### **Disease Signs**

*Contracaecum* infected common carp generally show following signs (NACA 1989).

- Weak or thin body
- Loss of blood into body cavity
- Abnormal protrusion of the eyeballs
- Roundworms in heart and body cavity

*Contracaecum* infection can be prevented by eradicating copepods, which can be done by drying and liming the pond. Masoten (25 ppm) or Dipterex (25 ppm) is also used directly into the ponds to reduce copepod populations in ponds. Calcium chloride (about 70 kg/ha) or calcium hydroxide (about 2 tons/acre) or calcium hypochlorite can be used in the drained wet ponds to eradicate copepods. There is no effective medicine to treat *Contracaecum* infected fish*.*

# **Phylometrosis**

Phylometrosis is caused by species of the family Philometridae. Many fish species including common carp are susceptible to this disease. Various Philometrid species infect a range of organs (e.g., skin, eyes, swimbladder, gonads, circulatory system, body cavity, etc.) of fish (Moravec and Ali 2013). In common carp, this disease is caused by *Philometroides cyprini,* which has several synonyms such as *Philometra lusii, Philometra schikhobalowae, Philometra lusiana* and *Philometroides lusiana* (Moravec and Cervinka 2005). *Philometroides cyprini* was originally distributed throughout East Asia, from where it dispersed into Europe in the early 1960s (Moravec and Cervinka 2005). *P*. *cyprini* may cause mortality of infected common carp particularly young individuals (Moravec and de Buron 2013).

*Philometra* has a two-host life cycle: copepods as the intermediate host and fish as the final host. Fish release *Philometra* larvae in their faeces or female parasites migrate to the fish skin surface to release larvae. Larvae of the parasites are ingested by copepods, in which the larvae molt several times. The life cycle of the parasite is completed in the fish body when infected copepods are consumed by the fish.

# **Causative Agent**

*Philometroides cyprinid*

## **Disease Signs**

Fish may show the following signs (NACA 1989).

- Lost balance
- Floating head down
- Reduced feed intake
- Appearance of red nodules on skin and under scales

The disease can be controlled by controlling copepod populations in ponds. 25 ppm masoten or dipterex can be used to reduce copepod populations in ponds. Calcium chloride (about 70 kg/ha) or calcium hydroxide (about 2 tons/acre) or calcium hypochlorite to eradicate eggs and larvae of copepods in the drained wet ponds. Infected fish can be treated with injections of Nilverm or Ditrazin into their body cavity (NACA 1989).

# **Fish Leech Infestation**

Species of the family Piscicolidae are parasites of many fish species living in fresh, brackish, and marine water ecosystems (Williams and Burreson 2006). The common fish leech *Piscicola geometra* is a well-known parasite of common carp. *Limnotrachelobdella sinensis*, another fish leech has been commonly found infesting common carp (Nagasawa and Tanaka 2011). Leeches need to attach to the fish only for their meal but they can survive for long periods without feeding. A single 2-4 cm leech can suck 150 ml fish blood within about 48 hours (Jhingran and Pullin 1985). Leech lay eggs in dark brown oval cocoons, which are usually attached to debris or plants in their habitats. They complete their life cycle within 24 days to several months depending on water temperature. They generally leave the host after sucking blood but the sucking area becomes injured. Leech do not directly cause any disease to fish but their infestation can lead to a secondary infection from fungus and bacteria. Leech infected fish generally rub or scratch the leech off by flashing. Severe leech infections can occur if fish are weak or unhealthy. Besides high fish stocking density, unsuitable temperatures and a high decayed organic matter load usually increase leech populations in the environment.

# **Causative Agent**

Species of the family *Piscicolidae*

#### **Disease Signs**

Leech infested fish generally show following signs:

- Fish may rub or scratch the infected area with any hard substrate present in the pond.
- Hyperactive swimming at the water inlet is commonly observed.
- Appearance of ulcers at the various places of the infected fish.
- Fish generally lose weight.

Trichlorfon at 0.5 mg/L (6 hours in tanks and 48 hours in ponds) treatment is very effective to control leech (Morrison and Fox 1993). Formalin (150 mg/L) or sodium chloride (1%) is also an effective leech control.

#### **Ergasilosis**

Ergasilosis is caused by the parasites of the genus *Ergasilus*. *Ergasilus* are often called gill lice. They are a host-specific ectoparasite that infect many freshwater fish species including common carp. Male *Ergasilus* are fee-living, while females are parasitic by nature. Female *Ergasilus* attach themselves to the fish gills and feed on blood and tissue of their host (Ojha and Hughes 2001). They cause extensive tissue damage and inflammation of the gill, and reduce oxygen uptake rate of fish. In the natural environment, Ergasilosis usually starts in April and lasts until November. Water temperature plays a very important role in the state of the *Ergasilus* population. Egg development is generally faster at a higher water temperature (Piasecki et al. 2004). Some scientists believe that a high load decomposed organic matter also accelerate the growth of *Ergasilus* populations. A mild infection is not harmful to fishes but a severe infection of *Ergasilus* may cause many detrimental effects on fish health and even cause mortality (Dezfuli 2011).

# **Causative Agents**

*Ergasilus* spp.

#### **Disease Signs**

Small white patches on gills, gill hyperplasia, necrosis of gill tissues are regularly observed signs of Ergasilosis. Restlessly swimming, weight loss, anemia, secondary infection of fungus and bacteria, mortality are frequently observed sings of this disease.

#### **Management and Control**

Removing decayed organic material from the pond bottom and sun-drying followed by liming before fish stocking are beneficial to prevent the Ergasilosis. The disease can be treated with a combination of 0.5 ppm copper sulfate and 0.2 ppm ferric sulfate for 6 to 9 days. A bath treatment with potassium permanganate at 10 mg/L for 20-30 minute is effective in killing the *Ergasilus*.

# **Lernaeosis**

Although Lernaeosis is caused by various species of the genus *Lernaea,* this disease is mostly caused by *Lernaea cyprinacea.* Adult *L. cyprinacea* are usually wormlike 9-22 mm long animals. There are about 37 valid *Lernaea* species (Kabata 1979), which are commonly known as anchor worms. The head of the worm is equipped with horns, which are used as an anchor to attach to the host fish. This disease generally occurs in many freshwater fishes including common carp. Lernaeosis with mass mortalities of common carp has been recorded many countries in the world. For example, Fatma (2014) conducted a study on hatchery reared common carp fry and observed 71.7% prevalence of lernaeosis among fry. However, common carp is one of the more preferred hosts for *Lernaea* species (Piasecki et al. 2004). *Lernaea* species are very dangerous parasites for some fish species particularly minnows, a single parasite in a critical location is enough to kill a minnow (Piasecki et al. 2004).

Only the female *Lernaea* has the parasitic activity and feeds on host's body fluid. Male *Lernaea* has no parasitic activity and it leaves the host after the copulation. Various *Lernaea* species have various temperature suitabilities for their reproduction but the majority of species prefer 25 °C to 28°C for their reproduction. Mild infections by *Lernaea* species may disfigure the fish making them low consumer preference, while a severe infection may kill the fish in short time. Infected fish are generally susceptible to secondary infections of bacteria.

#### **Causative Agents**

*Lernaea* spp.

#### **Disease Signs**

*Lernaea* can be seen on the body surface. Gill damage including epithelial hyperplasia, telangiectasis, and hemorrhage are common signs of this disease. Lethargy, reduced feed intake and damage to fins are frequently observed signs of Lernaeosis. A thick fibrotic capsule around the anchor may appear as the connective tissue of host reacts to the parasite

#### **Management and Control**

Bath treatment using the plant extracts carvacrol and cymene mixture (200 ppm) can eliminate 89% lernaea within 48 hours (Fatma 2014). Dipteiex (0.25 ppm active ingredient) can kill copepodite (a stage of their life cycle) within four to six hours. Gammexane (0.2 ppm for 72 hours) or chlorine (1 ppm for 3 days) may give good results to control *Lernaea.*  Traditionally salt, potassium permanganate or formalin baths were used to control *Lernaea.*

## **Argulosis**

Fish Argulosis is caused by many species of the genus *Argulus* (Crustacea: Branchiura). *Argulus* are commonly referred to as fish lice. They are obligate ectoparasites and cause frequent problems in fisheries and fish farms worldwide. They are transparent, disc shaped with a dorsoventrally flattened body and are visual to the naked eye. The length of most species is between 5 and 10 mm. *Argulus* infect a wide range of fish species including common carp. In early German literature, *Argulus* was commonly known as carp lice because they used to cause problems in European common carp farming (Taylor et al. 2005). They complete their life cycle including eggs, free-living infective larvae, and juvenile and adult stages on fish (Shimura 1981; Hakalahti-Siren et al. 2008).

Occurrence of argulosis varies by season with peaks of abundance generally during summer and autumn (Moller et al. 2012**)**. Temperature plays an important role in the development of the egg and in the post-hatching development of *Argulus* (Taylor et al. 2005). The suitable temperature for their rapid reproduction is from  $20^{\circ}$ C to  $28^{\circ}$ C. Eggs appear to lie dormant at temperatures of less than 10°C. Although *Argulus* have a wide host range, some fish species are observed to be more susceptible to *Argulus* than others. For example, Aalberg et al. (2016) observed the higher prevalence, mean intensity and abundance of *Argulus* sp. in Pike-perche (*Sander lucioperca***)** compared to common carp. *Argulus* generally infect fish from the side or beneath and gradually they move to a preferred site. Gills and skin are most preferred sites for *Argulus* infection. Young fishes are more prone to infection than old ones (Ozturk 2005). Argulosis may lead to secondary infections and other parasitic disease (Lester et al. 2006). It can cause significant morbidity and mortality when fish are heavily infested.

## **Causative Agents**

*Argulus* spp.

#### **Disease Signs**

*Argulus* can be seen on the body surface and fins of fish. Lethargy, reduced feed intake, abnormal swimming, excessive mucus production, small hemorrhages, fin erosion and anemia are commonly reported signs of this disease. Secondary infection of fungus and bacteria also frequently observed signs of Lernaea infected fish.

## **Management and Control**

Draining of the pond followed by liming can prevent the Argulosis outbreak. Lindane at 0.01 ppm can kill all free-swimming *Argulus* within five hours, while Lindane concentration of 0.013 ppm can kill all attached *Argulus* in the same time period. Bath treatment with salt (500-1000 ppm for 24 hours) or Potassium permanganate (2-5 mg/L for 24 hours) or Dichlorvos solution (0.2 mg/L for 24 hours) or Ammonium chloride (1.0-1.5% for 15 minutes) and pond treatment with gamrnaxine (0.2 mg/L) are effective to control *Argulus.*

## **ABSTRACT**

Data on abundances of  $>10^5$  cells/L of the widely distributed non-toxic benthicplanktonic pennate diatom *Cylindrotheca closterium* as a causative agent of harmful algal blooms (HAB) in the coastal waters of the northern Yucatan Peninsula, with an emphasis on four marinas (Chuburná, Yucalpetén, Telchac and Dzilam) in 2001-2014 (fortnight and monthly monitoring), are presented. The highest abundance of  $2.68 \times 10^{7}$  cells/L was recorded in San Crisanto in September 2011. The multivariate statistical analysis Canoco 4.5 applied to the marinas for the 2011-2013 period showed a positive correlation between the cell abundances and nitrites, phosphates, nitrates and urea. During the 2001- 2014 period the major proportion of HAB (with >10<sup>5</sup> cells/L) caused by *C. closterium* occurred since 2011; only in Chuburná were the highest abundances found in 2008. The

seasonality of the species remains unclear: in all the marinas HAB were observed during all months. In Dzilam, *C. closterium* was frequently accompanied by the marinebrackish-water potentially toxic dinoflagellate *Prorocentrum minimum*. An increase in frequency of HAB caused by *C. closterium* in Yucatan waters, especially in the marinas, seems to be due to the anthropogenic impact of increased nitrogen. This species has a wide geographical distribution, has been reported from various habitats, has high growth and reproductive rates and has a high potential for predominance in both planktonic and benthic microalgal assemblages. *Cylindrotheca closterium* became one of the dominant species throughout the year, forming almost monospecific blooms as well as those in association with other species.

#### **INTRODUCTION**

*Cylindrotheca closterium* (Ehrenb.) Reimann et J. C. Lewin is a non-toxic pennate benthic-planktonic widely distributed diatom, observed in the water column, superficial sediments and the lowermost layer of sea ice, distributed in both marine and brackish water in all climatic zones around the world. Underwood & Provot (2000) characterize it as epipelic estuarine, although it is one of the most frequent and abundant microplanktonic species in subtropical North Atlantic waters (Najdek et al., 2005; Halac et al., 2013) and tropical waters of the western Indian Ocean (Sá et al., 2013). Although Jahn & Kusber (2005) presented their solid arguments and re-established the genus *Ceratoneis* Ehrenb., in literature the name *Cylindrotheca closterium* is still in extensive use. In the present study, we keep using the latter, considering *Ceratoneis closterium* Ehrenb. as basionym and *Nitzschia closterium* (Ehrenb.) W. Sm. and *Nitzschiella closterium* (Ehrenb.) Rabenh. as synonyms. Herein, we followed the proposal to conserve the name *Cylindrotheca* against *Ceratoneis* (Prud'homme van Reine, 2011). Recently, based on molecular biological studies, *C. closterium* was proposed as a complex of cryptic species (Li et al., 2007). The results on the preferred salinity ranges by distinct clones of this species obtained previously (Underwood & Provot, 2000) confirmed the physiological and biochemical heterogeneity of *C. closterium*.

Most studies of this species are biochemical and ecophysiological and date back to the 1920s (Jameson et al., 1922; Peach & Drummond, 1924; Leigh-Clare, 1927). Recently, the species has been used as a model in molecular studies of diatoms (Vanormelingen et al., 2013). *Cylindrotheca closterium* is a species with high growth and reproduction rates, from 0.63-0.97 to 2.3 divisions per day in culture (Eppley et al., 1971; Sun et al., 2004; Affan et al., 2009; Kingston, 2009). Sexual reproduction also occurs rapidly, concluding in 24 h (Vanormelingen et al., 2013). As a harmful algal blooming species in Mexican waters, it has been known from the northwestern Pacific (Longhurst et al., 1967; Licea-Durán et al., 1999; Gárate-Lizárraga et al., 2001, 2009, 2016a, 2016b) and the southeastern Gulf of Mexico (Poot-Delgado et al., 2013; Muciño-Márquez et al., 2014). Recently, Gárate-Lizárraga & Esqueda-Escárcega (2016) reported the infestation of the copepod *Paracalanus* sp. by *C. closterium* cells. Blooms of *Cylindrotheca closterium + Akashiwo sanguinea* have been linked to fish, lobster and marine bird mortality along the west coast of Baja California, the northwestern Mexican Pacific (Gárate-Lizárraga et al., 2001). More recently, successive

infectious stages of *C*. *closterium* were described for the first time during the early development of sea urchins (Magesky et al., 2017).

To present the data on the occurrence of *C. closterium* during monitoring of the coastal waters of the northern Yucatan Peninsula in 2001-2014, with the aim of determining its variability and spatial-temporal abundance in the water column, were the main objectives of this study. To explain these, physical-chemical variables were also analyzed.

#### **MATERIAL AND METHODS**

Quantitative phytoplankton samples were taken in the uppermost surface layer of the water column with a 250-ml plastic bottle along the northern Yucatan Peninsula from July 2001 through April 2014 (Figure 1). Beach monitoring of harmful algal blooms (HAB) was performed in 2002-2013 at 18 stations at 20-30 m distance from the beach between Chuburná and Dzilam de Bravo (Dzilam, for short), monthly from October to April (with minor probabilities of HAB occurrence) and fortnightly from May to September (with major probabilities of HAB occurrence). Monitoring of four marinas (Chuburná, Yucalpetén, Telchac and Dzilam de Bravo) was carried out in 2002-2013, fortnightly from May to September in 2002-2013 and monthly from October to April in 2009-2013. All samples were fixed with an acid Lugol solution.

Figure 1. The study zone and sampling sites along the northern Yucatan Peninsula coast (2001-2014), including Chuburná, Yucalpetén, Telchac y Dzilam marinas (2002-2013).

Samples were analyzed using an Olympus CKX 41 or a Carl Zeiss Axiovert 100 inverted miscroscope equipped with phase-contrast objectives, using the Utermöhl technique (Hasle, 1978). Surface water temperature, salinity, turbidity, pH, dissolved oxygen, nitrates, nitrites, ammonium, phosphates, silicates, urea, *in situ* fluorescence and chlorophyll-*a* were determined in the field or in the laboratory. Selected samples were observed in a JEOL JSM-7600F Field Emission scanning electron microscope (SEM) at 5 kV. To correlate the *C. closterium* cell abundance with the physical-chemical variables, multivariate (MVA) and redundancy analyses (RDA) were applied using the Canoco for Windows 4.5 package.

#### **RESULTS**

Cell count results are given in Table 1 and Figure 2. For Table 1, only the abundances of  $>10^5$  cells/1 are shown. Electron micrographs are presented in Plate 1. The RDA applied to the four marinas (2011-2013) demonstrated a positive correlation between *Cylindrotheca closterium* abundance and some physical-chemical variables such as nitrites ( $p = 0.03$ ), phosphates ( $p = 0.05$ ), nitrates ( $p = 0.047$ ) and urea ( $p = 0.015$ ), where "p" is the level of statistical significance. The physical-chemical characteristics associated with the cell abundance of  $>10^5$  cells/L were as follows: temperature 21.6-31.2 °C, salinity 16.40-39.80, dissolved oxygen  $1.30-11.82$  mg/L, dissolved oxygen saturation  $18.3-118.5$  (178.9) %, nitrates (0.05) 0.84-174.02 (345.82) µM, nitrites 0.01-4.84 (26.68) µM, ammonium 0.35- 37.74 µM, phosphates 0.03-8.69 µM, silicates 0.82-115.00 µM, and urea 0.45-12.78 (45.34) µM. The chlorophyll-*a* concentration during HAB usually varied between 0.17 and 26.95 mg/m<sup>3</sup>; in only two cases were higher values measured (62.00 and 144.21 mg/m<sup>3</sup>) in Dzilam marina. The RDA performed for marinas in 2002-2013 showed  $p = 0.05$  for nitrites and  $p =$ 0.03 for chlorophyll-*a*.

Figure 2. Multi-year dynamics (2002-2013) of *Cylindrotheca closterium* abundance in the four marinas along the northern Yucatan Peninsula coast.

Table 1. Abundances of >10<sup>5</sup> cells/L of Cylindrotheca closterium in coastal waters along the northern Yucatan Peninsula<br>during the 2001-2014 neriod (beach and marina monitoring and at 50-1000 m from the coastline) **cells/L of Cylindrotheca closterium in coastal waters along the northern Yucatan Peninsula during the 2001-2014 period (beach and marina monitoring, and at 50-1000 m from the coastline).**  during the 2001-2014 p **Table 1. Abundances of >10**

# Table 1. (Continued) **Table 1. (Continued)**

Plate 1. Electron micrographs of *Cylindrotheca closterium*: entire cell (A) and close-ups of a frustule (B-F). Scale bars: 1 µm (D and E), 10 µm (A), and 100 nm (B, C and F).

During the 2001-2014 period most of HAB (>10<sup>5</sup> cells/L of *C. closterium*) caused in coastal waters of the northern Yucatan were observed since 2011 (Table 1). Only in Chuburná marina was the highest cell abundance found in 2008. The seasonality of the species is unclear: in all the monitored marinas HAB were observed throughout the year. In Dzilam marina *C. closterium* was frequently accompanied by the potentially toxic small-sized dinoflagellate *Prorocentrum minimum* (Pavill.) J. Schiller that is also characteristic of both marine and brackish waters.

#### **DISCUSSION**

In the samples analyzed with the use of an inverted microscope, it was difficult to distinguish between *Cylindrotheca closterium*, *Nitzschia longissima* (Bréb.) Ralfs in Pritchard and *N. reversa* W. Smith. Thus, when they occurred together obtaining reliable cell counts for each species was problematic. However, SEM observations confirmed that during pelagic HAB events *C. closterium* was the most abundant.

It is necessary to differentiate between morphologically similar species such as *C. closterium*, *N. longissima*, *N. reversa* and some others such as *Reimerothrix floridensis* A. K. S. K. Prasad (Prasad et al., 2001; Hernández-Almeida & Herrera-Silveira, 2014) and *Fragilaria longifusiformis* (Hains et Sebring) Siver et al. (=*Synedra planktonica* Hains et Sebring), the latter being widely distributed in freshwater continental bodies of North America, Europe (Siver et al., 2006) and South America (Ludwig et al., 2015), as well as the widely distributed marine diatom *Lennoxia faveolata* H. A. Thomsen et K. R. Buck (Thomsen et al., 1993).

#### **CONCLUSION**

The results obtained suggest increases in the frequency of HAB events caused by *C. closterium* in the northern Yucatan waters due to anthropogenic impact evidenced by elevated nitrogen content in coastal waters, especially in marinas, the areas where fishing boats are concentrated. This widely distributed species occurs in various habitats, grows and reproduces rapidly, and has a high potential to dominate both planktonic and benthic microalgal assemblages. With the increased anthropogenic influence on the coastal zone of Yucatan, taking advantage of the elevated nitrogen concentration (mainly in the form of nitrites, nitrates and urea), *C. closterium* was one of the dominant species throughout the year, causing almost monospecific HAB events as well as ones in association with other microalgal species. In spite of the high abundances of *C. closterium* found during this study, no marine fauna mortality was observed.

#### **ACKNOWLEDGMENTS**

We thank Dora A. Huerta-Quintanilla and Ana R. Cristóbal-Ramos for technical assistance in SEM observations and a financial support given to Patricia Quintana-Owen (FOMIX-Yucatán No. 108160 and CONACYT LAB-2009-01 No. 123913 projects), from the Laboratorio Nacional de Nano y Biomateriales, CINVESTAV-IPN, Unidad Mérida, and to Ismael Gárate-Lizárraga from the Departamento de Plancton y Ecología Marina, CINVESTAV-IPN, La Paz, Baja California Sur, for help with the literature. Also, we are thankful for the financial support for the multi-year monitoring effort from the following projects: (1) "Evaluación de daños en las zonas costeras de la Península de Yucatán por el huracán Isidoro" (SISIERRA-CONACyT, 2000-2004, responsible: J. I. Euán-Ávila), (2) "Coastal evolution of the western littoral of the Yucatán Peninsula: erosion and water quality" (CONACYT, 2000-2005, responsible: L. R. A. Capurro-Filograsso), (3) "Mareas rojas de Yucatán: caracterización de factores de disparo y dispersión" (FOMIX CONACyT-Gobierno del Estado de Yucatán, 2006-2007, responsible: JAHS), (3) "Monitoreo de la marea roja de Yucatán para la prevención y comunicación de riesgos" (CINVESTAV-Fundación PRODUCE, A. C., 2009, responsible: JAHS), y (4) "Análisis

## **ABSTRACT**

Phytoplankton chlorophyll-*a* data obtained on 27 oceanographic cruises in the southern Gulf of Mexico between 1979 and 2000 were analyzed. Four cruises were selected to report variations of chlorophyll-*a* associated with hydrographic conditions (temperature and salinity) in surface waters, one in April 1983 and three in 1987 in different seasons. The CTD casts were taken from 0 to 150 m depth aboard the R/V "Justo Sierra". Discrete water samples were collected to determine chlorophyll-*a*

 $\overline{a}$

concentration by fluorometry. The observations showed that the autumn was characterized by high chlorophyll-*a* values (0.05 to 6.00 mg m-3 ), suggesting a real effect of the coastal lagoons and river fronts in late summer – early autumn along with the obvious effect of the Yucatan Current that greatly influences the coastal zone of the southeastern Gulf westward at least to  $93^{\circ}$ W. In summer the highest chlorophyll-*a* concentrations (up to  $6.50$  mg m<sup>-3</sup>) were observed in the eastern part of the study area. The lowest summer values  $(0.06 \text{ to } 0.50 \text{ mg m}^{-3})$  were found in the northeastern region  $(< 0.10$  mg m<sup>-3</sup>). Summer presents a typical stratified condition with most of the sites characterized by strong thermoclines with surface water temperatures from 25.0 to 28.9°C. River runoff contributes to the formation of a surface plume 2-8 m thick that extends seaward. In autumn a mixed water column induced by the effect of the northerlies produces a clear temperature decrease with values from 25.0 to 26.0ºC from the surface to 55 m depth and a thermocline below.

#### **INTRODUCTION**

Hydrographic conditions in the southern Gulf of Mexico are highly influenced by the local rivers and evapotranspiration processes close to the coast and the presence of mesoscale eddies that can be locally generated (Bay of Campeche cyclone) or detached from the Loop Current. This current was observed to shed more eddies in summer and winter (Chang and Oey, 2012). The occurrence of winter storms between October and February (Hurlburt and Thompson, 1980) is also an important aspect. The Yucatan Current that enters the Gulf of Mexico through the Yucatan Channel causes an intensive upwelling on Cape Catoche, which, in turn, is responsible for high biological production (Bessonov et al., 1971). The current has a mean velocity of 1.5 m  $s^{-1}$  near the surface (Candela et al., 2005; Ochoa et al., 2005), reaching a maximum velocity of  $2.5 \text{ m s}^{-1}$  (Abascal et al., 2003). The core of the Yucatan Current is characterized by velocities of more than  $0.6 \text{ m s}^{-1}$  at any time, and it is approximately 50 to 100 km wide (Bagan et al., 2005; Athié et al., 2011). The intensity of the Yucatan Current changes the character of the horizontal circulation above the Bank of Campeche and determines the position of cyclonic and anticyclonic gyres in the Gulf of Mexico. In the northern part of the Bank of Campeche, at the shelf margin, a cyclonic gyre was observed during intensification of the Yucatan Current. In spring and autumn both types of circulation are observed. However, the character of circulation at the Bank of Campeche seems to depend, to a greater extent, on interannual fluctuations in the intensity of the Yucatan Current (Bessonov et al., 1971). The main zones of upwellings and downwellings are stable in both time (within a year) and space, which results in low variability in quantitative characteristics of plankton in the Bank of Campeche area (Bogdanov, 1965, 1967; Bogdanov et al., 1968; Bessonov and González, 1971; Nowlin, 1972; Molinari et al., 1978; Merrel et al., 1981; Salas de León and Monreal-Gómez, 1986; Vidal et al., 1992).

In addition, this region is mainly impacted by two rivers, the Coatzacoalcos River and the Grijalva-Usumacinta River System (GURS), that account for approximately one-third of all fluvial discharge into the coastal waters (Tamayo, 1990). Based on chlorophyll-*a* (Chl-*a*) estimations from SeaWiFS (Sea-viewing Wide Field-of-view Sensor) satellite images, the

ecoregion influenced by the rivers expands from  $95^{\circ}$ W to almost  $89^{\circ}$ W, covering a wide coastal zone of the states of Veracruz (its eastern part), Tabasco, Campeche and Yucatan (its western part) (Salmerón-García, 2011). There are also two big coastal lagoons in the southern Gulf of Mexico. The Terminos Lagoon is distinguished by its wide communication to the sea through its two inlets and shows Chl-*a* concentrations from 0.30 to 8.20 mg m<sup>-3</sup> (Day et al., 1982). The Alvarado Lagoon receives a large contribution from the rivers Papaloapan, El Blanco and El Limon, with Chl-*a* concentrations ranging from 3.20 to 10.60 mg m-3 (Lozano-Montes, 1993). The geomorphology described above creates a very dynamic coastal ecosystem that produces spatial-temporal hydrographic variations (Czitrom et al., 1986; Schirasago, 1991; Monreal-Gómez and Salas de León, 1992), giving the entire region unique conditions that support the most important commercial fisheries in the Gulf. Its production is highly influenced by a complex system of coastal lagoons and estuaries known for their significant local productivity (Cruz, 1968; Contreras, 1985; Yañez-Arancibia and Sanchez-Gil, 1986; Soto and Escobar-Briones, 1995; Arreguín-Sánchez, 1999). Estuarine outwelling and river runoff account for much of the input of dissolved nutrients discharged into the adjacent coastal waters; thus, the phytoplankton of coastal waters is subjected to both temporal and spatial fluctuations (Licea and Luna, 1999). In addition, winds, coastal currents and upwelling events contribute to the variations. The mesoscale heterogeneity characteristic of marine phytoplankton distribution appears to be a result of the hydrographic variability mentioned above (Duarte et al., 1992).

The Yucatan shelf is highly influenced by the upwelling along Cape Catoche and other areas of the northern Yucatan coast (Bogdanov et al., 1968; Cochrane, 1969; Bessonov et al., 1971; Ruiz and Merino, 1987; Merino, 1997; Salmerón-García, 2011), sometimes interrupted by northerly winds from October to February (Mariño-Tapia et al., 2014; Reyes-Mendoza et al., 2016) due to the synoptic scale of wind variability (Pérez-Santos et al., 2010). Other significant features are the absence of rivers along the coast (Merino and Otero, 1991) and the width of the shelf around the Yucatan Peninsula that extends seaward for over 260 km (Figure 1).

The main objective of this study was to present the data on the spatial-temporal variability of Chl-*a* in surface (down to 150 m depth) waters in relation to hydrographic conditions, with an emphasis on upwelling regions near the Yucatan Peninsula.

#### **MATERIAL AND METHODS**

During a long-term oceanographic survey of the southern Gulf of Mexico program (22°30' to 18°15'N) in the period from 1979 to 2000, 27 oceanographic cruises were conducted. During each cruise, Chl-*a* samples were taken from the water column, providing a total of 5398 data records that were graphed (Figure 1). The top left values ranging from  $\geq 0.5$ to 14.00 mg  $\text{m}^3$  (632 data points) were used for the most important conclusions of this study.

In addition, hydrographic information (water temperature and salinity) obtained on the 14 transects at 57 stations of three cruises in 1987 and another in 1983 was used. In all cases, a series of CTD (conductivity-temperature-depth) hydrocasts was carried out onboard the R/V "Justo Sierra", utilizing a Neil Brown CTD Mark-IIIB probe coupled to a General Oceanics Rosette sampler with 1.5-liter Niskin bottles. Casts were taken from 0 to 150 m depth,

depending on the site depth. Discrete water samples were obtained from each cast to measure Chl-*a* following the fluorometric method (Yentsch and Menzel, 1963). Samples of 250 ml were filtered immediately using a vacuum system with glass fiber filters of  $0.22 \mu$ m pore size; 90% acetone was used as the extraction solution within 24 h prior to the analysis in a Turner model 110 fluorometer (Turner Designs, San Jose, CA, USA).

Figure 1. Study area in the southern Gulf of Mexico. The approximate position of stations with chlorophyll-*a* values  $\geq 0.50$  mg m<sup>-3</sup> are indicated by circles. Top left graph shows the frequency of 632 values obtained from 1979 to 2000 during 27 oceanographic cruises (right side). Rectangles delineate the selected cruises referred to in the text.

A set of comparative graphs (Figures 2 and 3) were made by selecting all the stations that had Chl-*a* values of  $\geq 0.50$  mg m<sup>-3</sup> which were then grouped into five regions whose names were taken from the nearest place along the coast where the values were obtained (the Alvarado Lagoon, the Coatzacoalcos River, the GURS, the Terminos Lagoon and the Champoton River), to show regional hydrographic conditions. For this purpose, three cruises of 1987 were selected on the basis of the most complete and representative information obtained. The chosen periods were: winter, summer and autumn (February-March, July-August and November-December, respectively).

SeaWiFS images (SeaStar-Orbview2 satellite) and sea surface temperature (SST) images from the U.S. National Oceanic and Atmospheric Administration (NOAA) series of Advanced Very High Resolution Radiometer (AVHRR-14), both produced by the TeraScan system of SeaSpace Co. (Poway, CA, USA), were obtained in the nearest available periods to field sampling to compare field observations to those obtained by remote sensing (Figures 4 and 5).

To update physical-oceanographic information on the southeastern Gulf of Mexico, for discussion, some hydrographic data obtained during the oceanographic cruises XCAMBO IV (14 September to 2 October 2009; Figure 6) and XCAMBO V (2-20 June 2011, Figures 7 and 8) for PEMEX (Petróleos Mexicanos) were used.

Figure 2. Comparative vertical sections of salinity and temperature (degrees Celsius, in blue) of selected stations from five regions (the Alvarado Lagoon, the Coatzacoalcos River, the Grijalva-Usumacinta River System, the Terminos Lagoon and the Champoton River) with chlorophyll-*a* values  $\geq 0.50$  mg m<sup>-3</sup> during three periods: winter (February-March), summer (July-August) and autumn (November-December).

Figure 3. Five comparative regions (the Alvarado Lagoon, the Coatzacoalcos River, the Grijalva-Usumacinta River System, the Terminos Lagoon and the Champoton River) grouped by using stations with chlorophyll-*a* values  $\geq 0.50$  mg m<sup>-3</sup> during at least one of the three periods: winter (February-March), summer (July-August) and autumn (November-December). Empty graphs mean no values ≥0.50 mg m<sup>-3</sup>.

Figure 4. Comparative panels of surface water layer distribution of chlorophyll-*a*. Upper left panel shows winter distribution in February-March; middle left shows summer distribution in July-August; lower left shows autumn distribution in November-December. Green isolines show values  $\geq 0.50$  mg m<sup>-</sup> 3 (dots indicate the position of sampling stations). Right panels show SeaWiFS images for chlorophyll-*a* in the same periods in different years.

Figure 5. Top left panel shows sea surface temperature (SST) images in March 2000; bottom left panel shows SeaWiFS images in April 2000. Right panels show the distribution of chlorophyll-*a* in June 1983 at the surface (right top) and at the 10 m depth (right bottom). Dots indicate the position of sampling stations. Green isolines show chlorophyll-a values  $\geq 0.50$  mg m<sup>-3</sup>.

Figure 7. Surface (10 m) water temperature in the southeastern Gulf of Mexico in June 2011, a year when the upwelling was particularly strong.

#### **RESULTS**

#### **Regional Hydrographic Conditions**

Figure 2 shows a set of comparative vertical sections of salinity and temperature during three cruises (winter, summer and autumn). During winter the water tended to be homogeneous. Two groups of profiles were detected: one with temperatures ranging from approximately 22.5 to 23.5°C that encompassed stations located on the western side of the region (the Alvarado Lagoon, the Coatzacoalcos River and the GURS) and the other with temperatures ranging from 23.7 to 25.0ºC that included the stations located in the eastern region (the Terminos Lagoon and the Champoton River).

Winter was characterized by a vertically mixed water layer from the surface to 50 m depth from the effect of the northern winds that begin in autumn and last through the winter. During this period the local effect of the river plumes on the surface layer of the coastal waters is noticeable. Winter and autumn had nearly the same water column structure; however, summer was the period of maximum influence of river runoff. River plumes of the Coatzacoalcos River and the GURS were detected based on surface salinity over 100 km from the coast. During the rainy season river discharge intensified, thus generating a thin layer of water characterized by low salinity (<30) and temperatures from  $27^{\circ}$  to  $28^{\circ}$ C that could be traced almost 100 km off the mouths of the main rivers. Towards the end of the year temperature dropped  $(<25^{\circ}C$ ) and salinity fluctuated between 35 and 36; both parameters showed straight vertical profiles on the shelf (Figure 2). The Terminos Lagoon region always showed some turbulence as a consequence of the expelled brackish waters of this lagoon into the adjacent coastal zone.

In summer (Figure 2, middle graphs), a typical stratified condition occurred, with surface waters reaching the maximum temperature (25.0 to 28.9°C) and most stations characterized by strong thermoclines. At stations in the eastern region the top of the thermocline lay between 8 and 30 m, while in the western region it was between 25 and 40 m. During this period the stratified condition produced both vertical and horizontal gradients in both temperature and salinity. A marked seasonal thermocline was present very close to the surface, and its persistence in time was further prolonged by the cold oceanic water (temperature 22.0°C and salinity 36.5) upwelling onto the inner shelf boundary. The river flow contributed to the formation of a surface plume 2-8 m thick that extended seaward. Salinity profiles showed the effect of river runoff and high evaporation rates with values of >36. The section of the Alvarado Lagoon showed a strong vertical gradient in temperature and salinity near the surface and in the layer between the 10 and 20 m depth. Haline structure showed the effect of the Coatzacoalcos River by extending the river plume up to 35 km from the coast and 15 m in depth; below 20 m a homogeneous water mass with salinity of 36 was observed. The region of the GURS showed a thermic structure with almost vertical isotherms, suggesting upwelling of bottom water.

In autumn (Figure 2, bottom graphs) mixing into the water column induced by the effect of the northerlies clearly produced a temperature decrease down to 25-26ºC from the surface to 55 m depth with a residual thermocline below. In this period the highest values of salinity (36.0 to 36.3) were found at the western stations. Similarly, this region appeared vertically

uniform, and the influence of rivers was weak. However, the most important estuarine outwelling of the Terminos Lagoon occurred during this period.

#### **Chlorophyll-***a* **Distribution**

Chl-*a* concentration of the 5398 data records collected during the period of 1978-2000 ranged between  $0.02$  and  $0.50$  mg m<sup>-3</sup> and can be therefore considered as the most typical concentrations for the southern Gulf of Mexico. In contrast, values of  $\geq 0.50$  mg m<sup>-3</sup> up to 14.00 mg  $m<sup>3</sup>$  are restricted to some sites along the coast between the Tamiahua Lagoon to the Champoton River and Cape Catoche in the Yucatan Peninsula (Figure 1). These are mainly associated with river and coastal lagoon effects, depending on the local conditions that fluctuate both in time and space as well as in upwelling areas on the Yucatan shelf.

Figure 3 shows a set of five regions where Chl-*a* values were higher than 0.50 mg m-3 throughout the year. In summer the highest Chl*-a* concentrations were found toward the west (the GURS, Coatzacoalcos River and Alvarado Lagoon). The highest values were located at seven sites off the Alvarado Lagoon. In contrast, in autumn the pattern changed in the opposite direction; i.e., higher values were found toward the eastern side of the region from the GURS toward the Champoton River (Figure 3). In fact, the GURS produces a hydrographic effect creating a clear division between the western and eastern regions. This separation is indicated by the green isolines in Figure 4 (middle and lower left). In winter Chl-*a* concentrations reached the lowest values, fluctuating between 0.04 to 0.50 mg  $m<sup>-3</sup>$ . Very few values of  $\geq 0.50$  mg m<sup>-3</sup> were found (Figure 3, upper graphs).

SeaWiFS images confirm field observations. Figure 4 (right panel) illustrates the Chl-*a*  distribution in the surface layer in the nearest available periods of field sampling. In general, the field data fit well to those obtained by remote sensing in autumn and winter, but not in summer due to the almost permanent cloudy weather in this region. On the other hand, interannual variation could be significant.

The left panels in Figure 5 show satellite images (SST and SeaWiFS) of the Yucatan shelf in which Chl-*a* shows some heterogeneity in its distribution. However, at several sites in the region located north off Cape Catoche, high values between 0.50 and 2.03 mg  $\text{m}^3$  were found. Intermediate values of about 0.30 mg m-3 occurred between Progreso and Río Lagartos along the coast northeast of the shelf. No great difference between the surface and 10 m depth was found.

#### **DISCUSSION**

The results of the present study fit well with the patterns of pigments for the southern Gulf of Mexico (Müller-Karger et al., 1991). The use of different cycles of the CZCS (Coastal Zone Color Scanner) allowed us to confirm that Chl-*a* values of  $\geq 0.50$  mg m<sup>-3</sup> along the southern coast of the Gulf are typical for this region throughout the year. On the other hand, some authors have found that the frequent intrusions of the Loop Current bring relatively large amounts of nutrients into the southwestern Gulf of Mexico (Sturges and Evans, 1988; Merino, 1992). This circumstance allows water upwelled onto the shelf to remain trapped within the euphotic zone for long periods, which could increase the fertilizing potential in this region (Furnas and Smayda, 1987). In the Bank of Campeche area, the influence of upwelling on the phytoplankton is noticeable only in the coastal zone and almost unnoticeable in the oceanic zone (Vinogradova, 1976).

The results confirm that the highest phytoplankton production on the shelf is promoted by the river fronts of the Coatzacoalcos River and the GURS, as well as by the estuarine outwelling through the coastal Terminos and Alvarado lagoons that is dispersed onto the inner shelf boundary. This phenomenon occurs in July-August (Figure 3) when the stratified condition produces not only vertical but also horizontal gradients. The patterns of variability appear to be under the control of seasonal and regional influences. The stations located along the transects of the above-mentioned rivers showed that Chl-*a* was the highest not only in summer but also throughout autumn (Figure 3). The Chl-*a* increase was especially high during summer due to the maximum river discharge. This situation fits well with the Hydraulic State Program of 1988 (Vázquez-Gutiérrez, 1994). Other authors studying the abundance and distribution of benthic organisms in this region have found similar patterns (Soto and Escobar-Briones, 1995) and have reported relatively high Chl-*a* concentrations  $(3.20 \text{ mg } \text{m}^3 \text{ in May and } 10.60 \text{ mg } \text{m}^3 \text{ in December})$  in the Alvarado Lagoon as a consequence of the large quantity of nitrates of agricultural origin (Lozano-Montes, 1993). In the older literature the highest production in the water column, ranging between 50 and 108 mg C m<sup>-3</sup> day, was measured by the radiocarbon method in mid-April 1965 in the eastern part of the Bank of Campeche, NW off Celestun (Kabanova and López-Baluja, 1970).

After the rainy season it appears that the estuarine plume induced by discharges of the GURS and the Terminos Lagoon system influences the adjacent continental shelf, thus promoting an increase in Chl-*a* concentration. The local effect associated with river plumes and the coastal lagoons contributes to the Chl-*a* increase while its drastic decrease off the coast depends on the fact that nutrients introduced by the river discharge are gradually lost from the plume, and the additional input of few nutrients diminishes. Chl*-a* patches were detected along the limit of the continental shelf, possibly associated with fronts due to the cyclonic circulation patterns already established (Nowlin, 1972; Merrel and Morrison, 1981; Monreal-Gómez and Salas de León, 1985, 1990). However, the magnitude of such influence is yet to be determined.

Recent studies have shown that coastal lagoons and rivers in late summer-early autumn have their maximum runoff that contribute to the formation of surface plumes 2-8 m thick that can extend seaward. Figure 6 (upper panel) shows this effect of the rivers and lagoons of the southern Gulf of Mexico that could be observed from the coast to a latitude of  $21^{\circ}N$ during late summer-early autumn of 2009. The offshore movement of the river plume is enhanced by the local circulation shown in Figure 6 (lower panel) that can have a net northward trend along the shelf break, carrying the continental waters towards the offshore region.

In the case of the Yucatan shelf, the existence of the subsurface countercurrent (Merino, 1997) also suggests the close relationship between the countercurrent and the upwelling process in this region, with the expected effects along the eastern Yucatan slope. Data on phytoplankton abundance presented here support this suggestion that the countercurrent may be formed by upwelled water that sinks again as it flows along the slope. The area located between Progreso and Río Lagartos has been characterized as a region suitable for upwellings caused by wind, due to the position of the coast in relation to the direction of winds from the
