Since 2016, DOEE has been working with the Metropolitan Washington Council of Governments to sample trash along rivers and streams throughout the District. We provide this data annually to U.S. EPA Region III. This work builds upon a larger monitoring dataset the Council of Governments has been collecting in the Maryland portion of the Anacostia River watershed since the early part of this decade, making it one of the most robust datasets for trash for a waterbody anywhere in the nation. Having this data is imperative to making future strategic decisions for implementation and infom1ing development of new policies.

Graph displaying most common types of trash found by count in 2008 in the Anacostia River, its tributaries, Kingman Lake, and land in the Anacostia watershed.

# **Multi-Pronged, Innovative Approaches**

As with most environmental challenges, there is no "silver bullet" for eliminating the harm trash poses to our waterways and wildlife. The District has devised a plan that utilizes innovative policies, trash capture technologies, education and outreach.

As mentioned previously, our monitoring efforts helped us to determine the most common types of trash found in our waterbodies. The District utilized monitoring data described previously to justify the need to reduce three of the most common types of trash found during sampling: single-use plastic bags, expanded polystyrene foam products (commonly referred to as Styrofoam™), and other food service ware.

In 2009, the District enacted the Anacostia River Clean Up and Protection Act (also known as the Bag Law) to create a five-cent fee on single-use plastic bags. Starting January l, 2010, consumers in the District pay the fee at the time of purchase in a restaurant, grocery, liquor, or convenience store. DOEE employs an inspection team to ensure businesses are in compliance with the law. Revenue, fines and other contributions generated by the law goes into the Anacostia River Clean Up and Protection Fund to pay for projects like trash capture devices, stream restoration, stormwater management projects, education, outreach, and administrative costs. In Fiscal Year 2017, the Department found that 76% of businesses inspected were in compliance with the law. More information on the District's Bag Law, including annual revenue and expenditure reports, arc available at https://doee.dc.gov.bags.

In 2014, the District enacted the Sustainable DC Omnibus Amendment Act, which includes restrictions on food service ware packaged and intended for consumption without further preparation. Specifically, a ban on food service ware made of Styrofoam<sup>TM</sup> (foam) took effect January 1, 2016, and the law requires food service ware to be made of recyclable or compostable materials starting January 1, 2017. As with the Bag Law, DOEE inspects businesses to make sure they are in full compliance with the law. In fiscal year 2017, DOEE

found that 88% of District businesses inspected were in compliance. Further information on the District's food service ware requirements is available at https://doee.dc.gov/foodservice ware.

Examples of trash traps installed in tributaries to the Anacostia River in the District. Top: Proprietary device known as a Bandalong Litter Trap<sup>TM</sup> installed and maintained by Anacostia Riverkeeper. Bottom: custom trash weir designed, installed, and maintained by the Anacostia Watershed Society.

The District has also implemented innovative structural controls for capturing trash. Since 2009, the District has installed nine trash traps in the Anacostia River watershed. These traps have varied from proprietary products to custom devices designed by local non-profits. The pictures below display examples of the devices. These devices have primarily been funded by the Anacostia River Clean Up and Protection Fund and other local funding sources through grants to local nonprofits to design, install, and maintain these devices. The

nonprofits also collect data on trash collected in the traps to further inform policies. Since installation of the first device in 2009, these devices together have helped capture and remove over 60,000 lbs of trash and debris from the Anacostia River and its tributaries.

Lastly, the District has led many education and outreach activities over the years to change behavior. In 2010, DOEE funded the Alice Ferguson Foundation (AFF) to conduct a study of littering behavior that guided the development of an anti-littering campaign throughout the District The campaign's central message, *"Your Litter Hits Close to Home."*  was based on AFF's research that found people were most impacted by the effects litter has on their personal space, health, and well-being. Below is an example graphic from the antilittering campaign. Other local governments in the Potomac River watershed have adopted these campaign materials.

In closing, I want to again thank you and the Senate EPW committee for your interest in this important subject. As the nation's capital, the District has an important role to play in restoring urban waterways. We have set the stage for reducing trash in our rivers and streams using multi- faceted, innovative approaches, but we are not done. We are truly alarmed by the potential impacts microplastics could have on our aquatic resources such as some of our valuable fisheries. A 2014 study published in the journal, *Environmental Science and Technology,* found microplastics to be present in four tidal tributaries to the Chesapeake Bay.<sup>62</sup> 59 of the 60 samples collected during the study contained microplastics. We are actively engaged with the EPA Chesapeake Bay Program, the NOAA Marine Debris Program, and neighboring jurisdictions on research and management to address the issue. We hope Congress will also take a leadership role in finding solutions to this challenging pollution issue.

l

# **ABSTRACT**

Hokkaido is Japan's northernmost main island and is surrounded by the North Pacific Ocean, the Japan Sea, and the Okhotsk Sea. Some headlands in Hokkaido and their surrounding warm and cold currents restrict the travel and migration of fish and cetaceans and control the dispersal of environmental pollutants throughout the three seas. Three independent stocks of Pacific cod inhabit the three seas, and many cetaceans become stranded along their coasts. In this chapter, we used stranded cetaceans and Pacific cods as indicator species to compare the contamination levels of radiocesium in the three seas shortly after the Fukushima Daiichi Nuclear Power Plant accident in 2011. We assessed the contamination levels of perfluoroalkyl substances (PFASs), classical persistent organic pollutants (POPs), and naturally produced halogenated compounds (NHCs) in cetaceans and Pacific cods from the three seas around Hokkaido. We also compared the contamination levels between the North Pacific Ocean around Hokkaido and other areas around the world.

**Keywords:** Hokkaido, sea current, cetacean, pacific cod, radiocesium, stable isotopes, perfluoroalkyl substances (PFASs), persistent organic pollutants (POPs), naturally produced halogenated compounds (NHCs)

# **1. SEA AREAS OF HOKKAIDO**

# **1.1. Introduction to the Sea Areas of Hokkaido**

The seawaters surrounding Hokkaido (Figure 1) are complex and rich biodiversity. In particular, the area off Eastern Hokkaido is one of the world's top three fishing grounds. The region consists of four sea currents, which affect the physical seawater characteristics and show significant seasonal variability.

Hokkaido is located north of Honshu, the largest main island, and is therefore Japan's northernmost large island. The Japan Sea is located on Hokkaido's western coast, the Pacific Ocean is located on its eastern coast, and the Okhotsk Sea is located on its northern coast. The Tsugaru Strait lies between Hokkaido and Honshu and connects the Japan Sea and Pacific Ocean, and the Soya Strait connects the Japan Sea to the Okhotsk Sea.

Figure 1. Location, related lands and related sea currents of the sea of northern Japan. This figure was reprinted from Nakamura et al., (2015). Copyright (2015), with permission from Inter Research with slight modification.

### **1.2. Sea Currents around Hokkaido, Japan**

Three sea currents surround the island of Hokkaido. The largest current in the Japan Sea is the Tsushima Current, and the Tsugaru Current in the Tsugaru Strait is a branch of the Tsushima Current. The Oyashio Current is a dominant cold-water current running from the Kamchatka Peninsula to the Sanriku Coast via the east coast of Hokkaido.

The Tsushima Warm Current is the only source of oceanic water to the Japan Sea; it is sourced from the warm saline waters of the Kuroshio Current, which mixes with freshwater in the East China Sea. The surface current velocity and flow volume in the Tsushima Strait ranges from 0.3 to 0.4 m/s. The majority of the current flows out through the Tsugaru Strait, and the remainder flows northward along the western coast of Hokkaido. Part of the current flows out through the Soya Strait to the Okhotsk Sea, while the remainder reaches the northern Japan Sea (Gallagher et al., 2015).

The Tsugaru Warm Current is a branch of the Tsushima Current, and its outflow into the Pacific Ocean forms two oceanic modes: a gyre mode and a coastal mode (Conlon, 1982). The outflow of the Tsugaru Current forms a warm clockwise gyre in summer. The gyre disintegrates in winter, and the current flows southward along the coast of Honshu to the Sanriku Coast; this results in significant seasonal variability in the south of Hokkaido and the Sanriku Coast (Rosa et al., 2007).

The Oyashio Cold Current originates from the East Kamchatka Current, which is a part of the western boundary current of the subarctic North Pacific. Part of the East Kamchatka Current enters the Okhotsk Sea; the remainder flows along the coast of the Kuril Islands to the Eastern Hokkaido Coast to form the Oyashio Current. The current carries cold, fresh, oxygenated, and nutrient-rich water and has a profound impact on the fishing ground off the Sanriku Coast (Isoguchi and Kawamura, 2006).

## **1.3. Coastal Zone**

The coastal zone of Hokkaido is divided into 4 areas based on the surrounding sea water currents: the Japan Sea Coast, Okhotsk Sea Coast, Eastern Hokkaido Coast, and Southern Hokkaido Coast.

The Japan Sea Coast stretches to Cape Soya from the northern Honshu Island. The coasts facing the Tsugaru Strait (until Cape Esan and Cape Shiriya) also form part of the Japan Sea Coast. The water temperature is warm, especially in summer, due to the influence of the Tsushima and Tsugaru Currents. As a result, warm species of fish, including bluefin tuna (*Thunnus orientalis*), are frequently observed. Strong seasonal winds from the Eurasian Continent result in rough oceanic conditions in winter. In addition to the coastal area, the Musashi Bank located off the west coast of Hokkaido  $(44^{\circ} 40^{\circ} N, 140^{\circ} 25^{\circ} E)$  is an excellent fishing ground. According to the official statistics of the Hokkaido Government, the dominant fish in their fisheries include the Okhotsk atka mackerel (*Pleurogrammus azonus*), walleye pollock (*Theragra chalcogramma*), and chum salmon (*Oncorhynchus keta*). The Pacific herring (*Clupea pallasii*) was also abundant until the 1940s.

The Okhotsk Coast stretches from Cape Soya to Cape Nosappu. During winter, drift ice is transported to the coast from the west coast of the Okhotsk Sea. The melting of drift ice in spring due to increased surface temperatures releases abundant nutrients and increases regional primary production. The Japanese scallop (*Mizuhopecten yessoensis*) is cultured on the coast, and chum salmon is also an important fishery resource. The coastline from Cape Shiretoko to Cape Nosappu faces the Nemuro Strait, which connects the Okhotsk Sea to the

Pacific Ocean. Hydrographically, this coast forms a part of the Okhotsk Coast, but the fauna is occasionally strongly influenced by the Pacific Ocean.

The Eastern Hokkaido Coast stretches from Cape Nosappu to Cape Erimo and is strongly affected by the nutrient-rich Oyashio Current. The coastal area is a large habitat for the kelp species *Saccharina longissima*, *S. coriacea*, and *S. angustata*, which are common ingredients in Japanese cuisine.

The Southern Hokkaido Coast stretches from Cape Erimo to Cape Esan where the Tsugaru Warm Current mixes with the Oyashio Cold Current. The Tsugaru Warm Current dominates in summer and autumn, and the Oyashio Cold Current dominates in winter and spring. The aquaculture of Japanese scallop and of the kelp species *Saccharina japonica* and *S. angustata* is actively conducted on the coast. The walleye pollock and Japanese common squid (*Todarodes pacificus*) are also commonly fished.

The sea region off the Eastern Hokkaido Coast is one of top three fishing grounds in the world. The two dominant currents—the cold Oyashio and warm Kuroshio—form a transition zone, which results in a sharp gradient in oceanographic conditions, forming the sub-boreal, cool temperate, and warm temperate and subtropical zones. The high marine biodiversity in this area is attributed to the large topographical, physical, and chemical variability within a relatively small latitudinal range (Kida et al., 2015). Moreover, the high-nutrient Oyashio Current increases primary production and supports the high fish biomass for sustained fishery resources at higher trophic levels. The spatio-temporal variability of physical and biological seawater properties off the Sanriku Coast significantly impacts coastal ecosystems through the supply of nutrients and the transport of planktonic fish and invertebrates (Sakurai, 2007). Pelagic fish, including the Japanese sardine (*Sardinops melanostictus*), Pacific mackerel (*Scomber japonicus*), Pacific saury (*Cololabis saira*), and Bonito (*Katsuwonus pelamis*) are caught by large-scale commercial fishing in this region.

### **1.4. Cetaceans and Their Migrations**

Cetaceans and other marine mammals are apex predators. They have a major influence on the structure and function of some aquatic communities due to their large body size and high abundance (Bowen, 1997).

The Stranding Network Hokkaido (SNH) is collecting cetacean stranding information and specimens from Hokkaido's coasts for providing to a number of cetologists (Matsuishi, 2011). According to the SNH database (http://kujira110.com/), the most frequently reported cetacean species were the harbor porpoise (*Phocoena phocoena*), common minke whale (*Balaenoptera acutorostrata*), and Dall's porpoise (*Phocoenoides dalli*). Most of the cetacean samples presented in this chapter were supplied from the SNH.

Harbor porpoises are common in the coastal areas of the North Atlantic and northeast Pacific, and their migration and population structure in these regions have been extensively reported (e.g., Verfuß et al., 2007). By contrast, their migration and population structure in the northwest Pacific coast is not widely reported. Taguchi et al. (2010) suggested that the seasonal migration of this species occurs along the coasts of the northwest Pacific and the Okhotsk Sea, but the relationship between the populations in the Pacific and the Japan Sea remains unclear.
The common minke whale is also commonly distributed in the seas of northern Japan. According to the Japan Fisheries Research and Education Agency (FRA), the population in the Okhotsk Sea and the west North Pacific Ocean in the 1990's was estimated at 25,049 (13,700–36,600, 95% CI), assuming perfect counting in the sighting survey (Buckland et al., 1992). The population structure of the common minke whale in this region is still under discussion; however, it currently consists of two types: 1) the 'O-type' found primarily in the offshore Pacific Ocean, and 2) the 'J-type' found primarily in the Japan Sea and nearshore waters of Japan's Pacific coast (Wade et al., 2010). Under the JARPN II (the second phase of the Japanese Whale Research Program under Special Permit in the North Pacific), this species has been sampled lethally and non-lethally, and various biological information has been collected and reported (Tamura et al., 2016). The O-type is estimated to migrate northward during April to July and remains in the Okhotsk Sea during summer. The J-type is also assumed to have similar seasonal migratory behavior between the south and north (Hatanaka and Miyashita, 1997).

Dall's porpoises are widely distributed around the seas of northern Japan in both the Pacific and Japan Sea. This species has two color morphologies: the *dalli*-type and *truei*-type. The *dalli*-type is distributed in the Japan Sea and around Hokkaido, while the *truei*-type is distributed from the coastal area of Sanriku Coast to the central Okhotsk Sea. The two types are genetically different and are therefore considered distinct populations (Hayano et al., 2003). The populations of the *dalli*-type and *truei*-type are estimated at 174,000 and 178,000, respectively, based on the official report on the species' stock status published by FRA. This species is not controlled by the International Convention for the Regulation of Whaling, but the Fisheries Agency of Japan (JFA) manages its capture by implementing a catch quota based on the potential biological removal theory (Wade, 1998). In the Japan Sea, the *dalli*type migrates to the coast of Hyogo Prefecture (southern Honshu) in winter and to the Okhotsk Sea in spring where it remains for breeding in summer. In the Pacific Ocean, the *dalli*-type is distributed off the Sanriku Coast, and the *truei*-type is distributed near the Sanriku Coast in winter; both types migrate to the east coast of Hokkaido during summer (Amano and Hayano, 2007).

Baird's beaked whales (*Berardius bairdii*) are also frequently stranded and commercially caught around Japan under the permission of JFA. According to distribution and morphological information (Kishiro, 2007), three populations around Japan are thought to be distinguished, including the Japan Sea population caught off southwestern Hokkaido; the Pacific-Okhotsk population caught off Abashiri, Hokkaido; and the Pacific population caught off Honshu.

In 2019, Yamada et al. (2019) identified a new species known as the Black Berard's whale (*Berardius minimus*). This species has been confused with the Baird's beaked whale (*B. bairdii*) as a cryptic species (Kitamura et al., 2013). However, its body length is significantly smaller than *B. bairdii*, and the two species show clear genetic and morphological differences. *B. minimus* is thought to be distributed in the Okhotsk and Bering Seas.

## **1.5. Fishes and Their Migrations**

The Hokkaido region has an active fisheries operation, and a wide range of species are caught in both commercial and small-scale fisheries. Most of the fish species migrate seasonally along the coast, and are divided into three stocks: the Pacific stock, Okhotsk stock, and Japan Sea stock. For example, according to the Fisheries Research and Education Agency, the walleye pollock—the most abundant fish species in the region—is divided into at least three stocks with different spawning grounds and population dynamics.

The population structure of the Pacific cod—another common species in the region—is unclear, but it is assumed to be divided into three stocks: the Pacific Ocean stock, Japan Sea stock, and Okhotsk Sea stock (Chimura et al., 2019). In contrast, observations of its life history characters and catch trends point toward the existence of a large number of local stocks (e.g., Bakkala et al., 1984; Mishima, 1984; Kanno et al., 2001). A recent genetic study showed clear differences between the western part of Honshu and other samples around Japan (Suda et al., 2017). Genetic differences between stocks are caused by strict and long reproductive isolation and mutation; however, the spawning ground may change according to abundance, which fluctuates on decadal time-scales. This may explain the population structure discrepancy observed from population dynamics and genetic studies.

## **1.6. Conclusion**

Hokkaido is Japan's northernmost large island and is surrounded by the North Pacific Ocean, the Japan Sea, and the Okhotsk Sea. Some headlands in Hokkaido and their surrounding warm and cold currents restrict the migration of fish and cetaceans and control the dispersal of environmental pollutants throughout the three seas. Three independent stocks of fish—including the Pacific cod—inhabit the three seas and also migrate seasonally along the coast of Hokkaido. Many cetaceans become stranded along the coast of the three seas as they migrate annually from north to south. In the following sections, we assess the contamination levels of radiocesium, perfluoroalkyl substances (PFASs), classical persistent organic pollutants (POPs), and naturally produced halogenated compounds (NHCs) in Pacific cod and cetaceans in the three seas surrounding Hokkaido. We also make comparisons between the contaminations levels in the North Pacific Ocean and other regions around the world.

# **2. RADIOCESIUM CONTAMINATION AND MIGRATORY BEHAVIOR OF CETACEANS AND PACIFIC CODS FROM THE SEAWATERS OF HOKKAIDO**

# **2.1. Introduction**

A magnitude  $9.0-9.1$  (M<sub>w</sub>) earthquake occurred off the Sanriku Coast, the Tohoku district in main island of Japan at 14:46 JST on 11 March, 2011. The epicenter was approximately 70 km offshore, which triggered a large-scale tsunami of 40.5 m. The tsunami caused nuclear

accidents at three reactors in the Fukushima Daiichi Nuclear Power Plant (FDNPP), resulting in the large-scale release of radiocesium  $(^{134}Cs$  and  $^{137}Cs$ ) and other radionuclides to the atmosphere and across an extensive area of ocean off eastern Japan. The total amount of  $137Cs$ emitted from the FDNPP was 15 PBq (Honda et al., 2012) and a large proportion of these nuclides was transported and diffused eastward by the Kuroshio Current (Buesseler et al., 2011; Honda et al., 2012, see Figure 1). Following the FDNPP accident, the radiocesium contamination in seawater and fish in the vicinity suddenly increased, reaching a maximum (31 kq/kg as  $137Cs$ ) between June and August, 2011, followed by a rapid decrease thereafter (Aoyama et al., 2012; Takagi et al., 2014). In contrast, radionuclide contamination in the seawater off northern and western Japan was low (Inoue et al., 2012), likely due to the inhibited transport of radiocesium via the Tsugaru and Oyashio Currents to the coastal areas of Hokkaido in northern Japan (Inoue et al., 2012; Honda et al., 2012).

 $137Cs$  is a long-lived artificial radionuclide (half-life: 30.2 years) that bioaccumulates in the marine food chain; it is therefore a strong indicator of radionuclide pollution in the marine environment (Kasamatsu and Ishikawa, 1997). However, <sup>134</sup>Cs is detectable in seawater and marine biota shortly after the nuclear accident due to the shorter half-life of  $137Cs$  (2.06) years).

Shortly after the FDNPP accident, high levels of radiocesium  $(>100 \text{ Bq/kg-wet})$  were detected in many demersal and pelagic fishes in the surrounding western North Pacific Ocean. In contrast, little or no radiocesium contamination was reported in marine biota in the waters off Hokkaido, inferring little contamination in this region. However, radiocesium was detected in stranded cetaceans on the coast of Hokkaido in 2011 and 2012; high levels were also detected in Pacific cod caught in the North Pacific Ocean off Hokkaido in 2011–2015. In this section, we discuss the reasons for the detection of radiocesium in only cetaceans and Pacific cods.

# **2.2. Contamination of Radiocesium in Stranded Cetaceans on the Coast of Hokkaido**

Hokkaido is surrounded by the North Pacific Ocean, the Japan Sea, and the Okhotsk Sea. More than 50 cetacean strandings are annually reported along Hokkaido's coast by the SNH [\(http://kujira110.com/\)](http://kujira110.com/). We measured the radiocesium  $(^{134}Cs$  and  $^{137}Cs$ ) in muscle samples of 47 stranded cetaceans on the coast of Hokkaido between April 2011 and September 2012 (Nakamura et al., 2015). The species of odontocetes were the Pacific white-sided dolphin (*Lagenorhynchus obliquidens*; n = 11), harbor porpoise (n = 11), *dalli-type* Dall's porpoise (n  $= 10$ ), Baird's beaked whale (n  $= 1$ ), Stejneger's beaked whale (*Mesoplodon stejnegeri*; n  $=$ 1), Hubbs' beaked whale (*Mesoplodon carlhubbsi*; n = 1), pygmy sperm whale (*Kogia breviceps*; n = 2), Cuvier's beaked whale (*Ziphius cavirostris*; n = 1), and killer whale (*Orcinus orca*;  $n = 1$ ). The species of mysticetes were the common minke whale ( $n = 6$ ) and humpback whale (*Megaptera novaeangliae;* n = 2).

Radiocesium contamination ( $> 1.0$  Bq/kg-wet as <sup>137</sup>Cs) was predominantly detected in the cetaceans stranded along the coast of the Pacific Ocean (southern and eastern coasts of Hokkaido,  $(1)$ – $(4)$  in Figure 2) between June and October 2011, irrespective of species (Figure 3). The highest level of radiocesium contamination was found in a common minke

whale (19.9 Bq/kg-wet as  $^{137}Cs$ , (3) in Figure 2), which is in disagreement with the notion that contamination levels are generally higher in odontocetes than in mysticetes (Haraguchi et al., 2000; Simmonds et al., 2002). No contamination of radiocesium was found in the cetaceans stranded on the coast of the Japan Sea and Okhotsk Sea in 2011 and 2012. Furthermore, no radiocesium contamination was found in all cetaceans stranded in 2013 (data not shown Figure 3), likely due to the rapid decrease of seawater radiocesium contamination around the FDNPP. The contamination level of radiocesium in cetaceans may reflect that of the seawater along their travel routes and during their sojourn in the contaminated area. Radiocesium levels in marine mammals before the FDNPP accident were approximately 0.2 Bq/kg-wet (Kasamatsu and Ishikawa, 1997; Yoshitome et al., 2003).

Many cetaceans inhabiting the waters off Japan generally migrate from south to north in spring and vice versa in autumn. However, their detailed travel routes remain uncertain, despite the increasing development of research techniques. Figure 4 shows the putative travel routes of the Pacific white-side dolphin (A), *dalli*-type Dall's porpoise (B), and common minke whale  $(C)$  that inhabit the waters around Japan. The levels of  $137Cs$  and the date and location of stranding are shown in Figure 4. In addition to the stranded animals, the contamination levels of an incidentally caught (bycatch) Pacific white-sided dolphin  $(n = 1)$ and a *dalli*-type Dall's porpoise  $(n = 1)$  are shown in Figure 4A and B, respectively.

Figure 2. Map of Japan showing the Hokkaido and Tohoku areas. This figure was reprinted from Nakamura et al., (2015). Copyright (2015), with permission from Inter-Research with slight modification.

Radiocesium was detected in all Pacific white-sided dolphins stranded in 2011, six dolphins stranded along the coast of Volcano Bay (southern coast of Hokkaido), and one dolphin stranded on the coast of Rausu (Figure 4A). Furthermore, radiocesium was detected in a Pacific white-side dolphin incidentally caught in 2011. However, radiocesium was not detected in this stranded species in 2012. The Pacific white-sided dolphin can take two possible travel routes to Volcano Bay: 1) via the Sanriku and Shimokita Coasts (Pacific Ocean route), and 2) via the Tsugaru Strait from the Japan Sea (Japan Sea route) (Tsutsui et al., 2001). The radiocesium contamination of Pacific white-sided dolphins appears to provide direct evidence of their seasonal movements via the Pacific Ocean route.

Figure 3. Radiocesium  $(^{137}Cs)$  activity in cetaceans stranded along the coast of Hokkaido in 2011 and 2012. This figure was reprinted from Nakamura et al., (2015). Copyright (2015), with permission from Inter-Research.

Radiocesium was detected in 3 out of 5 stranded or caught *dalli*-type Dall's porpoises in 2011 and in an incidentally caught *dalli*-type Dall's porpoise in 2011 (Figure 4B); radiocesium was not detected in this species thereafter. As with the Pacific white-sided dolphin, two travel routes have been postulated for the *dalli*-type Dall's porpoise (Figure 4B): 1) via the Pacific Ocean route, and 2) via the Japan Sea route through the Tsugaru Strait (Hayano et al., 2003; Amano and Hayano, 2007). The <sup>137</sup>Cs contamination in *dalli*-type Dall's porpoises suggests that this species seasonally migrates via the Pacific Ocean route.

The <sup>137</sup>Cs contamination levels in two stranded common minke whales on the coast of the Pacific Ocean and in the red meat products of this species (supplied from the Japanese Whaling Research Program) are shown in Figure 4C; the caught off area is also indicated. Common minke whales—likely the O-type—may have migrated from the contaminated area of the western North Pacific Ocean (Figure 4C), which is in agreement with the estimated route by Wade et al. (2010).

As described in the previous section, there are three putative Baird's beaked whale populations in the waters around Japan: the Japan Sea population, the Okhotsk Sea population, and the Pacific Ocean population (Kishiro, 2007). A sample of a Baird's beaked whale stranded near Cape Soya in the border between the Okhotsk Sea and the Japan Sea ( $\Omega$ ) in Figure 2) showed no radiocesium contamination. As described later (Figure 7), stable carbon and nitrogen isotope ratios suggest that the beaked whale originated from the Japan Sea population.

Figure 4. Putative travel routes of the Pacific white-sided dolphin (A), Dall's porpoise (*dalli type*; B) and common minke whale (O –type; C) around Japan, and  $137Cs$  activity in those cetaceans after the Fukushima accident. Solid lines with arrows indicates the putative travel routes of Pacific white-sided dolphin, Dall's porpoise and common minke whale. This figure was reprinted from Nakamura et al., (2015). Copyright (2015), with permission from Inter-Research.

Radiocesium was detected in 4 out of 5 harbor porpoises stranded in 2011 but was undetected in 6 porpoises stranded in 2012. Although the seasonal migratory route of this species is unknown, a possible route may be through the Sanriku and Shimokita Coasts (see Figure 2, Taguchi et al., 2010).

Little is known about the migration of odontocetes inhabiting the waters of Hokkaido, such as the Stejneger's beaked whale, Hubbs' beaked whale, pygmy sperm whale, Cuvier's beaked whale, and killer whale. Among these odontocetes, radiocesium was only detected in pygmy sperm whales stranded in 2011 ( $n=2$ ), inferring their movement from the radiocesiumcontaminated area of the North Pacific Ocean surrounding the FDNPP. In contrast, radiocesium was undetected in a Stejneger's beaked whale and a Hubbs' beaked whale stranded in 2011; this likely rules out their movement across the radiocesium-contaminated area prior to stranding. Furthermore, radiocesium was also undetected in a Cuvier's beaked whale and a killer whale stranded in 2012.

## **2.3. Contamination of Radiocesium in Pacific Cod Caught Off Hokkaido**

The Pacific cod is a bottom-dwelling species and an important commercial food product in Japan. Several individual stocks of Pacific cod are reported to inhabit the waters off the Asian coast; these stocks only have limited migration and inhabit relatively small areas (Bakkala et al., 1984). As mentioned in the previous section, three independent stocks of Pacific cod are thought to inhabit the waters off Hokkaido; the North Pacific Ocean stock, the Okhotsk Sea stock, and the Japan Sea stock (Chimura et al., 2019). Two further stocks of Pacific cod are assumed to inhabit the western North Pacific Ocean off Tohoku, including the area surrounding the FDNPP and the northwestern areas of the Japan Sea off Tohoku (Savin and Kalchugin, 2011).

We measured the radiocesium concentrations in 42 Pacific cod samples purchased from retail outlets in Hokkaido; the cod samples were caught from the North Pacific Ocean ( $n =$ 22), the Okhotsk Sea  $(n = 8)$ , and the Japan Sea  $(n = 12)$  between 2011 and 2015 (Figure 5) (Nakamura et al., 2018). The highest <sup>137</sup>Cs level measured in our survey was 24 Bq/kg-wet. The highest level reported in another survey was 100 Bq/kg-wet in a Pacific cod caught in location A in the North Pacific Ocean in 2012 (Figure 5).

Radiocesium was predominantly detected in Pacific cod samples caught in the North Pacific Ocean during 2011 and 2015 (A–G in Figure 5) and undetected in samples caught in the Okhotsk Sea (H–J) and Japan Sea (K–M). The regional variability of radiocesium contamination in Pacific cod samples was similar to that of the stranded cetaceans in the three areas. The contaminated Pacific cod caught in the North Pacific Ocean around Hokkaido may have therefore migrated from the FDNPP region. The radiocesium contamination in Pacific cods was measured over 5 years, while contamination in stranded cetaceans was only measured over one year (Figure 3). Demersal fish are suspected to have more persistent radiocesium contamination relative to pelagic fish (Nakamura and Sugisaki, 2015). The difference in contamination term between Pacific cod and cetaceans may be due to differences in inhabiting area, migration route, and physiology.

Figure 5. Map showing the sampling locations for Pacific cod  $(n = 22)$ . This figure was reprinted from Nakamura et al., (2018). Copyright (2018), with permission from Elsevier.

Figure 6. Relation between <sup>137</sup>Cs and body weight of Pacific cod purchased in the period between 2011/11 to 2011/12, 2012/11 to 2013/01, and 2014/01 to 2015/01. This figure was reprinted from Nakamura et al., (2018). Copyright (2018), with permission from Elsevier.

We investigated the relationship between radiocesium contamination in Pacific cod and their age (Figure 6) using the Pacific cod growth curve reported by Sakuma (2016). Considerable radiocesium contamination was found in several Pacific cod samples from the North Pacific Ocean around Hokkaido with body weights (BWs) of 1.3–2.0 kg. Two cods, which were estimated to have hatched between 2009 and 2010 (3 yrs) and 2007 and 2008 (5 yrs), respectively, had BWs of 4.3 and 4.5 kg. No Pacific cod hatched after the FDNPP accident (2011) was included in this study. In agreement with our data, Pacific cods caught near the FDNPP showed highest radiocesium contamination in the 2009 year-class (yc) and the 2009 yc, followed by the 2010 yc (Narimatsu et al., 2017); radiocesium was rarely detected in the 2011 yc. Their results are further evidence that contaminated Pacific cods caught in the North Pacific Ocean around Hokkaido may have migrated from the waters in the vicinity of the FDNPP. Our study suggests the communication between the Pacific cod stocks off Hokkaido and off Tohoku. As of 15 March, 2012, the allowable levels of radiocesium (sum of  $^{134}Cs$  and  $^{137}Cs$ ) in foods (excluding milk, etc.) set by the Japanese Government is 100 Bq/kg-wet.

# **2.4. Stable Carbon and Nitrogen Isotope Ratios in Fish and Cetaceans in the Seawater around Hokkaido**

Figure 7 shows the dual isotope plot of Pacific cods and Baird's beaked whales. In agreement with the putative three stocks (Chimura et al., 2019), the stable carbon ( $\delta^{13}$ C) and nitrogen  $(\delta^{15}N)$  isotope results discriminated our cod samples between the North Pacific Ocean (n = 22), the Japan Sea (n = 13) and the Okhotsk Sea (n = 8). Similarly, the  $\delta^{13}C$  and  $\delta^{15}$ N discrimination of Baird's beaked whale samples between the three areas have also been reported (Endo et al., 2010). The  $\delta^{13}$ C values in both the Pacific cod and Baird's beaked whale samples occurred in the following order: Pacific Ocean > Okhotsk Sea > Japan Sea. The same  $\delta^{13}$ C order was also observed in stranded harbor porpoises and common minke whales on the coasts of Hokkaido's three seas (unpublished data). The  $\delta^{13}C$  value rather than the  $\delta^{15}$ N value was found to be a stronger indicator of inhabiting area (Kelly, 2000). In the next section, we demonstrate further evidence for the three Pacific cod stocks based on the different patterns of environmental contaminants (section 3.3 and 4.3).

Figure 7. Stable isotope ratios of carbon and nitrogen in Pacific cods and Baird's beaked whales caught off Pacific Ocean (P), Okhotsk Sea (O) and Japan Sea (J). This figure was reprinted from Nakamura et al., (2018). Copyright (2018), with permission from Elsevier.

# **2.5. Conclusion**

The occurrence of a large earthquake in 2011 at the Tohoku district on the largest main island of Japan lead to the Fukushima nuclear plant accident. As a result, the North Pacific Ocean off Tohoku became contaminated with high quantities of  $137Cs$ .  $137Cs$  was detected in cetacean species stranded along the coast of Hokkaido (a northern island of Japan) in 2011, which revealed their previously unknown migration routes.  $137Cs$  was also detected in Pacific cods caught off Hokkaido, inferring their potential migration from the waters off Tohoku. The Pacific cod stocks off Tohoku and Hokkaido are generally believed to be completely independent; however, our results suggest that they are able to migrate and communicate.

# **3. PERFLUOROALKYL SUBSTANCES IN CETACEANS AND FISH FROM THE SEAS OF NORTHERN JAPAN**

# **3.1. Introduction**

Perfluoroalkyl substances (PFASs) that contain both hydrophobic and hydrophilic moieties have been used as surface tension depressants and emulsifiers in industrial applications since the 1950s. They are commonly released into the environment during the fluoropolymer manufacturing process (EFSA, 2008), and perfluoroalkyl sulfonic acids (PFSAs) and perfluoroalkyl carboxylic acids (PFCAs) in particular are widely recognized global environmental contaminants (Gebbink et al., 2016) (see Figure 8). The concentrations of perfluorooctane sulfonic acid (PFOS; C8S) and perfluorooctane carboxylic acid (PFOA; C8A) have slightly declined in marine mammals since the early 2000s following their production phase-out by a major producer. Instead, long-chain PFCAs with 9–14 carbon atoms (C9A–C14A) have been increasingly distributed in the North Pacific. Unlike hydrophobic chemicals, PFASs tend to concentrate primarily in the blood or liver of marine organisms rather than in their fatty tissues (Ahrens et al., 2009). *In vitro* studies have shown that PFASs associate strongly with serum albumin and liver fatty acid-binding proteins (Luebker et al., 2002). PFASs have been shown to accumulate in the livers of marine mammals (Hart et al., 2008a) and in human serum from East Asian and some European countries (Fujii et al., 2017; Glynn et al., 2012; Harada et al., 2011). The seawaters around Hokkaido are one of the most important areas for commercial fishing in Japan, and many cetaceans have also been stranded along its coast. Pacific cod in this area is one of the major dietary fish species consumed by both cetaceans and humans. However, the distribution of PFASs in northern Japan is relatively unknown.

This section first summarizes the profiles and levels of PFASs—including PFOS (C9S), PFOA (C8A), and long-chain PFCAs (C9A to C14A)—in small cetaceans stranded on the coast of Hokkaido (Fujii et al., 2018a and 2018b) and in other coastal regions around the world (Figure 9). Secondly, in order to evaluate the current and historical release, we investigated the contamination levels of PFCAs (C8A to C14A) in Pacific cods from the Pacific Ocean, the Okhotsk Sea, and the Japan Sea around Hokkaido (Fujii et al., 2015 and 2019).

Perfluoroalkyl substances (PFASs)

Figure 8. Structures of PFOS (C8S), PFOA (C8A) and long-chain PFCAs (C11A and C13A).

Figure 9. Map of the sampling locations of Dall's and harbor porpoises in Hokkaido (A) and cetaceans from the other regions (B to M), which are listed in Table1. This figure was reprinted from Fujii et al., 2018a, Copyright (2018), with permission from Elsevier, with slight modification.

## **3.2. PFASs in Cetaceans**

## *3.2.1. Stranded Cetacean Samples for PFASs Analysis*

Small cetaceans accidentally stranded in fixed fishing nets in Rausu on the Shiretoko Peninsula between 2012 and 2013 (location A in Figure 9) were collected by the SNH following the standard protocol (Matsuishi, 2011) (section 1). Liver, blood, and blubber samples of Dall's porpoises ( $n = 10$ ) and harbor porpoises ( $n = 6$ ) were analyzed for PFOS (C8S), PFOA (C8A), and long-chain PFCAs, including perfluorononanoic acid (PFNA, C9A), perfluorodecanoic acid (PFDA , C10A), perfluoroundecanoic acid (PFUnDA, C11A), perfluorododecanoic acid (PFDoDA, C12A), perfluorotridecanoic acid (PFTrDA, C13A), and perfluorotetradecanoic acid (PFTeDA, C14A). The analytical methods for PFCAs are described by our group provisory in Fujii et al. (2012). The original data is mainly published in Fujii et al. (2018a).

### *3.2.2. Tissue-Specific Accumulation and Species Differences*

## **PFOS (C8S) and PFOA (C8A)**

Among the three tissues analyzed in the Dall's porpoises, the mean concentrations of C8S and C8A were the highest in liver (17 and 7.1 ng/g-wet, respectively), followed by blood, and the lowest in blubber. Harbor porpoises also showed the highest concentrations in liver (6.5 ng/g-wet) and the lowest concentrations in blubber (Fujii et al., 2018a).

#### **Long-Chain PFCAs (C9A-C14A)**

The mean concentrations of long-chain PFCAs in the Dall's porpoises were the highest in liver (573 ng/g-wet), followed by blood, and the lowest in blubber (Figure 10). The liver to blood (liver/blood) total PFCAs tissue distribution ratios were  $> 12$ , indicating that PFCA accumulation is liver-specific. Although PFOA and PFOS are bind to serum albumin (Jones et al., 2003), long-chain PFCAs are bind to the liver fatty acid-binding proteins (Luebker et al., 2002; Ng and Hungerbühler, 2013).

Figure 10. Concentrations of total long-chain PFCAs (C9-C14) in blood, liver and blubber of Dall's and harbor porpoises stranded along the coast of Rause, Hokkaido (Fujii et al., 2018a).

Figure 11. Concentrations of individual Perfluoroalkyl substances in liver of Dall's and harbor porpoises from Hokkaido (Fujii et al., 2018a).

The concentrations of long-chain PFCAs in the livers of harbor porpoises were significantly lower ( $p \le 0.05$ ) than in those of Dall's porpoise (Figure 10), despite their similar accumulation patterns. The difference in long-chain PFCA contamination between species is likely due to their different feeding habits as well as the higher biomagnification potency of PFCAs in Dall's porpoises relative to harbor porpoises (Ohizumi et al., 2003).

#### *3.2.3. Congener-Specific Accumulation*

Figure 11 shows the profiles of PFOS (C8S), PFOA (C8A), and long-chain PFCAs (C9A to C14A) in the livers of both porpoise species. PFUnDA (C11A) showed the highest concentrations in both species (305 ng/g-wet for Dall's porpoise and 98 ng/g-wet for harbor porpoise), followed by C13A (126 ng/g-wet for Dall's porpoise and 23 ng/g-wet for harbor porpoise). Combined, C11A and C13A contributed 70% of the total PFCAs, whereas the contributions of neighboring even-numbered PFCAs (C10A, C12A, and C14A) were less than 20%. The dominance of odd-numbered PFCAs has been commonly observed in all mammal species in East Asia-Pacific and Alaskan waters (Hart et al., 2008a; Rotander et al., 2012). The high proportion of odd-numbered PFCAs (C11A and C13A) is likely due to increased production during the synthesizing process or their slower elimination from marine biota (Verreault et al., 2005).

#### *3.2.4. Geographical Distribution*

Table 1 shows the levels of PFOS, PFOA and long-chain PFCAs in the five species of cetaceans (Dall's porpoise, harbor porpoise, killer whale, Pacific white-sided dolphin, and Baird's beaked whale) stranded on the coast of Hokkaido; this data is also compared with the data of other species in different regions (Location A to M in Figure 9).

### **PFOS (C8S)**

In non-Pacific regions, PFOS concentrations were the highest in harbor porpoises from the Danish North Sea (325 ng/g-wet, Location H, Figure 9) (Galatius et al., 2013), followed by the Black Sea (Location I) [\(Van De Vijver et al., 2007\)](#page-1472-0) (Table 1). In southern Asia, PFOS concentrations of 251 ng/g-wet were measured in Indo-Pacific humpback dolphins (*Sousa chinensis*) from Hong Kong (Location D) [\(Yeung et al., 2009\)](#page-1472-1).

In cetaceans around Hokkaido (Figure 12), the PFOS concentrations ranged from 0.6 to 24 ng/g-wet. Similar PFOS contamination levels were observed in stranded melon-headed whales (*Peponocephala electra*) from the coast of Chiba on the Boso Peninsula, Japan (Location B) [\(Hart et al., 2008a\)](#page-1472-2); in Beluga (*Delphinapterus leucas*) from Alaskan waters (Locations E, F) [\(Reiner et al., 2011\)](#page-1472-3); and in common minke whales and common dolphins from Korean waters (Location C) [\(Moon et al., 2010\)](#page-1472-4). The lower PFOS contamination in cetaceans around Hokkaido may reflect the reduced or alternative use of PFOS in northern Japan.

**Table 1. Mean concentrations of PFOS and PFCAs in livers of cetaceans from different location of world**

 $(A)$  to  $(M)$  location in Figure 9. nd = not detected, na = not analyzed

1) Fujii et al., 2018a; 2) Fujii et al., 2018b; 3) Hart et al., 2008a; 4) Moon et al., 2010; 5) Yeung et al., 2009; 6) Reiner et al., 2011; 7) Gebbink et al., 2016; 8) Galatius et al., 2013; 9) Van De Vijver et al., 2007; 10) Rotander et al., 2012; 11) Quinete et al., 2009

Figure 12. Geographical distribution of PFOS and PFUnDA in cetaceans around Japan. Data from harbor porpoises (Fujii et al 2018a), melon headed whales (Hart et al., 2008a), and long-beaked common dolphins in the east coast of Korea (Moon et al., 2010) are included. POP levels around Hokkido are illustrated in this figure (Fujii et al., 2018b).

## **PFOA (C8A)**

PFOA (C8A) is one of the most abundant PFCAs detected in seawater samples (Yamashita et al., 2008). Interestingly, PFOA was undetectable in 11% of all cetaceans around Hokkaido, indicating its low bioaccumulation potential (Conder et al., 2008).

## **Long-Chain PFCAs (C9A to C14A)**

Of the long-chain PFCAs (C9A-C14A), PFUnDA (C11A) is one of the most dominant congeners measured in all investigated cetaceans globally (Fujii et al., 2018a). We compared their levels between northern Japan and other regions around the world (Table 1). Among the five cetaceans stranded along the coast of Hokkaido, the concentrations of long-chain PFCAs were highest in killer whales (1509 ng/g-wet), followed by harbor porpoises (729 ng/g-wet) from the Japan Sea. Their levels in the same species were three to four times lower in the Pacific Ocean. In previous surveys, lower levels of PFCAs were observed in melon-headed whales (123 ng/g-wet) from Japanese coastal waters (Hart et al., 2008a) and in long-beaked common dolphin (52 ng/g-wet) from Korean waters (Figure 12) (Moon et al., 2010). In non-Pacific regions, PFCA levels were lowest in harbor porpoises (12 ng/g-wet) from the Danish North Sea (Galatius et al., 2013) (Location H in Figure 9). Based on the findings of these reports and our own results, cetaceans from the Japan Sea appear to be the most contaminated with long-chain PFCAs (especially C11A) relative to cetaceans from other sea regions around the world. In contrast, cetaceans around Hokkaido are less contaminated with PFOS and PFOA compared with Southeast Asian and North Atlantic cetaceans. The different contamination status of PFASs in cetaceans may be attributed to different emission sources of PFOS/PFOA, which are likely derived from fluoropolymer industries (Niisoe et al., 2015).

The concentrations of long-chain PFCAs (C11A) were higher in cetaceans from the Japan Sea compared with those from the North Pacific Ocean (Figure 12, Table 1) ; this suggests that effluents from East Asia to the Japan Sea (a closed ecosystem area) result to high contamination of long-chain PFCAs.

## **3.3. PFCAs in Pacific Cods**

#### *3.3.1. Profiles and Levels of PFCAs in Hokkaido*

Pacific cod are widely distributed around the coast of the North Pacific Ocean from California's Santa Monica Bay to Japan and Korea. They commonly inhabit the coastal to continental shelf region (Mishima, 1984). Pacific cods are suitable for monitoring the localized contamination status of seawater due to their limited migration range (Westrheim, 1984).

Pacific cods inhabiting the coastal areas of Hokkaido were divided into three stocks (section 2) to evaluate the geographical trend of PFCAs. The profiles and concentrations of PFCAs were investigated in the muscles of Pacific cods collected from the Japan Sea  $(n = 5)$ , the Okhotsk Sea  $(n = 5)$ , and the North Pacific Ocean  $(n = 12)$  during October 2012 and January 2013 (Fujii et al., 2015) (Figure 13). The mean concentrations of PFCAs (sum of C8A to C14A) in Pacific cods from the Japan Sea and the North Pacific Ocean were 2144 and 2066 pg/g-wet, respectively, which were both approximately two times higher than the measured concentrations from the Okhotsk Sea (Fujii et al., 2015). Lower PFCAs contamination in Pacific cods from the Okhotsk Sea may be attributed to the lower human use of PFCAs in the surrounding sparsely populated areas

Figure 13. Concentrations of individual PFCAs in muscle of Pacific cod from the North Pacific Ocean  $(n = 12)$ , the Japan Sea  $(n = 5)$  and the Okhotsk Sea  $(n = 5)$  around Hokkaido (Fujii et al., 2015).

The long-chain PFCAs profiles in the muscles of Pacific cods were dominated by C11A and C13A, contributing 43% and 27% of the total PFCAs, respectively. Similar compositional profiles in Pacific cods have also been observed in skipjack tuna (*Katsuwonus pelamis*) from the offshore waters of Japan between 1997 and 1999 (Hart et al., 2008b). The profiles in cods were similar to those in cetaceans, suggesting that prey fishes, such as skipjack tuna and Pacific cod, are dietary sources of long-chain PFCAs detected in small cetaceans around Hokkaido.

#### *3.3.2. Geographical Distribution*

To compare the PFCA contamination status between the seawater around Hokkaido and other coastal areas, we investigated the profiles and levels of PFCAs (C8A–C14A) in the muscles of Pacific cods collected from 14 coastal sites in the North Pacific Ocean (Figure 14) (Fujii et al., 2019). The mean concentrations of PFCAs in muscles of Pacic cods ranged from 216 to 770 pg/g-wet in the north and east Pacific Ocean (Seattle, Vancouver, Alaska and Russia), from 819 to 1710 pg/g-wet in Japanese coastal waters (three sites of Hokkaido, Aomori, Iwate, Miyagi, and Tottori/Shimane), and from 288 to 892 pg/g-wet in Korean waters (Sokcho, Busan and Yeosu) (Fujii et al. 2019). The long-chain PFCAs (C11A and C13A) contributed 96% of the total PFCA concentration across Japan and only 33% in the USA and Canada. The concentrations of C11A and C13A in cod samples were approximately three to four times higher in Japanese and Korean Pacific cods realtive to those from the USA, Canada, and Russia. Edible clams from five sites in Japan and one site in Canada also showed similar geographical trends in PFCAs (C6A–C15A) contamination, with highest mean concentrations in Japan (mean 1170 pg/g-wet) relative to Canada (48 pg/g-wet) (Fujii et al. 2020). Higher concentrations of PFCAs in fish or shellfish in Japanese coastal waters may be due to the higher industrial discharge near their habitats.

Figure 14. Geographical distribution of PFCAs in Pacific cods from the coast of different North Pacific areas. This figure was reprinted from Fujii et al., 2019, Copyright (2019), with permission from Elsevier.

#### *3.3.3. PFCAs in the Food Chain*

Figure 15 shows the percentage composition of PFCAs in tissues of cetacean, fish, human blood, and diet around Hokkaido. Among the three tissues (blubber, liver, and blood) in Dall's porpoises, the sum of C13A and C14A contributed 60% of the total PFCAs in blubber, whereas C11A was the major congener in liver and blood. This suggests that longer carbon-chained PFCAs are more lipophilic and tend to accumulate in fatty tissues. The PFCAs profiles in Pacific cod and cetaceans were similar, indicating that fishes such as cods are the main dietary source of long-chain PFCAs in cetaceans. In contrast, lower-chain PFOS (C8S) and PFOA (C8A) contributed 30% of the total PFCAs in human diet in Hokkaido and 60% in human serum. In our recent report, edible clams in Japanese coastal waters contained abundant PFOA (C8A), contributing 65% of the total PFCAs (Fujii et al., 2020); this was similar to the PFCA concentration ratios reported in the Yodo River basin in Osaka prefecture, Japan (Niisoe et al., 2015). These findings suggest that PFOS and PFOA may come from different emission sources from long chain PFCAs or they may have different bioaccumulation mechanisms (Fujii et al., 2020).

Figure 15. Percentage composition of Perfluoroalkyl substances in tissues from Dall's porpoise (This study; Fujii et al., 2018a), <sup>a)</sup> Pacific cod muscle (Fujii et al., 2015), <sup>b</sup>) the human diet (Karmanet et al., 2009; Fujii et al., 2017), and  $\circ$  human serum (Kato et al., 2016; Fujii et al., 2017).<sup>a)</sup> PFOS is not measured (Fujii et al., 2015). This figure was reprinted from Fujii et al., 2018a, Copyright (2018), with permission from Elsevier, with slight modification.

# **3.4. Conclusion**

We identified lower PFOS and PFOA concentrations  $\langle 24 \text{ ng/g-wet} \rangle$  in cetaceans from Japanese coastal waters, accounting for only 5% of the total PFASs. In contrast, long-chain PFCAs (C9A to C14A) showed higher concentration with a dominance of PFUnDA (C11A), followed by PFTrDA (C13A). Further investigation into their dominant sources and exposure routes are necessary for predicting the future change of PFAS contamination.

# **4. ANTHROPOGENIC ORGANOHALOGENS IN CETACEANS AND FISH FROM NORTHERN JAPAN**

## **4.1. Introduction**

Persistent organic pollutants (POPs), such as polychlorinated biphenyls (PCBs), and organochlorine pesticides (OCPs), such as DDTs, have been used in industrial and agricultural applications for more than 50 years. Polybrominated diphenyl ethers (PBDEs) have also been used as flame retardants in plastics, textiles, and electronic appliances. POPs accumulate in marine mammals or humans through their dietary seafood intake (Kajiwara et al., 2002; Nomiyama et al., 2011). This section describes the recent contamination status of selected OCs (such as PCB153, a representative PCB isomer and BDE47, frequently detected PBDE isomer, see Figure 16) in cetaceans stranded on the coast of Hokkaido as well as in Pacific cods from the surrounding three seas. We also compared our findings with POPs contamination in other regions around the world (Fujii et al., 2018a and 2018b).

Figure 16. Structures of PCB153 and BDE47.

## **4.2. POPs Contamination in Cetaceans**

POPs in the tissues of cetaceans stranded on the coast of Hokkaido during the period 2010–2014 were analyzed to determine the contamination status of legacy POPs (Fujii et al., 2018b). Table 2 shows the concentrations of POPs in therteen cetacean species from the North Pacific Ocean, six cetaceans species from the Japan Sea and two cetacean species from the Okhotsk Sea around Hokkaido; the POPs include a representative PCB congener (PCB153), a major congener of chlordanes (trans-nonaclor (trans-NC)), β-hexachlorocyclohexane (β-HCH), and a representative PBDE congener (BDE47). All analytes showed higher accumulation in cetaceans from the Japan Sea coast compared with those from the Pacific Ocean or the Okhotsk Sea. All POPs also showed highest accumulated concentrations in killer whales, followed by Pacific white-sided dolphins. Lowest concentrations of all POPs were observed in common minke whales. POPs concentrations were in the order of PCB153 > trans-NC >  $\beta$ -HCH > BDE47. As with the toothed whales, high concentrations of PCB153 and BDE-47 were observed in the livers of killer whales and Pacific white-sided dolphins.

Despite the low sample size in this study, POPs contamination was higher in toothed whales relative to baleen whales due to differences in their dietary habits. The concentrations of PCBs and PBDEs were also higher in cetaceans from the Japan Sea compared with those from the North Pacific Ocean (Table 2). This indicates an ongoing source of PCBs and DDTs

in cetaceans of the Japan Sea (closed system). Previous studies have shown that killer whales stranded in Hokkaido were highly contaminated with PCB153 at 17 µg/g-lipid (Haraguchi et al., 2009a)—the highest level among the toothed whales. PCBs levels in Dall's porpoises were also found to be higher than those of other cetacean species (Kajiwara et al., 2002). The PBDEs levels in the blubber of melon-headed whales stranded on Japanese coastlines between 1982 and 2006 (Kajiwara et al., 2008) and in killer whales stranded in Hokkaido in 2005 (Kajiwara et al., 2006; Haraguchi et al., 2009a) ranged from 0.2 to 0.5  $\mu$ g/g-lipid; this is similar to the PBDEs values observed in ceaceans around Hokkaido in the present survey from 2010 to 2014. Combined, these findings indicate no change in the contamination levels of PCBs and PBDEs in cetaceans throughout the last decade; therefore, POPs are continuing to be discharged from the coastal countries of the Asia-Pacific region.

# **4.3. POPs Contamination in Pacific Cod**

Pacific cod can be used as a suitable bioindicator for the global monitoring of environmental pollutants in Pacific Ocean ecosystems. In this study, Pacific cods  $(n = 22)$ collected from the three seawaters around Hokkaido were analyzed for legacy OCPs and PCBs (Fujii et al., 2015). Figure 17 shows the concentrations of dichlorodiphenyl dichloroethene (4,4'-DDE; a major metabolite of DDT), hexachlorobenzene (HCB), a representative PCB congener (PCB153), trans-nonaclor (trans-NC), and β-hexachlorocyclohexane (β-HCH) in the muscles of Pacific cods from the North Pacific Ocean, Japan Sea, and Okhotsk Sea around Hokkaido. The concentrations of 4,4'-DDE and HCB were an order of magnitude higher than those of PCB153, trans-NC, and β-HCH. The concentrations of 4,4'-DDE and PCB153 were slightly higher in Pacific cods from the Japan Sea (500 and 100 pg/g-wet, respectively) compared with those from the other two seas. This observation is consistent with the findings of other reports from Asian waters. For example, measurements of OCPs in skipjack tuna from the Japan Sea showed higher concentrations of DDTs and HCHs (Ueno et al., 2003b). Another report also showed higher levels of OCP in Japanese common squid (*Todarodes pacificus*) in the Japan Sea relative to those in the North Pacific Ocean (Ueno et al., 2003a). These findings infer the continuous discharge of PCBs and DDTs (as 4,4'-DDE) into the Japan Sea from the surrounding coastal countries.

Figure 17. Concentration of selected OCs in muscle of Pacific cod collected from the North Pacific Ocean, the Japan Sea and the Okhotsk Sea around Hokkaido (Fujii et al., 2015).

## **4.4. Conclusion**

The contamination levels of legacy POPs, such as PCBs, DDTs, and PBDEs, in toothed whales around Hokkaido were comparable to those in whale products from Japanese coastal waters. However, pesticide (e.g., trans-NC) levels were higher in toothed whales around Hokkaido relative to cetacean species from other areas. Due to their lower trophic level in the marine food web, OCPs and PCBs concentrations in fish were an order of magnitude lower than those in cetaceans, such as harbor porpoise, around Hokkaid. Our findings demonstrate that the contamination status of legacy POPs in the seawater around Hokkaido is still impacting the environmental health of both marine animals and humans.

# **5. CONTAMINATION OF NATURALLY PRODUCED ORGANOHALOGENS IN NORTHERN JAPAN**

# **5.1. Introduction**

In recent years, screening for POPs in the marine environment has resulted in the identification of naturally produced organohalogen contaminants (Vetter and Stoll, 2002; Teuten et al., 2005). Some NHCs are halogenated secondary metabolites produced by marine biota, such as marine sponges, algae, and symbiotic bacteria (Gribble, 2004; Cavalleri et al., 1978). At present, the major NHCs detected in whales and dolphins in Japanese coastal waters include two halogenated bipyrroles  $(3,3,3,4,4)$ -tetrabromo-5,5'-dichloro-1,1'-dimethyl-2,2'-bipyrrole ( $Br_4Cl_2$ -DBP), heptachloro-1-methyl-1',2-bipyrrole ( $Cl_7$ -MBP)) and two methoxylated tetrabrominated diphenyl ethers (6-methoxy-2,2',4,4'-tetraBDE (6-MeO-BDE47) and 2'-methoxdy-2,3',4,5'-tetraBDE (2'-MeO-BDE68)) (Figure 18). These products are known to accumulate in marine mammals and humans, and their concentrations were found to be similar to those of legacy POPs, such as PCBs and PBDEs (Haraguchi et al., 2006; Marsh et al., 2005). This section describes the profile, levels, regional variation, and sources of NHCs consisting of bipyrroles and MeO-BDEs in cetaceans stranded on the coast of Hokkaido during 2010–2014. Additionally, the contamination status of these products were compared with those of anthropogenic PFASs and legacy POPs in cetaceans from the Japan Sea and the North Pacific Ocean.

Figure 18. Structures of NHCs investigated (two bipyrroles and MeO-BDEs).

# **5.2. Profiles and Levels of NHCs in Hokkaido**

Of the cetaceans stranded on the coast of Hokkaido during 2010–2014, two baleen whales and twelve toothed whales were analyzed for NHCs. The analyzed species included odontocetes (Dall's porpoises, harbor porpoises, killer whales, and Pacific white-sided dolphins) and mysticetes (common minke whales) from the Japan Sea  $(n = 7)$  and the North Pacific Ocean ( $n = 14$ ). Liver samples of five cetaceans were analyzed for bipyrroles ( $Br_4Cl_2$ -DBP, Cl7-MBP) and MeO-BDEs (6-MeO-BDE47 and 2'-MeO-BDE68) (Fujii et al., 2018a and 2018b). Table 3 shows the mean concentrations of the major congeners in the livers of cetaceans from both the Japan Sea and North Pacific Ocean around Hokkaido.

#### *Br4Cl2-DBP*

The major congener of the three detected DBPs was  $Br_4Cl_2-DBP$  (Figure 18), which contributed 80–92% of the total DBPs. The Br<sub>4</sub>Cl<sub>2</sub>-DBP contamination levels of the five cetaceans around Hokkaido and of species from other regions are shown in Table 3.  $Br_4Cl_2$ - DBP concentrations ranged from 0.64  $\mu$ g/g-lipid in common minke whales from the Japan Sea to 70 ug/g-lipid in killer whales from the North Pacific.

The Br<sub>4</sub>Cl<sub>2</sub>-DBP values in cetaceans around Hokkaido were higher than those from any other region and similar to those of Dall's porpoises (2.54  $\mu$ g/g-lipid) from the Asia-Pacific region (Tittlemier et al., 2002). In ondontocetes of Japanese coastal waters,  $Br_4Cl_2-DBP$ levels were the highest in the blubber of killer whales  $(6.4–26 \mu g/g-lipid)$  from Hokkaido (Haraguchi et al., 2009a), followed by the blubber of bottlenose dolphins ( $12 \mu g/g$ -lipid) from southern Japanese coastal waters (Haraguchi et al., 2006).

Br<sub>4</sub>Cl<sub>2</sub>-DBP is widespread in a variety of commercially available fish and seafood in Canada (Tittlemier, 2004) and Japan (Haraguchi et al., 2009a; Haraguchi et al., 2009b). High accumulation of  $Br_4Cl_2$ -DBP in toothed whales from Hokkaido is likely due to the consumption of DBP-contaminated prey and/or the lowered ability of this species to metabolize  $Br_4Cl_2$ -DBP.

The source of  $Br_4Cl_2-DBP$  is still unclear; however, bipyrroles may be produced by a marine bacterium (e.g., *Pseudoalteromonas*) that is known to produce a structurally similar compound called hexabromo-bipyrrole (Andersen et al., 1974). Due to its detection in a variety of fish and seafood [\(Tittlemier, 2004\)](#page-1472-5), it is likely that  $Br_4Cl_2-DBP$  biomagnifies in cetaceans through the food chain. High exposures to Br4Cl2-DBP may enhance the toxicological risks of hepatic cytochrom P450 (CYP1A) induction in marine mammals (Tittlemier et al., 2003).

#### *Cl7-MBP*

Cl7-MBP—another type of halogenated bipyrrole—was detected in toothed whales from the North Pacific Ocean and Japan Sea at ranges of 36–1031 and 170–4000 ng/g-wet, respectively (Table 3). The highest concentration was found in killer whales and Pacific white-sided dolphins from the Japan Sea. The concentrations were comparable to those in the blubber of killer whales stranded in the same region in 2005 (Haraguchi et al., 2009a); this suggests a widespread contamination of Cl<sub>7</sub>-MBP that has remained unchanged over the past decades.

Currently, only a few studies exist on the global distribution of Cl7-MBP; however, Cl7- MBP levels in the blubber of bottlenose dolphins from Australia (Vetter et al., 2001) and in marine mammals from Africa and the Antarctic (Vetter, 2006) were found to range from 0.45 to 9.1  $\mu$ g/g-lipid. Cl<sub>7</sub>-MBP levels in cetaceans around Hokkaido were much higher than those in cetaceans from other regions around the world. Marine bacteria are assumed to be the dominant biogenic sources of Cl7-MBP, as a structurally similar chlorinated phenyl pyrrole was isolated from *Actinoplanes* sp. (Cavalleri et al., 1978) from around Hokkaido. Since killer whales feed on other mammals that accumulate these contaminants via the food chain, cetaceans or fish prey are likely to be the dominant source of  $Cl_7$ -MBP in killer whales around Hokkaido.

#### *MeO-BDEs*

The majority of NHC studies in marine biota have focused on two MeO-BDE congeners—6-MeO-BDE47 and 2'-MeO-BDE68—due to their environmental persistence and structural similarity to BDE47 (Figure 18). We measured the concentrations of the two congeners in the livers of five cetacean species from the Japan Sea and North Pacific Ocean around Hokkaido. The concentration of 6-MeO-BDE47 was 2–10-fold higher than that of 2'-

MeO-BDE68 in all cetaceans, except for the common minke whale and Indo-Pacific beaked whale. The concentration of  $6$ -MeO-BDE47 ranged from 89 ng/g-lipid in common minke whales to 2690 ng/g-lipid (Table 3) in killer whales in the Pacific Ocean. The levels of 6- MeO-BDE was higher in toothed whales than in baleen whales and higher in cetaceans from the Japan Sea than those from the Pacific Ocean. Differences in the accumulation of 6-MeO-BDE in different cetacean species may be due to differences in their feeding ecology, migration, and lifestyle.

MeO-BDE levels in cetaceans from Hokkaido were higher than those in harbor porpoises from the Danish North Sea (Weijs et al., 2010). However, more recent surveys have shown that the levels of MeO-BDEs in the livers of bottlenose dolphins in the southwest Atlantic off Brazil are an order of magnitude higher than those from Japan (Alonso et al., 2014, Dorneles et al., 2010; Table 3). Symbiotic cyanobacteria (Malmvärn et al., 2008), marine sponges (Unson et al., 1994; Haraguchi et al., 2011), and marine algae—such as *Sargassum* sp. (Haraguchi et al., 2010) and *Ceramium tenuicorne* (Malmvärn et al., 2008)—are all possible sources of MeO-BDEs. Although the biological effects of MeO-BDEs are still unknown, their O-demethylated products have been reported as endocrine disruptors (Meerts et al., 2001).

# **5.3. Comparisons between Natural and Anthropogenic Compounds**

## *PFCAs and NHCs*

The percentage compositions of selected congeners in the five species are shown in Figure 19. The relative contribution of  $Br_4Cl_2-DBP$  was higher in killer whales and common minke whales from the North Pacific Ocean and the Japan Sea, whereas the contribution of PFUnDA was higher in common minke whales from both seas (section 3). These findings indicate that the contamination of NHCs (Br<sub>4</sub>Cl<sub>2</sub>-DBP, Cl<sub>7</sub>-MBP) and PFCAs (PFUnDA) are regionally different and species-specific. We observed no regional differences in the distribution ratios of the two MeO-BDEs, inferring a wide distribution of MeO-BDEs in both seas.

## *PCBs and NHCs*

We investigated the regional differences in NHC and PCBs contamination in the five cetaceans between the North Pacific Ocean and Japan Sea (Figure 20).  $Br_4Cl_2$ -DBP was distributed at relatively higher concentrations in cetaceans from the North Pacific, whereas Cl7-MBP and PCBs were abundant in cetaceans from the Japan Sea. No regional differences were observed in the levels of MeO-BDE. Our findings suggest that the North Pacific Ocean (open sea) is a high souce of  $Br_4Cl_2-MBP$  in cetaceans, whereas the Japan Sea is a high source of Cl<sub>7</sub>-MBP and PCBs. PCBs were highly corerlated with Cl<sub>7</sub>-MBPs ( $r = 0.892$ ,  $p <$ 0.01) (Fujii et al., 2018b), emphasizing their similar bioaccumulation mechanisms despite their different emission sources (industrial and biogenic).

Figure 19. Composition of  $Br_4Cl_2$ -DBP,  $Cl_7$ -MBP, MeO-BDE47 and PFUnDA in the liver of five cetaceans from the Pacific Ocean, the Japan Sea and the Okhotsk Sea around Hokkaido. This figure was reprinted from Fujii et al., 2018b, Copyright (2018), with permission from Elsevier.

Figure 20. Regional difference in concentrations of NHCs (Br<sub>4</sub>Cl<sub>2</sub>-DBP, Cl<sub>7</sub>-MBP and 6-MeO-BDE47) and PCB153 in liver of five cetaeans (K = killer whale,  $D =$  Dall's porpoise, P = Pacific white-sided dolphin,  $H =$  harbor porpoise,  $C =$  common minke whale between the North Pacific (NP) and the Japan Sea (JS) stranded in Hokkaido.

# **5.4. Conclusion**

Cetaceans around Hokkaido were found to be contaminated with comparable levels of NHCs and long-chain PFCAs based on several cetacean surveys. The contamination of legacy POPs (PCB153 or BDE47) in cetaceans occurred in the order of killer whale > Pacific whitesided dolphin > common minke whale. We observed different NHCs distribution ratios in the livers of cetaceans between the Japan Sea and the North Pacific Ocean. The source of  $Br_4C_{12}$ -DBP is likely localized in the North Pacific Ocean, whereas the sources of  $Cl<sub>7</sub>-MBP$  are abundant in the Japan Sea. 6-MeO-BDE47 and 2'-MeOBDE68 in cetaceans showed no regional differences and were widely distributed at higher concentrations than PBDEs.

The relative contribution of NHCs to anthropogenic chemicals can serve as markers of localized inputs, prey preferences, or global variation of anthropogenic pollutants in cetaceans and fish around Hokkaido and across the world. In further studies, it is necessary to determine the correlation between high accumulation of contaminants (NHC. PFCA and POPs) and various abnormalities in aquatic mammals and fish.

# **ABSTRACT**

Growing interest in aquatic resources and marine coastal ecosystems is concomitant with depletion of their resources. Human activities in shelf area may contribute to marine environmental degradation due to the domestic, industrial, agricultural and maritime transport effluents that are produced as a consequence of an increasing population and growth of economic development. Regarding the vulnerability of several species in relation to their life history traits of slow growth, maturation at relatively old age and longevity have prompted stock assessment studies and estimates on the effects of environmental and anthropogenic factors impacting fish populations. Marine environment acts as a sink for different kinds of contaminants including heavy metals, organic substances, [nanoparticles,](https://scholar.google.com/scholar?hl=en&as_sdt=0,5&q=nanoparticles) plastics, [pharmaceuticals,](https://scholar.google.com/scholar?hl=en&as_sdt=0,5&q=pharmaceuticals) and etc. Together with the climate change, overfishing and anthropogenic pollution of the marine environment result negative consequences to biota, especially fish. Therefore, assessment of the health status of marine fish species forms an important approach that can be applied internationally. Such approaches use combination assessment of externally visible damage of tissues and organs and internal evaluation of pathology, in particular of the biomarkers of oxidative stress. In polluted areas, exposure of fish to xenobiotics leads to interactions between these chemicals and biological systems, which give rise to biochemical disturbances. Oxidative stress is induced by the reactive oxygen species (ROS), associated with the different kinds of pollutants and unfavorable living conditions. Thus, toxic substances,

that enter the fish tissues and organs, directly affect the vigour of the organism. Therefore histological and biochemical biomarkers can serve as a potent indicators of stressful conditions and fish health. Histological and biochemical changes associated with pollutants in marine environment are efficient indicators of water quality and fish health exposed to both natural and anthropogenic stressors. The aim of the present work was to assess health of Black Sea fish species, belonging to different ecological groups. The hystopathological and biochemical biomarkers of the blood, spleen and liver of scorpion fish *Scorpaena porcus* L. and peacock wrasse *Crenilabrus tinca*, caught in the coastal waters of Black Sea, Sevastopol, (Crimea) were studied. The significant differences of the number of melanomacrophage centers (MMCs) in the liver and in the spleen of both fish species were shown. Antioxidant enzyme activities superoxide dismutase (SOD), catalase (CAT), peroxidase (PER) and glutathione reductase (GR) were higher in red blood cells of the *S. porcus* as comparted with *C. tinca*, while glutathione content demonstrated the opposite trend. Antioxidant enzyme activities in fish muscle and liver was not uniform. In muscle of *C. tinca* antioxidants level was greater than in *S. porcus*, in the liver the similar results were shown also with the exception of SOD activity. Our findings demonstrated the interspecies differences of histopathology of liver and spleen and antioxidants content in blood, muscle and liver in both tested Black Sea teleosts, that were associated with different level of their adaptations to the environment and mechanisms of action of pollutants on their physiological functions.

**Keywords:** histopathology, antioxidant enzymes, Black sea, fish ecological groups, blood, liver, spleen, melanomacrophage centers, oxidative stress, biomarkers

#### **INTRODUCTION**

In recent years, water ecosystems is facing a harsh loss of biodiversity that includes climate alterations, nutrient swings, acidification, habitat loss, exploitation, biological invasions and anthropogenic pollution. Marine coastal waters are recognized as highly productive systems with great natural biodiversity. They are important spawning and nursery grounds for many invertebrates and fish species. Aquaculture farms account for substantial contribution to world economy with annual production of 80 million tonnes, which provides livelihood to millions of people (Kolkovski and Kolkovski, 2011). To the other hand, coastal waters are also impacted by multiple anthropogenic stressors, derived from the intense human activities, namely domestic, agricultural and industrial effluent discharges, maritime transport, port activities, bank reclamation, dams and fishery (Fonseca et al., 2011a; Serafim et al., 2012; Franca et al., 2012).

Fishes are very important for commercial purposes, including fishery and aquaculture (Ababouch, 2006). Fish species play the key role in ecosystem because they belong to the vertebrates, which are at the top of the food chain. Fishes are very sensitive to anthropogenic pollution, and some of them may be tested as biomonitors and test-organisms for the evaluating of the effects of contaminant-related stress on marine environment and used widely in aquatic monitoring (Sole et al., 2009). Fish is a well known bioindicators, as presence of the toxicant in aquatic system is capable to alter fish biochemistry, physiology, morphology, behavior; thus serves an appropriate model for ecotoxicological studies, which is also important for human health (Jindal et al., 2019). Fishes are valuable organisms to asses toxicological effects caused both traditional toxicants namely heavy metals, oil, PCB,

detergents, pesticides, and etc. and emerging contaminants (ECs) represent relatively newly discovered groups, such as pharmaceuticals, personal care compounds, plastic and nanoparticules (Ale et al., 2018; Jindal et al., 2019; Vidya et al., 2019).

Many investigations have proved that fish are valuable organisms to asses toxicological effects caused by different toxicants, both traditional and emerging contaminants. Therefore, health parameters of fish, especially physiological and biochemical responses, are evaluated as indicators of habitat quality of coastal marine waters. The relation between environmental variability and fluctuations of fish health parameters and biomarkers of exposure to contaminants could provide important information on their abundance (Pasquaud et al., 2013; Fonseca et al., 2013a; Rudneva et al., 2012;). Indicators of negative effects allow the direct determination of pollutant impact on living organisms in aquatic systems.

Usually the investigators demonstrate the elevated levels of the man-made pollution and its negative effects on marine organisms in all levels of their biological organization. Environmental pollutants transfer to fish organism and accumulate in it, caused early biological effects firstly in cell and molecular levels. Accumulation of these alterations provokes damage of organ structure and function, tissues and systems disfunction, and during some time the pathologies and morphological anomalies are observed. Histopathological analysis of various organs and tissues is an important tool of environmental monitoring of water pollution, which allows assessing of structure changes, and lesions that caused by environmental toxicants and various negative factors (Chalghmi et al., 2016).

Liver is associated with the detoxification and biotransformation processes. It is the most important organ that detoxifies toxicants, including heavy metals and organics both endogenous and exogenous nature and due to its function, location and blood supply it is also most affected by contaminants in the water. Because liver has effective system of detoxification, the hepatic histological changes are the good tool of the evaluation of the negative impact on the organism (Feist et al., 2015; Vidya et al., 2019). The microscopic examination of the liver tissues of the fish inhabiting polluted areas showed mononuclear inflammatory cell infiltration, cloudy degenerations, congestions and also micro- and macrovesicular fatty degenerations. Analysis of histological changes in the fish liver is a highly perceptive and precise way to assess the effects of xenobiotics on aquatic organisms both in field and experimental studies.

The most common pathological changes in the liver of fish as the primary organ for xenobiotic accumulation and detoxication include alterations of the mural architecture (degenerative hepatocyte lesions: hepatocyte hypertrophy, pyknotic nuclei, nuclear pleomorphism and peripheral nucleoli, focal necrosis of hepatocytes that can be noticed by the presence of darkly stained eosinophilic debris as a result of cellular component disintegration). Extensive dilation of sinusoids with blood congestion, hypertrophy and hyperplasia of bill duct cells, fibrosis of blood vessels, increased numbers of Kupffer cells are also often occur in fish inhabiting polluted environments (Abdel-Warith et al., 2011). Among the other pathological alterations it needs to be noted a loss of lipid vacuoles in hepatocytes, pancreatic atrophy characterized by decreased number of acini and appears as remnants around hepatic blood vessels (Kaewamatawong et al., 2013). Subcapsular edema and fat accumulation in liver is a common problem in aquaculture that can be induced by parasites, inappropriate nutrition, pesticides and toxins (Pietsch, et al., 2014) as well as steatosis – fatty degeneration (Feist, et al., 2015). Histopatological lesions also include lymphocytic infiltration, hypertrophied hepatocyte nuclei with coarse chromatin, hepatocellular and

nuclear pleomorphism (Feist, et al., 2015; Al-Mamoori et al., 2015), presence of syncitia characterized by multiple nuclei and granular cytoplasm (Maharajan et al., 2016).

In fish, the spleen and head kidney are the most important immune organs that can trap and detoxify xenobiotics and maintain stable internal environment (Wang et al*.*, 2013). Therefore, spleen and head kidney play a role in haematopoiesis and since the majority of pollutants absorbed by fish are transported within the body by blood. They accumulate in these hematopoietic organs and can induce toxic effects on many physiological and biochemical processes (Kondera et al., 2014), which disturb homeostasis, and defense systems such as the antioxidant system and the immune system of fish (Santana et al., 2018). Therefore, histological alterations of spleen of fish are also good biomarkers of health status.

In polluted areas, exposure of fish to xenobiotics leads to accumulate these chemicals and interactions between them and biomolecules, cells and tissues, which result to biochemical and physiological disturbances. Many toxicants, distributed in the environment, accumulated in tissues and organs of the aquatic organisms cause oxidative stress, characterizing the increase of reactive oxygen species (ROS), accumulation of the oxidized biomolecules in cells and the induction of the components of antioxidant defense system (Livingstone, 2001; Van der Oost et al., 2003; Rudneva, 2012). Homeostasis of the living organisms is characterized a balance between production and elimination providing certain steady-state ROS level. This balance can be disturbed leading to enhanced ROS level and damage to cellular constituents which is attributes with "oxidative stress" (Lushchak, 2011). At this case the parameters of oxidative stress are most informative indicators for unfavorable living conditions (Van der Oost et al., 2003).

At the other hand, for the elimination of ROS products there is antioxidant system in the aquatic organisms, which comprises both—low molecular mass scavengers namely vitamins A, E, C, carotenoids, glutathione, and high molecular weight antioxidants, which involve special adopted antioxidant enzymes (Livingstone, 2001). Among the biochemical biomarkers antioxidant activities in the tissues of aquatic organisms are good tool for the evaluation of the homeostasis (Adams, 2005, Rudneva et al., 2012), because they destroy ROS molecules. The main antioxidant enzymes are catalase (CAT), which exclusively degrades H<sub>2</sub>O<sub>2</sub>, superoxide dismutase (SOD), which destroys superoxide anion, glutathionedependent enzymes namely glutathione peroxidase (GPX), glutathione reductase (GR) and glutathione-S-transferase (GST) and some others. Previously we described high diversity of antioxidants in various fish species and the dependence of their activity on fish species, their belonging to different ecological groups, season fluctuations, abiotic (temperature, oxygen concentration, depth, light) and biotic factors (feeding behavior, life cycle, reproduction, development stage, and etc.) (Rudneva, 2012; Rudneva et al., 2014; 2016a,b; 2018).

The investigators demonstrated the correlations between the antioxidant biomarkers and histopathological changes (Gul et al., 2004; Rudneva et al., 2016c) and the pollution impact. In our previous study we use the antioxidants and liver histopathology biomarkers, characterizing fish health in various Black Sea sites, characterizing different pollution levels (Rudneva et al., 2016c). The presence of different kinds of chemicals in estuaries and marine bays trends monitoring and risk-assessment procedures essential to ensure the preservation of their biological function and, especially, biodiversity and has led to the search for improved monitoring methods that can express the biological and ecological implications of pollution beyond environmental health (Fonseca et al., 2011a; 2011b; 2013; Vinagre et al., 2006; Sadauskas-Henrique et al., 2011).

Therefore, both biochemical parameters and histopathological observations can be assumed as sensitive indicators of fish tissues metabolism for polluted areas (Gul et al., 2004), the aim of the present study was to determine the hystopathological indicators in spleen and liver and antioxidant biomarkers in the red blood cells, muscle and liver of scorpion fish *Scorpaena porcus* L and peacock wrasse *Crenilabrus tinca* L caught in the coastal waters of the Black Sea in the region of Sevastopol (Crimea).

# **MATERIALS AND METHODS**

#### **Biological Characteristics of Tested Fish Species**

Scorpion fish *Scorpaena porcus* (n = 10) and peacock wrasse *Crenilabrus tinca* (n = 5) are highly distributed teleost species in Black Sea coastal waters.

Scorpion fish *S. porcus* (Figure 1) is among the most common fish species in Black Sea coastal waters. Previously we selected it as biomonitor species for the monitoring of the coastal waters of Black Sea (Rudneva, 2012; Rudneva et al., 2016b). It is demersal termophilic fish species inhabiting bottom waters on the depth of 1-40 m, however it prefers the depth of 1-10 m. Because it is settled species, the fish migrates on a short distances at the bottom, and it is active at night time. Spawning time covers the period of the end of May to the middle of September. Female produces the eggs in twin sacks, which are dissolved in marine water, and the embryos in the eggs are developed in pelagic zone. Scorpion fish is the species with many spawning portions, and the female produces eggs every 1-2 day. Every portion contains 1100- 27200 eggs. Scorpion fish is predator, its preferable prey is small fish. (Svetovidov, 1964).

Figure 1. Scorpion fish *Scorpaena porcus.*

#### 3150 *Irina I. Rudneva, Maria P. Rudyk, Victoria V. Shepelevich et al.*

Peacock wrasse *C. tinca* (Figure 2) is omnivorous bentopelagic fish species inhabiting the coastal waters of the sea. It is settled form, the spawning time is covered the period from May to June, female and male are differed each from other. The fecundity is estimated as 12—58 000 eggs. The preferable food is mollusks, polyhaets and crustacean. Its abundance is varied from 1 to 50 m. (Svetovidov, 1964).

Figure 2. Female and male of peacock wrasse *Crenilabrus. tinca.*

#### **Sample Preparation for Histochemical Studies**

Scorpion fish  $(n = 10)$  and peacock wrasse  $(n = 5)$  were caught in spring period in the coastal waters of Black Sea in the region of Sevastopol (Crimea). The animals were immediately placed in the aerated tank, transferred to the laboratory and anesthesy.

The liver and spleen were removed from fish of both species for histochemical studies. Liver samples were fixed in 10% neutral buffered formalin following by dehydration in a graded series of ethanol solutions of increasing concentrations. Fixed specimens were processed to paraffin embedded blocks by accepted, routine methods and sections were cut at 6 μm on a sledge microtome. Tissue sections were stained with Boehmer's haematoxylin and 1% eosin by standard method and mounted into Canadian balm. Samples were examined using light microscope and MICROmed digital camera. To count melanomacrophage centers (MMCs), 8–10 fields were randomly selected on each slide, captured using the camera, and readings were performed at 200X magnification. After each field of liver tissue samples had been photographed, the area of MMCs was measured  $(\mu m^2)$  (MICROmed digital camera software). Quantitative changes in the numbers and size of the liver MMC were determined by counting the mean number of MMCs per field and by measuring of the average absolute (μm<sup>2</sup> ) and relative (% of the field area) size of single MMC (the percentage of organ area occupied by MMC) and total MMCs per field (Kranz, 1989; Kurtovic, et al., 2008; Manrique et al., 2014).

#### **Sample Preparation for Biochemical Studies and Antioxidants Assay**

For biochemical determinations blood was taken by caudal arteria puncture and serum was separated. The red blood cells were processed as we described previously (Rudneva, 2012). The sediment was washed three times with 0.85% NaCl solution and then lysed by addition of 5 vol of distilled water for 24 h at the refrigerator. The enzyme activity was determined in the lysates immediately after preparation. Liver and muscle samples were washed several times by cold 0.85% solution of NaCl, homogenized and centrifuged at 8000 g during 15 min at cool conditions.

Antioxidant activities in the fish liver and muscle extracts were determined according the methods, which we described previously with small modifications. Catalase (CAT) was measured by the method involving the reaction of hydroperoxide reduction (Asatiani, 1969). Superoxide dismutase (SOD) was assayed on the basis of inhibition of the reduction of nitroblue tetrasolium (NBT) with NADH mediated by phenazine methosulfate (PMS) under basic conditions (Nishikimi et al., 1972). Peroxidase (PER) activity was detected by spectrophotometric method using benzidine reagent (Litvin, 1981). Glutathione reductase (GR) was determined according the method of NADPH degradation and glutathione (GSH) concentration was indicated spectrophotometrically used Spectrophotometer Specol–211 (Carl Zeiss, Iena, Germany) (Goldberg, Sparner, 1987). Enzyme activity was estimated in arbitrary units per protein concentration which was determined used the kit of Filicit (Ukraine, Katalog…, 2005).

#### *Statistical Analysis*

Biochemical measurements were detected in duplicate for each sample. Descriptive statistics were performed using an ANOVA (Halafian, 2008). P value of 0.05 was used for the determination of statistical significance between the values of both examined fish species. Statistical analyses were performed using Statistica software. The graphs were constructed using Microsoft Office Excel software.

## **RESULTS**

#### **Hystopathological Characteristics of Fish Liver and Spleen**

#### *Scorpion Fish*

Fish liver tissue that does not exhibit histopathological changes displays only few MMCs in the parenchyma or their absence (Abdel-Warith et al., 2011). Polygonal shaped or classical hexahedral hepatocytes with large spherical nucleolus and variable amount heterochromatin were detected in samples of fish liver (Figure 3). Hepatocytes formed hepatic cell cords locating among blood capillaries (hepatic sinusoids). Erythrocytes were mainly observed in the lumen of sinusoids. Kupffer cells (tissue-resident macrophages with large processes and bean-shaped nucleus) were registered in the space between hepatocytes and on the luminal surface of the sinusoid endothelium.

Figure 3. Section through liver of Black Sea Scorpion fish (*S. porcus*) captured in the marine coastal waters showing melanomacrophage center (big arrow), hepatic sinusoids (small arrows) and hepatic blood vessel. H&E,  $200X$ , Bar =  $25 \mu m$ .

Hepatic MMCs were not detected in 60% (3/5) of tested scorpion fish and occurred very rarely in the rest 40% of the animals, in which they were relatively small and associated with the blood vessels.

Spleen MMCs were indicated in 100% on tested samples of Scorpion fish (Figure 4). The average number of MMCs in spleen was approximately 5.

The microscopic pictures of peacock wrasse *C. tinca* liver and spleen are present in the Figures 5 and 6. In the liver of peacock wrasse *C. tinca* MMC in hepatocytes were large and dark color (Figure 5). High concentration of migrated melanomacrophages was indicated in parenhima as compared with the corresponding data of *S. porcus*. Among 5 tested fish samples high variability of histopathological changes in the spleen was observed: in two samples the hyperemia was shown and the boundaries between white and red pulpa were differed in the majority of fish samples (Figure 6).

The quantitative parameters of the MMC in the liver and spleen in both examined fish species are present in Table 1.

The average number of MMC in spleen was the similar in both fish. However, in *S. porcus* liver the average number of MMC in the field of vision was in 10-fold lower than in spleen  $(p < 0.01)$ , while in *C. tinca* the values were identical (Table 1). The average size of MMC in the spleen of both checked animals were significantly higher in the spleen than in the liver, and in *C. tinca* they were greater as compared with *S. porcus*.

Figure 4. Section through spleen of Black Sea Scorpion fish (*S. porcus*) captured in marine coastal waters showing melanomacrophage center (big arrow). H&E, 200X, Bar = 25 μm.

Figure 5. Section through liver of Black Sea peacock wrasse *C. tinca* captured in marine coastal waters showing melanomacrophage center (big arrow), hepatic sinusoids (small arrows) and hepatic blood vessel. H&E, 200X, Bar = 25 μm.

In both tested fish species the similar liver pathology was observed (Figure 3, 5), which characterized the increase of hepatic sinusoids and hyperemia, degenerative changes of hepatocytes. The infiltration of the tissues on leukocytes was also indicated, which was explained by the infections connecting with the increase of the number of Kuppfer's cells and elevated the number and size of MMC. At the same time the animals without any hepatic pathologies and low number of MMC were also were shown in the tested waters.

In the spleen tissues in both examined fish species the MMC contained dark-brown and black pigments, which were identified as hemosyderine and melanin, while in the liver the color was light and yellow, and they may contain hemosyderine and lipofuscin.

Figure 6. Section through spleen of Black Sea peacock wrasse *C. tinca* captured in the coastal marine waters showing melanomacrophage center (MMC), separate melanomacrophags (MM), capsule with high concentration of lymphoid cells in under capsule zone. H&E, 200X, Bar = 25 μm.

#### **Antioxidant System of the Fish Species**

It is necessary to point out a significant individual variability of MMCs area in the liver and spleen of the fish captured in marine coastal waters. The goal of our further investigations was to study the response of fishes, belonging to different ecological groups, used the biomarkers of antioxidant activity. The results observed the differences between blood, hepatic and muscle biomarkers in both tested fish species. (Figure 7, 8).

Figure 7. Antioxidant enzyme activities in the RBC (ml<sup>-1</sup> red blood cells  $\cdot$  min<sup>-1</sup> of *S. porcus and C. tinca*, captured in the coastal waters of Black Sea, Sevastopol (Crimea).

Significant differences of PER activity and GSH content ( $p < 0.05$ ) were shown in both studied fish species red blood cells (RBC) (Figure 7). SOD and GR activities tended to decrease in the RBC of *S. porcus* as compared with the *C. tinca*, while the activity of CAT was insignificantly greater in *C. tinca.*

The antioxidant enzyme activities in muscle and in the liver of two tested Black Sea teleosts are present in the Figure 8.

Figure 8. Antioxidant enzyme activities in the muscle and liver (mg protein<sup>-1</sup> min<sup>-1</sup>) of *S. porcus and C. tinca*, captured in the coastal waters of Black Sea, Sevastopol (Crimea).

The activity of checked antioxidant enzymes in both fish species were higher in muscle as compared to liver. In all cases the enzymatic activity was significantly higher in the muscle of *C tinca* than in *S. porcus* ( $p < 0.05$ ). In the liver SOD activity was the similar in both fish species, while hepatic PER, CAT and GR activities were significantly higher ( $p < 0.05$ ) in the *C. tinca* as compared with *S. porcus*.

#### **DISCUSSION**

The results of hystopathological and biochemical studies of the liver and spleen in both tested Black Sea teleosts *S. porcus* and *C. tinca*, caught in Sevastopol coastal waters demonstrated impact of the negative ecological living conditions in the abundance on fish health. One of the great advantages of using histopathological indicators in the evaluation of environmental status is that this battery of biomarkers allows examining specific target organs of fish and thereby histopathological responses are highly ecologically relevant. The toxicants enter into the body and from blood circulatory system they can easily enter tissues, including liver and spleen, that are responsible for vital functions, such as red blood cells production and the accumulation and biotransformation of xenobiotics in the fish. Histopathological damage may decrease individual fitness through disturbing the homeostasis and proper functioning of vital physiological and biochemical processes (e.g., detoxification, metabolic rate, oxygen consumption, endocrine functioning, respiration, osmoregulation, nutrient absorption, and etc.).

Taking into account that the liver is the important metabolic organ, in which toxic chemicals are accumulated and detoxified resulted biotransformation processes, parameters of the evaluation of its status could reflect the environment influence and its harmful for fish. Fish hepatic pathology is widely used by histological observations and it is good tool in ecotopxicological studies (Camargo, Martinez, 2007; Trinchet et al., 2011; Vydia et al., 2019).

The degenerative changes of the hepatocytes were shown in the liver of both fish species. The infiltration of liver tissues by leukocytes could be connected with the infection accompanied with the increase of Kuppfer cells number and the elevation of the quality and size of the MMC. The level of water pollution significantly influences on the patterns of fish liver pathology. Lesions in the liver of scorpion fish captured in coastal waters of Sevastopol mainly included extensive dilation of hepatic sinusoids, hyperemia, and degenerative changes in hepatocytes. Marked focal infiltration by lymphocytes in liver tissue possibly indicating infection process was observed and it was associated with increase in the number of Kupffer cells and in the number and size of MMCs. At the same time, fish without significant signs of hepatic pathology and low MMCs count were detected also in the coastal waters. However, large MMCs were found in liver as well as focal infiltration by lymphocytes and hyperemia were detected indicating marked pathological changes in liver and plausible focal inflammatory lesions. The similar histopathological changes were demonstrated in the fish species, caught in the polluted water bodies (Table 2) (Pietsch et al., 2014; Feist, et al., 2015).

It is a common knowledge, that MMCs in fish tissues can contain four types of brown pigments: melanin (catabolic product of fatty acids degradation at low temperatures), lipofuscin (product of the destruction of cellular membranes and the end product of lipid peroxidation which is utilized in the lysosoms), ceroid and hemosiderin (product of red blood cells degradation) (Kranz, 1989; Manrique et al., 2014). Morphologic features of MMCs vary markedly depending on fish species, organ of their location and physiological status (age, physiological stage, starvation, tissue type, iron and hemoglobin metabolism, anatomopathological conditions). The composition and functions of liver MMCs are differ from spleen or kidney MMCs because liver is the key organ for the metabolic state that plays important role in the processes of cell renovation and storage as well as in detoxication and biotransformation processes (Manrique et al., 2014).

The histopathological alterations in aquatic organisms impacted unfavorable environmental and anthropogenic factors were present in Table 2. The researchers had been shown that the number of MMCs was significantly higher in the liver of Sea bass (*Dicentrarchus labrax*) exposed to the various environmental pollutants. It can be used as a bioindicator of environmental stress. Besides that, the biological pollution also plays a role in the organ pathology and causes the tissues defects. Strong correlation between the appearance of MMCs and high level of resistant intracellular bacteria and parasites had been demonstrated. MMCs play important role as the main locations for long-term pathogen retention (Kurtovic et 2008; Biyasheva et al., 2014). It corroborates usefulness of the bioindicator for potential monitoring of fish health and their environment.

Histopathological alterations in the liver of examined Black Sea fish species were mainly characterized by the dilated hepatic sinusoids and marked focal infiltration by lymphocytes, increase in the number of Kupffer cells, hyperemia appeared as congested hepatic blood vessel and sinusoids. Moreover, vacuolization in the cytoplasm of hepatocytes, which was presumably caused by fat accumulation, was observed. Similar patterns of histopathological changes were shown in many fish species exposed to the toxicants or caught in polluted waters (Ferreira, 2011; Hansson, et al., 2006). At the other hand, we demonstrated the tissue specific differences between the histopathological alterations in the spleen and liver. For instance, in both tested fish species the number and size of MMCs were higher in the spleen as compared with the liver. Besides that we could detect the interspecies differences of the MMCs characteristics in the spleen and liver of both examined fishes. In *C. tinca* the parameters of MMCs higher as compared with the *S. porcus* which was connected with the ecological peculiarities of these animals and the different sensitivity to anthropogenic impact. Therefore, fish liver and spleen histology could serve as a model for studying the interactions between environmental factors and hepatic structure and functions. The parenchymatous hepatic tissue in teleosts has many important physiological functions and also detoxification of endogenous waste products as well as externally derived chemicals. Due to these reasons, the hepatic cells are damaged severely, on chronic exposure to xenobiotics. The liver and spleen exhibited several pathological changes including hyperplasia, degeneration of blood vessels, vacuolisation, hypertrophy; pyknotic nuclei, necrosis, and accumulation of blood vessels.

High concentration of xenobiotics in the water causes oxidative stress in fish resulted their transfer via water and food in the organism. Liver is the main organ of pollutants accumulation and biotransformation resulted ROS-generation and accumulation of their products (Palluel et al., 2018). Growth of lipid peroxidation production in tissues of the animals in contaminated habitats are postulated as the non-specific response of the organism to the stress effects and it was documented at the case of environment pollution by various chemical agents and their complex (Liu et al., 2006; Napierska et al., 2009; Martinez-Gomez et al., 2009; Martinez-Porchas et al., 2011). In polluted areas the exposure of aquatic organisms to xenobiotics results to interaction between these compounds and biological systems, which may give elevation to biochemical and physiological damage or/and adaptive mechanisms via the induction of defense immune and antioxidant systems (Liu et al., 2006). Thus, biochemical and physiological parameters are used as biomarkers for contaminants and could be applied for evaluation of environmental stress and its after-effects. However, biomarkers exposure to environmental stressors vary widely depending on the type of anthropogenic activity, ecological and biological peculiarities of fish species (Adams, 2005).

Antioxidant enzyme activity in the red blood cells was not significant differed in two tested fish with the exception of PER activity, which was higher in *S. porcus* as compared with *C. tinca*. At the other hand the concentration of GSH was greater in RBC of *C. tinca*. Therefore, we could postulate the insignificant interspecies differences of antioxidants content in the red blood cells of both animal species. The interspecies variations of AOA defense may reflect the specific adaptations to the oxidative stress and protective mechanisms against ROS damage. Thus the activity of antioxidant enzymes in fish blood correlated with their swimming capacity. In previous studies the investigators found that CAT activity in fast swimming pelagic fish were significant higher than in blood of slow swimming gobies, scorpion fish and flounder (Filho & Boveris, 1993; Filho, 1996, 2007; Rudneva, 2012).

Table 2. Relationships between histopathological alterations and antioxidant system of aquatic organisms tissues **Table 2. Relationships between histopathological alterations and antioxidant system of aquatic organisms tissues**

Table 2. (Continued) **Table 2. (Continued)**

The researchers suggested, that antioxidant defense in marine species in the liver and blood may be related to the oxygen consumption of the tissues and of the whole organism, while in freshwater fish it may be related to physical and chemical characteristics of the living conditions rather than to physical activity (Filho, 1996). At the same time the changes in the sturgeon blood prooxidant-antioxidant status, as a consequence of adaptation to marine conditions, were not reflected in the liver and other tissues (Martinez-Alvarez et al., 2005).

Liver of the vertebrates exhibits a high metabolism and oxygen consumption and it is the main organ of xenobiotic detoxification. Fish liver displayed the high levels of the key antioxidant enzymes. This could be related to the fact that the liver is the site of multiple oxidative reactions and maximal free radical generation (Gul et al., 2004). Antioxidants level in liver appears to indicate that the active species of teleosts had greater enzyme activity compared with low mobile forms (Filho & Boveris, 1993). The higher activity of antioxidant enzymes in liver of active fish correlated with the higher oxygen consumption in fast swimming species and their high metabolic rate (Filho, 2007; Martinez-Alvarez et al., 2005). In our studies hepatic antioxidant concentrations in active *C. tinca* were greater as compared with sluggish *S. porcus*, with the exception of SOD activity. Animals with high metabolic rate exhibits the high rates of free radical production and caused the induction of antioxidant defense mechanisms (Zelinski & Portner, 2000). Physical activity of fish is often associated with fitness, reproduction or predator avoidance. Therefore, the link between oxidative stress and physical activity may appear to be more complex.

Muscle tissue also comes in close contact with pollutants dissolved in water. Hence, reactions in the histopathology of the muscles are spontaneous. The histopathology of muscle show progressive damage in the structure of the tissues with increasing concentrations of toxicants (Ramesh, Nagarajan, 2013). The alterations in muscle histopathology accompanied with the antioxidant status of the tissues. In our studies the antioxidant enzyme activity in muscle was higher in *C. tinca* than in *S. porcus*. Therefore, their antioxidant status depends on specificity on abundance and complex of living conditions in biotope. Ecological conditions of the habitats play an important role in fish antioxidant status and their adaptation to the living conditions. Previously we described enzyme activities in various tissues in several Black Sea teleost (Rudneva, 2012; Treberg et al., 2003). Therfore, the obtained results supports the great interspecies differences in antioxidants activity in various tissues between examined species, which agrees with the opinion of many researchers studying fish antioxidants (Mukherjee et al., 2017). In our previous studies we showed the differences of low molecular weight scavengers in fish blood.

We could note the possibility of the histological alterations and the specificity response of antioxidant enzymes in fish liver and spleen to different toxicants expose in the water and sediments as well as synergic and antagonistic effects at the case of interactions between xenobiotics and with the water. These interactions could modulate organism response and result histopathological damage and adaptive effect or toxic response of antioxidant defense system.

## **CONCLUSION**

Hystopathological and biochemical biomarkers apparently are useful indicators of the health status of fish in monitoring studies, and they reflect the sensitivity/resistance of the fish to unfavorable factors. The response of biomarkers in fish tissues such as liver, spleen, muscle and blood is important tool for the evaluation of fish abilities to protect against chemical pollution and keeping life in the polluted environments. The present study provides additional evidence for the usefulness of a set of liver and spleen histological and biochemical biomarkers in assessing the health of aquatic systems. Therefore, it is important to note that the responses of biochemical biomarkers depend on the frequency of release of pollutants and type and degree of contamination. However, in most cases stressed environment corresponds to chronic or subacute conditions. Hystopathological changes in liver and in spleen disturb various biochemical reactions as indicated by antioxidant enzyme activities. Antioxidant enzyme activity changes can be considered as a 'early-warning' adaptive or toxic response, while liver and spleen hystopathologies are 'second' adaptive/toxic response, depending on the level of water contamination and chronic exposure. Therefore, water pollution is capable of inducing both histopathological and biochemical alterations in liver and spleen, which may cause metabolic dysfunction. Histopathological alterations and antioxidant enzyme response can be used as indicators for the effects of various pollutants on fish and their abundance. These biomarkers are closely related to other indicators for stress because many pollutants have to undergo metabolic activation in order to be able to provoke cellular changes and biochemical alterations in the affected organism.

### **ABSTRACT**

Recently the research of marine knowledge and information technology has grown rapidly by the increasing interest in the rich repository of natural resources in the sea. For marine knowledge services, accurate marine environmental data must be continuously collected to deeply understand and analyze the marine circumstances. However, there is an insufficiency of research on the observation of marine circumstances in South Korea for the marine knowledge services. The ocean data buoy, a marine environmental monitoring equipment currently operating in South Korea, is large in size and high in production cost because it consumes a lot of power for communication. It also provides only marine data and lacks information on marine knowledge. In this paper, we have proposed a Containerized Marine Knowledge System by means of IoT-Cloud and LoRaWAN to improve marine environment monitoring. The proposed system enables flexible construction of the system and can analyze the marine knowledge through visualizing the gathered data and the knowledge processing with respect to the prediction of red tides. LoRaWAN-based IoT devices are able to collect long-range marine environmental data in an energy efficient manner. Our proposed method is helpful for researching low cost marine monitoring buoy and flexible marine knowledge systems.

**Keywords**: marine knowledge system, IoT, cloud, LoRaWAN, realtime processing, batch processing

## **1.INTRODUCTION**

In recent years, the ocean has been attracting attention as a valuable resource pool, and the marine environment has been widely studied worldwide. For marine knowledge services through analysis and understanding of the marine environment, information on the marine circumstances must be continuously gathered. Especially in South Korea, there are various marine aquaculture industries in the south coast and the west coast because the three sides of Korea are the coast. The Korea fishery industry is highly influenced by marine circumstances and the natural phenomena. In other words, the damage of fisheries is increasing by changing the marine environment every year. The damage of the fishery industry is growing since typhoons, coastal pollution, an oil seep, and blooms of red tides. The harmful algal blooms (HABs) of South Korea have inflicted massive mortality on fin fish and shellfish, damaging the economies of fisheries for almost every year from 1993 to 2019. Particularly, there were huge harmful algal blooms of Cochlodinium polykrikoides in 1995, resulting in about 95 million dollars in fishery damage [1].

Collecting and analyzing coastal environments data can help to reduce the damage of coast disasters. But there is very limited research on marine knowledge services that collect and analyze environmental information from Korea's sea. Studies on marine knowledge Systems include sea buoys, radar of weather at sea, radio microwave at coast, coast circumstances observation system, and underwater circumstances observation system [2-13]. Tateson et al. studied a marine monitoring communication model using temperature and pressure measurement sensors. In this method, an antenna for transmitting and receiving is installed by fixing the position of a buoy, and a sensor package is installed to connect underwater by wire [2]. Yoon et al. [3] constructed a marine data communication network for water quality monitoring. These methods are composed of 9 sensors that can measure the water environment using Ethernet and CDMA-based web camera, temperature, salinity and dissolved oxygen amount in Gyeongpo Lake of South Korea. In addition, the studies on ocean weather monitoring include the use of radar to detect rainfall and snowfall, and the measurement of sea water temperature using a microwave radiometer [4]. Yoo et al. [5] studied the drift buoy for the marine environment monitoring. These drift units are designed to be able to flow by sea currents and sea wind which the measured data of temperature and salinity are transmitted to the server using a satellite communication model. Lee et al. [6] proposed a prototype of a gateway that can transmit data on the ground by integrating data from sensors using different protocols.

The Korea National Fisheries Research and Development Institute has been operating various surveillance systems to utilize basic data of the fishery area and predicting future fishery resource changes due to climate change [1, 11]. Park et al. [12] proposed a model of marine environmental monitoring and analysis system that automatically collects marine environmental information. Their model can intelligently monitor the marine environment and analyze collected marine data. In addition, they designed the new concept of convergence type maritime devices based on software definition devices in accordance with the new paradigm change [13]. The Korea Meteorological Administration operates 17 ocean data buoys on the coast of South Korea to provide real-time service of marine meteorological data. The ocean data buoy collects wave height, mean wave period, wave direction, wind direction, wind speed, barometric pressure, humidity, temperature, and water temperature. The transmission of the monitored data at the buoy uses CDMA and satellite communications. The size of the buoys and the high production costs are due to the inclusion of solar panels and batteries to maintain communication. The 3-meter discus buoy for ocean data costs \$ 400,000 USD and the 6-meter NOMAD buoy costs \$ 800,000 USD. The high production price of ocean data buoys is limited to marine data collection. There is a need for a technical solution to this limitation. In addition, there is a need for research on marine knowledge information services that can generate added value by processing collected data from research currently focused on marine data collection [1, 12, 13].

In order to reduce red tide damage, another study on marine knowledge service is a study on predicting red tide based on Case-Based Reasoning (CRB) and Machine Learning (ML). Song et al. [14] proposed a CRB (case-based reasoning) based red tide monitoring system using past cases and simple classification methods has been proposed. Fdez-Riverola et al. [15] carried out a forecasting system of red tide blooms [15] using CBR by means of multiinference stage. Rong et al. [16] proposed a forecasting method of red tide events using a neural network based on fuzzy. Our previous studies proposed forecasting models for the predicting of red tides events of the South Korea coast, which uses neural networks [17], fuzzy inference [18], ensemble method [19], and fuzzy reasoning and Naive Bayes classifier [20]. We also proposed the forecasting system of red tides events [1] using integration methods of fuzzy inference and ensemble technique. The CBR method [14, 15] and the classifier methods [16-20] show the red tide prediction results in numerical or categorical type. The categorical prediction has a high accuracy but is displayed as a simple binary number of 1 and 0. The numerical prediction can forecast the density of red tide algae but is less accurate than categorical prediction. Our previously proposed red tides prediction system [1] improved precision of prediction of red tides occurrence by using integration of the categorical type and the numerical type. In this paper, we modified our previously proposed red tide prediction system to design and implement marine knowledge analysis in our marine knowledge system.

In this chapter, the containerized marine knowledge system by means of IoT-Cloud and LoRaWAN is designed for low cost marine monitoring buoy and flexible marine knowledge system. The designed system consists of the hardware of marine knowledge system and the marine knowledge service. The marine knowledge system hardware consists of an IoT device to collect marine data and a marine server to store and process the collected information. IoT devices for collecting marine environment data can support long distance data transmission with low power using LoRaWAN communication module. The marine server can support a private Nano cloud that uses the LXD container to easily manipulate the increasing new infrastructure of marine knowledge service. The marine knowledge service is designed to support real-time marine knowledge processing and batch marine knowledge processing, such as the Lambda architecture. The real-time marine knowledge processing can analyze coastal information from visualizing gathered data by containerized visualization module. The batch marine knowledge processing can predict the red tide events by knowledge processing of data gathered over a period using a containerized prediction module.

# **2. MARINE KNOWLEDGE SYSTEM**

#### **2.1. Proposal System Concept**

In this sub chapter, we explain the concept of our containerized marine knowledge system that provides the visualization of collected data and marine knowledge services to collect the coast circumstances data and analyze the coast knowledge. Figure 1 shows a conceptual picture of the marine knowledge system, which consists of Figure 1(1) Marine μBoxes (MB) and Figure 1(2) Marine IoT-Cloud Hub (MICH). The MB is the IoT device of marine data collection, which continuously collects coast circumstances data and transmits the gathered data to the MICH using LoRaWAN communication. The MICH is the marine knowledge server for the marine data visualization and red tide event prediction. The marine data is concentrated through the LoRaWAN gateway (i.e., concentrator) of MICH. It stores the collected marine data in the Hadoop distributed file system for marine big data processing, which it supports a real-time visualization analysis using a Grafana on the stored time series data. It also analyzes red tide occurrences using the proposed red tide prediction algorithm.

#### *2.1.1. Marine μBox (MB)*

The hardware and software of Marine μBox (MB) modules is designed, which plays the role of IoT device for marine information collection. The MB transmits the gathered coast circumstances data by the marine sensors to the MICH (Marine IoT-Cloud Hub) using the LoRaWAN communication module.

The Marine Box hardware consists of a battery pack, a LoRaWAN communication module, a sensor and an Arduino. LoRa is an abbreviation for Long Range, which is alarge, low-power long-range wireless communication technology with low stand bypower and low module prices. LoRa can transmit and receive a small amount of data at low power by putting chipset on device without separate base station or relay equipment. The communication speed of LoRa is 0.3 to 5 kbps, and the propagation reaches up to 21 km in a visible range.

Figure 1. Conceptual diagram of Marine knowledge system.

In South Korea, SK Telecomhas installed the LoRa network nationwide to provide IoT service. LoRa Korea frequencies were announced in LoRa 1.0.2 in October 2016 from 920.9 to 923.3 MHz [21]. LoRaWAN is the communication protocol and the network architecture for the long-range communication link of the physical LoRa layer. The characteristics of LoRaWAN is a star topology connected to the Marine IoT-Cloud Hub (MICH) in which gateway serves to relay messages between MB and MICH. The gateway module of MICH has two independent communication links with respect to LoRa communication and IP backhaul. LoRa protocol structure consists of MAC and PHY. The PHY includes LoRa modulation for regional LoRa frequency bands. The MAC consists of Class A (baseline), Class B and Class C (optional). Class A is utilized for the low-energy LoRa communication module of MB, which allows bi-directional communication between MB and LoRa gateway module of MICH.

Figure 2 shows the composition of MB hardware. As shown in Figure 1(1), the LoRa Arduino Shield (i.e., Dragino's LoRa communication module) [22] transmits the sensed data from LoRaWAN node (i.e., MB) to LoRaWAN gateway. The frequency band of the LoRaWAN module in Figure 2(1) sets 920.9 MHz, which is allocated to South Korea. Figure 2(2) Arduino Mega 2560 [23] gathers the coast circumstances data by sensors and sends the gathered data through LoRaWAN communication module. DHT11 is a temperature and humidity sensor in Figure 2(3), which senses the digital data of temperature and humidity. DS18B20 is a water temperature sensor in Figure 2(4), which senses the digital data of water temperature. YDDYP01 is a Xiaomi 20000 mAh auxiliary battery in Figure 2(5), which gives power to the MB.

Figure 2. Composition of MB hardware.

Figure 3 shows the MB software module, while Figures 3(1) and 3(2) show the SMDM (Sensing Marine Data Module) and the LCM (LoRaWAN Communication Module), respectively. MB software module is operated in the Arduino. The marine environmental data (i.e., sea temperature, temperature and humidity) is collected by the MDCM (Marine Data Collection Module). The collected marine environment data are transmitted by LoRaWAN communication module to LoRaWAN gateway of MICH. It can also handle data transmission error. The MB software module is implemented using C language. Figure 3(3) shows the example of a software module to send data from LoRaWAN communication module to LoRaWAN Gateway.

Figure 3. Marine μBox software module.

#### *2.1.2. Marine IoT-Cloud Hub*

Marine IoT-Cloud Hub stores coastal environment data as time series data, which serves red tide forecasting and visualization of coast circumstances data for marine knowledge services. The MICH consists of a hardware module and software module.

#### **Table 1. Marine IoT-Cloud Hub (marine server): Container node hardware specification for private nano cloud**

<b>CPU</b>	ΆM	Sata SSD	$m.2$ SSD	NIC
Xeon E5-2630v4 x 2	128GB		'TB	$C*2$

**Table 2. Marine IoT-Cloud Hub (LoRaWAN gateway): Dragino (LG01-P) hardware specification [25]**

The MICH hardware module contains a marine server and LoRaWAN gateway. Table 1 shows the hardware specifications of cluster nodes, which consist of one server with two Xeon CPUs. The cluster nodes' hardware is efficiently used by using virtualized software modules based on resource pooling. The LoRaWAN gateway module is implemented by using Dragino LG01-P [24] LoRaWAN gateway. Table 1 shows the hardware specification of Dragino LG01-P LoRaWAN gateway.

MICH software contains marine server software module and LoRaWAN gateway software module. As shown in Figure 4, the marine server software module is designed based on a private Nano cloud, which can support the virtualization of the LXD container for flexible resource utilization. The Nano cloud of MICH is constructed by clustering compute

nodes, storage and container networking based on LXD containers. Any number of LXD servers share the same distributed database for the compute node of MICH, which can be managed uniformly using lxc client or the REST API. The storage of MICH is used in the LXD's file storage pool. The MICH container networking is supported by virtualizing the network within the container. As shown in Figure 4, the Ubuntu 16.04 Linux is installed on all LXD container nodes for marine server software modules and Ubuntu 18.04 is installed on the host node of the server. Hadoop is a software framework with the Apache open source project that allows distributed applications to run in a cluster by clustering computing resources to handle large amounts of data. Hadoop can store data in the Hadoop Distributed File System (HDFS), which the distributed processing system can handle large amounts of data using MapReduce [25]. LXD is Canonicals' open source lightweight container hypervisor, which improves Linux Containers (LXC) features and provides new features and functionality for handling of LXC [26].

Figure 4. Marine IoT-Cloud Hub: Marine server software modules.

As shown in Figure 4(2), Hadoop 2.7.3 [25] is clustered on the containerized four nodes to share a resource pool. As shown in Figure 4(3), NoSQL database, Hbase 1.2.6 [27], is installed in the upper layer of HDFS (Hadoop Distributed File System), in which a large amount of data can be processed by a distributed file system. HBase is open source software as a NO-SQL distributed database system that runs on the Hadoop platform, which was developed for the Hadoop project of Apache Software Foundation. The data tables of HBase provide input and output for MapReduce operations running on Hadoop, which can be accessed through Java APIs, REST, Avro or Thrift gateways [27]. In this paper, the Zookeeper in Figure 4(4) acts as a coordinator of distributed clusters to the Hadoop cluster in Figure 4(2) and Hbase cluster in Figure 4(3). Zookeeper 3.4.6 [28] is installed on node 2, node 3 and node 4, which Zookeeper Ensemble is configured. Zookeeper is developed by the Yahoo development team for the Apache project. It is a distributed cluster coordinator that manages and coordinates the application programs composed of multiple nodes. In addition, Zookeeper manages the state (i.e., dead or alive) of cluster nodes such as synchronizing specific data. Zookeeper is low in latency and high in throughput, because it is an in-memory based tool which stores data in memory and snap shots in storage [28]. OpenTSDB 2.3.0 [29] is installed on an OpenTSDB container as shown in Figure 4(5), which the marine circumstances data are saved as time series data to HBase using TSD (Time Series Daemon) of OpenTSDB. OpenTSDB is a scalable time series database based on Hbase. It consists of time series daemons (TSDs). Each TSD is independent and processed without state sharing which uses HBase to fetch and storetime series data. Users can communicate with TSD using telnet protocol, HTTPAPI, built-in GUI, etc. [29]. Grafana 4.4.3 [30] is installed on Grafana server containers as shown in Figure 6(6), which visualizes the marine environment time series data by displaying graphs. Grafana is a dashboard for displaying time series data and measurement information, and it supports visualization of time series data stored in various data sources such as Graphite, Elastic search, OpenTSDB, Prometheus, InfluxDB, and Cloudwatch [37-39].

Figure 5. Marine IoT-Cloud Hub: Software modules of LoRaWAN gateway.

Figure 6. Example of running LoRaWAN gateway software modules.

As shown in Figure 5, the software module of LoRaWAN gateway includes the LoRaWAN Communication Module (RCM), the Buffered Marine Data Module (BMDM) and the Storage Marine Data Module (SMDM), which runs on Dragino LG01-P LoRa gateway. The RCM in Figure 5(1) receives the coast circumstances data from the LoRaWAN communication module of MB. It also requests data retransmission if a transmission error occurs. The BMDM shown in Figure 5(2) temporarily stores the marine environment data before transmitting to the OpenTSDB Server. The SMDM in Figure 5(3) sends the coast circumstances data to the marine server's OpenTSDB and stores the sent data as time series data. Figure 6 shows an example of running the LoRaWAN gateway software module.

#### *2.1.3. Red Tide Prediction Server*

The prediction server in Figure 4(7) containerised the revised of our previous red tide prediction system for ocean knowledge service. Generally, results of red tide prediction consist of categorical type and a numerical type. The categorical type is high precision but it represents a simple binary result of 0 or 1. The numerical type can forecast how much density to increase in red tide bloom, but the prediction result is less accurate than the results of the category type. In our previous work [1], we proposed a hybrid-based red tide prediction systemthat uses fuzzy reasoning and the ensemble method (i.e., bagging of decisiontree) to obtain prediction results for the categorical and numerical types. Please refer to [1] for details of our previous red tide prediction system. In this paper, we use Random Forester method [31] instead of the decision tree of ensemble method to improve the performance of our previously proposed method. The revised red tide prediction method forecasts the density of red tide algae and red tide events. As shown in Figure 7, the revised method consists of four phases: Preprocessing, Fuzzy Reasoning, Random Forester, and Postprocessing. Preprocessing phase normalizes training and test data of classifiers for Fuzzy Reasoning method and Random Forester method. The Fuzzy Reasoning phase forecasts numerical prediction values about the algae density of red tide blooms. Random Forester phase predicts the categorical prediction binary value of 0 or 1 for red tide events. Post-processing phase enhances the results of numerical prediction with respect to the Fuzzy Reasoning phase. The revised method uses Python 3.5 and Python machine learning frameworks (i.e., scikit-learn, scikit-fuzzy, tensorflow, and keras) for easy implementation in a short time.

#### **2.2. Test of Designed Marine Knowledge System**

In this sub chapter, to evaluate the performance of the proposed system, we evaluate the operational test of the marine knowledge system and the accuracy of red tide forecasting of the prediction server. The marine environmental monitoring system for operational testing is configured as shown in Figure 8. As shown in Figure 8 (1), the Marine  $\mu$ Box consists of two boxes which collect temperature, humidity and water temperature data through two sensors. The collected data are saved as time series data of OpenTSDB in the marine server of MICH in Figure 8(2). The stored time series data are visualized by Grafana to display as a graph.

Figure 7. Revision of our previous method for ted tide prediction. Figure 7. Revision of our previous method for ted tide prediction.

Operational testing of the proposed marine knowledge system consists of visualization of coastal environments data and visualizing workload of cluster nodes. The visualization of coastal environments data visualizes the collected data from MB in real time. The visualizing workload visualizes the usage of the CPU of each clusternode of the MICH in 1-minute and 5-minute increments. The first MB (node 1) is located in the same laboratory 2 m away from the MICH and the second MB (node 4) measures the indoor environment information located in another laboratory 30 m away from the MICH. The MB (node 1) is open in the room, and the MB (node 4) is packed in a paper box for mobility.

Figure 9 is a graphical representation of the data gathered from two MBs in a month (2018). Figure 10 shows the visualization results of the data collected over the last 12 hours. Figure 9(1) and Figure 10(1) are temperature data gathered from two MBs. Figures 9(2) and 10(2) are the humidity data. The Figures 9(3) and 10(3) show the water temperature data. In Figure 9 and Figure 10, the green graph is the MB (node 1) and the yellow isthe MB (node 4).

Figure 8. Test configuration diagram of the proposed system.

Figure 9. Visualization results of monthly (2018) gathering data from MB.

Figure 11 shows the visualizing of the CPU utilization data gathered from the four cluster nodes of the MICH. Figure 12 shows the visualization results of CPU utilization data collected during the last 3 hours. Figure  $11(1)$  and Figure  $12(1)$  are CPU utilization data collected for 1 minute from 4 cluster nodes of Marine IoT-Cloud Hub. Figure 11(2) and Figure 12(2) are 5-minute CPU usage load data. In Figure 11 and Figure 12, green line is data node 1, yellow line is data node 2, blue line is data node 3, and orange line is data node 4.

Figure 10. Visualization results of 12-hour gathering data from MB.

Figure 11. Visualization result of monthly (2018) collection data of CPU load from data node in MICH.

Figure 12. Visualization results of 3-hour collected CPU load data from data node in MICH.
To evaluate the revised red tide prediction method, we used the experimental data of 746 actual events of harmful algal (i.e., Cochlodinium p.) and unharmful algae in the eighteen years from 2002 to 2019 that occurred on the coast of South Korea. Red tide events data was collected from the red tide information system of Korea National Institute of Fisheries Science [32]. Temperature and rainfall data related to red tide events was gathered from the Korea National Weather Service [33]. Water temperature data in connection with red tide events was collected from Korea National Institute of Fisheries Science [34]. The ratio of classifier training data and predictive test data is a cross-validated of 70 and 30, respectively.

Figure 13. Results of comparison of the classifiers for red tide events prediction.

We compared the average prediction accuracy with respect to the nine methods, RHBD, BPN, GRN, SVM, FZR, NBC, CART, BNG, and HBD. BPN and GRN are the back propagation neural network classifier and the general regression neural network classifier, respectively [17]. SVM is the support vector machine classifier [17]. FZR is the fuzzy reasoning classifier [18]. NBC is the Naïve Bayesian classifier [19]. CART is the decision tree classifier based on the CART algorithm [1]. BNG is a bagging classifier based on the CART decision tree [1]. HBR is our previous method which hybrid-based red tide prediction system uses fuzzy reasoning classifier and CART bagging classifier [1]. RHBD is the proposed method in this chapter by revising our previous method of HBD based on Random Forester. In Figure 13, the average prediction accuracy of RHBD is approximately 27.75% higher than that of BPN, 14.48% higher that of GRN, 7.57% higher that of SVN, 7.27% higher that of FZR, 5.64% higher that of NBC, 5.85% higher that of CART, 2.21% higher that of BNG, and 1.143% higher that of HBD.

# **CONCLUSION**

We have designed the containerized marine knowledge system, which consist of Marine μBox for IoT data collection devices and Marine IoT-Cloud Hub for marine knowledge services. The Marine μBox can gather long-range coast circumstances data at low power by LoRaWAN. The infrastructure of IoT-Cloud hub is designed as a private Nano cloud with LXD container, which new infrastructure of marine knowledge service can be easily created. The marine knowledge services of IoT-Cloud hub can support real-time processing for visualizing marine information and batch marine knowledge processing with respect to prediction of red tides blooms.

# **METHODS OF DETERMINATION OF MICROPOLLUTANTS IN DIFFERENT MARINE MATRICES**

*Mouna Necibi1,\* , Amani Atayat1,2 and Nadia Mzoughi1,†*

<sup>1</sup>Sciences and Environmental Techonologies Laboratory, High Institute of Environmental Sciences and Technologies of Borj Cedria, University of Carthage, Hammam Lif, Tunisia <sup>2</sup>Faculty of Science of Bizerte, University of Carthage, Bizerte, Tunisia

# **ABSTRACT**

In recent years there has been growing environmental concern, especially regarding the use and discharge of toxic substances. Many organic and inorganic pollutants are detected in marine ecosystems such as pesticides; heavy metals (HM), synthetic musk compounds (SMs), and polycyclic aromatic hydrocarbons (HAPs). Because of their toxicity, bioaccumulation, and persistence in the environment, they cause harmful effects to organisms and human health. Many extraction techniques such as Soxhlet extraction, ultrasonic extraction, supercritical fluid extraction, microwave extraction, QuEChERS, accelerated solvent extraction have been used for the determination of micropollutants in different marine matrices. Extraction techniques in analytical chemistry provide an effective separation of the analytes from the matrix with minimal use of solvent and duration. Many techniques are used for the detection of micropollutants in marine matrices such as high-performance liquid chromatography (HPLC), gas chromatography (GC) for organic pollutants, and atomic absorption spectrometry (AAS), *inductively coupled plasma* (ICP) for inorganic pollutants. In this chapter we investigate a comparison between different extraction and detection techniques used for the determination of organic and inorganic pollutants in environmental matrices such as biota, water, and sediment.

**Keywords:** micropollutants, marine environmental matrices, extraction, analytical detection techniques

# **1.INTRODUCTION**

The natural environment continuously receives foreign chemicals due to urban and industrial activities. Pesticides present a huge class of compounds that are used everywhere in the planet for several decades regarding their advantages and benefits. The appliance and release to the aquatic ecosystems of those organic compounds has become a matter of concern (Pinto et al. 2016). Within the last century, thousands of organochlorine pesticides (OCPs) are produced and released into the environment which constitutes one among the foremost important persistent organic pollutants (POPs) (Zhou et al. 2006). Many of those pesticides belong to endocrine-disrupting chemicals and due to their persistence, high lipid solubility, and carcinogenic properties, OCPs threatened the ecosystem, human health and wild animals (Yan et al. 2014; Tang et al. 2008).These compounds and their metabolites were the most explanation for birth defects, system dysfunction, endocrine disruptions, and cancer (Montuori et al. 2016). Many people are poisoned and hundred are dying annually around the world from POP, and a huge number of them live in the developing countries (Sarkar et al. 2008). Their intensive use throughout the agricultural world for crop protection within the past has caused their persistence within the environment. Emerging contaminants are natural and artificial chemicals or micro-organisms that are not commonly monitored within the environment but has the potential to enter the environment and cause ecological and human health effects (Kuster et al. 2008). Synthetic musks (SMs) have recently been classified as a new class of emerging contaminants of the marine environment (Heberer et al. 2002). These compounds became indispensable to our modern society and are utilized in a good range of applications (fragrance additives in perfumes, lotions, sunscreens, deodorants, antiseptics and laundry detergents) (Hu et al. 2011). The SM compounds contaminate the environments with the discharge of effluents into lakes and rivers (Hu et al. 2011). Because of their high octanol–water partition coefficient (Log  $K_{\text{OW}} \ge 5$ ) and their lipophilic nature, SMs are easily absorbed by suspended particulate matter and, eventually are deposited and accumulated in sediments. The evaluation of the impacts of anthropogenic activities on marine environment requires the analyses of sediment samples which represent the last sink for hydrophobic pollutants (Zeng et al. 2008). Many researches shows that OCPs are still detected in various media including: Mud (Ju et al. 2009), SPM (Liu et al. 2013), surface sediment (Liu et al. 2013), beverage (Eissa et al. 2013), surface water (Schreiber et al. 2013), ground water (Raposo Junior et al. 2007), even after their use has been banned for the past several decades. The presence of SMs in coastal and marine environments has been previously reported in several environmental matrixes: water, mussels, fish, sludge and sediment. Most of the analytical methods adopted for the analysis of SMs in sediment matrices are supported traditional liquid solid extraction followed by a cleanup procedure. The necessity of huge amounts of organic solvents (200 to 500 ml), the time-consuming extraction steps (8-24 h) and therefore the great deal of sample used  $(1-10)$  g) are the most drawbacks of traditional extractions (Sumner et al. 2010). The replacement trend in analytical chemistry is the development of "environmentally friendly" sample pre-treatment methods, which are solventfree or solvent-minimized and, at an equivalent time, faster and more selective than classic procedures (Pinto et al. 2010). Anastassiades et al. (2003) developed a QuEChERS procedure to extract pesticides from fruits and vegetables. High-quality results with a high sample throughput, low solvent and glassware consumption, little work, low cost and time of study per sample was provided by this method (Pinto et al. 2010).

# **2. THE ORGANIC POLLUTANTS**

#### **2.1. Organochlorine Pesticides (OCPs)**

Organochlorine pesticides (OCPs) include various groups of chemicals, which tend to share certain structural characteristics. They have an aliphatic radical or an aromatic ring structure, which is strongly substituted with chlorine atoms (Shen et al. 2005). As a result, most of these compounds are sparingly soluble and semi-volatile. In May 2001, the Stockholm Convention on POPs, which was adopted by the United Nations Environment Program (UNEP) stressed the need to control the global contamination produced by toxic chemicals in the environment.

The convention promotes global regulations on the production and use of persistent OCPs, such as aldrin, dieldrin, endrin, heptachlor, chlordane, hexachlorobenzene, Mirex, toxaphene, PCBs and DDTs. Although most of the developed countries have already banned or restricted the production and use of these compounds, some developing countries still use OCPs in agriculture (Gao et al. 2008). Several studies have shown the presence of OCPs and PCBs in the various compartments of the marine ecosystem: surface water, suspended particles and sediments. It has been proved in other studies the presence of its organic pollutants persistent in the plant matrix and even in living tissues with more or less significant concentrations (DGPA 2008; APEK 2005).

**Table 1. Presence of pesticides in different matrices in Tunisia**

Tunisia signed the Stockholm convention on May 23, 2001 and the parliament ratified it on March 9, 2004. Within the framework of this convention, Tunisia is required to prohibit all production and use of POPs and to take the necessary measures to remove and eliminate POPs that are already in the country (on storage sites and in the natural environment). Although OCPs and PCBs have never been produced in Tunisia and their import and use have been banned, these compounds continue to exist in the various matrices of the marine environment: sediment, biota and even in breast milk. Table 1 summarizes the different pesticides, their levels and their methods of analysis.

#### **2.2. Synthetic Musks**

Musk is a secretion from the glands that has been used for centuries as a component in perfumes. The discovery of natural musk dated from ancient China, where the musk deer was killed to obtain the musk gland (Rimkus et al. 2004). At the end of the 19th century, the first synthetic musk was synthesized in the laboratory, "musk Baur," allowing the use of a cheaper synthetic compounds (Heberer et al. 2002) instead of very expensive natural musk which was the main because of the almost extinction of the musk deer (Yang et al. 2003). Polycyclic musks are the most used in cosmetics and detergents and, therefore, those supposed to be found in high concentrations in the environment (Rimkus et al. 2004). The extensive use of SM in cosmetic products results in large quantities going down the drain after being applied to skin, hair and clothing. They enter sewage and wastewater systems and find their way into the aquatic environment through effluents and wastewater, primarily wastewater from treatment plants (Ricking et al. 2003; Stevens et al. 2003).

Once in the aquatic environment, synthetic musks can enter the food chain, being taken by fish and crustaceans. Because of their octanol-water partition coefficient (log  $K_{ow} \ge 5$ ) and their lipophilic nature. The SM is easily absorbed by suspended particles which are then deposited and accumulated in sediments which represent the ultimate location for hydrophobic pollutants (Zeng et al. 2008). Synthetic musks have different chemical structures than natural compounds. The physical and chemical properties of synthetic musks are similar to those of persistent chemicals which are known by their biomagnifications such as PCBs and OCPs (Peck et al. 2004).

**Table 2. Concentrations of synthetic musks in the environment**

Due to its properties, synthetic musks are widespread environmental contaminants, particularly in freshwater and marine ecosystems (Tanabe et al. 2005). They have been measured in rivers, lakes, sediments, soils, sewage sludge and effluents from wastewater treatment plants in Canada, the United States, the United Kingdom and Europe. Recent research has shown that levels have increased dramatically in lake sediments in North America over the past 15 years, in keeping with increased US consumption of chemical scents in consumer products (Peck et al. 2006). Due to their use in many consumer products, synthetic musks have also been detected in outdoor air (Peck et al. 2004). Table 2 shows the concentrations of SM in different matrices.

#### **2.3. Triazole Pesticides**

In the 1970s, triazoles were introduced as pesticides and exactly from fungicide class due to their relatively low persistence risk and high antifungal activity (See et al. 2010). Triazole contain five-chain heterocyclic compounds in each one three nitrogen atoms and having at least two double bonds. They work by disrupting the biosynthesis of one of the compounds in the wall of fungi. Among the wild range of triazoles studied, there are; Mesosulfuron-methyl, Fludioxonil, Tebuconazole, Cyproconazole, Triticonazole, Penconazole, Bromuconazole, Hexaconazole, Propiconazole, Fluquinconazole, Triadimenol, myclobutanil, and Epoxiconazole. Myclobutanil, for example, is a preventive and curative fungicide with multiple diseases. It acts by inhibiting the demethylation of sterols, thus blocking the synthesis of ergosterol necessary for the proper development of fungi. Tebuconazole is very effective against many cereal diseases. In other side, triazole fungicides can give rise to endocrine-related side effects on humans and fauna (Zam et al. 2003).

Despite the fact that their use provides undeniable benefits by increasing agricultural production, however, pesticide residues can be found in food and constitute a potential risk for consumers. Moreover, owing to their characteristics such as the high chemical and photochemical stability also low biodegradability and easy transport in the environment, gives them back persistent in soil and water (Bromilow et al. 1999; Wang et al. 2011).

# **3. DETECTION TECHNIQUES FOR ORGANIC POLLUTANTS**

#### **3.1. Gas Chromatography**

Gas chromatography (GC) is a separation technique that applied to gaseous compounds or compounds that can be vaporized by heating without decomposition (Santos et al. 2002). Since its introduction in the 1960s, GC has been quickly used for the analysis of pesticide multi-residues, thanks to the high selectivities and sensitivity that can be achieved. It is generally used for the analysis of thermostable, volatile or semi-volatile molecules, or moderately polar (Santos et al. 2002). Today, GC is applied to approximately 60% of the pesticides and their metabolites available on the market. The development of capillary columns has greatly contributed to the significant increase in separation power. The possibility of using sensitive and selective detectors also contributed to the rise of the GC (Van der Hoff et al. 1999).

It is indeed compatible with many detectors: Flame ionization detector (FID), the thermoionic detector (TID) or the electron capture detector (ECD). The FID is considered to be the least selective detector for the analysis of pesticides. The EDC is particularly suitable for the analysis of electronegative compounds including many halogenated pesticides. Detection limits can be up to a hundred times lower than those obtained with an FID detector. The thermionic detector is used for molecules composed of nitrogen and phosphorus atoms such as pesticides from the triazine family and organophosphates (Santos et al. 2002; Tanabe et al. 2005).

# **3.2. High Performance Liquid Chromatography**

High performance liquid chromatography (HPLC) makes it possible to separate the constituents of a mixture based on the selective distribution of the analyses between a liquid mobile phase in which they are soluble and a stationary phase which exerts on them a retarding effect. It allows the separation of a large number of compounds and in particular those which are thermosensitive (Thammana et al. 2016).

To the triazole detection, HPLC seems to be the most suitable separation method for pesticides for the accuracy and precision of detection. Among the different types of existing liquid chromatography, the reverse phase partition one is specifically useful in pesticide analyses.

In general, the choice of the detection system depends closely on the nature of the solutes to be sought and their concentrations. The detection systems coupled to the chromatography are varied and each has specific sensitivities. Only the mass spectrometer offers universal detection of a majority of molecules, it is a powerful tool with high sensitivity and high specificity (Malviya et al. 2010).

# **3.3. High Performance Liquid Chromatography Coupled to Mass Spectrometry Detector and Quadrupole Time of Flight Analyzer (HPLC-MS-QTOF)**

For triazole detection, the best analytical instrument used is the HPLC-MS-QTOF named also HPLC-MS en tandem. It was largely cited in bibliography due to its high selectivity, sensibility and rapidity (Hernàndez et al. 2005; Baker et al. 2004; Jin et al. 2007; Xu et al. 2019).

#### *3.3.1. Mass Spectrometer*

Mass spectrometry is a physico-chemical analysis technique used to detect, identify and quantify molecules of interest by measuring their mass. Its principle lies in the separation in the gas phase of charged molecules (ions) according to their mass / charge ratio  $(m / z)$ . In addition, mass spectrometry allows characterization the chemical structure of molecules by fragmenting them. Mass spectrometry consists in a first step to produce ions of the desired molecule in the gas phase (Figure 1). We obtain the mass spectrum of the molecule,  $m / z$  as a function of intensity, with m the mass and z the charge carried by the ion or the fragment (Wilhelm et al. 2003; Medhe et al. 2018).

The composition of a mass spectrometer is as follows:

- A source of ionization allowing the passage in the gas phase of the sample but also the ionization of molecules
- An analyzer allowing to separate the ions according to their m / z ratio,
- A detector transforming the impact of ions into an electrical signal.

Figure 1. Mass spectrometer (Neetu et al. 2012).

# **3.3.1.1. Ionization Source: Electrospray Ionization Source (ESI)**

Electrospray ionization has become the interface of choice for studies of dissociation in the source and in the collision cell of organic compounds in tandem mass spectrometry, due to its ability to ionize macromolecules and its strong field of application.

# **3.3.1.2. Electrospray History**

The action of an electric field on a liquid is a phenomenon known since the end of the 19<sup>th</sup> century. Lord Rayleigh was the first to describe the instability of a charged droplet in 1882.

A liquid subjected to a sufficiently strong electric field polarizes. The liquid then containing an excess of charges takes the form of a cone, which emits a jet of liquid at its tip. The liquid jet, then forms a multitude of charge droplets in order to compensate for the instability of the charged liquid by surface tension forces. The first scientific observation of this phenomenon was reported by the physicist John Zeleny in 1914. The interaction between a liquid and an electric field was physically described 50 years later by Taylor. Finally, it was Malcolm Dole's experiments in the late 1960s and early 1970s who suggested that the electrospray mechanism could be used to measure high masses of molecules. Electrospray analysis of polymers such as polystyrenes resulted in the formation of single and multicharged ions. It was in 1984 that Yamashita and Fenn successfully reported the coupling of an electrospray ion mass spectrometer with a quadrupole (Yamashita et al. 1984). They demonstrate with this device that ions can be obtained without fragmentation from nonvolatile molecules. A little later, the first examples of biomolecule spectra obtained by electrospray appear.

#### **3.3.1.3. Desolvation/Ionization Mechanism**

The principle of the ESI is developed in three stages, making it possible to obtain, at the end, single or multi-charged ions in the gas phase.

- 1. Electrospraying of the liquid in the presence of an electric field creating charged droplets,
- 2. Coulomb explosion of charged droplets activated by strong desolvation of the liquid,
- 3. Consecutive disintegration (fission) of the charged droplets leading to highly charged micro-droplets emitting solvated ions in the gas phase, which will be released from the residual solvent in the desolvation zone.

#### **3.3.1.4. Electro-Nebulization of Liquid under Influence of an Electric Field**

The solution is injected at a low flow rate  $(10 \mu L \text{ min}^{-1})$  via a very fine introduction capillary  $(0.75 \mu m)$  internal diameter). This capillary is separated a short distance  $(3 \text{ cm})$  from a counter-electrode whose opening allows the passage of ions to the analyzer. A potential of 2 to 5 kV is then applied either to the capillary or to the counter-electrode, thus creating an electric field of high intensity at the level of the capillary (Bruins et al. 1998).

The value of this electric field can be evaluated, in the absence of a solution, by equation 1, where Vc represents the voltage applied to the capillary, d the distance separating the counter electrode from the capillary and rc the internal radius of the capillary.

$$
E_c = \frac{2Vc}{rc \ln rc(4d)}\tag{1}
$$

This relation indicates to us that the field Ec is proportional to Vc and inversely proportional to rc. Under the effect of the electric field (positive for the study of positive ions and negative for that of negative ions), ions of the same polarity migrate to the surface of the liquid.

The polarity of these ions is fixed by that of the potential applied (positive or negative) to the introduction capillary or to the counter electrode. For example, as far as we are concerned, charges in positive mode are redistributed in the liquid, creating an excess of positive ions on its surface (Tang et al. 1999) and negative charges are eliminated. The surface of the liquid is thus deformed by the accumulation of positive charges on its surface.

This phenomenon is the consequence of the opposition of two opposite forces: one of electrical origin attracting positive ions to the surface of the liquid, the second of mechanical origin preventing the ions from escaping from the liquid. The shape of the surface of the liquid thus becomes conical; it is the Taylor cone (Wilhelm et al. 2003; Tsuchiya et al. 1998).

#### **3.3.1.5. Factors Influencing Ionization**

Electrospray ionization is a process by which polar and ionic species solution can be converted into ions in the gas phase. A large number of instrumental and experimental factors control the process of ionization.

Despite the debates over the theoretical characteristics describing the theory of the Electrospray Ionization Mass Spectrometry (ESIMS), the experimental dependencies are not concentrated on a factor, but rather on a series of variables. Indeed, the variables surrounding the solution, the gas phase and the transition between them influence the ionization process. The ESI strongly depends on the chemistry of the solution (pKa, conductivity and surface tension), electrophoretic migration, proton affinity and molecular structure of the analyte, as well as the experimental conditions used, such as the composition of the solution (pH, type of additives and the ratio of organic solvent / aqueous solvent), interface parameters (voltage, gas flow rate and geometric configuration), and mass spectrometer parameters (temperature, voltage and type of orifice) (Andries et al. 1988).

#### *3.3.2. QTOF Analyser*

The performance of an analyzer is linked to its limit of the mass-to-charge ratio of the analyzable ions (m/z), its ion transmission and its resolution.

The transmission is the ratio between the number of ions arriving at the detector and that produced in the source. For example, a quadrupole (scanning) or time of flight analyzer will transmit ions differently during the analysis. Finally, the resolution corresponds to the ability to provide signals that can be distinguished for two ions of neighboring masses. We admit that two peaks are resolved when the intensity of the valley between these peaks is equal to 10% of the intensity of the weakest peak (we will speak of resolution at 10%). The resolution for an isolated peak is calculated by the ratio between the width of the peak δm at 10% of its maximum and mass.

Q-TOF is the most performant analyzer due to its capacity to analyse higher molecular weight (Allen et al. 2019).

The Q-TOF-MS is a 'hybrid' instrument combining quadrupole technologies with a timeof-flight mass analyzer. It works by accepting ions coming from quadrupole, where they will be reaccelerated inside the ion modulator region of the time-of-flight analyzer and by an electric field ion are pulsed and accelerated orthogonally to their original direction (Chernushevich et al. 2001). Then, ions having captured the same kinetic energy come in the flight tube where ions mass separation will take place which is a field free drift region where mass separation occurs. Ions revealing a lighter mass will acquire a shorter time of flight than the heavier ones. Modern time-of-flight analyzers use a reflective device which cares for adjusting the kinetic energy dispersion and spatial extended of ions present the same *m/z* but different velocities and contribute to the same *m/z* arrival at the detector at the same time.

# **4. EXTRACTION TECHNIQUES OF ORGANIC POLLUTANTS**

#### **4.1. Soxhlet Extractor**

In 1879 von Soxhlet developed an extraction system which has long been the most widely used technique (Jensen et al. 2007). Indeed, extraction with the Soxhlet extractor has been a standard technique for more than a century. It allows the treatment of solid samples of all particle sizes with organic solvents. The solid matrix is introduced into a cellulose cartridge fixed on a solvent container which is surmounted by a coolant (Figure 2). The heat solvent is vaporized then condensed at the level of the tank and remains in contact with the solid. When the volume of solvent condensed in the tank reaches a certain level, the solvent goes back into the tank heater by a siphon phenomenon to be recondensed again while entraining the compounds of interest in the tank where they will finally be concentrated after several cycles of extraction (Wang et al. 2006).

Figure 2. Schematic diagram of soxhlet extractor (Aris et al. 2014).

#### *4.1.1. The Advantages and Disadvantages of Soxhle Extraction*

The advantages of the Soxhlet extractor are as follows: the sample quickly comes into contact with a fresh portion of the solvent, which helps to shift the transfer equilibrium towards the solvent. This method does not require filtration after extraction. The Soxhlet is independent of the solid matrix (Luque de Castro et al. 2010).

The most significant drawbacks of this method, compared with other conventional techniques are: the long extraction time and the large amount of solvent consumed, which not only leads to economic losses but also poses environmental problems. As the samples are brought to a high temperature for a relatively long period, the risk of thermodestruction of certain compounds should not be overlooked if the organic matter contains thermolabile compounds.

Given the large amount of solvent used, the subsequent evaporation/concentration step becomes limiting. Local warm-ups are also possible. This technique is limited from the point of view of the selectivity of the solvent and is not easily automated (Luque de Castro et al. 2010).

### *4.1.2. Example of Study 1: Distribution of Organochlorine Pesticides in Sediment Cores from the Bizerte Lagoon (Tunisia) (Necibi et al. 2019)*

The Bizerte Lagoon is one of the most economically important areas in Tunisia, known as a fishery and aquaculture parks related to the presence of three mussel sectors. It is subject to intensive industrial activities such as oil refineries, metallurgical activities, naval constructions and tire productions (Ben Ameur et al. 2013)(Figure 3).

The analysis of the OCPs in the different sediment layers was carried out in two sediment cores (SCs) results and average compositions of studied compounds are presented in Table 3. Levels of OCPs for SC1 and SC2 ranged between  $26.98 \pm 0.04$  and  $11.65 \pm 0.02$  ng g<sup>-1</sup> at 3cm depth and varied between  $14.48 \pm 0.03$  and  $1.47 \pm 0.02$  ng g<sup>-1</sup> at 20 cm depth. The pp' DDT and its metabolites pp' DDD and pp' DDE were higher than other OCPs investigated in this study. The sedimentary profile observation shows low concentrations of OCPs in the deeper sediments notably in SC2. The comparison of the contamination in the deep sediments with that of the superficial sediments in SC1 shows a decrease in the concentrations of the OCPs and the ΣDDT down to the bottom of the SCs. The OCPs concentrations remain relatively height at 9 and 12 cm depth (Table 3). The vertical evolution of the organic matter in sediments shows, on the majority of the SCs, a decrease of the TOC contents with the depth. Higher TOC contents in SC1 than in SC2 could greatly contribute to OCPs accumulation due to their high affinity for organic matter (Table 3). The increase in the organic matter, content promotes the accumulation of hydrophobic pollutants. Therefore, sediments rich in organic matter have a better ability to retain the hydrophilic pollutants.

Figure 3. Study areas with sampling locations in the Bizerte Lagoon (Necibi et al. 2019).

*4.1.3. Example of Study 2: Distribution of Organochlorine Pesticides in Suspended Particulate Matter and Sediment from the Bizerte Lagoon, Tunisia (Necibi et al. 2019)*

#### **4.1.3.1. Residual Levels of OCPs in SPM**

The concentrations of OCPs compounds in SPM samples are summarized in Table 4. Levels of total OCPs ranged from 0.91 to 15.15 ng  $g^{-1}$  in SPM. The less contaminated stations of SPM were S1, S3 and S5 with ∑OCPs concentration 0.91, 3.65 and 3.30 ng  $g^{-1}$ respectively. The most polluted stations of SPM were S9, S10 and S13 with ∑OCPs concentrations 13.74, 15.15 and 12.94 ng  $g^{-1}$ , respectively. The highest concentration of OCPs in the SPMsamples was 15.15 ng  $g^{-1}$  recorded for station S14, while the lowest one was 0.91 ng  $g^{-1}$  observed at station S1. It could be explained for station S1 by the exchange of water between the lagoon and the Mediterranean Sea, which reduced the concentration of such type of organic contaminants. Station S14 was near the city of Menzel Abderrahman which receives direct inputs of untreated urban and industrial sewage (Figure 4). The ∑DDT represented the sum of pp' DDD, pp' DDE and pp' DDT. The ∑DDT were detected in five sampling stations from the Bizerte Lagoon SPM samples. The highest level of ∑DDT was observed in S5 (5.05 ng  $g^{-1}$ ) near the mouth of Tinja River which represent a dumping site for agricultural inputs.

Figure 4. Study areas with sampling station and different types of industrial areas (A, B, C and D) in the Bizerte Lagoon (Necibi et al. 2019).

#### **4.1.3.2. Residual Levels of OCPs in Sediment**

Fourteen samples of superficial sediments were analyzed. The results of the OCPs analysis are summarized in Table 4. HCB and pp' DDE were detected in the thirteensampling station. The highest concentration of ΣOCPs was registered in station S5 (16.29 ng  $g^{-1}$ ) while the lowest concentration was recorded at station S3 (0.09 ng  $g^{-1}$ ). Relatively high concentrations of  $\Sigma OCPs$  (15.96 ng g<sup>-1</sup>) were also found in station S10 located in Zone D which is characterized by significant industrial and agricultural activities. The levels of pp' DDT and its metabolites in this study varied in the order of pp' DDT> pp' DDE> pp' DDD. The levels of ΣDDT obtained varies between 0.03 and 13.49 ng g<sup>-1</sup>, between ND and 8.89 ng  $g^{-1}$  for pp' DDD and between ND and 3.66 ng  $g^{-1}$  for pp' DDE. The highest concentration of pp' DDT (8.79 ng g-1 ) was recorded in station S5. This station is close to zone B characterized by industrial activities (cement and metallurgy). The TOC% in sediment ranges from 0.05% recorded in station S3 to 5.22% recorded in station S5. The TOC% found in the different stations are presented in table 4. The lowest percentages of TOC% are founded at stations S12 (0.43%), and S13 (0.47%), these two stations are therefore considered the least rich in organic matter. The TOC % of the rest of the sediment samples are also considered relatively low  $\left( < 2\% \right)$ .

**Table 4. Concentrations of OCPs in SPM and sediment (ng g-1 ) collected from the Bizerte Lagoon**

# **4.2. Liquid-Liquid Extraction (LLE)**

Liquid-liquid extraction (LLE) is an ancient enrichment technique based on the distribution of analytes between two immiscible liquid phases, usually an aqueous phase, which contains a polar solvent, for example, water, and an organic phase non-polar which contains an organic solvent. The purpose of the extraction is to transfer analytes from the water to a more suitable solvent for injection into the gas chromatograph and at the same time increasing the concentration of the analytes. Depending on the distribution coefficients of the analyte between the two phases, the extraction can be more or less complete. In addition, its selectivity is low and non-polar solvents can extract the analytes from the aqueous matrix, so that interference may occur during the analysis.

#### *4.2.1. The Advantages and Disadvantages of Liquid-Liquid Extraction*

The advantages of LLE are its simplicity, which allows rapid development of the method, however the extraction time is quite long, it uses a large amount of solvents (some are very expensive and sometimes toxic), it does not meet the current requirements of green chemistry (Robles-Molina et al. 2013) it has not been automated and the risk of emulsion formation is high.

*4.2.2. Example of Study: Distribution and Partitioning of Aliphatic Hydrocarbons and Polycyclic Aromatic Hydrocarbons between Water, Suspended Particulate Matter, and Sediment in the Harbours of the West Coast of the Gulf of Tunis (Tunisia) (Mzoughi et al. 2011).*

Harbors of la Goulette, Rades and Sidi Bou Said are the principal largest and most important port within the Gulf of Tunis characterised by an instantaneous influence of various activities (sailing, industry and fishing) to the Mediterranean (Figure 5).

Figure 5. Location map of studied samples (Mzoughi et al. 2011).

Concentrations of total aliphatic hydrocarbons (PAH) in water and SPM samples ranged from 251.4 ng L<sup>-1</sup> to 1096.5 ng L<sup>-1</sup> and from 3976 ng g<sup>-1</sup> to 10 067.7 ng g<sup>-1</sup> respectively in summer and from 311.5 ng L<sup>-1</sup> to 1054.3 ng L<sup>-1</sup> and from 1299 ng g<sup>-1</sup> to 12 484 ng g<sup>-1</sup> respectively in winter (Tables 5 and 6). The highest concentrations of PAH in water and SPM in summer and in winter were recorded for station P1 of la Goulette harbour and therefore the lowest level of PAH was recorded for station SB3 of Sidi Bou Said harbour. In fact, the distribution of aliphatic fraction (F1) in water and SPM varied from 24% to 63% of total hydrocarbons (average 50%) and from 42% to 69% (average 60%) respectively in summer and from 46% to 85% of total hydrocarbons (average 66%) and from 38% to 88% (average 65%) respectively in winter. Percentages of aliphatic fraction (F1) in water and SPM found during the summer and winter were statistically significantly different ( $p < 0.05$ ). Total PAH concentrations in water and SPM samples varied from 149.8 ng  $L^{-1}$  to 1008.3 ng  $L^{-1}$  and from 2573.5 ng g<sup>-1</sup> to 8222.4 ng g<sup>-1</sup> respectively in winter and from 139.2 ng L<sup>-1</sup> to 693.8 ng L<sup>-1</sup> and from 909.9 ng  $g^{-1}$  to 5858.2 ng  $g^{-1}$  respectively in summer (Tables 5 and 6).

# **Table 5. Concentration of aliphatic (AH), polycyclic aromatic (PAH) in sediment (ng g-1 ) and different ratios characterizing the origin of hydrocarbons**

# **Table 6. Concentration of aliphatic (AH), polycyclic aromatic (PAH) in SPM (ng g-1 ) and different ratios characterizing the origin of hydrocarbons**

Pristane to phytane: Pr/Ph, phenanthrene to anthracene: Phe/An, fluoranthene to pyrene: Fl/Py, benz(a)pyrene to benz(e)pyrene: BaP/BeP, benz(a)anthracene to chrysene: BaA/Chr and Total toxic benzo(a)pyrene equivalent: Total TEQ. Rades (Rd), La Goulette fishing (P) and passenger (G), and Sidi Bou Said (SB).

As for AH the highest concentrations of PAH in water and SPM were observed for station P1 in La Goulette harbour and the lowest levels at station SB3 in Sidi Bou Said harbour. The distribution of PAH concentrations in water and SPM varied within the range of 36% to 76% (average 50%) and 26% to 58% (average 41%) respectively in summer and between 19% to 54% (average 34%) and 12% to 62% (average 35%) respectively in winter. Percentages of PAH in water and SPM found during the summer and winter were statistically significantly different ( $p < 0.05$ ). The reduced AH and PAH water concentrations within the least stations could also be explained by the transfer of hydrocarbons to SPM and to decantation and accumulation in the marine sediments. This accumulation might be associated with the sediment's characteristics, seawater flux and other physical parameters.

### **4.3. QuEChERS Extraction Method**

A new trend in analytical chemistry is the development of "ecological" methods of sample pre-treatment, which are solvent-free or minimize the amount of solvent used; they must be at the same time, faster and more selective than conventional procedures (Pinto et al. 2010).

Figure 6. Schematic representation of a QuEChERS procedure applied to environmental samples (Tette et al. 2016).

The QuEChERS procedure, an acronym for the quick; cheap; effective; robust and safe was developed by Anastassiades and his colleagues in 2003 (Anastassiades et al. 2003). It has been used as a new approach to extract pesticides from fruits and vegetables. Since then, it has become a very versatile technique and has been adapted to a wide range of substances and matrices (Lesueur et al. 2008; Norli et al. 2011). This procedure is a simple sample preparation technique based on liquid extraction with an organic solvent followed by cleaning using dispersive solid phase extraction.

The principle of the QuEChERS method reveals three main stages:

- 1. The first step consists of a liquid / solid extraction of the sample with manual stirring for one minute with an organic solvent.
- 2. The second step consists in adding a buffer and salts to promote the separation of the two organic and aqueous phases and also the preferential transfer of organic pollutants to the organic phase. This step is particularly important if the sample contains a large amount of water. When analyzing dry sediments, this step may not

be considered. The sample is then centrifuged and the collected supernatant is optionally concentrated.

3. The third step is to purify the extract on different solid phases. It is carried out by adding one or more adsorbents (C18, primary and secondary amine adsorbent (PSA)). The mixture is then stirred manually for one minute. The interfering compounds of the matrix will become trapped on the adsorbents. The supernatant is recovered for analysis (Romero-Gonzalez et al. 2011). Figure 6 shows an example of the QuEChERS procedure applied to environmental samples.

#### *4.3.1. The Advantages of Extraction with QuEChERS*

This method offers many advantages. First, it appears as effective and robust as conventional extraction methods (Soxhlet, ultrasound, etc.). The method replaces many complex analytical steps commonly used in traditional methods, and provides high quality results with a short analysis time (10 min as extraction time), low amount of solvent, minimum of glassware used, little of work and low cost of analysis by sample (Pinto et al. 2010).

This extraction technique is considered to be relatively gentle (extraction with an organic solvent and mechanical stirring) thus minimizing the risks of extraction of interference and a priori simplifying the chromatographic analysis. The QuEChERS technique provides good recovery and reproducibility and is much cheaper than other sample preparation techniques.

# *4.3.2. Example of Study 1: Determination of Synthetic Musks in Surface Sediment from the Bizerte Lagoon by QuEChERs Extraction Followed by GC-MS (Necibi et al. 2016)*

The QuEChERS method was then applied for the determination of SMs compounds for thirteen surface sediment samples collected from the Bizerte Lagoon (Figure 7). The concentrations found for SMs were presented in table 7. For HHCB and AHTN, concentrations were 1.09-2.8 ng  $g^{-1}$  and 0.31-1.7 ng  $g^{-1}$ , respectively. The concentration levels for ADBI, AHTN, ATII, MM, MX and MK were clearly below the LOQ (Table 7).

Figure 7. Study areas with sampling locations and different types of industrial areas (A, B, C and D) in the Bizerte Lagoon (Necibi et al. 2016).

<LOD: Below limits Of Detection.

The highest concentrations of  $\Sigma$ SMs were found at the station S1 (3.0 ng g<sup>-1</sup>) and S2 (4.5 ng g-1 ) in the mouth of the Bizerte channel and were slightly higher along the channel in comparison with the rest of the stations. The concentration of  $\Sigma$ SMs was 2.3 ng g<sup>-1</sup> at S11 and 1.4 ng  $g^{-1}$  at S10 and S13, respectively. The predicted no effect concentration (PNEC) in sediment for marine organisms was set at 8.4 mg/kg dw for HHCB and at 5.2 mg/kg dw for AHTN (HERA 2004). The levels of HHCB and AHTN investigated in this study were much lower that the PNEC. In order to take into account variable input of organic matter in surface sediment from Bizerte Lagoon its influence on SMs concentrations, TOC were measured in the sediment of the different sampling stations (Table 7). The highest TOC % was recorded in sampling site S5 (5.22 %), while the lowest was found in S11 (0.43 %). The SMs in marine environment were subject to different degradation process which could explain the absence of relationship between synthetic musk concentrations and TOC.

#### **4.4. Solid Phase Extraction (SPE)**

#### *4.4.1. Definition of SPE*

Solid phase extraction (SPE), first introduced in the mid-1970s, is the most widely used technique today when analyzing traces in liquid samples (Sabi et al. 2000). It is a powerful and necessary tool for the development of methods for analyzing organic pollutants at very low concentrations in water. Since its introduction into the sample pretreatment protocols, this method has undergone many modifications and adaptations depending on the nature of the analytes to be extracted and according to the objectives to be achieved moreover (SPE), is certainly the most commonly used extraction and purification technique for aqueous or organic matrices. The goal is to isolate and concentrate the analytes from the matrix and obtain an extract which can be injected on an analytical device. The SPE was developed to replace the long, tedious and hard to reproduce liquid-liquid extraction methods. The basic principle of SPE is that one of liquid chromatography. In chromatography, the migration of the various families of molecules is slowed down by selectively retaining them on an adsorbent, in SPE these same molecules are blocked on this adsorbent and then they are selectively eluted with a specific solvent.

#### *4.4.2. SPE Protocol*

The extraction protocol on an SPE cartridge includes several steps.

Activation of the adsorbent

This involves percolating through the column a few mL of an appropriate solvent, such as methanol, for adsorbents based on grafted silica, or an acid / base solution for ion exchangers.

• The conditioning of the adsorbent.

In order to obtain an adsorption environment similar to that of the water sample, the activated adsorbent is washed with a few mL of demineralized water or a suitable buffer solution.

Application of the sample.

It consists in passing a volume of water through the pre-concentration column. The interesting solutes are fixed on the adsorbent.

Purification

Extraction on a solid phase is unfortunately not always selective enough, which means that there will be other compounds which will be trapped by the adsorbent. Some interferences can be eliminated by applying a washing solution consisting of water and a small proportion of an organic solvent.

• Drying

The drying step is necessary in the case where the solvent for elution of the trapped solutes is not miscible with water. The drying is carried out by a water bath.

Desorption

It is a question of recovering the fixed solutes by eluting them with a small volume, either of a hydro organic mixture, or of pure organic solvent.

*4.4.3. Example of Study 1: Response Surface Methodology Approach for the Preparation of a Molecularly Imprinted Polymer for Solid Phase Extraction of Fenoxycarb Pesticide in Mussels (Atayat et al. 2019)*

The SPE was widely applied in various ways for the extraction of different analytes from water (Sanchís et al. 2012; Székács et al. 2015; Binsalom et al. 2016), soil (Yegemova et al. 2015) and environmental matrix (Faraji et al. 2019). The solid-phase extraction was developed using molecularly imprinted polymer (MISPE) for the analysis of fenoxycarb (Fnx) pesticide from mussel's sample. In this work, the optimization of the MIP synthesis for the recognition of Fenoxycarb was performed toward two factors, VACN and QEGDMA, using the ED approach. The Response Surface Methodology approach demonstrated to be useful for the determination of the optimum polymer that was obtained with VACN of 2.2 mL and QEGDMA of 1.345 mmol. Finally, the optimum MIP showed good selectivity properties compared to other carbamates and was successfully used as sorbent of a MISPE cartridge for the determination of Fnx in real mussel samples. The range of linearity was 0.3– 30 mg/L of Fnx  $(R2 = 0.991)$ , with a LOD value of 0.247 mg/L. The recovery of Fnx extracted from mussel samples of the Mediterranean Sea was around 97% ( $n = 3$ ) with RSD between 6 and 7%, proving the reliability of the developed method. Therefore, the MISPE device developed in this work can be a promising alternative for the selective extraction and analysis of Fnx from mussel samples.

# **5. DETECTION TECHNIQUES OF INORGANIC POLLUTANTS**

#### **5.1. Heavy Metal**

Metals occur naturally within the crust, and their contents within the environment can vary between different regions leading to spatial variety of background concentrations. The distribution of metals within the environment is governed by the properties of the metal and influences of environmental factors (Morais et al. 2010). Of the 92 present elements, approximately 30 metals and metalloids are potentially toxic to humans, Be, B, Li, Al, Ti, V, Cr, Mn, Co, Ni, Cu, As, Se, Sr, Mo, Pd, Ag, Cd, Sn, Sb, Te, Cs, Ba, W, Pt, Au, Hg, Pb, and Bi. Heavy metals are that the generic term for metallic elements having a relative mass above 40.04 (the mass of Ca) (Ming-Ho et al. 2005). Heavy metals enter the environment by natural and anthropogenic means. Such sources include: natural weathering of the earth's crust, mining, erosion, industrial discharge, urban runoff, sewage effluents, and pest or disease control agents applied to plants, pollution fallout, and variety of others (Ming-Ho et al. 2005). Although some individuals are primarily exposed to those contaminants within the workplace, for several people the foremost route of exposure to those toxic elements is through the diet (food and water) (Yuan et al. 2004). The contamination chain of heavy metals nearly always follows a cyclic order: industry, atmosphere, soil, water, foods and human. Although toxicity and thus the resulting threat to human health of any contaminant are, of course, a function of concentration, it's well-known that chronic exposure to heavy metals and metalloids at relatively low levels can cause adverse effects Agency for Toxic Substance and Disease Registry (ATSDR). Therefore, there has been increasing concern, mainly within the developed world, about exposures, intakes and absorption of heavy metals by humans (Che et al. 2002).

#### **5.2. Atomic Absorption Spectrometry**

Atomic absorption spectrometry (AAS) was a technique during which free gaseous atoms absorb electromagnetic radiation at a selected wavelength to supply a measurable signal. The absorption signal is proportional to the concentration of these free absorbing atoms within the optical path. Therefore, for AAS measurements the analyte must be first converted into gaseous atoms, usually by application of warmth to a cell called the atomizer. The type of atomizer defines the two main AAS-based analytical techniques: flame AAS (FAAS) that gives analytical signals during a continuous fashion and electrothermal AAS (ETAAS) delivering analytical signals in a discontinuous mode (2–4 min per sample). In both cases, liquid (or dissolved) samples are easily introduced into the analyzer, as an aerosol in the case of FAAS or as well-defined low microliter volumes in ETAAS. Furthermore, the coupling of hydride generation and cold vapor methods allow the introduction of analytes in the atomizer as a gas phase. Also, especially in ETAAS, direct elemental analysis of solids without previous dissolution is possible (Luisa et al. 2005).

The analytical application of AAS was considerably delayed due to the apparent need for very high resolution to form quantitative measurements (typical atomic absorption lines could also be narrower than 0.002 nm, while themonochromators capable of isolating spectral regions narrower than 0.1 nm are rather expensive (Fernández et al. 2006). In 1955 Walsh (Australia) overcame this obstacle with a light source emitting narrow lines. The use of the hollow cathode lamp (HCL) as the light allowed the demonstration of the analytical applicability of AAS measuring the radiation absorbed by atomic vapor during a flame. The idea was pursued independently by Alkemade in the Netherlands and Walsh in Australia, their works being published in 1955 (Fernández et al. 2006). Nowadays, AAS is routinely employed for elemental analysis of about 70 elements. Fundamentals, key components of atomic absorption spectrometers and analytical performance characteristics of AAS-based techniques are briefly described below (Thomas et al. 1994).

# *5.2.1. Example of Study 1: Assessment of Heavy Metals in Sediment and in Suspended Particles Affected by Multiple Anthropogenic Contributions in Harbors (Chouba et al. 2011).*

Metal concentrations in summer and winter found in sediment harbours varied between  $(1.586-0.242 \mu g g^{-1}dw$  (dry weight)) for Cd,  $(527-70 \mu g g^{-1}dw)$  for Zn,  $(246-12 \mu g g^{-1}dw)$ for Pb,  $(132-70 \,\mu g \, g^{-1} \, dw)$  for Cu,  $(45-25 \, mg \, g^{-1} \, dw)$  for Fe and  $(281-173 \,\mu g \, g^{-1} \, dw)$  for Mn (Figure 5). Concentration difference test was carried out for the heavy metals in sediment between the four sampling areas. Significant result differences  $(P(0.05)$  showed an equivalent evolution profile for the following metals: Cd, Pb, Zn and Cu. On the opposite hand, no significant difference was noticed for the Mn and Fe metals. Generally, the highest levels of all metals analyzed in summer and in winter were registered in sediment for all stations from Rades (RD) (industrial area) and La Goulette (P) (fishing) harbors (Figure 8) indicating the presence of local source of contamination. It might be attributed to many reasons as these harbours are characterized by the discharge materials, activities of fishing, antifouling paint and the two steam electrical power plants situated near the harbour and drainage sewage during this zone. The lowest metal contents were measured in Sidi Bou Said harbor (yachting) in summer and in winter sediment, only copper showed a high level after fishing

harbour (P). The levels of Pb, Cu, Zn and Fe were found in SPM. Whereas Cd and Mn weren't detected (Table 8).

Figure 8. Concentrations (µg g<sup>-1</sup>dw) of Cd, Pb, Zn, Cu, Mn and Fe in sediment collected from Rades, La Goulette (fishing and passenger), and Sidi Bou Said (yachting) harbors.

Table 8. Concentrations of Pb, Cu, Fe, Zn, Cd and Mn in the SPM ( $\mu$ g g <sup>-1</sup> ) La Goulette
(fishing and passenger), Rades (commercial) and Sidi Bou Said (yachting) harbors

These activities explained the source of Cu and Zn in SPM. Copper and Zinc based antifouling paints and cathodic protection devices are previously identified as important sources of those metals in estuaries and harbor sediments (Turner et al. 2010). These values observed within the SPM are due probably to the fine particles generated by sanding or blasting of boat hulls or that are produced gradually by antifouling paint (Turner et al. 2010). The levels of Pb, Cu, Zn, and Fe in SPM of varied harbours are much but those found in other harbours. Birch and O'Hea (2007) explained that the high levels of Cu and Zn in SPM caused by the difference of metal dissolutions. However, dissolved Cu concentrations increased with the increasing ambient energy, i.e., from quiescent to high precipitation to high rainfall/high wind conditions, and dissolved Zn concentrations the highest during high precipitation.

# *BIOGRAPHICAL SKETCH*

### *Nadia Mzoughi*

**Affiliation:** She is the Vice President of the University of Carthage in charge of programs, training and international cooperation Ex Director of High Institute of Environmental Sciences and Technologies of Borj Cedria, University of Carthage, Tunisia and professor of chemistry at the same institute.

**Education:** She received the diploma of engineer in analytical chemistry from the Faculty of Sciences of Tunis in 1994 where she completed a master's degree in the same field in 1997, a PhD and a HDR degree.

**Business Address:** UCAR, Avenue de la République-BP 77- 1054. Carthage Amilcar. Tunis. Tunisie E-mail :nadia.mzoughi@isste.run.tn; presidence.univcarthage@gmail.com. +216 71 745 514.

**Research and Professional Experience:** She began her career as a researcher in the marine pollution at the National Institute of Marine and Technologies of the Sea and as member of marine environment research laboratory. She is a member of Environmental Sciences and Technologies research laboratory, of Association of Sea Sciences and Vice president of Tunisian Association of Industrial, Environment and Research. She is a reviewer in many international journals (International Journal of Soil and sediment contamination, The Open Environmental Pollution & Toxicology Journal, Polycyclic Aromatic Compounds, Desalination and Water Treatment, Bulletin of the National Institute of Marine and Technologies of the Sea...). She is the author of more than 30 publications and 50 national and international communications. She participated in many projects essentially with International Atomic Energy Agency (RAF, Med Pol), University of Pau in France and in many Erasmus + projects with different universities (France, Italy, Morocco, Senega)

**Professional Appointments:** Professor, Analytical chemistry, High Institute of Environmental Sciences and Technologies of Borj Cedria, university of Carthage. Vice president of the University of Cartage. Ex Director of the Higher Institute of Environmental Sciences and Technologies, university of Cartage.

# **ABSTRACT**

Pesticides have been extensibility used in the control of agricultural and sanitary pests. From World War II onward, more efficient and cheaper synthetic pesticides, such as organochlorine pesticides (OCPs), including DDT, lindane, or endosulfan, replaced the relatively environmentally friendly pesticides. OCPs were widely used worldwide; however, in the 1970s these compounds were began banned due to their harmful effects on both, biota and humans. Nevertheless, half a century later, due to their high persistence and the existence of some active sources, OCPs remain a problem for the health of marine ecosystems.

Once in the environment, their distribution depends on the interaction of several factors -explained in detail in this chapter- such as the physical-chemical properties of

 $\overline{a}$ 

<sup>\*</sup> Corresponding Author's Email: sunpark@gist.ac.kr.

each compound; interactions with the matrix; characteristics of the environment; and intensity, distance, and seasonality of the source, between others.

This chapter reviews current levels, environmental behavior and fate, and effects on biota of organochlorine pesticides in global marine coastal environments, noting that these compounds are still detectable and could be harmful to marine biota.

**Keywords:** persistent organic pollutants, organochlorine pesticides, DDT, lindane, endosulfan, coastal environments, marine pollution, environmental fate, environmental behavior

## **INTRODUCTION**

Pesticides have been used to control pests in agriculture for over 4,500 years. Until the mid-1900s, inorganic compounds, such as sulfur and copper, and plant extracts were used. In the first decades of the XX century, new synthetic pesticides such as organochlorine pesticides (OCPs) were developed; for instance, during the Second World War, these substances were used to control insect vectors of disease. At the end of the war, OCPs were adapted for pest control in agriculture and public health, being considered a miraculous pesticide due to their high effectiveness and low cost. However, in 1962, Rachel Carson documented the environmental impacts, especially on bird populations, of the widespread use of DDT in the United States, in the famous book "Silent Spring". This publication highlighted the collateral effects of the inappropriate use of some chemical substances and the controversy between benefits and costs that accompany the industrial growth and the welfare state. The publication raised the alarm of public and political opinion, generating environmental movements and massive protests, which ended with the banning, from 1972, of the agricultural use of DDT and other organochlorine pesticides in many countries (Hayes and Hansen 2017).

After the 1960s and 1970s, the harmful effects of pollutants and their presence in the environment began to be studied, and our knowledge of chemicals is quite extensive. However, new substances that threaten the environment are created daily, and sometimes, the discovery of their harmful effects arise too late. This was the case with the OCPs, which despite having been banned or restricted in almost all countries, they are still being detecting in the environment. Moreover, due to their long-term toxicity, sometimes, current environmental levels could pose a risk to biota (Girones et al. 2020) since even when environmental concentrations are low they can cause damage to the biota (Petrovic et al. 2013; Sosa-Ferrera et al. 2013).

Marine pollution processes are one of the most important problems which humanity is facing at present (Lohmann 2007). Among the most affected marine environments, coastal environments stand out as the heaviest chemically polluted. These are the areas where the main aquatic and terrestrial interactions occur. On the one hand, waste or effluents that come from different sources (urban, industrial, or agricultural) are dumped directly (sewage, landfills) or through rivers due to runoff. On the other hand, many coastal environments, especially semi-closed ones such as bays, estuaries, fjords, or coastal lagoons, have great potential to accumulate organic pollutants because the loss of pollutants by export and dilution is limited by the long residence times of water (Diamond et al. 2005), and also

because the adsorbent materials levels, especially organic carbon, are generally high. Further, coastal areas, including coastal wetlands such as coral reefs, mangroves forest, salt marshes, or seagrass beds, are very important to biota and humans because they provide invaluable ecosystem services, such as refuge, cross-ecosystem nutrient transfer, erosion control, and pollution control, between others (Barbier et al. 2011).

Then, considering this complex scenario, this chapter aimed to comprehensively review the available organochlorine pesticides data about their distribution, production, regulation, main current sources, physic-chemical properties, environmental fate and behavior, documented effects on marine biota and humans, and the current levels in global coastal and marine sediments.

# **PRODUCTION AND USE**

The first organochlorine pesticide massively used worldwide was DDT, beginning in 1939 when Paul Hermann Muller discovered its properties as an insect poison and its low toxicity to humans. DDT was indiscriminately used during World War II (1939-1945), to protect soldiers and civilians against insect-borne diseases such as malaria, dengue, and typhus (Wheeler 1946). After the war, the used amounts increased exponentially (Hayes 1991). The effectiveness, persistence, versatility, and low cost turned DDT massive in agriculture, forestry, and public health for 30 years (USEPA 1975). In addition to protecting crops and kill household insects, the use of DDT for public health avoided the death of more than 5 million people per year worldwide. Thus, for example, in India, there were 75 million malaria cases in 1952 and after using DDT massively, only 100,000 cases have been registered in 1964 (WHO 1971). Regarding the agricultural purposes of DDT, it was used in a wide variety of crops, reaching more than 36,000 tons per year until its prohibition or restriction (Hayes and Hansen 2017). Currently, the World Health Organization recommends the use of DDT in areas where malaria is a public health problem due to its effectiveness in its control (WHO 2006), and so that, about 3,300 tons are produced annually worldwide (Hayes and Hansen 2017). Given the proven insecticidal capabilities of DDT, after World War II, other organochlorine pesticides with similar features were synthesized, such as chlordane (1945); aldrin and dieldrin (1948); heptachlor (1949); toxaphene (1949); endrin (1951); endosulfan (1956); hexachlorocyclohexane (HCH and lindane; 1940), and mirex (1950; Kennish 1997). These pesticides showed several uses and applications depending on their characteristics and regions (UNEP 2003). Following DDT, the most popular OCP worldwide was hexachlorocyclohexane (HCH) as lindane (pure  $\gamma$ -HCH) or technical HCH (a mixture of various isomers, including  $\alpha$ -HCH, 55-80%, β-HCH, 5-14%, and γ-HCH, 8-15%), which was used as a broad-spectrum insecticide in seeds, soils, foliage, trees, fabrics, and wood, as well as a treatment against ectoparasites in veterinary and human applications. Voldner and Li (1995) estimated the global use of 550,000 tons of technical HCH and 720,000 tons of lindane between 1948 and 1993. Another group widely used worldwide was the cyclodienes, which includes aldrin, dieldrin, endrin, chlordane, heptachlor, and endosulfan. Aldrin and dieldrin were used as insecticides (1950-1970) to control soil insects, the corn rootworm, the rice weevil, the grasshopper, and for crops of corn, potatoes, and cotton, and for protect wooden structures from termites. Endrin was used as an insecticide in cotton, rice, sugar cane,

corn, and other cereal crops, and as a rodenticide in orchards (Larini 1999; UNEP 2002). Meanwhile, chlordane was mainly used as an insecticide in rice, oilseeds, corn, sugar cane, and citrus crops, and in the control of domestic pests (e.g., cockroaches, ants, and termites). Heptachlor was used primarily in the control of soil insects and termites, and, sometimes, it was used against cotton insects, grasshoppers, and some crop pests, such as sugarcane, as well as to fight malaria. Endosulfan is a broad-spectrum acaricide and insecticide, for agricultural or domestic use, in a wide variety of vegetables, fruits, cereals, and cotton, as well as ornamental shrubs, trees, vines, and ornamental plants (Ulberth 2000), wood preservation (UNEP 2002), and in the control of vectors of diseases such as the tsetse fly (Li and Macdonald 2005). Another important group of OCPs was the cyclopentadienes, including toxaphene and mirex. The first was used intensively (450,000 tons from 1950 to 1993 according to Voldner and Li, 1995) as an insecticide and acaricide in cotton, cereals, fruits, nuts, and vegetable crops, and in the control of ectoparasites in livestock, such as lice, flies, ticks, scabies, and mites. While the second, mirex, was used mainly for the ant's control and, lesser degree, as a flame retardant in plastics, paint, paper, and electrical equipment (UNEP 2002). Meanwhile, the hexachlorobenzene (HCB) has been a fungicide used since 1945 to treat grain crops and to manufacture inks, fireworks, ammunition, and synthetic rubber. This compound is also a by-product of the manufacture of chlorinated industrial chemicals, such as solvents (e.g., carbon tetrachloride, trichloroethane, and pentachlorobenzene) and various pesticides (e.g., pentachlorophenol, dicloram), and the incineration of chlorinated waste.

# **MANAGEMENT**

In 1962, Rachel Carson published "Silent Spring", the first ecological manifesto against the indiscriminate use of organochlorine compounds. There she denounced that the widespread use of DDT could be the main cause of the population reduction of various bird species, many of them occupying the top of the food chain, such as the peregrine falcon and the bald eagle, symbol of the United States (Baird 2018; D'Amato et al. 2002). Because of the results of this and other studies presented by the scientific community, Sweden, in January 1970, was the first country to ban chlorine insecticides (D'Amato et al. 2002). In the same year, the ex-USSR banned the use of DDT as a household pesticide and, in 1981, as an agricultural pesticide, except for use in disease control programs (Turusov et al. 2002). Between 1970 and 1980, the use of pesticides was banned in most developed countries (Kutz et al. 1991). It took a few more years for developing countries to ban or restrict their use, either by their own regulations or by signing international conventions. In 1998, the UN countries signed the Rotterdam Convention, where guidelines for the transport, storage, and disposition of organochlorines were proposed (Hough, 2000). Years later, in 2001, they signed the Stockholm Convention, which entered into force in May 2004, where the progressive elimination or minimization of the use and production and the safe elimination of an initial list of twelve contaminants was proposed. These compounds and those added later are considered persistent organic pollutants (POPs) due to their high environmental persistence, toxicity, and ability to bioaccumulate and transport long distances. Among the POPs listed in the Stockholm Convention are the following organochlorine pesticides: aldrin, endrin, dieldrin, chlordane, heptachlor, DDT, HCB, mirex, and toxaphene, added to the initial list that entered into force in 2004; α-HCH, β-HCH, γ-HCH (lindane), and Chlordecone,

added in 2009; and endosulfan and Dicofol, incorporated in 2011 and 2019, respectively. However, the Stockholm Convention notes exceptions to the use of some pesticides: DDT can be used in the fight against disease vectors when there are no safe, effective, and affordable local alternatives; endosulfan can be used in specific crop and pest combinations; lindane can be used as a second-line treatment for the control of pediculosis and scabies in humans.

# **CURRENT SOURCES TO COASTAL ENVIRONMENTS**

Although the use and production of organochlorine pesticides have been restricted worldwide since the 1970s, the marine environment continues incorporating them. One of the main sources is the continental exports from obsolete reserves and contaminated areas, which act as secondary sources. In a global report published in 2003 (UNEP 2003) and many current national implementation plans, it was observed that information on OCPs stockpiles in most developing countries is poor, scarce, or null (UNEP 2003, Girones et al. 2020). Anyway, the UNEP global report (UNEP 2003) was able to record the existence of large stockpiles in Europe (80,000 tons, mainly in central and eastern Europe) and in Sub-Saharan Africa (120,000 tons). Moreover, agricultural and urban soils where pesticides were used or produced in the past and river sediments associated with these areas constitute deposits that slowly release pesticides into the marine environment, reaching the coastal waters by processes, which will be explained later.

Another current source for the marine environment, probably less important due to its severe restriction, is the use and legal production of some OCPs. These are contemplated in the exceptions of international treaties and some national laws.

Finally, a potentially important source appears to be the illegal use of pesticides in agriculture in some countries (Van Den Berg et al. 2017). Several authors observed patterns between the parent pesticides and their metabolites (e.g., DDT/(DDE+DDD) and technical endosulfan/ endosulfan sulfate) that would indicate recent use of them (Carvalho et al. 2009; Chen et al. 2020; Girones et al. 2020; Jin et al. 2017; Rizzi et al. 2017a).

# **ENVIRONMENTAL FATE AND BEHAVIOR OF OCPS**

Once OCPs enter the environment, their fate, behavior, and spatio-temporal distribution are controlled by a combination of three groups of factors (Mackay et al. 2006). First are the physic-chemical properties of pollutants such as molecular composition, structure, weight, and volume, and solubility in the different media, which influence the partition and reaction trends between environmental compartments and the rate of degradation in other chemical species. Second are the environmental conditions such as temperature, fluxes, and the composition of the various environmental compartments, i.e., air, water, and solids. Third are the patterns of use/release to the environment, such as the periodicity and intensity of the source.

# **Factor: Nature and Physic-Chemical Properties of OCPs**

Organochlorine pesticides are a group of chemicals that share certain structural characteristics. They have a highly chlorinated aliphatic or aromatic cyclic structure, and in some cases are associated with oxygen or sulfur atoms. Consequently, most OCPs are resistant to biological, physical, and chemical degradation. This makes the behavior profiles of the OCPs in the environment, such as the phase distribution and the transport processes, tend to play a fundamental role in the control of their environmental fate and distribution. The variability in these profiles, usually, is attributed to some key physicochemical properties inherent in each chemical compound: solubility in water, solubility in octanol, vapor pressure, the three partition coefficients between air, water, and octanol (Figure 1), and susceptibility to degradation or transformation reactions. Furthermore, other essential molecular descriptors are molar mass and molar volume.x

Solubility is the maximum ability of a solvent, such as distilled water or octanol, to dissolve chemicals. Since most OCPs exhibit low solubility in water, which is even lower in seawater due to the salty effect, up to 5.8 times lower (Cetin et al. 2006), and high solubility in octanol (a compound assimilable to lipids and organic matter) the octanol-water partition coefficient  $(K<sub>OW</sub>)$  is high, i.e., they are hydrophobic and lipophilic.

Meanwhile, the vapor pressure (VP), which can be considered as "air solubility", is the saturation concentration or solute pressure in a gas phase, and is expressed as  $mol/m<sup>3</sup>$ . The relationship between VP and the solubility in water (mol/m<sup>3</sup>) determines Henry's law constant (H; Pa.m<sup>3</sup>/mol) and the partition coefficient between air and water ( $K_{AW}$ ), which is calculated as  $K_{AW} = H/RT$ , where R is the ideal gas constant (8,314 J/mol.K) and T is the absolute temperature (K). Vapor pressure affects the atmospheric transport of the OCPs. Compounds with the higher VP reach longer distances to the source (Muir et al., 1999), therefore, the different congeners of the same pesticide but with different VP, such as the α-,  $β$ -, γ-HCH isomers, leave the atmosphere at different speeds due to precipitation and air-water gas deposition, resulting in discrimination in long-distance transport (Iwata et al. 1993). However, there is a common misconception that substances with very low VP, i.e., "nonvolatile" (or very poorly soluble in the air) such as DDT and other OCPs, cannot partition to the atmosphere (Mackay et al. 2006). This is not necessarily the case because these substances also have low solubility in water, therefore Henry's law constants are relatively high and can be appreciably divided from water to the atmosphere (Mackay et al. 2006). This partition is very sensitive to change in temperature due to the large enthalpy change associated with transfer to the vapor phase, which would explain the global distillation of OCPs, evaporating in warm areas and condensing in cold areas.

Another important partition coefficient to understand the environmental behavior of  $OCPs$  is the octanol-air partition coefficient,  $K<sub>OA</sub>$ , which is mainly used in continental environments to evaluate the diffusive exchange between air and foliage, aerosol particles, or soils (Finizio et al. 1997; Mackay et al. 2006), and is calculated experimentally, although it generally follows this equation:  $K_{OA} = K_{OW}/K_{AW}$ .

In addition to  $K_{\text{OW}}$ ,  $K_{\text{AW}}$ , and  $K_{\text{OA}}$  (Figure 1), other partition coefficients are used to model and predict the environmental fate of OCPs, such as  $K_{OC}$  (organic carbon-water partition coefficient),  $K_D$  (sorption partition coefficient for all the soil on a dry weight basis),  $K_{OM}$  (organic matter-water partition coefficient), and  $K_B$  or BCD (water-to-fish bioconcentration factor). These coefficients are calculated from laboratory or field

measurements or are estimated from the relationship with other coefficients, for example,  $K_{OC}$ is often estimated to be equivalent to  $0.35$  K<sub>OW</sub> (Seth et al. 1999), K<sub>OM</sub> is  $0.56$  K<sub>OC</sub> (i.e., 56%) organic carbon in organic matter; Mackay et al. 2006), and  $K_B$  is 0.05 Kow (i.e. 5% lipid in fish; Mackay 1982). However, these estimates can vary considerably from the real values due to the complexity of the matrices and environmental conditions, either due to the variation in pH, content and type of organic carbon, temperature, pollutant concentration, polarity, and age, or the metabolic capacity of the organisms, and so that, care must be taken when using them.

Figure 1. Diagram of relationships between the three solubilities  $(C_A, C_W, C_O)$  and the three partition coefficients  $(K_{AW}, K_{OW}, K_{OA})$ .

Another characteristic that notably affects the environmental fate and distribution of OCPs is their half-life in the environment. Since this is affected by the nature of the compartments and the environmental conditions, it is impossible to document a single reliable value for this parameter. However, a quite reliable half-life range can be established for each compound. Hence, Table 1 summarizes the ranges for the half-life of the OCPs estimated for average environmental conditions according to Mackay et al. (2006) for the main abiotic media: air (A), sediment (S), and water (W). Given the different exposures to weathering agents, in general, the OCPs half-life class in water is 3 times higher than in air (30 times slower degradation) and the half-life class in sediments is 2 times higher than in water; i.e., if the half-life class in the air is 2, in water will be 5 and in sediments will be 7. This is summarized and shown in Table 1, in conjunction with the structure and physicochemical properties of parent OCPs and their main metabolites.

#### **Factor: Environmental Characteristics and Conditions**

As mentioned above, knowing the physicochemical properties of OCPs is not enough to understand and predict their behavior and environmental fate, it is also necessary to know the advective transport, the phase heterogeneity, and the prevailing environmental conditions (Ciffroy 2018). Advective transport is understood as the transport of the pollutant given by the movement of the phases in which it is dissolved or associated, for example, the movement of air masses and water in a river or ocean currents, and sedimentation or sediment resuspension (Figure 2). While the heterogeneity of the phases is understood as the presence of different fractions or domains within the same environmental compartment (atmosphere, water, soil, or sediment; Figure 2). The partition between the different fractions or domains of each compartment is a determining factor in the distribution, bioavailability, and toxicity of OCPs and, therefore, their study is essential to understand the environmental behavior of OCPs.

#### *Water*

Despite being hydrophobic, water is the main transport means for OCPs from their source to their sink, i.e., the atmosphere, sediment, or biota. Rains can wash particles or water from OCP-contaminated stockpiles or soils into rivers or storm/sewage drains by runoff and subsequently discharge them into the sea (Figure 2). At all stages (source, transport, and sink) several processes affect the phase distribution of the OCPs, mainly, the division between fractions of the same phase and other phases, and loss due to degradation or irreversible sorption.

Figure 2. Schematic representation of the main organochlorine pesticide fate processes in coastal environments. A: air; A<sub>P</sub>: air particulate fraction; A<sub>D</sub>: air dissolved fraction; W: water; W<sub>P</sub>: water particulate fraction;  $W_D$ : water dissolved fraction S: sediment;  $S_P$ : sediment particulate fraction;  $S<sub>D</sub>$ : sediment dissolved fraction; C: consumer (C1, C2, C3: trophic levels); Ph: producers; SO<sub>AGR</sub>: agricultural soil;  $SO<sub>NAT</sub>$ : natural soil;  $SO<sub>U</sub>$ : Urban soil;  $SW<sub>U</sub>$  and  $SW<sub>I</sub>$ : urban and industrial sewage; Veg: vegetation.

As can be seen in Table 1, the  $K_{OW}$  range is from x to x showing low water solubilities, hence, the OCPs tend to concentrate in the water particulate fraction. This trend is even greater in salty media because the solubility of OCPs can be up to 5.8 times lower than in distilled water due to the salty effect (Cetin et al. 2006).

The fraction of particles comprises solids that, according to their mass and the predominant local hydrodynamics, remain as suspended particles or yield to gravity, settling and becoming the sediment bed. Due to its high affinity for particles, the OCPs distribution both in sediments and in water in marine coasts is generally associated with the sedimentation patterns characteristic of inland discharges, in which coarser particles precipitate near the river mouth and finer and lighter particles and colloids (particles of  $\phi$  <1 µm) precipitate further away or remain in suspension (Burgess 2012). However, other processes such as resuspension, bioturbation, turbulence, and changes in salinity and temperature play an important role in the fate of particles and OCPs in these environments (Ciffroy 2018).

#### *Sediment*

Dissolved, organism-accumulated, or particle-associated OCPs in the water column can become part of the sediment by advective transport, e.g., precipitation of particles or organic matter, and, lesser degree, by diffusive transport, through a concentration gradient. In the sediment, OCPs associated with particles/organic matter can bury under sediment layers or adsorb irreversibly and persist for decades (Doody 2002), metabolize by microbiological or chemical activity, or become secondary sources of contamination by resuspension or diffusion into the water column, either naturally, i.e., abiotic disturbances or bioturbation (action of benthic organisms), or anthropic, as occurred during dredging tasks.

In this compartment, as in the water column, OCPs are distributed between the dissolved and particulate fractions. This partitioning is largely regulated by the interaction of the compound with dissolved organic matter (DOM) or sedimentary organic matter (associated with sediment particles; SOM). Since the Kow and Koc of OCPs are in the high range, normally, under the same environmental conditions, their sedimentary levels are directly correlated to the content of SOM. However, sometimes, this relationship fails because the SOM is heterogeneous, varying the sorption capacity of OCPs from the sediment. Thus, two different types of SOM can be physically and chemically differentiated: the amorphous or "soft" domain and the condensed, "hard", or vitreous domain (Weber et al. 1992). The first is the dominant form of SOM and comprises mainly humic and fulvic substances (Xiao et al. 2004). Furthermore, it has a low sorption capacity of OCPs (and other chemicals) because it has linear sorption isotherms and relatively fast sorption and desorption rates, with little or no difference between both rates (e.g., Weber et al. 1992; Xiao et al. 2004). Instead, the condensed domain is a minor part of the SOM, which is formed as a consequence of the geological and thermal alteration of the amorphous domain, and comprises mainly kerogen, soot, charcoal, black carbon (BC), and humic acids in the vitreous form (Xiao et al. 2004). They are more structured forms, with higher H/O ratio, higher aromaticity, and greater sorption capacity due to presenting non-linear sorption isotherms, slow sorption and desorption rates, and sorption-desorption hysteresis, i.e., OCPs are trapped and retained (in some cases irreversibly) in micropores of condensed organic matter that can be deformed leading to different sorption and desorption isotherms (Weber et al. 1992, 1998; Xiao et al. 2004). This sorption/desorption kinetics plays an important role in the environment since they regulate the exchange of contaminants between the dissolved and particulate fractions

(Lasaga 2014), hence, influence their bioavailability. Consequently, according to the bioavailability of OCPs, three fractions can be established: immediately available in the dissolved fraction; potentially available, associated with DOM and the amorphous domain of the SOM; and the little or not available fraction, associated with the condensed domain of the SOM (Figure 3).

However, although the sediment sorption capacity is essential, other factors influence the OCPs bioavailability in sediments such as the nature and properties of the compounds, including  $K_{\text{OW}}$  and molecular size (Lyytikäinen et al. 2003), environmental conditions such as temperature, pH, salinity, and bulk density (Akkanen and Kukkonen 2001), and age of the OCPs in contact with the sediment, which increases the importance of the unavailable fractions (Reichenberg and Mayer 2006).

Figure 3. Schematic representation of the main phases and domains of geosorbents in sediments in the aquatic environment.

In addition to sorption processes, most of the OCPs degradation occurs in sediments, either by microbial or chemical action. Chemical degradation occurs by photolysis (in the photic zones of the sediment), hydrolysis, oxidation, and reduction (Andreu and Pico 2004). Meanwhile, the microbiological degradation of pesticides occurs by consumption, as a source of carbon and energy, by microorganisms generating structural modification, generally by dehydrochlorination (Vollhardt and Schore 2000), and by cometabolism (microbial consortium), which generates a series of consecutive transformations up to the total degradation of the pesticide (Borja et al. 2005; Alexander 1981). Usually, the degradation rate in the sediment is related to some key factors: the nature and properties of the chemical compound, the existence and abundance of relevant degradation agents, the bioavailability of the compounds (De Weert et al. 2008; Harwood et al. 2012), and the prevailing environmental conditions such as temperature, oxygen level, solar radiation, and pH (Kang and Kondo 2005; Ying and Kookana 2003).

#### *Air*

Atmospheric transport is one of the main ways of pollutant dispersion (Takeoka et al. 1991) and is the main pollution source in the polar regions and oceanic environments (Bacon et al. 1992; Ono et al. 1987). Due to the temperature gradient and consequently the KAW gradient, OCPs tend to volatilize in low latitude regions, enter atmospheric circulation cells, and transport to high latitudes, where they tend to condense and incorporate into soil and water bodies. This phenomenon is known as global distillation and may be responsible for the high concentrations of some OCPs in temperate and polar regions (Simonich and Hites 1995). OCPs with low molecular weight and high vapor pressure, such as hexachlorobenzene (HCB) and hexachlorocyclohexanes (HCH), are usually more effectively dispersed in cells, instead, those with low pressure and large molecular sizes, such as DDT or toxaphene, do not transport effectively to high latitudes (Iwata et al. 1994; Simonich and Hites 1995). However, the combination of the broad global use, environmental persistence, and relatively high Henry's law constant of these OCPs, promotes their presence, generally associated with biota or sediments, at high latitudes. In addition to global distillation, successive steps of volatilization/deposition and transport of OCPs occur throughout the world through so-called "grasshopping"; hence, they can affect all environments and ecosystems (Jurado and Dachs 2008). These processes influence the OCP levels in coastal waters, especially in remote areas such as Antarctica (Wu et a. 2020), Patagonia Argentina (Commendatore et al. 2015), and Arctic (Jin et al. 2017; Ma et al. 2015), since the chemicals can be incorporated by water-air exchange in these areas or in the soil, vegetation, and water of the influence drainage basins (Dachs and Méjanelle 2010; Figure 2).

#### *Biota*

Marine organisms can be exposed to OCPs through different routes. OCPs dissolved in the air can enter organisms through lung respiration. Meanwhile, OCPs dissolved in water, a fraction considered bioavailable, can enter organisms from ingested water or through external surfaces such as gills or skin tissues. Moreover, potentially available particle-associated OCPs (i.e., those associated with the amorphous domain of organic matter) and organismincorporated OCPs can enter the consuming organisms through food intake and be incorporated from the intestine (Knezovich et al. 1987). Generally, OCP levels in small organisms are regulated by the equitable partition between body lipids and water  $(K<sub>OW</sub>)$ . Instead, OCP levels are better related to diet than to Kow and lipid content in consuming organisms. The effect of diet is particularly important due to OCPs, being lipophilic and persistent compounds, increase their concentration through the trophic web; therefore, the concentration in top predators is usually higher than in those organisms with low trophic levels (biomagnification), reaching differences of up to 10,000 times greater (Kajiwara et al. 2004; Kleivane et al. 2004; Tanabe et al. 1994). Likewise, OCP levels show great interspecific and intraspecific variability, determined by the complexity of chemical, biological, and ecological factors that influence diets, such as habitat, feeding behavior, and digestion mechanisms, as well as the metabolizing capacity, chemical lipophilicity, and molecular size (Belfroid et al. 1996; Lyytikäinen et al. 2003; Weston et al. 2000).

After organisms assimilate them, the fate of OCPs in the body can be complex: they can store, metabolize, or excrete them. Mainly, OCPs tend to migrate towards lipid reserves due to their high Kow, and it is common to find a concentration gradient gastrointestinal tract> liver or brain> kidney> muscle (Bryan et al. 1987; Dang et al. 2016; Zhao et al. 2014). While excretion through the urine is considered to be negligible, due to its low solubility in water. In contrast, the removal of OCPs by lipid mobilization in processes such as gonadal maturation, ovulation, pregnancy, or lactation is remarkable (Aguilar 1987). In lipid mobilization, some OCPs remain in the tissue, but others leave the tissue with the lipids (Aguilar 1987). This

explains the low residue concentrations in adult females of marine mammals about adult males (Girones et al. 2020; Kajiwara et al. 2004). Another way for removal OCPs is degradation, in which the organisms themselves transform the chemical compound into metabolites, which are sometimes the same or more harmful and persistent than the parent pesticide. This process occurs in most organisms and the main metabolic pathway is through the cytochrome P-450 system (CYP-450), which contains hemiproteins with iron used in the oxidation of hydrophobic xenobiotic compounds. Through a cytochrome P-450 reductase enzyme, the reduction of Fe3 + to Fe2 + occurs, which attracts an oxygen molecule and oxidizes the pollutant forming a hydroxyl group (hydroxylation), which makes the molecule more hydrosoluble and allows is excreted through the urine (Parkki et al. 1977). However, not all organisms have the same ability to degrade and remove OCPs, this ability is based on biochemical detox adaptations that would be mainly related to diet, for example, the detoxification ability of herbivores is greater than that of carnivores because they are frequently exposed to a greater number of natural toxins in their diet (Focardi et al. 1988; Fossi et al. 1988).

# **TOXICITY**

#### **Wild Animal Toxicity**

Organochlorine pesticides were designed to eliminate arthropods by neurotoxic action, i.e., acting directly on the nervous system and causing sensory disturbances to seizures (ATSDR 2002). The magnitude and nature of this effect are determined partly by the way and concentration in which the OCPs reaches the receptor sensitive to it. If the OCP concentrations in the active site are too low, or if the pesticide has been metabolized to an inactive form, no impact will be observed.

Exposure to high environmental concentrations of OCPs generates harmful effects on the biota in the short and long term. The most notable effect was the decrease in the population of some wild bird species associated with agricultural sites with intensive use of DDT, where this compound was associated with the thinning of the eggshells, and consequently to their breakage and reproductive failure (Bitman et al. 1969; Burnett et al. 2013).

However, what generated the most interest in the scientific community were the effects that low OCP levels can produce on the reproduction and development of non-target organisms. These chemicals can act as endocrine disruptors (Petrovic et al. 2013; Sosa-Ferrera et al. 2013) because they can interfere with endogenous chemical messengers such as hormones, neurotransmitters, growth factors, and inhibitory substances, affecting direct development, control of homeostatic regulation and the function of these systems (Colborn et al. 1993). This hormonal system alteration has been linked to the increase in some types of neoplasms, malformations, and reproductive system dysfunctions, and immune response failures (Diamanti-Kandarakis et al. 2009). Its effects are more noticeable in embryos, fetuses, and newborns, producing in many cases irreversible effects as a product of delayed development and organization of the organism (Guillette et al. 1995; Mori and Nagasawa 1988).

Due to the large number of chemical indicators present among the cells of developing systems, there are numerous targets on which OCPs can act as chemical messengers. Therefore, detecting the small effects they cause and predicting developmental injuries or modifications is very difficult. Moreover, there may be a long delay between exposure and effects, hence the latter may not be expressed until the maturity of the individual. These individuals may appear normal but often experience early death or infertility as a result of exposure (Colborn and Smolen 1996). If the problem were to spread, these alterations in individuals could have serious consequences on population levels.

#### **Human Toxicity**

Where OCPs are still in use, dermal and aerial exposure is important, for example in cases where DDT is used to control malaria (Van Dyk et al. 2010). Furthermore, in some places, the consumption of contaminated fish and shellfish could be a source of human exposure to OCPs (Beard 2006). Both sources of OCPs exposure mean that significant levels can still be measured in serum, adipose tissue, or breast milk samples from populations not occupationally exposed (Gajski 2012).

Exposure to OCPs, even at very low levels, is associated with short gestational periods, low weight in newborns, and below-average head circumference measurements (Jacobson and Jacobson 1993). Furthermore, it can affect the fertility of the individual, especially if this exposure occurs during prenatal periods (Sharpe and Skakkebaek 1993), and generate liver, neurological, pulmonary, and cardiac problems (Furuya et al. 2005; Nakanishi et al. 2005). Besides, some pesticides would have a genotoxic (Canales-Aguirre et al. 2011) and/or carcinogenic capacity in humans, e.g., lindane is carcinogenic, DDT and dieldrin are probably carcinogenic, and others such as HCHs, HCB, and chlordane are possibly carcinogenic, according to IARC (IARC 2020).

# **CURRENT OCP LEVELS IN COASTAL SEDIMENTS**

#### **Literature Review and Information Processing**

Scientific articles on OCPs in coastal sediments worldwide published in recent years (2015-2020) were reviewed. A comprehensive search was performed on the most common search engines using different word combinations. The compounds reviewed were: DDTs (o,p′-DDE, p,p′-DDE, o,p′-DDD, p,p′-DDD, o,p′-DDT, and p,p′-DDT); HCHs (α-HCH, β-HCH, γ-HCH, and δ-HCH); endosulfans (α-endosulfan, β-endosulfan, and endosulfan sulfate); heptachlor (heptachlor and heptachlor epoxide); chlordanes (*trans*-chlordane, *cis*chlordane, *trans*-nonachlor, and *cis*-nonachlor); drins (aldrin, dieldrin, endrin, and endrin aldehyde); HCB; mirex; and methoxychlor. Levels below the detection limit were replaced by half the detection limit when necessary. Data analysis of OCP levels was performed with ArcGIS 10.3 (Esri, 380 New York Street, CA 92373, USA) and Microsoft Excel (ver. 2013, Microsoft, Redmond, WA, USA), and concentrations were expressed as  $ng.g^{-1}$  dry weight (dw). Moreover, to determine the ecotoxicological risk associated with OCPs in the

sediments, the mean levels of each site were compared with the Norwegian Environmental Quality Classification System (NEQCS; Bakke et al. 2010; Molvær et al. 1997) and the guidelines proposed by Long et al. in 1995 and Macdonald et al. in 1996 (Table 2). NEQCS establishes five risk classes for five ranges of OCP concentrations in coastal marine environments: background (CI); no toxic effects (CII); toxic effects following chronic exposure (CIII); toxic effects following short term exposure (CIV); severe acute toxic effects (CV). Meanwhile, the guidelines proposed by Long and Macdonald are similar, they establish two limit values that define three ranges according to the frequency of adverse effects occurring in biota: rarely, occasionally, and frequently. Long et al. defined these limit values as "effects range low" (ERL) and "effects range median" (ERM), while Macdonald et al. defined them as "threshold effect level" (TEL) and "probable effects level" (PEL; Table 2).

#### **Results and Discussion**

#### *DDTs*

The current environmental concentrations of DDTs were higher than those of the other OCPs, between 3 and 20 times depending on the group of compounds compared. The general mean for 70 reviewed coastal sites in the world was 8.43 ng.g<sup>-1</sup> (SD = 30.84) with a global median of 1.71 ng.g<sup>-1</sup>. The global spatial distribution of DDTs in coastal sediments was highly variable and was related to the proximity to the sources and the hydrodynamic characteristics of each environment, with Africa and Asia being the continents most affected by DDT pollution, which are regions where its use has not been totally discontinued (Van den Berg et al. 2017; Figure 4). When comparing the levels of DDT in the sediments with the international guidelines on ecotoxicological risk, it was observed that in many places these compounds would cause some damage to the biota (Table 3). In Jiulong Jiang, China (Lv et al. 2020) and iSimangaliso Wetland Park, South Africa (Buah-Kwofie and Humphries 2017) these levels were 209.23  $ng.g^{-1}$  and 138.14  $ng.g^{-1}$ , respectively, and they could cause severe and frequent adverse effects on the biota according to the guidelines proposed by Long et al. (1995), Macdonald et al. (1996) and NEQCS. Moreover, the levels of DDTs from other sites could generate damage to the biota occasionally according to these guidelines (Table 3). Regarding the distribution of DDT congeners, a general predominance of DDT metabolites was observed over the original DDT, suggesting a historical input to the systems (Figure 4). Meanwhile, the DDE/DDD ratio varied mainly according to the oxygen conditions and the solar exposure of the evaluated sediments. In general, the subtidal sediments showed a predominance of DDD and the intertidal sediments showed a predominance of DDE. For example, the DDE/DDD ratios found in mangrove sediments studied by Chen et al. (2020) and Mitra et al. (2019) were much greater than 1. Instead, the DDE/DDD ratios found in subtidal sediments studied by Akhil and Sujatha (2014), Oliva et al. (unpublished), and Jin et al. (2017) were much lower than 1. However, in some places such as the Brazilian continental shelf (Santos et al. 2020) and Guanghai Bay (Haijun et al. 2019), where the sediments are permanently submerged, the DDE/DDD ratios were close to 1. This demonstrates that the prevalence of anaerobic or aerobic degradation depends not only on the waterlogging condition, but also on other factors, such as the diffusion of oxygen from the water column to the sediments, influenced by the content of organic matter, particle size, and the predominant hydrodynamics.

#### **Table 2. Guidelines on ecotoxicological risk for organochlorine pesticides in marine sediments. Values expressed as ng.g-1**

Figure 4. Spatial distribution and composition of the mean levels of DDTs in coastal sediments.

#### *HCHs*

HCH levels in sediment were on average 3 times lower than those of DDTs, with a general mean of 2.85 ng.g<sup>-1</sup> (SD = 12.03) and a median of 0.41 ng.g<sup>-1</sup>. Even so, high concentrations were found in some places around the world (Figure 5). The highest levels were found in iSimangaliso Wetland Park, South Africa (Buah-Kwofie and Humphries 2017), followed by Sado Estuary (Carvalho et al. 2009), Unguja Island, Tanzania (Mwevura et al. 2020), Guajará Bay, Brazil (Neves et al. 2018), the Yangtze Estuary, China (Adeleye et al. 2016), and the Nile River Estuary, Egypt (Abbassy et al. 2018) with an average of 95.8, 15.8, 4.65, 4.05, 3.93, and 3.61 ng.g-1 , respectively.

Due to its high toxicity, HCHs in sediment could cause damage to the biota in the short or long term in most of the sites analyzed in recent years (Table 3) according to the Norwegian

Environmental Quality Classification System (NEQCS; Bakke et al. 2010; Molvær et al. 1997). The sites most affected by HCHs were the iSimangaliso Wetland Park, South Africa (Buah-Kwofie and Humphries 2017), and the Sado Estuary, Portugal (Carvalho et al. 2009), where these compounds could generate severe damage to the biota in the short term.

Figure 5. Spatial distribution and composition of the mean levels of HCHs in coastal sediments.

In turn, the ecotoxicological risk associated with the current levels of the  $\gamma$ -HCH isomer (lindane) in sediments according to the guideline proposed by MacDonald et al. (1996) coincided with that of the HCHs and is also shown in Table 3.

Meanwhile, the  $\alpha$ -HCH $\gamma$ -HCH ratio, which determines the predominant use of technical HCH when it is in the 3 and 7 range and of lindane ( $\gamma$ -HCH) when it is <1, indicated a predominant use of lindane in the most places (Figure 5). However, some sites in Africa, China, and the Arctic (Buah-Kwofie and Humphries 2017; Jin et al. 2017; Lv et al. 2020; Ma et al. 2015) showed indices higher than 3, indicating a predominant use of technical HCH or at least fast and efficient atmospheric transport from distant sources in progress (Ma et al. 2015).

#### *Drins*

The study of the other OCPs is much less extensive than that of HCHs and DDTs. Aldrin, dieldrin, and endrin were analyzed in 62%, 72%, and 62% of the reviewed studies, respectively. These compounds, usually grouped under the name of "drins", were found in considerably lower concentrations than DDTs and HCHs (Figure 6). The global mean and median concentrations were 1.44 ng.g<sup>-1</sup> and 0.05 ng.g<sup>-1</sup> for aldrin, 3.13 ng.g<sup>-1</sup> and 0.02 ng.g<sup>-1</sup> for dieldrin, and 3.65  $ng.g^{-1}$  and 0.13  $ng.g^{-1}$  for endrin, respectively. However, some places presented levels that could pose a risk to the associated biota according to the guidelines suggested by Long et al. (1995) and MacDonald et al. (1996) (Table 3). The mean levels of dieldrin in Cochin Estuary, India (Akhil and Sujatha 2014), iSimangaliso Wetland Park, South Africa (Buah-Kwofie and Humphries 2017), and Sado Estuary, Portugal (Carvalho et al. 2009) could cause frequent adverse effects on the biota according to both guidelines. The concentration of dieldrin in other sites around the world could cause occasional adverse effects on biota (Table 3). Meanwhile, endrin levels would not cause adverse effects at the studied sites, except in Cochin Estuary, India (Akhil and Sujatha 2014), Isimangaliso Wetland

Park, South Africa (Buah-Kwofie and Humphries 2017), and Island Unguja, Tanzania (Mwevura et al. 2020), where they could cause occasional damage to the associated biota, according to the guideline proposed by MacDonald et al. (1996).

#### *Endosulfans*

The two isomers of technical endosulfan  $(\alpha$  and  $\beta)$  were poorly studied, they were analyzed only in 55% of the reviewed studies, and endosulfan sulfate, its main metabolite, was analyzed in less than 40% of the studies. The global mean concentration of endosulfans was 3.75 ng.g<sup>-1</sup>, although with widely dispersed values (SD = 15.8; median = 0.11 ng.g<sup>-1</sup>). The high standard deviation was mainly generated by high endosulfan concentrations at two sites: iSimangaliso Wetland Park, South Africa (Buah-Kwofie and Humphries 2017), and the Cochin Estuary, India (Akhil and Sujatha 2014) with averages of 93.5 ng.g<sup>-1</sup> and 21.01 ng.g<sup>-1</sup>, respectively (Figure 7). These levels could generate acute toxic effects on the associated biota according to the NEQCS (Table 3). Furthermore, according to this guideline, the average levels found in some estuaries in Egypt, Vietnam, China, Argentina, and Portugal (Abbassy 2018; Carvalho et al. 2009; Chen et al. 2020; Lv et al. 2020; Oliva et al. unpublished; Tham et al. 2019) could cause damage to the associated biota in the short or long term (Table 3).

Figure 6. Spatial distribution and composition of the mean levels of drins in coastal sediments.

Regarding the distribution of congeners, a clear pattern was observed. In intertidal sediments, endosulfan sulfate was predominated over parent endosulfans (e.g., Chen et al. 2020; Lv et al. 2020) while in subtidal sediments the parent endosulfans were predominated (e.g., Abbassy 2018; Akhil and Sujatha 2014; Commendatore et al. 2018; Ma et al. 2015; Oliva et al. unpublished). This would be explained by the oxygen level in the sediments: under aerobic conditions, the parent endosulfan is easily oxidized to endosulfan sulfate, while in anaerobic or low-oxygen conditions, small amounts of this analyte are produced (Ghadiri and Rose 2001; Guerin 1999). Besides, in coastal sediments, under unfavorable environmental conditions for oxidative degradation, the recent use of technical endosulfan would promote the prevalence of the parent endosulfan over endosulfan sulfate. Meanwhile, the predominance of  $\alpha$  or  $\beta$  isomers of endosulfan depended on both the environmental

conditions and the physicochemical properties of the isomers and the composition of the technical endosulfan (i.e., 70% α-isomer and 30% β-isomer). The β isomer is more resistant to environmental degradation and is less volatile than the  $\alpha$  isomer (Breysse et al., 2015; Rand et al. 2010), which is why it is usually predominant in water, fish, and aerobic sediments (Granados- Galván et al. 2015; Rand et al. 2010). This pattern was observed in intertidal sediments in China (Chen et al. 2020; Lv et al. 2020), but also in subtidal sediments of the Nile River estuary, Egypt (Abbassy et al. 2018). The prevalence of α-isomer was observed in subtidal sediments of Svalbard, Norwegian Arctic (Ma et al. 2015), Bahia Blanca Estuary, Argentina (Oliva et al. unpublished), Cochin Estuary, India (Akhil and Sujatha 2014), and San Jorge Gulf, Argentina (Commendatore et al. 2015). This could be due to a recent entry of technical endosulfan into the system or to the low capacity to degrade both isomers in the absence or shortage of oxygen and/or low temperatures (Ghadiri and Rose 2001).

#### *Other Organochlorine Pesticides*

Heptachlor was analyzed in 57% of the studies. The current global mean concentration was 2.25 ng.g<sup>-1</sup> (SD = 7.61) and the median was 0.04 ng.g<sup>-1</sup>, which were low values about the previously analyzed OCPs. However, the mean concentrations of heptachlor epoxide found in iSimangaliso Wetland Park, South Africa (28.60 ng.g<sup>-1</sup>) and Cochin Estuary, India (2.77 ng.g<sup>-1</sup>) <sup>1</sup>) would cause frequent damage to the associated biota according to the guideline proposed by Macdonald et al. (1996; Table 3). Regarding the distribution of heptachlor congeners, it was reported in the literature that heptachlor would transform into heptachlor epoxide in aerobic conditions through enzymatic epoxidation (Pokethitiyook and Toemthip 2012). However, a prevalence of this metabolite over parental heptachlor was not observed in intertidal sediments, where the oxygen level would be higher than in subtidal sediments. On the other hand, it should be taken into account that under oxygen-deficient conditions heptachlor would be metabolized to chlordane and 1-hydroxychlordene-2,3-epochloride chloride (Pokethitiyook and Toemthip 2012), and these metabolites were generally not analyzed. Consequently, the study of the parent heptachlor/metabolites ratio and its relationship to environmental conditions was very limited.

Chlordanes were evaluated in only 43% of the reviewed studies. The general mean levels were very low, with a mean of 0.18 ng.g<sup>-1</sup> (SD = 0.58) and a median of 0.07 ng.g<sup>-1</sup>. Among the sites for which values were reported, the levels of this pesticide would only cause occasional damage to the biota in Anadim, Guajara Bay, Brazil (Neves et al. 2018), according to the guidelines proposed by Long et al. (1995) and Macdonald et al. (1996; Table 3). Regarding the distribution of congeners, *cis*-chlordane/*trans*-chlordane ratio ranged between 0.7 and 1.6 (Commendatore et al. 2015; Jin et al. 2017; Lv et al. 2020; Ma et al. 2015; SFEI 2014) and their main metabolite, oxychlordane, was hardly studied.

HCB was analyzed only in 27% of the studies reviewed. The mean levels (mean of 2.12  $mg \cdot g^{-1}$ , SD = 4.18, and median of 0.18 ng.g<sup>-1</sup>) were similar to those of endosulfans and heptachlors. The sites with the highest HCB concentrations were Congo River estuary, Congo DR (Suami et al. 2020), Bahía Blanca Estuary, Argentina (Tombesi et al. 2018), and Rhone River delta, France (Salvadó 2013), with means of 14.06, 6.36, and 2.12 ng.g<sup>-1</sup>, respectively. Even so and according to NEQCS, HCB levels in sediment would be biota-safe at all sites reviewed.

contemplated were: p,p'-DDT (DDT); p,p'-DDE (DDE); p,p'-DDD (DDD); Sum of p,p'-DDT, p,p'-DDE, and p,p'-DDD (DDTs);<br>lindane (y-HCH); Sum of α, β, γ, and δ HCH (HCHs); Sum of α and β endosulfans and endosulfan sulfate (Endos **contemplated were: p,p'-DDT (DDT); p,p'-DDE (DDE); p,p'-DDD (DDD); Sum of p,p'-DDT, p,p'-DDE, and p,p'-DDD (DDTs); Table 3. # Table 3. (Continued) **Table 3. (Continued)**

Mirex was determined in only 17% of the studies reviewed, in which it was presented at very low levels. The general mean concentration was  $0.03$  ng.g<sup>-1</sup> (SD = 0.04) and the median was  $0.01$  ng.g<sup>-1</sup>. Meanwhile, for methoxychlor, the frequency of analysis was 23% and the global mean was  $1.43$  ng.g<sup>-1</sup> with high SD (1.92) and a median of 0.4 ng.g<sup>-1</sup>. Neither of these two pesticides is included in any ecotoxicological classification systems used in this chapter, hence, we could not determine if the levels found would pose any risk to the associated biota.

Figure 7. Spatial distribution and composition of the mean levels of endosulfans in coastal sediments.

# **CONCLUSION**

Although it seems that the problem associated with the production and use of organochlorine pesticides has disappeared due to the worldwide restrictions, they remain as one of the most important pollutants for both the environment and humans. At almost all the coastal sites where were recently evaluated, OCP levels showed detectable concentrations of at least one congener. In some cases, mainly in sub-Saharan Africa and Southeast Asia, these concentrations were high and would pose a risk to the biota associated with these environments.

DDTs were the most abundant legacy POP in marine coastal sediments, 3 times more abundant than HCHs and much more abundant than the rest of the OCP. However, from an environmental point of view, other pesticides were shown to be more dangerous due to their greater ecotoxicity.

Regarding the environmental fate and behavior of OCPs, the factors influencing them were exhaustively described from the literature analysis. This information was then used to assess current levels of OCPs in the world's coastal sediments in various studies. We observe that the environmental behavior of these compounds is very complex and depends fundamentally on the intrinsic characteristics of each compound and the environment.

Parent pesticides were found at almost all the sites studied, which could represent a recent input into the system or poor system capacity to degrade them. This was observed mainly in subtidal sediments, which would have low oxygen content and little or no light exposure, i.e., unfavorable conditions for the aerobic degradation of the OCPs, which is the main route of degradation in the environment. Moreover, this phenomenon was more noticeable in cold or temperate environments.

The predominance of each metabolite and parent isomer varied according to the prevailing environmental conditions. In intertidal sediments, the metabolites and isomers typical of oxygenated environments predominated, i.e., DDE, endosulfan sulfate, heptachlor epoxide, β-HCH, and β-endosulfan. Instead, metabolites typical of anaerobic environments such as DDD and the majority isomers of the technical mixtures ( $\alpha$ -endosulfan, lindane, and α-HCH) predominated in subtidal sediments.

Finally, we must highlight the need to sustain permanent monitoring networks for these legacy pollutants, with a focus on non-surveyed regions and potentially polluted areas such as African and Asian coastal wetlands.

# *BIOGRAPHICAL SKETCHES*

#### *Lautaro Girones*

**Affiliation:** Instituto Argentino de Oceanografía (IADO) - Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET) and Universidad Nacional del Sur (UNS), Bahía Blanca, Provincia de Buenos Aires, Argentina.

**Education:** Bachelor's Degree in Environmental Science, Universidad Nacional de Avellaneda (UNDAV), Avellaneda, Argentina.

PhD student, Universidad Nacional del Sur (UNS), Bahía Blanca.

**Business Address**: Instituto Argentino de Oceanografía. Florida 8000 (Camino La Carrindanga km 7,5), Complejo CCT CONICET Bahía Blanca | Edificio E1, B8000FWB Bahía Blanca | Argentina
#### **Research and Professional Experience:**

Since April 2017 I have been a CONICET doctoral fellow developing my research activities at the Persistent Organic Pollutants Laboratory of the Instituto Argentino de Oceanografía (IADO), in Bahía Blanca, Argentina. My directors are Dr. Andres Hugo Arias and Dr. Jorge Eduardo Marcovecchio. I specialize in the study of Persistent Organic Pollutants such as organochlorine pesticides (OCPs), polychlorinated biphenyls (PCBs), chlorinated paraffins (SCCPs and MCCPs), and polycyclic aromatic hydrocarbons (PAHs) in marine and continental aquatic environments. I have participated in several research projects, including research stays abroad, some of which have already been published in international scientific journals or will be published in the coming years. Among them, the study of pollution by POPs and their behavior and environmental fate in the Southwest of Buenos Aires stands out, analyzing both rivers and the Bahía Blanca Estuary, through the use of abiotic (e.g., sediments and water) and biotic matrices (e.g., snails, mussels, and fish). Besides, I also participate in the study of the river discharges impacts on the marine benthic community of the Province of Buenos Aires; the role of coastal wetland plants in the biogeochemical cycle of POPs; and the occurrence and environmental behavior of POPs in the Argentine continental shelf, among others.

#### **Professional Appointments**: Chemistry Doctoral fellow

**Honors:** Argentine Chemical Society Prize 2019 for the best average in a Degree University Career, 11/22/2019.

## *Dr. Andres H Arias*

**Affiliation:** Instituto Argentino de Oceanografía (IADO) - Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET) and Universidad Nacional del Sur (UNS), Bahía Blanca, Provincia de Buenos Aires, Argentina. Analytical Chemistry Area of the Chemistry Department of the National South University (Argentina)

**Education:** *PhD Biological Sciences* Marine Environmental Chemistry: water, soil and organism. Biogeochemistry. Environment Pollution and Monitoring. National South University, Argentina. Awarded with honour (10/10). *Biochemistry Sciences* (Analytical Chemistry and Environmental Sciences Degree) at National South University, Argentina. Awarded with Honours. First award in qualifications.

**Business Address:** Instituto Argentino de Oceanografía. Florida 8000 (Camino La Carrindanga km 7,5), Complejo CCT CONICET Bahía Blanca | Edificio E1, B8000FWB Bahía Blanca | Argentina

**Research and Professional Experience:** My area of expertise falls between marine biogeochemistry and ocean monitoring, focusing in the pollution of the marine and coastal environments: Persistent Organic Compounds/Environmental Pollution Monitoring and Assessment. Plastics and Microplastics in the aquatic environment. Atmospheric transport of POPs to the coastal environments. Dry/Wet Deposition. Bioaccumulation and Biomagnification of POPs. Top predators. My main interests are to explore Persistent Organic Pollutants (POPs) and microplastic dynamics occurrence and bioaccumulation in marine and freshwater environments, the understanding of POPs movement through the trophic web, exploring POPs sources, origin and age of inputs PAHs, PBDEs, PCBs, OCs, OPs, emerging pollutants and microplastics in the marine/freshwater environment.

**Professional Appointments:** At present, researcher at the Argentinean Institute of Oceanography -IADO- (National Council of Scientific and Technological Research, CONICET, Argentina) at the Marine Chemistry Division. He is also Head of Laboratory (Teaching Position, permanent) at the Analytical Chemistry Area of the Chemistry Department of the National South University (Argentina). In addition, UNEP representative at Scientific Advisory Comitee Microplastics and Marine Litter and representative of Argentina at the GESAMP WG40. Member of the Directive Council Board of the Argentinean Institute of Oceanography (CONICET), he has performed posdoc at the University of Lille-1, Lille, France (CNRS) and UNAM, Mexico (CONACyT).

**Honors:** Awarded with the WIENER LAB Foundation prize (academic award), to the best overall qualification average of the year (2003) of the Biochemistry University Degree. First award for a conference paper at the VII Jornadas Chilenas de Física y Química Ambiental (Concepción; Chile, 2011). First award on conference paper in marine environments (Environment and Argentina, 2015). Has been awarded with several grants (PICES, Erasmus Mundus, Matsumae, IMBER ClimEco, etc)

## *Dr. Jorge Eduardo Marcovecchio*

**Affiliation:** Senior Researcher at CONICET, in the Chemical Oceanography Area , at the Argentine Institute of Oceanography (IADO – CONICET-UNS).

Member (Academic) of the National Academy of Exact, Physical and Natural Sciences (ANCEFN), Argentina. Main Professor, National Technological University (UTN), Bahía Blanca (Argentina).

Main Professor, Universidad FASTA, Mar del Plata (Argentina)

Invited Professor, Universidad Nacional del Sur (UNS), Bahía Blanca (Argentina)

**Education:** Lic. In Biological Sciences (Marine Biology oriented), UNMdP, Argentina Doctor in Biological Sciences; UNMdP, Argentina Post Doctoral Researcher, Environmental Chemistry or. – Ehime University, Japan.

**Business Address:** Instituto Argentino de Oceanografía. Florida 8000 (Camino La Carrindanga km 7,5), Complejo CCT CONICET Bahía Blanca | Edificio E1, B8000FWB Bahía Blanca | Argentina

**Research and Professional Experience:** Published more than 250 papers in international journals like Journal of Shoreline Management, Marine Pollution Bulletin, Environmental Technology Letters, Archieves of Environmental Contamination & Toxicology, Marine Environmental Research, Environmental Monitoring & Assessment, The Science of Total Environment, Environmental Contamination, Chemical Speciation & Bioavailability, UNEP Regional Seas Reports & Studies, Heavy Metals in the Environment, Oceanologia, Wetland Environmental Management, Journal of Coastal Research, Continental Shelf Research, Chemosphere, Journal of Marine Systems, etc. Also has published 60 chapters in international books, and has edited seven books. Has communicated more than 200 short papers in International and National Scientific Meetings.

Teaching Background: has supervised 12 Graduate Students thesis, as well as 23 Doctoral thesis (10 of them has been aproved on the last 5 years). At present is supervising 5 doctoral students fellowships (from CONICET and ANPCyT).

He has received various national and international scientif awards.

At present is referee at various international journals (The Science of the Total Environment (UK), Marine Pollution Bulletin (UK), Environmental Pollution (UK), Caribbean Journal of Science (Puerto Rico), Pesquisa Antártica Brasileira (Brasil), Natura Neotropicalis (Argentina), Environmental Technology (UK), Boletín del Instituto Oceanográfico de Venezuela (Venezuela), Interciencia (Venezuela), Food Chemistry (UK), Archives of Environmental Contamination and Toxicology (USA), Estuarine, Coastal and Shelf Science (UK), Ecotoxicology and Environmental Safety (UK), Journal of Coastal Research (USA), Geochímica Brasiliensis (Brasil), Chemosphere (UK), Environmental Science & Technology (USA), Water, Air & Soil Pollution (UK), Acta Biológica Colombiana (Colombia), Atmospheric Environment (UK), Spectroscopy Letters (UK), Brazilian Journal of Ornithology (UK), Latin American Journal of Sedimentology and Basin Analysis (Argentina), Polish Journal of Environmental Studies (Poland), Food and Chemical Toxicology (UK), Revista de Biología Marina y Oceanografía (Chile), among others.

He is a member of various International Scientific Societies (International Asociation for the Physical Sciences of the Oceans" (IAPSO); Sociedade Brasileira de Geoquímica; Royal Society of Chemistry, Green Chemistry Network (GCN).

# **ABSTRACT**

Atmospheric input of POPs (e.g., organochlorine pesticides [OCPs], halogenated aromatic hydrocarbons -polychlorinated biphenyls (PCBs), chlorinated or brominated dibenzofuran and dibenzo-p-dioxins [PCDDs/DFs, PBDDs/DFs]) and polycyclic aromatic hydrocarbons [PAHs]) mainly comes from anthropic activities, including as primary emission sources those from agricultural production and industrial processes. Although the commercial use and application of some POPs have been totally prohibited or severely restricted (Stockholm Convention), they continue to be found in the air and other environmental compartments around the world.

Global atmospheric long-range transport has been widely demonstrated for these compounds and represents a dominant process by which POPs reach the oceans. This is far more relevant for POPs, such as OCPs and PCBs than for PAHs, as the first ones are only generated in the continental sector. On the contrary, PAHs can be generated in the marine environment, as in oil spills from ships. In addition to the atmospheric transport, atmosphere-sea interactions and the inter-compartmental transfer play an essential role in terms of deposition and subsequent entry of POPs into marine ecosystems. The transfer of POPs from the atmosphere to the ocean can take place by dry deposition, wet deposition and by diffusive gaseous flows. Fundamentally, in open marine systems,

 $\overline{a}$ 

Corresponding Author's Email: mouna23necibi@gmail.com.

atmospheric deposition determines that the oceans could act as reservoirs for POPs. Also, aquatic planktonic species are believed to be impacted by atmospheric deposition, supporting the accumulation of POPs through the food chain. Once in the ocean, the fate of POPs will ultimately depend on several events such as movement flows, chemical transformations, physical and biological processes.

In this context, highlighting the important links between the atmospheric and oceanic systems, the objective of the present chapter is to consider the implication of atmospheric transport in the circulation of POPs and to present the relevance of atmospheric deposition to the oceans as a key process that affects the marine environments.

**Keywords**: POPs, atmospheric deposition, open ocean

## **INTRODUCTION**

Among the thousands of chemical products that impact marine environments from anthropogenic activities, persistent organic compounds (POPs) present a scenario of special relevance due to their ability to remain intact in the environment for long periods of time, showing bioaccumulative characteristics in the fatty tissue and high toxic effects to both humans and biota. Polycyclic aromatic hydrocarbons (PAHs), organochlorine pesticides (OCPs), halogenated aromatic hydrocarbons, polychlorinated biphenyls (PCBs), chlorinated or brominated dibenzofuran and dibenzo-p-dioxins (PCDDs/DFs, PBDDs/DFs) are semivolatile at atmospheric conditions (vapour pressures at 298 K in the range  $10^{-6}$ - $10^{-2}$  Pa) (Mulder et al. 2010) and subject to long-range atmospheric transport (LRAT), even when reaching remote zones such as open oceans. Except for PAHs, which can be generated in the marine environment by oil spills from ships, long-range transport enables terrestrial POPs to reach the remote oceanic environment (Castro-Jiménez et al. 2015).

The atmosphere plays an important role in the distribution of POPs at a global scale. The Convention on Long-Range Transboundary Air Pollution (CLRTAP Convention, 1979) is one of the first treaties on the potential of POPs to reach remote environments, including oceans, high mountains and the Arctic and Antarctic areas, where they have never been produced or used. Thus, POPs have been studied and incorporated into different atmospheric monitoring programmes around the globe (Global Monitoring Plan [GMP], Global Atmospheric Passive Sampling [GAPS] Network, and Arctic Monitoring and Assessment Programme [AMAP]). Furthermore, given the importance of persistence and LRAT, the Stockholm Convention (UNEP, 2017) recognises the need to eliminate, restrict or reduce the use and release of POPs. Despite the implementation of these treaties and regulations, POPs continue to cycle through the atmosphere and in aquatic and terrestrial environments. Due to the continuing threat that they pose to human health and the environment, it is necessary to identify and understand the distribution of POPs among environmental compartments. Different investigations and monitoring networks have aimed at better characterising the global fate of these toxic substances. Among them, the Integrated Atmospheric Deposition Network (IADN), in operation since 1990, evaluates the extent of atmospheric deposition in the Great Lakes region in North America (Castro-Jiménez et al. 2015).

Atmospheric deposition is the main mechanism by which POPs are removed from the atmosphere and deposited in other compartments. The atmospheric input of POPs into continental aquatic systems, coastal sites, large lakes and open oceans occurs through rainscavenging, falling particles and gas absorption. Also, some water bodies receive the contribution of POPs from local sources, run-off and discharge by tributaries. The coastal waters of the Mediterranean, Black, Aegean, and North Seas and of northeastern USA (Castro-Jiménez et al. 2012; Lammel et al. 2015; Lohmann et al. 2011; Mai et al. 2016; O'Driscoll, 2014), in the vicinity of primary emissions, reflected the influence of local sources, such as riverine input. Conversely, in the remote ocean, the main source is atmospheric deposition, and depositional processes are more relevant (Castro-Jiménez et al. 2015). Global oceans cover 3/4 of the planet's surface, the Pacific being the greatest of all, and they represent a key compartment during the global cycling of POPs. Nevertheless, few simultaneous measurements have been made in air and surface seawater in the open ocean, and POPs occurrence in the ocean-atmosphere system requires more research attention.

This chapter focuses on the relevance of the atmosphere as the main transport route for POPs to the open ocean. It describes long-distance transport and atmospheric deposition, considering the relevance of the depositional processes and gas exchange that allow POPs to reach oceanic waters. Moreover, it considers the implication of ocean biogeochemistry in the control of depositional flows, through the sinking fluxes (physical and biological) that accumulate POPs in the deep ocean. Finally, the chapter presents evidence that suggests the volatilisation of POPs in the open ocean.

#### **CONSIDERATIONS ON THE ATMOSPHERIC TRANSPORT OF POPS**

As for POPs to be distributed by LRAT, first, they must enter the atmosphere because they are directly emitted into it or by means of volatilisation from the medium where they were previously applied. Then, given their persistence in the air (half-life $> 2$  days), they can be transported through the atmosphere by air circulation. Furthermore, their behaviour and the probability that POPs undergo LRAT depend on the interaction of air-surface partitioning coefficients, the advective transport, and transformation and degradation processes (Hageman et al. 2015).

$$
hops = \frac{\tau}{\frac{hventory}{OutputFlux}}\tag{1}
$$

Wania and Mackay (1996) described the migration of POPs using the "grasshopper effect", defined as successive cycles of volatilisation and deposition undergone by these compounds at normal ambient temperatures because of their sufficient volatility. This travel through the atmosphere in multiple hops, as opposed to a single emission-deposition event, is the key process that enables long-distance transport (Gouin et al. 2004).

The LRAT potential of each POP is associated with both its physical-chemical properties and the environmental characteristics where it is found. Therefore, the global fractionation of POPs will take place as a consequence of their volatility and the latitudinal variation in temperature. Thus, within the mixture of POPs, those more volatile will remain in the air longer than those less volatile, which will undergo partition faster on some surfaces. In turn, in tropical and subtropical regions, warm temperatures will enhance volatilisation from the surfaces. In areas of higher latitudes, colder temperatures favour deposition on surfaces and,

in mid-latitudes, seasonal temperature changes will regulate these cycles (Wania and Mackay, 1996).

In the case of an emitted molecule, a hop consists of a complete deposition-volatilisation cycle, which means that in air, the number of evaporation events defines the number of hops. By contrast, if the molecule is initially on a surface, the number of hops will be the number of depositions it undergoes. That number is an indicator of POP recycling in the atmosphere, and it is expressed as the residence time  $(\tau)$  divided by the time a certain molecule of POP flushes out of the atmospheric compartment (Jurado and Dachs, 2008):

Equation 1 indicates how many times, on average, the molecules complete a depositionvolatilisation cycle while residing in the atmosphere (average time).

During the LRAT, it is important that transport and fractionation do not occur in a single hop. Multiple hops ensure that POPs will persist, and even if their emissions cease, they could be transported for years (Gouin et al. 2004).

Jurado and Dachs (2008) evaluated the grasshopping potential of POPs in the global oceanic atmosphere and observed that, during LRAT over the oceans, the number of hops had considerable spatial and seasonal variability. Although the air-surface partition coefficients are much more affected by temperature than the partitions involving other compartments, such as water-sediment or water-soil (Wania and Mackay,1996), the atmosphere-ocean exchange fluxes are fundamentally influenced by processes associated with the biogeochemistry of the water column. Thus, the global fractionation of POPs, as a complex interaction of many processes that maximise or minimise the number of hops, affects the transport potential of LRAT.

# **OCEANIC ATMOSPHERIC DEPOSITION: RELEVANCE, CONTROL AND IMPLICATIONS**

Transfer of POPs from the air to the ocean surface occurs fundamentally through atmospheric deposition. POPs originate in the continental area from point or diffusive sources (agricultural, industrial and numerous combustion emissions), and like all semivolatile compounds, they are distributed in the atmosphere between the particulate and gas phases. The degree of association with the particulate phase will be determined by the vapour pressure of each compound, ambient temperature and the amount and nature of particles (aerosol) present. As shown in Figure 1, POPs arrive in the oceans after undergoing longdistance transport and are removed from the atmosphere by deposition processes involving dry particle deposition, wet deposition and gaseous deposition.

Atmospheric dry deposition occurs when the compounds are removed by gravitational settling associated with particle flux (Bidleman, 1988). Thus, in the open ocean, POPs adsorbed onto marine aerosols follow a downward way to the water surface.

Experimental measures of dry deposition fluxes  $(F_{\text{DD}}$ , pg m<sup>-2</sup> d<sup>-1</sup>) are estimated by Eq. (2) (Jurado et al. 2004):

$$
F_{DD} = v_D C_P \tag{2}
$$

where  $v<sub>p</sub>$  is the overall particle dry deposition velocity (m d<sup>-1</sup>) and  $C<sub>p</sub>$  is the POP particulatephase concentration (pg m<sup>-3</sup>). Dry deposition velocity shows a high dependency on particle diameter distribution and wind speed (turbulence or stability atmospheric).

Figure 1. Key atmospheric processes that allow the arrival of POPs at the surface water of the open oceans. Adapted from Castro- Jiménez et al. (2015) and Lohmann and Dachs (2019).

Atmospheric wet deposition involves the removal of POPs through rain, fog, clouds and snow. Among these forms, rain is the most relevant washing mechanism (Simcik, 2004). Precipitation will deposit POPs in dissolved and particulate form. Wet atmospheric removal is very different for particle-associated compounds than for gas-phase compounds. POPs that are in the gas phase will be eliminated according to Henry's Law  $(H' = H/RT)$  equilibrium between the vapour and aqueous phases and will partition in the water droplets to be washed, falling on the ocean surface, while those that are in the atmospheric particulate matter will be eliminated by precipitation. Particle scavenging is a more complex process involving cloud weather conditions and the physical-chemical properties of the aerosol (Castro-Jiménez et al. 2015; Ligocki et al. 1985).

Wet deposition fluxes  $(F_{WD},$  pg m<sup>-2</sup> d<sup>-1</sup>) can be calculated using Eq. (3) (Jurado et al. 2005):

$$
F_{WD} = p_0 C_R \tag{3}
$$

where  $p_0$  is the precipitation rate per day (m<sup>3</sup> m<sup>-2</sup> d<sup>-1</sup>) and  $C_R$  is the concentration (atmospheric gas and particulate phases) of POP in rain (pg m<sup>-3</sup>). Considering that the gas phase POP concentrations have been estimated using Henry's law constant  $(H', P_a m^3 mol^{-1})$  and that particle scavenging results from processes controlled by properties of the aerosol,  $F_{WD}$  can be estimated by Eq. (4) (González-Gaya et al. 2015):

$$
F_{WD} = p_0 \left( \frac{c_G}{H'} + W_p C_p \right) \tag{4}
$$

where  $p_0$  is the precipitation rate per day (m<sup>3</sup> m<sup>-2</sup> d<sup>-1</sup>),  $C_G$  the POP concentration in the gas phase,  $H'$ , Henry's Law constant and particle scavenging, based on the washout ratio  $(W_{p})$  and  $C_{p}$  the POP concentration in the particulate phase.

The relative importance of each depositional process will depend on a combination of factors, such as the levels of atmospheric particulate matter, rain intensity, POP affinity to aerosols, etc.).

Generally, dry particle deposition is important for POPs with low-medium volatility and strong affinity to particle (PAHs and dioxins and furans of higher molecular weight). By contrast, more volatile POPs highly associated with the atmospheric gas phase (PCBs and HCHs) would be more affected by diffusive processes. Besides, particulate matter deposition depends on the aerosol diameter, wind speed, and atmospheric stability, including the effects of spray formation under high wind speed conditions and particle growth due to high relative humidities. POP partitioning to aerosols can occur through absorption into the organic phase of aerosols and adsorption onto soot carbon (Jurado et al. 2004).

Given the hydrophobic nature of POPs, removal from the atmosphere by wet deposition would be expected to be much less effective than removal by dry deposition of particles. Also, within clouds, interstitial aerosols are excluded from the aqueous phase and the particle scavenging is very inefficient. In addition, wet deposition is an episodic and intense process that strongly removes POPs when it first occurs and then loses capacity as a transport vector since the atmosphere has become depleted of POPs. However, during periods of abundant rainfall, the washout of POPs from the atmosphere is significant and wet deposition plays an important role in the mobility and environmental fate of POPs (Cetin et al. 2016, González-Gaya et al. 2015; Skrdlíková et al. 2011).

Diffusive air-water exchange (or dry gaseous deposition) consists in the transfer of POPs from the atmospheric gas phase to the water dissolved phase (Castro Jiménez et al. 2015)

In order to understand the diffusive processes, the fugacity approach is used. Fugacity is "a measure of chemical potential or partial pressure of a chemical in a particular medium that controls the transfer of chemicals between media" (Wang et al. 2011). The fugacities of POPs in the air  $(f_a)$  and water  $(f_w)$  were calculated using Eqs. (5) and (6) (González-Gaya et al. 2015), as follows:

$$
f_A = C_G RT \tag{5}
$$

$$
f_W = C_W H'RT \tag{6}
$$

where  $C_G$  and  $C_W$  are the POP concentrations in the gas phase (pg m<sup>-3</sup>) and dissolved phase (pg m<sup>-3</sup>), respectively; **R**, the gas constant  $(8.314 \text{ Pa m}^3 \text{ mol}^{-1} \text{ K}^{-1})$ , **H'**, Henry's law constant (dimensionless) and  $\overline{T}$  (K).

The fugacity ratio  $f_A/f_W$  between the air and water for POPs can be calculated using Eq. (7) (Nizzetto et al. 2010), and  $K_{AW}$  is the temperature corrected dimensionless air-water equilibrium partition coefficient (Henry's Law constant).

$$
\frac{f_A}{f_W} = \frac{c_G}{c_W K_{AW}}\tag{7}
$$

A fugacity ratio  $f_{A}/f_{W} = 1$  indicates a condition of thermodynamic equilibrium of POPs between the air and water phases and no net transfer in either direction. Net deposition or volatilisation is indicated by values of  $f_{A}/f_{W}$  significantly smaller or greater than unit, respectively (Bigot et al. 2016). Thus, values of  $f_A/f_W > 1$  indicate deposition and  $f_A/f_W < 1$ indicate the potential for re-emission of compounds from surface water (Nizzetto et al. 2010).

The net air-water diffusive flux is always from high to low fugacity (González-Gaya et al. 2015). Thus, the concentration gradient is driven across the air-water interface and the tendency depends on environmental conditions (wind speed, temperature) and specific compound physical-chemical properties, all of which influence the mass transfer coefficient  $(k_{AW}, \text{m d}^{-1})$ . Absorption  $(F_{AW}, \text{pg m}^{-2} \text{ d}^{-1})$  and volatilisation fluxes  $(F_{AW_{null}}, \text{pg m}^{-2} \text{ d}^{-1})$  are obtained using Eqs. (8) and (9) (Dachs et al. 2002):

$$
F_{AW} = k_{AW} \frac{c_G}{H}
$$
 (8)

$$
F_{AW_{vol}} = k_{AW} C_W \tag{9}
$$

Fluxes of POPs across the air-water interface will be controlled by the rate of gaseous exchange and is given by Eq. (10) (Dachs et al. 2002):

$$
F_{AW} = k_{AW} \left( \frac{c_G}{H'} - C_W \right) \tag{10}
$$

 $k_{AW}$  may be estimated by implementing the two-layer surface resistance model as the result of mass transfer coefficients in each phase  $(k_A \text{ and } k_W)$ , using Eq. (11) (Dachs et al. 2002):

$$
\frac{1}{k_{AW}} = \frac{1}{k_A H'} = \frac{1}{k_W} \tag{11}
$$

where  $k_A$  and  $k_W$  are the POP mass transfer coefficients (m d<sup>-1</sup>) in the air and water layers, respectively. For their calculations, empirical standard coefficients are used:  $H<sub>2</sub>O$  in the air  $(k_{A,H2O})$  and CO<sub>2</sub> in the water  $(k_{W,CO2})$  (González-Gaya et al. 2015).

On the air side,  $k_A$  may be calculated from the mass transfer coefficient of H<sub>2</sub>O ( $k_{A,H2O}$ ) m d-1 ) by Eq. (12) (Dachs et al. 2002)

$$
k_{A} = k_{A,H2O} + \left(\frac{D_{POP,a}}{D_{H2O,a}}\right)^{0.61}
$$
\n(12)

where  $D_{POP,a}$  and  $D_{H2O,a}$  are the diffusivity coefficients of the POP and H<sub>2</sub>O in air, respectively.

In addition,  $k_{A,H2O}$  is given by Eq. (13)

$$
k_{A,H2O} = 0.2U_{10} + 0.3\tag{13}
$$

where  $U_{10}$  is the wind speed at 10 m height from the atmosphere-ocean interphase.

Similarly, in the water,  $k_w$  may be calculated from the mass transfer coefficient of  $CO_2$ on the water side  $(k_{W,CO2}, \text{m d}^{-1})$  (Eq. 14)

$$
k_W = k_{W,CO2} + \left(\frac{Sc_{POP}}{600}\right)^{-0.5}
$$
\n(14)

where  $Sc_{pop}$  is the Schmidt number of the POP and 600 accounts for the Schmidt number of CO<sup>2</sup> at 298 K, respectively.

And  $k_{W,CO2}$  is given by Eq. (15)

$$
k_{W,CO2} = 0.24U_{10}^2 + 0.061U_{10}
$$
\n<sup>(15)</sup>

Therefore,  $k_{AW}$  is strongly dependent on wind speed and also on temperature, Schmidt numbers, and  $H'$  (Dachs et al. 2002).

The dynamics of the atmosphere-ocean system is critical to global cycling and the fate and behaviour of POPs. From the surface ocean waters, they can enter the atmosphere and, by coupling to other mechanisms, they become susceptible to physical or biological alterations, such as degradation, incorporation into the food chain and deposition in the deep ocean.

The control on POPs fate includes the following processes:

- Geochemical processes: air-water exchange, degradation in air, degradation in water ("degradative pump") and vertical fluxes with settling particles to deep waters (sinking fluxes).
- Biological pump

In the atmosphere, POPs can undergo chemical reactions with oxidants, such as hydroxyl radical (·OH), the nitrate radical (NO3) and ozone (Keyte et al. 2013). The main degradation of POPs occurs by reaction with ·OH and depends on the concentration of ·OH in the atmospheric boundary layer and on the half-life  $(t1/2)$  of POPs. However, within-ocean biogeochemical processing of POPs is the most relevant control in the global dynamics and the role of oceans as sink of POPs.

As Figure 2 shows, in the ocean-surface mixed layer, POPs partition between dissolved and organic particulate phases (Jaward et al. 2004). Phytoplankton uptake and vertical fluxes of particles are the key to controlling the surface recycling, impact and sinks of POPs (Dachs et al. 2002). Although there are multiple and complex interactions in the water column that would greatly affect the atmospheric depositional processes (Jaward et al. 2004), under certain environmental conditions, the removal of POPs concentrations from the water column would deplete their concentrations in surface waters and modify the equilibrium conditions, thus enhancing the air-water diffusive flux.

Once POPs enter the ocean-surface mixed layer, POPs fluxes are established between water and plankton  $(F_{wp},$  ng m<sup>-2</sup> d<sup>-1</sup>), as described in Eq. 16 (Dachs et al. 2002):

$$
F_{WP} = k_{WP} \left( C_W - \frac{k_d}{k_u} C_p \right) \tag{16}
$$

where  $C_P$  is the POP concentration in phytoplankton (ng kg<sup>-1</sup>),  $k_u$  (m<sup>3</sup> kg<sup>-1</sup> d<sup>-1</sup>) and  $k_d$  (d<sup>-1</sup>) are the uptake and depuration rate constants, respectively. The mass transfer coefficient between water and plankton ( $k_{WP}$ , m d<sup>-1</sup>) depends on the mixed layer depth (*MLD*, m), the phytoplankton biomass ( $B_p$ , kg m<sup>-3</sup>), and the uptake constant, as described in Eq. 17:

$$
k_{WP} = MLD \cdot B_p \cdot k_u \tag{17}
$$

Therefore, the dynamics of POPs in the marine environment is linked to the phytoplankton dynamics. POPs sorb to phytoplankton and a fraction will sink associated to cells, fecal pellets, and other aggregates. The biological carbon pump is the sinking of phytoplankton from the surface layers to the seabed. This mechanism involves a "sequestration" of atmospheric carbon (captured by phytoplankton) and its quick and efficient transfer to great depths. Thus, carbon captured at the surface is retained in the deep ocean for hundreds of years (Agusti et al. 2015). The biological pump induces depletion of POP concentrations in the photic water column by sequestering them in the particulate organic carbon that sediments, and therefore, the biological pump favours the diffusive air-water exchange.

Considering the role of the ocean as a final sink for POPs, the vertical sinking of particulate matter is a key process in removing organic carbon and POPs from the sea surface to the deep ocean. Particle sinking is a net unidirectional and non-fugacity driven process. According to Dachs et al. (2002), vertical fluxes of POPs out of the mixed-layer are given by the product of POP concentrations in sinking particles to the vertical flux of sinking organic matter  $(\mathbf{F}_{\mathbf{OM}}, \text{ng m} \textsuperscript{-2} \text{d} \textsuperscript{-1})$ 

$$
F_{sink} = k_{sink} \frac{k_d}{k_u} C_p \tag{18}
$$

where  $k_{\text{sink}}$  (m d<sup>-1</sup>) is the mass transfer rate coefficient for sinking POPs.

$$
k_{\text{sink}} = F_{\text{OM}} \frac{k_u}{k_d} \tag{19}
$$

Despite the limited number of studies conducted empirically in the open ocean, atmospheric deposition has been empirically verified in oceanographic campaigns along ocean transects. Diffusive air-water exchange is the mechanism that dominates the removal of atmospheric POPs and their entry into oceanic surface water. However, the occurrence of dry and wet deposition has been evaluated in some oceanic regions.

On the one hand, Jurado et al. (2004) evaluated the relative importance of dry particle deposition and air-water exchange for the Atlantic Ocean and at the global scale and determined that for all PCBs congeners and lower PCDD/Fs, air-water exchange dominates the dry deposition mechanism. However, these authors were able to show a consistent spatial variability in depositional fluxes. The dry deposition fluxes increase at mid-high latitudes in association with the marked presence of marine aerosols, lower temperatures that improve the partition of pollutants in the aerosols and high wind speeds that favour turbulence and aerosol accumulation. The zone influenced by the Saharan-Sahel dust (between 10° N and 25° N) and the zone around 30° S registered the highest values of dry deposition fluxes in association with high concentrations of marine aerosol. On the other hand, Jurado et al. (2005) observed that wet deposition was highest in the Intertropical Convergence Zone (ITCZ), where convective precipitation rates are elevated.

Figure 2. Main ocean biogeochemical processes that affect the distribution and fate of POPs. Adapted from Dachs et al. (2002), Jaward et al. (2004) and Lohmann and Dachs (2019).

These works characterize the atmospheric deposition of PCBs and PCDD/Fs to the Atlantic Ocean, reporting average values of dry aerosol deposition flux in the order of 66 ng.m<sup>-2</sup> yr<sup>-1</sup> and 9 ng.m<sup>-2</sup> yr<sup>-1</sup> respectively, and, average values of wet deposition fluxes in the order of 110 and 45 ng.m<sup>-2</sup> yr<sup>-1</sup>. Furthermore, the total dry deposition results in 2200 kg.yr<sup>-1</sup> (PCBs) and 500 kg.yr<sup>-1</sup> (PCDD/Fs); the total wet deposition results in 4100 kg.yr<sup>-1</sup> (PCBs) and 2500 kg yr-1 (PCDD/Fs); the net air-water exchange is higher, 22000 kg.yr-1 for PCBs and 1300 kg.yr-1 for PCDD/Fs.

In addition, other works presented evidence of atmospheric deposition in the open ocean. For instance, PAHs deposition over tropical oceans has been reported (Del Vento and Dachs, 2007). Atmospheric dry deposition velocities ranged between 0.1 and 0.3 cm  $s^{-1}$ . The important atmospheric input of Saharan dust in the Northeast Subtropical/Tropical Atlantic Ocean was reflected as dry deposition in the region between  $26^{\circ}$  and  $21^{\circ}$  N. In this region, for the more volatile PAHs outbreaks of Saharan dust there is a significant increase in the deposition velocities, reinforcing what was observed by Jurado et al. (2005). The South Atlantic and the Southern Ocean showed a net flux for α-HCH, γ-HCH and for Endosulfan

from air to seawater, indicating that these oceans remain net sinks for these pesticides (Lueck et al. 2017). The fugacity ratio calculations for hexachlorobenzene (HCB) and γ-HCH suggested that they were deposited from air to water in the North Atlantic (Zhang et al. 2012). The observed air–sea gas exchange gradients in the Arctic Ocean mainly favoured net deposition of OCPs (Cai et al. 2012). In the Southern Ocean, Bigot et al. (2016) determined that the Indian-Pacific sector acts as an environmental sink for OCPs and the air-water fugacity ratios and fluxes indicated net deposition for γ-HCH, dieldrin and chlorpyrifos.

Furthermore, trophic levels were coupled to air-water exchange through phytoplankton. Air-water fugacity ratios demonstrated the potential for lindane ( $\gamma$ - HCH) gas deposition to water and γ-HCH concentrations found in krill samples (*Euphausia superba*) and have been correlated with seawater concentrations in the Southern Ocean. Thus, it shows bioconcentration of HCHs from seawater (Cincinelli et al. 2009). High concentrations of PCBs in crustaceans from the deep Pacific Ocean illustrated their penetration into even the most remote regions of the ocean from atmospheric deposition (Jamieson et al. 2017). In addition to this, the strong bioaccumulation and magnification of PCBs, particularly in apical predator marine species, account for the impact of atmospheric deposition on the ecosystem. Thus, the presence of POPs in biota reflects the influence of atmospheric deposition from the base of the trophic pyramid of the marine ecosystem to apical predators. While phytoplankton exposure to POPs occurs only through water, so that bioaccumulation could respond to the dynamics of the equilibrium between cells and the surrounding water, zooplankton accumulates POPs from the water and from its diet. This suggests that zooplankton biomagnifies contaminants, such as PCBs and OCPs (Hallanger et al. 2011). As a consequence, top predators, such as large pelagic fish, of ecological importance in open oceans, have presented predominance of OCPs, especially DDTs, versus PCBs in the Indian Ocean (Munschy et al. 2020).

Phytoplankton plays a key role not only in acting as the first link in transferring these pollutants to higher trophic levels, but also as a carbon transporter from the atmosphere to deep waters and sediments (biological bomb). The latter role favours the sinking of POPs into the ocean. Morales et al. (2015) correlated PCDD/Fs and PCBs concentration with plankton biomass in the Atlantic, Pacific, and Indian Oceans, suggesting that atmosphere depositionwater column- plankton are coupled. The settling fluxes of organic matter bound PCDD/Fs and PCBs are of 400 and 10,500 kg y−1, respectively. The atmospheric inputs are nearly 3 and 10 times larger for PCDD/Fs and PCBs. Thus, they support the role of the biological pump in the accumulation of POPs in deep ocean. With regard to the biological pump, it is expected to be a much more efficient process for higher hydrophobicity POPs than for the less hydrophobic ones. However, in areas of high productivity such as the North Atlantic region adjacent to the Arctic Ocean, the transport of HCB and HCHs (two OCPs of less hydrophobicity) was evidenced by the action of the biological pump (Galbán- Malagón et al. 2013).

More recently, Buesseler et al. (2020) have applied a metric approach to the ocean depths and the euphotic zone, determining the existence of regions where the action of the biological pump would significantly increase its carbon sequestration efficiency. Therefore, its relevance would be even greater, promoting the accumulation of POPs in the deep ocean and hence the atmospheric deposition (Nizzetto et al. 2012).

# **OCEANIC POPS OUTGASSING**

Considering the global cycling of POPs, Meijer et al. (2003) suggested two possible scenarios based on primary emissions.

- i) Primary emission levels are high and dominate the atmospheric concentrations. Once the chemical compound is released from its "primary source", it is deposited and remains retained, which prevents its volatilisation. Thus, the reservoirs (soil or sediments buried in deep ocean waters) would act as sinks.
- ii) Emissions from the environment capacitors (secondary sources, such as soils and oceans) dominate the atmospheric level concentration. Environmental reservoirs control POPs atmospheric levels.

Historically, the ocean has acted as an ultimate sink for POPs. During the peak usage of POPs, primary sources dominated their atmospheric levels and important biogeochemical drivers, causing POPs burial in sediments. As expected, atmospheric levels of POPs gradually decreased after the application of regulatory actions and strict controls. In this new global environmental scenario, the sinks could play a role in the air input of POPs by re-emitting these compounds from the major environmental repositories.

Although POPs re-emission from ocean waters has rarely been documented, some research on modelling suggests the feasibility of occurrence of these compounds. Stemmler and Lammel (2009), for instance, employed global simulation and historical data on the usage of DDT. They observed that, in ocean models, some marine regions acted as the most significant secondary DDT source, coinciding with a decline in the large number of applications (1970s–1990s). The global multi-compartment chemistry-transport model with coupled atmosphere and ocean determined that the Western North Atlantic region was the most significant secondary DDT source. In large parts of the Tropical Ocean and in the midlatitude meridional areas, there has been evidence for net volatilisation, showing a reversal of the usual net flux in the marine air system. For instance, Nizzetto et al. (2008) found PAHs along a North-South Atlantic transect ( $\Sigma_{10}$  PAHs ≈ 1.4- 2.5 ng m<sup>-3</sup> air, and 0.7-1 ng L<sup>-1</sup> seawater) and calculated  $f_A/f_W$  for selected compounds. For fluoranthene and pyrene  $f_A/f_W$  $\approx$  1, suggesting air–water partitioning near equilibrium in remote, open ocean areas. In the remote tropical Atlantic Ocean, for anthracene and phenanthrene,  $f_A/f_W$  were < 0.3, suggesting net volatilization.

A relevant study on the evidence of degassing in the open ocean was carried out by Zhang and Lohmann (2010). These authors reported, for the first time, that PCBs could volatilise in the oligotrophic open ocean during a decline in land-based emissions. The fugacity ratio indicated that PCBs were volatilising from surface waters to the atmosphere, and air-water exchange fluxes were  $\sim$ 0.5 to  $\sim$ 30.4 ng m<sup>-2</sup> d<sup>-1</sup>.

These authors attributed the volatilisation of PCBs in the Pacific mainly to the following two causes:

A reduction in POPs in the environmental concentrations. During periods of high PCBs levels of emissions, the oceans act as PCBs accumulators. After the cessation of their use and production, due to the decrease in emissions, the atmosphere responds more quickly than large bodies of water (buffer function), resulting in low air-water fugacity ratios.

The extremely low rate of particle sinking in the South Pacific (one of the most oligotrophic oceanic regions). The South Pacific Gyre, part of the remote Pacific, presents low sedimentation rates because of the low surface concentrations of chlorophyll and the low surface biological production. It would cause an increase in the PCBs concentrations in the dissolved phase. This factor, together with the high temperatures of the water, would move the fugacity gradient towards net volatilisation. In this way, the South Pacific would be a secondary source of PCBs.

Although the cause of net volatilisation has not yet been elucidated, the removal of PCBs from the Open Pacific surface into the lower atmosphere has been clearly demonstrated. After the elimination of primary emission sources, the ocean subsurface can provide the ocean surface and the atmosphere with POPs. Whether due to rapid changes in the atmospheric patterns or to a longer-term trend in ocean occurrence, the ocean could act as a source rather than a sink for some POPs.

Nizzetto et al. (2010) provided experimental evidence across the Atlantic Ocean to illustrate that the ocean has a buffering capacity to moderate the rate at which the system would respond to an underlying change in continental emissions. This buffering capacity showed dependence on the type of POP.

While several polychlorinated dioxins and furans (PCDD/Fs) have experienced a marked decrease (even greater than that experienced in continental areas), the levels of PCBs have not decreased significantly over the remote oligotrophic Atlantic Ocean.

The analysis of loss/sink velocities for a range of PCBs and PCDD/Fs congeners evidenced that the main difference between these compounds was the reaction in surface water, with PCDD/Fs being faster (1-2 orders of magnitude) than PCBs. Given the oligotrophic characteristics of these waters, the mechanism by which POPs are degraded is likely the indirect photochemical pathway and not the biodegradation. During the day, the irradiation of chromophores found in the dissolved organic matter (DOM) of the surface water originates hydroxyl radical, which more reactively attacks the structure of PCDD/Fs (the four C atoms neighbour of O atom). Thus, PCDD/Fs decline faster  $(t_{1/2})$  than PCBs. Although this mechanism requires further investigation, it suggests a remarkable role for the ocean DOM in controlling the global fate of POPs.

More recently, Li et al. (2020) presented the first field study describing the open Pacific Ocean as a secondary source of OCPs, reporting fugacity ratios that suggest volatilization of HCH from surface water to the atmosphere, with air-water exchange fluxes in the range 0.3- 11.1 ng m $^{-2}$  day $^{-1}$ .

#### **CONCLUSION**

The transport dynamic of POPs to the open ocean is particularly associated with another dynamic: that of ocean-atmosphere system interactions. Not only has the Pacific Ocean atmosphere been affected by the arrival of these semivolatile organic compounds, travelling long distances from their source of origin, but also that of the Atlantic, Indian and polar oceans. The atmosphere deposition is the undisputed mechanism through which POPs may be introduced into the oceans. One of the most important depositional processes involves the airwater exchange.

The evaluation of these fluxes between the atmosphere and the ocean surface water provides the key to monitoring POPs in open oceans. Although oceans are proved to be compartments of great relevance to POPs environmental fate, studies considering the simultaneous measurements of these compounds in air and water are scarce.

Even though many ocean biogeochemical mechanisms have not been clearly studied, the highly hydrophobic properties of POPs allow them to be coupled to organic particles, and this assembled combination will then be present at greater depths. Apart from sedimentation, biological pumping processes encourage atmosphere deposition. As a consequence of their volume, oceans are the greatest final sinks for POPs. However, there have been historical changes in these compounds' emissions, and this fact is associated with the demonstration of surface waters acting as buffers between the atmosphere and the deepest ocean layers. This produces the re-emission of some POPs to the atmosphere, reversing the net deposition fluxes, with the oceans playing a degassing role.

In spite of the difficulties inherent in oceanographic campaigns, such as the costs involved in the use of ships, the required sample volume, the complication of comparing the data due to the influence of air masses, and ocean gyres, it is extremely important to increase the database of air-water exchange directions and the number of flux calculations in order to gain a better understanding of the dynamic and global fate of the main POPs in the open ocean. Moreover, as the atmospheric deposition of POPs has an impact on phytoplankton and thus on POPs accumulation at different trophic levels, it would be essential to evaluate the implications of depositional processes because they can pose a risk to the ocean value as a resource, thus affecting the health of the ecosystems.

# *BIOGRAPHICAL SKETCH*

# *Melina Mirta Orazi*

#### **Affiliation:**

Instituto Argentino de Oceanografía IADO – CONICET/UNS Bahía Blanca, Argentina.

#### **Education:**

- PhD in Biochemistry, Universidad Nacional del Sur, Bahía Blanca, Argentina.
- Biochemistry, Universidad Nacional del Sur, Bahía Blanca, Argentina.

#### **Business Address:**

Camino La Carrindanga km 7.5, 8000 Bahía Blanca, Argentina.

#### **Research and Professional Experience:**

- Internship in the Marine Chemistry Area, Instituto Argentino de Oceanografía (IADO– CONICET/UNS), learning techniques for the determination and analysis of organic and inorganic pollutants, Tutor: Ph.D. Natalia Buzzi. Date: March-December 2014.
- Doctoral fellow in the Marine Chemistry Laboratory, Instituto Argentino de Oceanografía (IADO – CONICET/UNS). Advisors: Marcovecchio, Jorge E., PhD and Arias, Andrés H., PhD.
- Research activities related to the evaluation of the presence, composition, and sources of polycyclic aromatic hydrocarbons (PAHs) in air and soils of the southwest of the Buenos Aires province (Argentina).
- Posdoctoral fellow in the Marine Chemistry Laboratory, Instituto Argentino de Oceanografía (IADO – CONICET/UNS). Directors: Arias, Andrés H. and Marcovecchio, Jorge E.
- Research tasks activities related to the evaluation of the transport, deposition and airseawater exchange of organochlorine pesticides (OCPs) and polychlorinated biphenyls (PCBs) in the Atlantic coastal areas of the southwest of Buenos Aires (Argentine).

#### **Professional Appointments:** Postdoctoral fellow.

#### **Publications from the Last 3 Years:**

# **ABSTRACT**

Microplastics are amongst the contaminants of emerging concern for aquatic systems. These ubiquitous environmental contaminants began to be reported since the 1970s, with increasing studies about their distribution and impacts from 2004. Although marine microplastics research remains at the forefront, studies on freshwater and terrestrial environments have begun to occur in this field as a matter of priority in recent years. This chapter addresses the influence of plastic pollution on marine environments through continental water bodies. Rivers and effluents have been identified as significant pathways from terrestrial sources releasing between 4.8 and 12.7 million metric tons of microplastics per year that reach the ocean. Microplastics are present in different sizes, colors, shapes and textures influencing their behavior in the environment. Also, their interaction with the biotic and abiotic systems influence the final fate and transport of them. The varied hydrological characteristics (water flow velocity, water flow seasonal variation, water depth) in lakes and rivers significantly affect plastics transport within freshwater systems towards the ocean. In estuarine environments, the combined effect of turbulence and salinity can interact with particle density, size, and charge. Added to this, storms, floods and runoff contributes to microplastics incorporation in the watersheds

from soil and atmosphere. Therefore, the study of continental microplastics sources and pathways are critical to understanding them as emerging global contaminants.

**Keywords**: microplastics, marine systems, continental sources, microplastics pathways

# **INTRODUCTION**

The large scale of plastic production, the massive consumption and plastic waste production has been increasing since 1950 (Rochman, 2018). The global production of plastic reached approximately 360 million tons in 2018 and is expected to continue increasing in the next years (Plastics Europe, 2019). In a global approach, plastic production and consumption are not the same between developed and developing countries. Nowadays, China is considered the world's largest producer and consumer of plastic materials (Zhang et al., 2018) while pollution in non-developed countries is significantly lower (Xia et al., 2020); therefore, plastic impact is expected not to be uniform around the world.

From this plastic production, at the end of its life, more than 80% ends in the marine systems (Rochman, 2018), positioning plastic litter as a significant problem for the environment, particularly for aquatic systems. Plastics disposal mismanagement causes their spread in environments where they are fragmented, forming microplastics (MPs) (Cole et al., 2011). MPs are plastic particles less than 5 mm in diameter (Thompson et al., 2004) and can be divided into primary (directly produced MPs) or secondary MPs (resulting from plastics fragmentation) being the latter those most registered in worldwide aquatic systems. Among the identified MPs, polystyrene (PS), polyethylene (PE), polyamide (PA), polyethylene terephthalate (PET) and polypropylene (PP) were the most detected polymers in aquatic systems. Polystyrene (PS) is used in packagings such as foam cups, trays, food containers and eating utensils. Meanwhile, PET and PA are widely used in textile industries for synthetic clothes. PE is used in food packaging, films, plastics bottles and beauty care products.

According to Rochman (2018), rivers and effluents have been identified as significant pathways from terrestrial sources releasing between 4.8 and 12.7 million metric tons of microplastics per year that ultimately reach the ocean. Evertheless, the continental inputs' dynamics into the marine environments are poorly documented, as the information on the sources, fate and pathways of continental MPs is limited. Nowadays, MPs are ubiquitous in a broad type of environments from marine (Arias et al., 2019), freshwater (Besseling et al., 2017; Piehl et al., 2019; G. Wong et al., 2020), terrestrial (van den Berg et al., 2020) to the atmosphere (Dris et al., 2016; Enyoh et al., 2019). They are present in different sizes, colors, shapes and textures influencing their behavior in the environment. Also, the interaction with the biotic and abiotic systems influence their final fate and transport among these different environments. MPs in soil could be suspended due to wind action, then deposited by dry/wet atmospheric deposition processes and transferred by runoff to freshwater environments to finally end in the sea. MPs cycle is similar to C, N and other elements cycles where all compartments interact, making a complicated situation to determine a single pathway for MPs from continental to marine environments. Moreover, the varied hydrological characteristics significantly affect the plastic transport within freshwater systems towards the ocean. These comprise water flow velocity, water depth, bottom topography and water flow seasonal variation in lakes and rivers (Campanale et al., 2020). In estuarine environments, the

combined effect of turbulence and salinity can interact with particle density, size and charge (Díez-Minguito et al., 2020). Added to this, storms, floods and runoff contribute to MPs incorporation in the watersheds from the soil and atmosphere (G. Wong et al., 2020). Therefore, the study of continental MPs' sources and pathways is crucial to understanding them as emerging global contaminants.

#### **The Relevance of Microplastics Contribution from Continental Sources**

Since scientists began to study MPs, they were found in water, soil, air and biota registering a long-range transport between these compartments (Dris et al., 2016; Eckert et al., 2018; Arias et al., 2019; Ronda et al., 2019). Determination and quantification of MPs transport pathways from continental sources to the marine environment have been significant challenges. The results from numerous monitoring programs indicate that environmental plastic pollution problems can only be solved by attacking the pollution sources. In contrast, MPs removal from the environments is hardly possible (Bitter and Lackner, 2020). Longrange atmospheric transport from urban centers has been registered in remote mountain catchments (Allen et al., 2019) and Arctic snow (Bergmann et al., 2019) demonstrating that MPs are transported atmospherically to both local and faraway places. Thus, identifying the most relevant point sources of plastics release into the environment is a crucial factor.

Rivers and effluents have been identified as significant pathways from terrestrial sources (Rochman, 2018). From these releases, wastewater treatment plants (WWTP) and landfills are responsible for a considerable proportion (Kazour et al., 2019), with several factors influencing their discharge such as treated water volume, flow rate, filtration processes and sewer systems (Mason et al., 2016; Ziajahromi et al., 2017). MPs removal efficiencies in WWTPs generally range between 72 and 99.4% (Sun et al., 2019); nevertheless, a large amount of these residues still reach lakes and river catchments (Mathalon and Hill, 2014; Murphy et al., 2016). Moreover, sludges from WWTP are usually used in agricultural fields, returning a significant MPs proportion to the environment (van den Berg et al., 2020).

#### **Continental MPs Sources**

Although marine microplastics research remains at the forefront, studies on freshwater and terrestrial environments have begun to occur in this field as a matter of priority in recent years (Table 1). Therefore, it is possible to determine the different inputs and influence of plastic pollution from terrestrial environments through continental water bodies that reach the ocean (Fig. 1). In the last years, more studies quantifying MPs presence in soils (van den Berg et al., 2020), dust (Yukioka et al., 2020), atmosphere (Dris et al., 2016, 2018; Stanton et al., 2019), lakes (Wang et al., 2018; Zhang et al., 2018; Alfonso et al., 2020a, 2020b) and rivers (Lebreton et al., 2017; Piehl et al., 2019) were worldwide developed. Nevertheless, the connected pathways among all these compartments still need for more research. Moreover, all MPs do not end in the ocean without first having passed through terrestrial and freshwater environments. Therefore, according to Rochman (2018), MPs' study in these ecosystems will give us more information about their source as the particles will be less weathered, fouled and fragmented than in the ocean.

# Table 1. Overview of microplastic sources, sample type, lower particle size limit (mm), **Table 1. Overview of microplastic sources, sample type, lower particle size limit (mm),**  concentration, main category and affected sea/ocean **concentration, main category and affected sea/ocean**

Abbreviations: SW: surface water, SE: sediment, S: soil, RD: road dust, A: atmospheric fallout, WWTP: wastewater treatment plant, NA; no available.

*Soil*

The presence of MPs in soil dust is becoming more apparent. As research advances, we know that soils can act as a long-term sink for microplastics (Rochman, 2018; Wang et al., 2020). Plasticulture application on agricultural fields (e.g., plastic sheeting in greenhouses or plastic film mulching covering) for production, contributes to MPs presence from its continuous weathering and fragmentation in situ (Wang et al., 2019). Other sources of MPs in soils are open waste dumping (Wang et al., 2020), road littering with tire abrasion (Yukioka et al., 2020) and landfills (Bläsing and Amelung, 2018). However, the application of sewage sludge from WWTP in worldwide agricultural lands was recognized as the leading cause of MPs presence in soils (van den Berg et al., 2020). According to Nizzetto et al. (2016), the annual MPs input into agricultural lands from sewage sludge/biosolids application could exceed the total amount of MPs in oceans.

Most previous studies concerning soil MPs were conducted in China, one of the greatest producers and consumers of plastic (Zhang et al., 2018). A study in coastal soils adjacent to the Bohai Sea and Yellow Sea in China showed that MPs concentrations ranged from 1.3 to 14712.5 MPs kg<sup>-1</sup> (Zhou et al., 2018) and were associated with local anthropogenic activities as aquaculture, port construction and tourism. Also, soils from farmlands and forest zone around Dian Lake, registered MPs concentration between 7100 and 42960 MPs kg<sup>-1</sup> (mean value 18760 MPs kg<sup>-1</sup>) (Zhang and Liu, 2018). Furthermore, it was estimated that sewage sludge application in farmlands from Europe and North America, releases about 63000 to 430000 and 44000 to 300000 tons of MPs per year, respectively (Nizzetto et al., 2016b). Furthermore, a study in four WWTP and 16 agricultural fields from Spain found that on average, soils' plastic loads increased by 280 light density MPs kg<sup>-1</sup> and 430 heavy density MPs  $kg<sup>-1</sup>$  with each successive application sewage sludge (van den Berg et al., 2020). For South America, a study case in agricultural fields from Chile found soil MPs contents ranging from 600 to 10400 MPs kg<sup>-1</sup>, depending on sludge rates applied (Corradini et al., 2019).

#### *Atmosphere*

The ubiquitous presence of MPs in the environment from soil, biota and aquatic systems leads us to think about their presence in the atmosphere. Nevertheless, the number of studies about the occurrence and distribution of suspended atmospheric microplastics (hereafter SAMPs) is recently beginning to increase in comparison with other environmental compartments (Dris et al., 2015, 2016; Liu et al., 2019), considering the atmospheric transport as a potential pathway for continental MPs to the ocean. First studies were carried out in urban areas, as the developed-in Greater Paris, located on the River Seine basin (that drains in the North Atlantic Ocean) and where concentrations from 29 to 280 SAMPs  $m<sup>2</sup>$  day<sup>-1</sup> were registered (Dris et al., 2015). The higher concentrations were associated with rainfall events, suggesting that this could be an important environmental factor for atmospheric deposition. Another study developed in London found deposition rates ranging from 575 to 1008 SAMPs  $m<sup>-2</sup>$  day<sup>-1</sup>, where fibers dominate the shape category in 92% of the samples (Wright et al., 2020). Therefore, more studies should focus on environ-mental variables' effects on atmospheric MPs presence, emphasizing the plastic sources in the catchments exposed to severe anthropogenic impacts, mainly urban areas.

A recent study sampled sea air during a cruise in the western Pacific Ocean, founding SAMPs concentrations from 0 to 1.37 MPs m<sup>-3</sup> (Liu et al., 2019), and fibers dominated the samples (60%). Higher SAMPs concentrations were registered in the coastal area (0.13  $\pm$  0.24

SAMPs m<sup>-3</sup>), than in the pelagic area  $(0.01 \pm 0.01 \text{ SAMPs m}^{-3})$ , and during the daytime  $(0.45 \text{ m})$  $\pm$  0.46 SAMPs m<sup>-3</sup>) than the nighttime (0.22  $\pm$  0.19 SAMPs m<sup>-3</sup>) (Liu et al., 2019). These are the first results providing consistent evidence that SAMPs are critical MPs sources pollution in the oceans and emphasize textile microfibers' presence. Another recent study using highresolution spatial and temporal data revealed that near 132 SAMPs  $m<sup>2</sup>$  day<sup>-1</sup> are deposited in remote U.S. conservational areas trough atmospheric deposition (Brahney et al., 2020). The authors remark that microfibers dominated the sample composition, suggesting that laundry drying could be the primary source in which microfibers are released several times more than through wastewater during the washing (Pirc et al., 2016). They also estimated averaged deposition rates of >1000 metric tons per year in these protected lands (Brahney et al., 2020). According to these results, urban centers and resuspension from soils or water are the primary sources of plastics wet-deposited; meanwhile, under dry conditions, SAMPs smaller in size were associated with longer-range or global transport (Brahney et al., 2020).

#### *Lakes, Rivers and Estuaries*

Lakes, rivers and estuarine systems are among the most studied MPs sources to the date, linking the continental systems to marine environments (Sighicelli et al., 2018; Arias et al., 2019; Meng et al., 2020; Xia et al., 2020). The studies developed in these systems focused on quantifying water and sediment MPs as the most relevant plastic sources. Most of these studies were focused on pollution monitoring alone, rather than discussing the possible pathways or their interaction with the environmental factors in their way into the ocean (Ajith et al., 2020).

The vast majority of these studies were developed in North America, Europe and Asia and still increasing in South America and Africa during the last years (Blettler et al., 2017; Alfonso et al., 2020a). These studies are particularly relevant, considering that freshwater and estuarine ecosystems are highly diverse. MPs found in these systems give us relevant information about their sources on their way to the oceans. Based on the literature, MPs concentrations in continental surface waters are comparable and even higher than marine systems in some cases (Table 1) (Grbić et al., 2020). Besides those MPs studies developed in endorheic lakes, most of them were developed in lakes and rivers that directly or indirectly connect with estuaries and the ocean, contributing to their final deterioration.

Microplastics were first reported in freshwater lakes in 2013 when a study developed in the Great Laurentian Lakes recorded MPs abundances up to 466,000 MPs km-2 downstream from two major cities, with a mean value of 43,000 MPs km<sup>-2</sup> (Eriksen et al., 2013). A recent study in Lake Ontario, Canada, analyzed the MPs' presence in surface waters (800 MPs m<sup>-3</sup>), stormwater runoff (15400 MPs  $m<sup>3</sup>$ ), agricultural runoff (900 MPs  $m<sup>3</sup>$ ) and treated wastewater effluent (13300 MPs m−3) (Grbić et al., 2020). Studies in larger shallow lakes from China registered similar or higher MPs concentrations ranging from 900 to 4650 MPs m<sup>-3</sup> in Dongting and Hong lakes, respectively (Wang et al., 2018); between 1660 and 8925 MPs m<sup>-3</sup> in 20 urban lakes from Wuhan (Wang et al., 2017); and up to  $34,000$  MPs m<sup>-3</sup> in Poyang Lake, the largest freshwater lake from China (Yuan et al., 2019). In European lakes, MPs concentrations in the Bolsena and Chiusi lakes in Italy were 2.51 and 3.02 MPs  $m^{-3}$ , respectively (Fischer et al., 2016). In South America, there are few studies in lakes registering concentrations from  $143.3 \pm 40.4$  MPs m<sup>-3</sup> in a shallow lake (Alfonso et al., 2020a) and 0.9 MPs m<sup>-3</sup> in nine deep lakes from Patagonia (Alfonso et al., 2020b); nevertheless, all of them correspond to closed basins, with no connection to the ocean. The only study in a lake

discharging the Atlantic Ocean through the Paraná River is in a floodplain lake (Setúbal Lake) where concentrations of 704 MPs  $m<sup>2</sup>$  in sediment samples were found (Blettler et al., 2017).

MPs concentrations from rivers worldwide resulted in similar or higher than lakes depending on the contamination level. For example, a study in two rivers from China registered 2516.7  $\pm$  911.7 MPs m<sup>-3</sup> and 2933  $\pm$  305.5 MPs m<sup>-3</sup> in the Yangtze River and Hanjiang River, respectively (Wang et al., 2017). Another study in the Seine River and Marne River in France found lower concentrations between 4 and 108 MPs  $m<sup>-3</sup>$  with a plankton net, and between 0.28 to 0.47 MPs  $m<sup>3</sup>$  with a manta net (Dris et al., 2015); nevertheless, in a more recent study in the Marne River, higher concentrations  $(100.6 \pm 99.9 \text{ MPs m}^{-3})$  were registered (Dris et al., 2018). In South America, a study in an Andean tropical river from Ecuador (Guayllabamba River Basin) registered concentrations up to 1,186,339 MPs m-3 (Donoso and Rios-Touma, 2020). It is estimated that 1.15 and 2.41 million tons of plastic waste, currently enters the ocean every year from rivers, with over 74% of emissions occurring between May and October. It has been reported that the 20 most polluted rivers reported in the world, mainly located in Asia, account for 67% of the global total plastic debris that enters the ocean every year (Lebreton et al., 2017). In Europe, studies estimated that the Danube River releases 530–1,500 tonnes of plastic into the Black Sea annually (Lechner et al., 2014) and that 20–31 tons flow into the North Sea every year from the Rhine River (van der Wal et al., 2015). Reported range in raw and treated wastewater in WWTPs from Europe, USA and Australia were between 1–3160 MPs L<sup>-1</sup> and 0.0007–125 MPs L<sup>-1</sup>, respectively, with PS and PE as the most detected polymers (Sun et al., 2019).

Finally, estuarine systems are the final step of MPs from continental sources into the ocean where urban discharges trough river could be significant sources of these particles to coastal ecosystems (Figueiredo and Vianna, 2018) and the ocean (Andrady, 2011). Populated catchments estuaries have been documented as hotspots of plastic pollution (Lam et al., 2020). A study developed in the Mississippi Sound, located along the coasts of Mississippi and Alabama in the northern Gulf of Mexico, registered concentration between 1200 to 381000 MPs m<sup>-3</sup>, founding higher concentrations in the estuaries than in their riverine inputs (Scircle et al., 2020). The authors' explanation is based on that estuary acts as a sink for these plastics from the river where mechanical and photolytic degradation to smaller particles increases their concentrations (Scircle et al., 2020). A study in the Pearl River Estuary, China, registered concentrations of  $2.376 \pm 0.700$  MPs m<sup>-3</sup>, where the highest values were found in the river mouth (Lam et al., 2020). In a previous study, the Pearl River was tagged as the third-largest source of continental-based plastics in oceans, with an annual discharge of 0.1 million tonnes of plastic debris into the South China Sea (Lebreton et al., 2017). These results reveal the critical role of rivers and estuaries to transport MPs from continental sources to the oceans. In Spain, a study developed in the estuary from Ría de Vigo registered concentrations of 0.64  $\pm$  0.10 MPs m<sup>-3</sup> and 0.48  $\pm$  0.11 MPs m<sup>-3</sup> during upwelling and downwelling conditions, respectively (Díez-Minguito et al., 2020). Another estuary from the Elbe River (Germany) found 600,000-fold higher MPs concentrations in sediments (3,350,000 MPs m-3 ) than in water  $(5.57 \text{ MPs m}^{-3})$  (Scherer et al., 2020). Finally, a study in Brazil, including the Juagaribe and the Timonha-Ubatuba estuaries, found concentrations between null and 0.31 MPs m-3 (Garcia et al., 2020).

# **Pathways of Continental Microplastics: Environmental Variables and Particles Characteristics**

There are complex and multiple relations between the environmental variables and human activities influencing MPs' presence and distribution in the environment. Therefore, determine their pathways and transport from continental sources to the ocean has been a significant challenge. In a first approach, the scientific community has considered lakes, rivers and coastal inputs as the principal sources of marine plastic pollution (Rochman, 2018). However, the latest studies also recognized that atmospheric MPs deposition could also be a significant source for marine MPs pollution (Brahney et al., 2020).

Figure 1. Microplastics sources and pathways from the continent to the ocean.

Nowadays, it is senseless to think about marine plastic pollution remediation actions without assessing and performing practical solutions focusing on the understanding and managing emissions and pathway processes on continental sources. Scientists should elucidate the "microplastics cycle" to understand MPs' global fate in oceans (Rochman and Hoellein 2020). Here we proposed a conceptualization of how different MPs pathways interact in an agro-urban global context based on the consulted bibliography (Figure 1). As we establish in previous sections, the anthroposphere (1), which includes urban and agricultural environments, is the leading continental source of plastic pollution to the oceans. From it, primary and secondary MPs enter and cycles between the four environment compartments: the lithosphere (soil) (2), the atmosphere (3), the hydrosphere (lakes, rivers, estuaries and oceans) (4) and the biosphere (5). As the interactions between plants and animals are broad and complicated because of trophic interactions, in this section, we will focus on the sources and pathways between compartments from 1 to 4.

In the anthroposphere, we can cite many MPs pathways across the complex gradient between urban and rural environments. Among them are industrial emissions, resuspension from lithosphere (soils), building and traffic dust to the atmosphere. Plastics may also reach the hydrosphere through direct MPs inputs in aquatic systems due to irresponsible in situ disposal wastes, urban WWTP in rivers, or runoff on catchments. Simultaneously, WWTP sludge on agricultural soils and atmospheric plastic particles fallout contributes to the lithosphere contamination. Finally, trough wind resuspension or runoff, MPs can reach aquatic systems again. Little is known about the MPs behavior inside and between these spheres and their interaction with the environmental variables as flow velocity, turbulence, seasonal flow, water depth variation, catchments topography, salinity and tidal activity in estuarine environments, precipitations and runoff, atmosphere radiation and oxidative processes, among others.

#### *Dry and Wet Atmospheric Deposition*

Atmospheric transport, which has been recently considered one of the pathways by which continental MPs reach the ocean, has been poorly investigated and understood (Liu et al., 2019). A recent study quantified the wet and dry fallout of MPs, suggesting that as in the case of soil transport (Mahowald et al., 2014), those MPs with a size  $<$  25  $\mu$ m can be transported in a long-range or global scale distance (Brahney et al., 2020). Meanwhile, more prominent MPs as fiber can be transported on a regional scale (10 to 1000 km) (Lawrence and Neff, 2009). Moreover, if we consider that MPs densities are lower than those of soil particles (0.65  $-1.8$  g cm<sup>-3</sup> vs.  $\sim$ 2.65 g cm<sup>-3</sup>), it can be expected that MPs will be more transportable. Also, microfibers with higher surface area/volume ratios will increase dragging forces and reduce settling velocities (Brahney et al., 2020). Therefore, according to these results, it is expected that large MPs and wet deposition will contribute less than dry deposition, highlighting the role of regional storms in the local fallout of MPs and a broader scale of atmospheric pattern to a global dispersion (Brahney et al., 2020).

According to SAMPs studies, rain, snow and wind events are responsible for the atmospheric deposition (Dris et al., 2016; Liu et al., 2019; Brahney et al., 2020). It has been reported by Allen et al. (2019) that rainfall and snowfall events duration was negatively correlated with SAMPs fallout, suggesting that frequency and intensity of these events are more relevant than duration. According to climate models, these results are relevant, considering that more frequent and intense rainfalls are expected in the future (Westra et al., 2013).

Microfibers are the most cited MPs type in worldwide studies, and those related to atmospheric deposition are not the exception (Dris et al., 2018; Liu et al., 2019). A recent study found that fibers (60%) dominate the SAMPs in the Pacific Ocean, also accompanied by fragments (31%), granule (8%) and microbeads (5%) (Liu et al., 2019). The authors found that SAMPs decreased in abundance from the coastal area towards the ocean by ten times and that during the daytime was twice than nighttime, as a result of the settlement caused by the high relative humidity at night, especially on the sea (Liu et al., 2019). According to Liu et al. (2019), the nighttime could potentially contribute to SAMPs settlement since relative humidity is higher, being crucial this period for the SAMPs entering to oceans from the atmosphere. They speculated that 52% of SAMPs could deposit and dispersed in the ocean during the daytime (Liu et al., 2019). These results confirm that atmospheric deposition from the continent is an essential pathway of MPs pollution in the ocean, especially that caused by textile microfibers. Besides considering the distance from continental sources, other variables as time sampling hour, wind speed and relative humidity should be considered when atmospheric MPs pollution pathways are assessed.

Respect to the shape composition of SAMPs, it was observed that samples become less diverse as the distance from the coastline increases (Liu et al., 2019). Also, it was observed that the number of SAMPs decreased at night, being fibers the shape that most decreased, which are prone to the settlement due to their density and size. Agreeing with previous studies the authors finally state that small-sized SAMPs could be easily spread to more remote areas by the wind (Allen et al., 2019; Brahney et al., 2020). Respect to polymer composition, the study found a high percentage of PET in SAMPs samples, and that the proportion PET and PE−PP decreased at night compared with the daytime. These results could be explained by their physicochemical properties (density and hygroscopicity) and relative humidity conditions. In the case of Allen et al. (2019), the authors registered that SAMPs with different composition varies with climate, registering higher amounts of PS when rain or snow events were lower, and higher amounts of PE when these events increased.

In conclusion, the concentration of SAMPs in the atmosphere will vary with changing atmospheric pressure, wind, temperature, rainfall and snowfall conditions (Allen et al., 2019; Enyoh et al., 2019). The dispersion of SAMPs increases with higher wind speed and turbulence conditions. On the other hand, low atmospheric pressures generate strong air turbulence and, thus, increasing SAMPs dispersion; finally, high pressures systems generate air stability developing episodes of plastic pollution (Enyoh et al., 2019). A vertical temperature gradient could also improve SAMPs ascending movement. In the case of temperature inversion, plastic particles may be blocked in the atmosphere's low layers, which prone pollution episodes. Finally, it should be considered that SAMPs are under the effect of humidity and solar radiation, which may contribute to smaller particles formation that could be easily transported to long distances (Allen et al., 2019; Enyoh et al., 2019; Liu et al., 2019; Brahney et al., 2020).

#### *Precipitation Patterns and Runoff*

Rainfall events affect MPs' presence and dispersal: inland lakes and rivers are how pollutants are transported by runoff from their terrestrial anthropogenic sources (urban and agricultural areas) by rivers towards estuaries and finally reaching the ocean (Xia et al., 2020). Recent studies remarked the importance of rainfall over MPs and other associated contaminants due to the first flush effect (Piñon-Colin et al., 2020). This process consists that during a precipitation event with the surface runoff increase, high concentrations of pollutants are recorded at the beginning of the event to decrease gradually. Finally, when MPs are present in lakes and rivers, they can enter to the lower trophic chain levels by
adsorption/absorption or ingestion, to subsequently move upwards by bioaccumulation, which presents a considerable risk to the ecosystem and people that make use of these systems (Bradney et al., 2019). Nevertheless, the accuracy of MPs' emission estimates is currently hindered by the lack of data about MPs transport efficiency in runoff and streams.

A study developed in the Keelung River and the Xindian River found positive correlations between precipitations and MPs concentrations (G. Wong et al., 2020). This positive relation was also registered in rivers such as Los Angeles River in the USA (Moore et al., 2011), River Seine in France (Dris et al., 2015) and Venoge River in Switzerland (Faure et al., 2015). According to G. Wong et al. (2020), this could be explained by deposited MPs' resuspension in the river banks. The authors also suggest that when storm sewers cities network is not connected to WWTP, all kinds of pollutants directly flow into the rivers through the runoff (G. Wong et al., 2020). They also reported that an increasing amount of MPs indicating a land-based origin was observed after heavy rainfall events. Furthermore, authors suggest a lag period of 24 hours between the rainfall and the MPs concentrations increase corresponding to the time that the rainwater takes to drag the particles from land into the storm sewers to finally deposit them in the river (G. Wong et al., 2020).

Depending on precipitation patterns (G. Wong et al., 2020), catchment soil characteristics (Nizzetto et al., 2016a), and river hydrodynamics (Besseling et al., 2017), MPs retention as well as vertical distribution may vary significantly along with rivers (Lebreton et al., 2017). Studies in rivers registered temporal differences in MPs concentrations associated with seasonal rainfall differences and runoff. A study in three rivers of California found differences of three orders of magnitude (Moore et al., 2011). Likewise, a study in four estuarine rivers around the Chesapeake Bay showed that the highest MPs concentrations occurred after significant rain events (Yonkos et al., 2014). These results emphasize the role of runoff and seasonality of freshwater contamination by MPs. Respect to rainfall and global runoff patterns, a study found two distinct river plastic input peaks: one for African, North and Central American rivers occurring between June and October, and the other for European, South American and Australia-Pacific rivers occurring from November to May (Lebreton et al., 2017). According to the authors, rainfall and global runoff patterns for Asia are not as pronounced as for other continents since there is a balance between inputs from East Asia plus the Indian Subcontinent and Southeast Asia during the northern hemisphere and southern hemisphere summer, respectively (Lebreton et al., 2017).

#### *Hydrodynamics*

Another factor to consider when MPs are studied in lakes and rivers is that the hydrodynamics determine the speed in which MPs arrive to the ocean. We can assume that for a singular plastic particle, the buoyancy will be different in the case of estuaries where fresh and saline water effect are combined added to turbulence, which will interact with particle size, density and charge, respect to freshwater environments as rivers (Eerkes-Medrano et al., 2015; Leslie et al., 2017; J. K. H. Wong et al., 2020). Therefore, a greater particle flocculation and deposition were observed in estuaries in comparison with other aquatic environments. The advance in knowledge about modeling in aquatic systems and the increase in MPs field data, starts to clarify the mechanisms influencing these particles' presence and distribution pathways in diverse aquatic environments. A study based on a literature review developed a hydrological model to determine spherical MPs fate and transport (100 nm to 10 mm). The authors assessed the advective transport effect, homo- and

hetero-aggregation, sedimentation-resuspension, polymer degradation, biofilm presence and burial (Besseling et al., 2017). They found that river hydrodynamics affect MPs size distributions with consequences in their emission to the ocean. Spatial characteristics such as width, depth and flow rate result in net sedimentation and resuspension areas (Quik et al., 2015). Also, MPs size has a relevant effect on their fate and accumulation in hot spots along with river sediments (Besseling et al., 2017). Polymer density and biofilm formation effects were not significant since heteroaggregates formation was observed between suspended solids and MPs. The authors conclude that intermediate-sized particles of about 5 mm will be less retained (18-25%) than the smaller submicron size range particles as well as micro- and millimeter-sized MPs (Besseling et al., 2017).

On the other hand, a study developed in the Thames River upgraded a mathematical model to assess catchment hydrology, soil erosion and sediment budgets effects on rivers MPs fate (Nizzetto et al., 2016a). The model assumed that physical controls on soil erosion and sediment transport are the same that control MPs' transport. According to their results, those particles with a size  $< 0.2$  mm will not be retained in streams; meanwhile, those larger particles with higher densities than water will be retained in sediments, which could be remobilized under high flow periods (Nizzetto et al., 2016a). Furthermore, those river sections experiencing low stream power are likely hotspots for MPs deposition on sediments. Therefore, MPs storage in soils and river sediments should be considered temporary or permanent sinks of relevance, contributing to the delay or prevention of the MPs to reach the marine environment.

Internal currents of water bodies are responsible for plastic litter accumulation. It has been demonstrated that in the ocean, currents are responsible for accumulating these particles in different sizes in the subtropical convergence zones (Van Sebille et al., 2015). Previous studies in large lakes as the Laurentian Great lakes or Qinghai Lake, found that plastic debris distribution is affected by the currents lake (Hoffman and Hittinger, 2017; Xiong et al., 2018). Moreover, source inputs and wind direction are responsible for MPs distribution in some small lakes (Imhof et al., 2013; Free et al., 2014; Zhang et al., 2016).

In estuarine systems, a recent study assessed the MPs distribution patterns in a coastal upwelling environment, Ría de Vigo estuary (Spain). Using water and sediment MPs field data during upwelling and downwelling conditions and modeling (2D-vertical model), the authors investigated the relative importance of river discharge, wind-driven and densitydriven circulation (Díez-Minguito et al., 2020). According to their results, wind force was the main driver of MPs mobilization/sedimentation. Its domain on the water circulation is more significant than those of the density-driven and river flows circulation. Also, they observed that MPs' presence was higher in surface waters at the outer half of the estuary during upwelling. The flush out of MPs to the sea was affected by wind-induced circulation in the water surface; meanwhile, near the bottom, the effect of wind landward and gravitational circulation produces the presence of a maximum MPs concentration inside the estuary (Díez-Minguito et al., 2020). Therefore, according to their modeling results, MPs pathways circulation in estuarine environments are dominated by winds in the estuary's outer part, and near the head are dominated by the gravitational circulation. Nevertheless, according to Wolanski and Elliott (2015), MPs transport in lower rivers and estuaries could differ among studies because their differences in river morphology and tidal activity, tidal currents, circulation and geometry of each estuary.

#### **Worldwide Continental Influence on Ocean Pollution by MPs**

To solve marine plastic pollution, we should quantify and understand the plastic debris from inland sources to seas and the actual plastic pollution damage to human and environmental health. According to modeling studies, MPs exports differ spatially among European rivers, according to their socio-economic status and technological development of WWTP (Siegfried et al., 2017). Therefore it is wise to assume that MPs exports will differ in the same manner a global scale, founding significant differences among countries and continents as we can observe in the different studies reviewed here (Table 1).

In a first attempt to determine the global contribution of plastic from continental sources trough rivers, a modeling study calibrated with available data in the literature, found that up to 2.41 million tons year<sup>-1</sup> of plastic waste end in the ocean only from rivers (Lebreton et al., 2017). According to their results, more than 90% of plastic inputs corresponds to the top 122 polluting rivers (4% of total surface area and 36% of the global population), from which, 103 are located in Asia, eight in Africa, eight in South and Central America and one in Europe (Lebreton et al., 2017). These results agree with the values found in the literature (Table 1) and the fact that most MPs studies are developed in China. Nevertheless, the authors point out that this input estimate is conservative, as it only comprises plastic litter from 0.3 mm to 0.5 m, and neglect the contribution outside this size range. According to their modeling, 1.21 million tons per year (range: 1.00–2.06) are only contributed from Asia, with China and Indonesia as significant contributors. The remaining 14% of river plastic mass input is distributed as follows: 7.8% coming from Africa (109,200 tons per year), 4.8% from South America (67,400 tons per year), 0.95% from Central and North America (13,400 tons per year), 0.28% from Europe (3,900 tons per year) and 0.02% from the Australia-Pacific region (300 tons per year) (Lebreton et al., 2017). A study suggests that MPs atmospheric transport into the ocean seems weak compared to rivers (Liu et al., 2020). This study estimated that between 7.64 and 33.76 tons of atmospheric microplastic fibers were generated in 2018 in the world. Compared to MPs input from the Yangtze River and The Pearl River, they only represent 3% and 31% of riverine input, respectively (Liu et al., 2020).

Finally, quantifying MPs abundance in the ocean environment for actual and future conditions is a crucial aspect to understand and sort out marine plastic pollution. Using numerical model approaches allows us to map the abundance of MPs in the past, present and future (Isobe et al., 2019). Understand how plastic debris is transported from continental and marine sources is essential to quantify the global inventory of marine plastics, which is relevant for mitigation or policy strategies (Van Sebille et al., 2020). A study for the Pacific Ocean determined that pelagic MPs concentrations will increase approximately twofold by 2030 and therefore, fourfold by 2060, from condition registered in 2016 (Isobe et al., 2019). Furthermore, it was projected that plastic debris weight concentration would exceed 1000 mg m<sup>-3</sup> in summer in parts of the East Asian seas by the 2060s onward (Isobe et al., 2019). According to the authors, these values will vastly exceed the suspended particular matter in the North Pacific Ocean, which will place MPs as the predominant non-organic suspended matter in the Ocean before the 2060s (Isobe et al., 2019).

Figure 2. Percentages per continent of inland microplastics contributions and ocean plastic pollution studies based on literature research.

It is worth mentioning that, from literature searching, most of the plastic pollution research efforts were developed in China, North America and Europe; nevertheless, in Africa and South America, two of the most critical contributors have a lesser study (Table 1, Fig. 2). Therefore, investigation efforts should increase in these continents. A review of marine MPs studies suggests that only 22.9% (44 from 192) of the world's countries have developed research on this topic, mainly focused on the Pacific and Atlantic Oceans. Meanwhile, very few have included the Arctic and Antarctic oceans and minimal studies in the Indian Ocean, where plastic pollution is probably high (Ajith et al., 2020). From studies developed between 2010 and 2019, 86% of them were distributed in Europe (38%), Asia (36%) and North America (12%) being the remaining 14% distributed in South America (7%), Africa (2%), Australia (4%) and Antarctica (1%) (Ajith et al., 2020).

## **CONCLUSION**

Microplastics are among the contaminants of emerging concern for aquatic systems. Nowadays, MPs are ubiquitous in broad environment types from marine, freshwater, terrestrial to the atmosphere. Plasticulture application on agriculture, the massive use of plastic disposals, WWTP and road dust are among the anthropogenic activities that contribute to ocean plastic pollution in the world. Lakes, rivers and estuarine systems are among the most studied MPs sources, linking the continental systems to marine environments. Rivers and effluents were identified as significant pathways from inland sources. Microplastics are present in different sizes, colors, shapes and textures, and their final fate and transport among the different compartments of natural environments are influenced by their interaction with the biotic and abiotic variables. More studies should be focused on discuss MPs pathways or their interaction with the environmental factors in their way into the ocean, besides their pollution monitoring alone. There are complex and multiple relations between the environmental variables and human activities influencing MPs' presence and distribution in the environment. As with global biogeochemical cycles, the elucidation of the "microplastics cycle" helps us understand their global fate for future remediation. MPs reach aquatic systems

through direct MPs inputs, urban WWTP in rivers, or runoff on catchments. Simultaneously, the use of WWTP sludge on agricultural soils (containing MPs) and atmospheric plastic particles fallout, contributes to the soil's contamination, which trough wind resuspension or runoff, leads MPs to aquatic systems again. The varied hydrological characteristics as water flow velocity, water flows seasonal variation, water depth and the combined effect of turbulence and salinity in aquatic systems, affect the plastics transport within freshwater systems towards the ocean. It is worth to mention that most plastic pollution research efforts were developed in China, North America and Europe. Nevertheless, Africa and South America have lesser studies; therefore, investigation efforts should increase in these continents in the next years.

## *BIOGRAPHICAL SKETCHES*

#### *María Belén Alfonso*

**Affiliation:** Instituto Argentino de Oceanografía (CONICET/UNS), Bahía Blanca, Buenos Aires, Argentina

#### **Education:**

2018 – PhD in Biology, Universidad Nacional del Sur, Bahía Blanca, Argentina 2013 – Biology, Universidad Nacional del Sur, Bahía Blanca, Argentina

**Business Address:** Florida 4500, Bahía Blanca (B8000FWB), Buenos Aires, Argentina

#### **Research and Professional Experience:**

- 2020 2021. Posdoctoral fellow in the Kyushu University, Fukuoka, Japan. Directors: Ph.D. Atsuhiko Isobe. Research tasks activities related to the modelling of microplastics transport.
- 2018 2020. Posdoctoral fellow in the Instituto Argentino de Oceanografía (IADO CONICET/UNS), Bahía Blanca, Argentina. Directors: Ph.D. María Cintia Piccolo and Ph.D. Andrés H. Arias. Research tasks activities related to the effect of climate variability in the presence and dispersion of microplastics, organochlorinated pesticides and polycyclic aromatic hydrocarbons in lakes.
- 2013 2018. Doctoral fellow in the Instituto Argentino de Oceanografía (IADO CONICET/UNS), Bahía Blanca, Argentina. Directors: Ph.D. María Cintia Piccolo and Ph.D. Horacio E. Zagarese. Research tasks activities related to the effect of climate variability and water management on zooplankton ecology and water quality of lakes.
- 2011 2012. Student Fellow BENTR11 from the Centro de Investigaciones Científicas (CIC, Pcia. Buenos Aires) in the Instituto Argentino de Oceanografía (IADO – CONICET/UNS), Bahía Blanca, Argentina. Research tasks activities related to the study of zooplankton communities in lakes. Director: Ph.D. María Clara Menéndez and Ph.D. María Cintia Piccolo.

#### **Professional Appointments:**

2020 – 2023. Member of the Collaborative Climate Committee in the Global Lake Ecological Observatory Network

#### **Publications from the Last 3 Years:**

# *Maria Cintia Piccolo*

**Affiliation:** Instituto Argentino de Oceanografia – Universidad Nacional del Sur (UNS)

**Education:** PhD in Oceanography

**Business Address:** Florida 4500. Bahia Blanca 8000 Argentina

**Research and Professional Experience:** Climate variability in Wetlands

## **Professional Appointments:**

- Emeritus Professor UNS
- Senior Researcher CONICET

## **Honors:**

- 2005. Prize "Geographical Merit 2005" for his participation in the work "Urban Climate of Bahía Blanca". GAEA Argentine Society of Geographical Studies.
- 2011. On International Women's Day, Diploma of Honor and an award, in recognition of her professional career, commitment to research and national development. Command of the Third Division of the Argentine National Army "Tte. Gral. Julio A. Roca "
- 2011. INNOVAR 2011 2nd Prize for the project 9402 Buoy for Environmental Monitoring in Hydrology (Lakes, Rivers and Ocean). In conjunction with Drs. G. M. E. Perillo and A. Vitale.
- 2013. Gold medal awarded by the Senate of the Province of Buenos Aires to Outstanding Women on International Women's Day in recognition of their scientific career (Women who have excelled in any of the disciplines into which Science is divided).
- 2013. Distinction awarded by the Bahía Blanca Industrial Chemical Association (AIQBB) for scientific career and community support.
- 2016. ESRI ESPAÑA 2016 Award granted by Papeles de Geografía Journal to the work: Downscaling of climatic variables from the NCEP / NCAR Reanalysis in the southwest of the province of Buenos Aires (Argentina) Coauthors F. Ferrelli, ML Bustos, MC Piccolo, MA Huamantinco Cisneros and G. M. E. Perillo.

## **ABSTRACT**

World marine ecosystems are constantly impacted by anthropogenic activities, accumulating pollutants from the tropics to the poles. Physical, chemical, and biological stressors produced by industrial processes, intensive agriculture and urban development, have the potential to alter the balance of ecosystems by triggering changes in the biotic communities, including the marine environment. Traditionally, the pollution assessment at these ecosystems has been based on the analysis of specific xenobiotics levels in selected matrices. However, the present challenges require an integrated assessment of contamination levels along with their possible adverse effects on organisms, even if they are found in concentrations below to the permitted limits. Then, it is essential to develop consistent tools for biomonitoring, while also assessing their potential impacts on human health. Essentially, bioindicators are organisms, populations, or communities that undergo through a certain change when exposed to contamination; these changes are based on the complexities of the ecosystem and provide representative responses which allow the assessment of the environmental health from a dynamic perspective. A suitable bioindicator should have a wide range of properties; however, the selection in marine environments should be based on specific criteria considering the different habitats (from coastal areas to offshore, from benthic environments to pelagic waters) and the sensitivity degree of organisms to diverse pollutants (or pollutants complex) to which they are

exposed. This chapter summarizes numerous marine species from different taxonomic groups that have been tagged in the last 20 years to be used as bioindicators of diverse physicochemical pollutants in marine environments; it will address their suitability according to the different habitats and life habits, ranging from microorganisms to marine mammals. Besides, this chapter presents the most important challenges and advances in the field of marine bioindicators in recent years, which could be relevant for integrative monitoring purposes and the development of new approaches and technologies in marine pollution monitoring.

**Keywords:** bioindicators, pollution, molluscs, metals, plastics, emerging contaminants

## **INTRODUCTION**

Our oceans health is essential for maintaining the planet. However, it is one of the ecosystems most severely affected by anthropic impact (Moura 2012; Potters 2013). Marine ecosystems are constantly being impacted by pollution caused by human activities, from the tropics to the poles. Physical, chemical, and biological stressors produced by industrial processes, intensive agriculture, and urban development, have the potential to alter ecosystems balance by triggering changes in the biotic communities that constitute them (Bellas et al. 2020; Moura 2012). A wide variety of effects produced by marine pollution have been reported, such as the promotion of algal blooms, reduction of biodiversity, stress, mortality and failure of organisms development and reproduction; and diseases that can also affect humans (Potters 2013). The alarming loss of biological diversity in the last decades represents a major challenge to the scientific community. Additionally, together with the ecological consequences, important economic processes can be affected. Consequently, the development of proper management strategies and monitoring tools are essential to maintain oceans health (Zuarth and Vallarino 2014). Traditionally, marine ecosystems assessment has been based on the analysis of specific pollutant levels in selected matrices. However, these studies only offer a partial approach to the question of how marine organisms and ecosystem functioning are affected by pollutants. The current challenges require an integrated assessment of contamination levels and their possible adverse effects on organisms (Bellas et al. 2020). In the intense search for precise, inexpensive, easy-to-implement methods that allow the early detection of environmental disturbances, the use of bioindicators is a method that has gained popularity over the years (Zuarth and Vallarino 2014).

Bioindicators are organisms, populations or communities used to indicate the pollution adverse effects on an ecosystem, taking into account changes in their presence/absence, abundance, morphology, physiology or behaviour (Gerhardt 2002). These are based on the complicated intricacies of ecosystems, providing representative responses that allow assessing the health of the environments from a dynamic perspective (Holt and Miller 2011). The terms "bioindicators", "biomonitors" and "sentinels" are used and defined in different ways by the different authors. In strict terms, bioindicators assess qualitative responses while biomonitors assess quantitative responses. The term sentinel refers to a special kind of indicator organism that accumulates and concentrates pollutants in its tissues. However, the concept of "bioindicator" is generally used for most of the authors as a collective term including all terms related to biotic responses detection to environmental stress (Gerhardt 2002; Holt and Miller 2011; Parmar et al. 2016; Zuarth and Vallarino 2014). In this chapter, the term "bioindicator" encompasses all these concepts (Figure 1).

Figure 1. Bioindicator concept used in this chapter.

A suitable bioindicator should have several properties such as a wide distribution, sensitivity, environmental representativeness, practicability (easy for sampling, taxonomy, recognition and grow in the laboratory and low cost), societal importance, and ecological characteristics (abundance, specificity, and good knowledge about the position in the trophic system, feeding strategy, position in ecosystem compartment; Gerhardt 2002; Zuarth and Vallarino 2014). The ideal bioindicator should fulfil all these criteria; however, until now no species, community or population has been found that can comply with all of them at the same time. Marine ecosystems are complex, multivariate, and simultaneously exposed to a wide variety of stressors with poorly understood cumulative effects (Zuarth and Vallarino 2014). Because of this, bioindicator selection in marine environments is based on specific criteria considering the different habitats (from coastal to offshore areas, from benthic environments to pelagic waters) and the degree of organism sensitivity to the diverse pollutants to which they are exposed (Fossi et al. 2017). Also, every monitoring program or search will have its objectives, in terms of spatio-temporal scale and areas investigated, founding the bioindicator selection on these criteria (Fossi et al. 2017).

This chapter is a review of numerous marine species belonging to different taxonomic groups that have been used as bioindicators over the past 20 years (total of revised works: 182), including the new challenges in marine pollution monitoring taking into consideration pollutants of emerging concern and new techniques and technologies (Bellas et al. 2020). For this chapter, the works focused on the evaluation or use of bioindicators were selected, considering their suitability according to the different habitats and life habits. Bioindicators of diverse pollutants, such as persistent organic pollutants (POPs), polycyclic aromatic hydrocarbons (PAHs), plastics, metals, nutrients, emerging pollutants (EPs) and noise pollution were reviewed (Figure 2), ranging from microorganisms to marine mammals. Many works were found for pollutants such as metals (74 works), POPs (38 works), plastic (35

works), and nutrients (22 works); compared to EPs (12 works) and noise pollution (one work; Figure 2). This revision could be relevant for future comprehensive monitoring development with new approaches and technologies that result in representative data to support environmental decision-making and regulations.

Figure 2. Number of works reviewed for each pollutant.

# **NUTRIENT POLLUTION BIOINDICATORS**

Pollution from nutrients, also called over-enrichment, represents one of the largest sources of water quality degradation at coastal waters (Howarth et al. 2000). Nutrient loading that leads to eutrophication arrive in the marine environments due to human activities, such as fossil fuels combustion, use of agricultural fertilizers and mainly from untreated and treated sewage effluent emissions present in many coastlines in the world (Benson et al. 2008; Dudley and Shima, 2010). Nutrient over-enrichment has a range of effects on coastal systems, such as fish mortalities, coral reef destruction and ecological changes that decrease the biological diversity. Eutrophication changes the ecological communities' structures by two mechanisms: indirectly through oxygen depletion and directly by increasing nutrient concentrations. The main nutrients causing eutrophication are nitrogen (N) and phosphorous (P); although silica (Si) may also play a role in regulating algal blooms in coastal waters and, in determining some eutrophication consequences (Howarth et al. 2000). Therefore, it is important to detect and monitor the nutrients flow in coastal areas to predict and prevent harmful effects of eutrophication. A potentially informative way of monitoring an increase in environmental nutrients is using bioindicators (Lilliesköld and Mork 2009; Todd et al. 2006).

Traditional monitoring of dissolved nutrients in the water column is complicated by short term fluctuations, especially when their levels are low and have a fast turnover. As nutrient bioindicators, algae seem to be preferred (Figure 3). Macroalgae integrate nutrients overtime in their tissues from those that are bioavailable in the environment, the use of these organisms as nutrient bioindicators may be less expensive and labour-intensive than traditional water quality sampling (Dudley and Shima 2010; Lilliesköld and Mork 2009; Lin and Fong 2008). Additionally, algae as bioindicators since changes in the composition of their population, abundance and dominance relationships of species proved to be an effective method to monitor nutrient contamination (Sliskovic et al. 2011). Experiments under controlled conditions using the alga *Gracilaria edulis* have been shown that amino acids, tissue nitrogen and chlorophyll content response to nutrient pulses indicating that this alga species could be a suitable bioindicator for investigating the source and geographical extent of nutrients entering oligotrophic coastal waters (Costanzo et al. 2000). *In situ*, *Ulva* spp. was able to reflect N gradients, with up to 90% higher tissue N levels in the vicinity of major cities compared to adjacent areas (Lilliesköld and Mork 2009). The brown macroalgae, *Sargassum flavicans*, was investigated as a potential bioindicator for monitoring time-integrated uptake of nitrogen from nutrient-enriched industrial effluent since increased 3-4-fold in  $\delta^{15}N$  (nitrogen stable isotope) compared to reference sites (Alquezar et al. 2013). Moreover, the red macroalgae *Acanthophora spicifera,* has been used as a bioindicator to monitor the enrichment of nutrients from the shrimp culture (Lin and Fong 2008). Other herbaceous species such as *Zostera marina* was also described as a proper bioindicator of eutrophication, measuring δ<sup>15</sup>N in sewage areas (Schubert et al. 2013).

Figure 3. Bioindicators for nutrient pollution. Number of papers reviewed.

Algae have also been used as bioindicators along with other organisms to propose them jointly as bioindicators of nutrient contamination. Thus, the macroalgae *Gracilaria* sp. was evaluated together with the oyster species *Crassostrea virginica* to determine spatial and temporal patterns of nitrogen sources through  $\delta^{15}N$  (Ferting et al. 2009). While the macroalgae responded quickly without fine-scale spatial patterns, the oyster responded slowly over time and exhibited a spatial scale at a slight gradient. Also, Babaranti et al. (2018) confirmed the use of the *Ulva lactuca* algae and the mussel *Mytilus galloprovincialis* to monitor the impact of sewage-derived organic matter. Dudley and Shima (2010) used three different trophic levels species: a kelp (*Carpophyllum maschalocarpum*), an isopod (*Amphoroidea media*) and a filter-feeding crab (*Petrolisthes elongatus*) as bioindicators along a sewage exposure gradient. δ<sup>15</sup>N measuring was useful in *C. maschalocarpum* and in *A. media* while  $\delta^{13}C$  evaluation was useful in *P. elongatus*, suggesting multiple-isotope and multi-species bioindicator approaches for detecting both patterns to understand the nutrients incorporation into food webs (Dudley and Shima 2010).

Zooplankton has also been evaluated as a bioindicator of nutrient contamination by some authors elsewhere (Neto et al. 2014; Xu et al. 2016). Both works evaluated changes in their structure, number and/or biomass of the population, however, these studies were nonconclusive and more studies were suggested to postulate them as appropriate bioindicators.

Microbial communities respond rapidly to environmental disturbances, therefore, bacteriplankton was also described as a sensitive bioindicator of eutrophication, with changes significantly correlated with the abundance of 27 families (Dai et al. 2017). Abundance and pattern of species richness of ciliate, such as tintinnids and aloricate (Xu et al. 2011; Sivasankar et al. 2018) and benthic foraminifera (Mojtahid et al. 2006; Vidovic et al. 2014) have been proposed as excellent bioindicators of eutrophication.

Taking into account crustaceans as nutrient bioindicators, density of the amphipod crustacean *Metaprotella sandalensis* was effective nitrogen and phosphate bioindicator in coral reefs, showing the highest densities in more stressed sites (Guerra-García and Koonjul 2005) while prawns (family *Penaeidae*) from different sites along Asia-Pacific coastlines were suitable for nitrogen monitoring through isotope measurement (Fry et al. 2016).

Although less studied, some other organisms were suggested as bioindicators for nutrients. The gastropod *Amphibola Crenata* proved to be a proper bioindicator of nutrient changes levels in estuaries through their growth and survival measurements (Marsden and Baharuddin 2014). Also, studies on mollusc community structure (35 taxa identified) (Atalah and Crowe 2012) and polychaete assemblages (Surugiu 2005) were useful to indicate marine eutrophication. Finally, the jellyfish *Cassiopea xamachana* proved to be an effective bioindicator for integrating relevant information about phosphate availability in low nutrient environments (Todd et al. 2006).

# **METAL POLLUTION BIOINDICATORS**

Heavy metals are natural constituents widely distributed in the environment. Their sources include industrial and agricultural activities and flow into the sea through effluents and sewage or are directly discharged affecting the physicochemical and biological parameters of the water (Chiarelli et al. 2014). In coastal areas, heavy metals involve a serious concern in terms of environmental and ecological degradation (Conti et al. 2008; Chakraborty et al. 2014). Some of them have essential functions and are toxic only in an overdose, others are extremely toxic, and others are essential for some organisms but toxic for others (borderline). Thus, metals can be divided into three class: essentials, nonessentials, and borderline classes (Chiarelli et al. 2014). When they are highly concentrated are harmful to animals and plants, can bioaccumulate in different organisms and through the different trophic levels affecting finally to humans (Conti et al. 2008; Chakraborty et al. 2014). Heavy metal overload can cause serious ecotoxicological effects having inhibitory effects on the development or could disrupt oxygen levels, reproductive, physiological and metabolic processes from organisms (Gheorghe et al. 2017). Thus, bioindicator organisms are commonly used to predict the toxicity of metals in biota (Chakraborty et al. 2014).

Among the papers reviewed in this chapter (74 works in the last 20 years), bivalves were the metal bioindicator most widely used (20%, Figure 4). They have the ideal characteristics to be bioindicators such us being cosmopolitan, sedentary, and filter-feeding organisms that bioaccumulate pollutants dissolved and present in the particulate matter due to their low metabolic transformation, providing time-integrated information on contaminants levels in coastal zones. Additionally, numerous laboratory and experimental studies have shown that these organisms accumulate metals in proportion to the bioavailable metals in the environment (Chandurvelan et al. 2015; Ozden et al. 2010). From a multiple biomarker approach, the mussel *Perna canuliculus* proved to be a useful bioindicator in New Zealand with significant metal accumulation correlations with metallothionein-like protein content, catalase activity and lipid peroxidation (Chandurvelan et al. 2015). Studies on indigenous *Mytilus galloprovincialis* had also demonstrated that it can provide a measure of observable cellular and physiological responses, such as oxidative stress due to cellular oxy-radical generation. However, these responses may also be affected by seasonality (Vlahogianni et al. 2007). Similarly, *Mytilus galloprovincialis* from aquaculture farms in an estuarine ecosystem, have been used as bioindicators of copper (Cu), chromium (Cr), nickel (Ni), zinc (Zn), iron (Fe) and manganese (Mn). However, they presented high seasonal variability, strongly influenced by the abiotic and biological parameters of the marine environment (Catsiki and Florour 2006). Bivalves *Perna perna*, *Brachidontes variabilis,* and the clam *Anadara granosa* proved to be proper heavy metal bioindicators, but seasonal variations were also described (Belabed et al. 2013; El-Moselhy et al. 2016; Januar et al. 2019). Therefore, environmental parameters and seasonal variations must be considered when using bivalves as heavy metal pollution bioindicators. Mussels *Mytilus galloprovincialis* and *Perna perna* were also used as bioindicators by other authors and including more heavy metals such us cadmium (Cd), mercury (Hg), lead (Pb), cobalt (Co), tin (Sn), vanadium (V), silicon (Si) and arsenic (As) (Jovic et al. 2011; Spada et al. 2013; Ozden et al. 2010). For *P. perna*, the use of shells as bioindicators for metal pollution has been validated. Significant correlations between concentrations in soft tissue and shells were demonstrated under controlled conditions of laboratory (Belloto and Miekeley 2007). Heavy metals and trace elements (As, Cd, Cr, Cu, Pb, selenium-Se, and Zn) were also analyzed in bivalve blood (Yusof et al. 2004). Different clam species were proved to be proper heavy metal bioindicators such us *A. granosa, Polymesoda expansa, Tivela mactroides, Gafrarium tumidum (*Dabwan and Taufiq 2016; Acosta and Lodeiros 2003; Hédouin et al. 2011). Moreover, it has been demonstrated that the rock oyster *Saccostrea glomerata* could be a precise bioindicator for heavy metals in port areas (Jahan and Strezov 2019).

Algae were also widely used as bioindicators for heavy metals (15%; Figure 4) being recognized as useful bioindicators for metal pollution in seawater due to their sedentary lifestyle. Also, they are representative of the study area, are abundant throughout most of the world's rocky coasts, accumulate contaminants without being severely affected, have a long life span and are easy to sampling and identify (Burger et al. 2007; Chakraborty et al. 2014; El-Din et al. 2014). In Australia, twelve species of estuarine macrophytes, including red, green, brown algae and seagrasses were evaluated as potential metal bioindicators (As, Cd, Cu, Pb, Se and Zn). The authors suggested that the analysis of multiple species may be necessary for a comprehensive understanding of estuary-wide metal pollution and concluded that *Ulva australis*, *Zostera muelleri* and *Ruppia megacarpa* have potential as heavy metal pollution bioindicators, based on their availability and bioaccumulation pattern (Farias et al. 2018). In the Gulf of Kutch (India), *Ulva lactuca* has been shown to accumulate the highest levels of Cu, Fe and Zn; *Padina gymnospora* the highest levels of Cd, Mn and Ni; *Enteromorpha sp.* accumulate the maximum Pb concentrations, while *Dictyota D.* 

*bartayresiana* accumulate the maximum Cr levels, demonstrating that different algae specie can be used as bioindicators depending on the metal in question (Chakraborty et al. 2014).

Figure 4. Bioindicators for metal pollution. Percentage of papers reviewed.

Also, in the Egyptian Mediterranean Coast, demonstrated that others three algae species were useful metals bioindicators: the green alga *Enteromorpha compressa*, the brown alga *Padina boryana* and the red alga *Jania rubens* (El-Din et al. 2014). This study was based on the maximum metal pollution index (MPI), the bioconcentration factor (BCF) and the Tomlinson pollution load index (PLI). Four other brown algae (*Sargassum angustifolium*, *Sargassum boveanum*, *Sargassum latifolium*, and *Padina gymnospora*) were described as effective bioindicators for Zn in Saudi Arabia due to consistency of the concentrations in all the algae evaluated (Alkhalifa et al. 2012). The brown alga *Lobophora variegata* has been shown to take up Cd, Co, Cr, Ni and Zn in direct proportion to their ambient dissolved concentrations describing it as a useful metal bioindicator with a fast response not only in laboratory experiments (Metian et al. 2008) but also *in situ* (Hedouin et al. 2008). In Poland, seven macrophytobenthonic algae (*Polysiphonia fucoides*, *Furcellaria lumbricalis*, *Coccotylus truncates*, *Stuckenia pectinate*, *Zanichellia palustris*, *Cladophora spp*., and *Chara baltica*) proved to be suitable metal bioindicators (Pb, Cd, Hg and Ni), based on the efficiency of heavy metal accumulation, frequency of occurrence and biomass (Zalewska and Danowska 2017). *Ulva lactuca* alga was described to be a proper bioindicator for Cu, Co, Ni, Cr, Mn, Zn, Cd, Pb, and Fe (Mourad and El-Azim, 2019; Parus and Karboska, 2020). However, Kalesh and Nair (2005) determined low levels of Ni, Cr, strontium (Sr) and Ag bioaccumulation in this species, concluding that it may not be a good bioindicator for such metals. Other reports have been shown that some metals are differentially accumulated but not others in several algae specie (*Centroceras clavulatum*, *Grateloupia filicina*, *Chaetomorpha antennina*, *Enteromorpha intestinalis*, *Gracilaria corticate, Alaria nana*) demonstrating that depending on their physiology and place these herbacea organisms could be suitable bioindicator of a specific metal. Moreover, considering that some algae can be more than 25 m long, authors warn about different concentration patterns in particular parts of the algae, in addition to seasonal variations, recommending harmonized protocols.

Seabirds have been used as useful bioindicators of metals for years, especially to monitor Hg concentrations in biological systems at different spatial and temporal scales (Sadat and Hosseini 2018). Among the reviewed papers, seabirds were the third most widely used bioindicator for metals (14%, Figure 4). *Anas crecca* (migratory) and *Ringa solitaria* (resident) were used as bioindicators of Hg and methyl mercury (MMHg) pollution and variations among species and tissues were found, confirming that mercury concentrations were strongly affected by habitat and feeding habit (Sadat and Hosseini 2018). Other species of seabirds (*Pterodroma baraui*, *Puffinus lherminieri bailloni*, and *Phaethon lepturus*) have also been used as bioindicators of Hg, as well as Cd, Cu, Fe, Mn, Se and Zn finding differences between tissues (liver, kidney, pectoral muscles, and feathers) (Kojadinovic et al. 2007). Among 17 species studied, it has been concluded that common eider (*Somateria mollissima*), Leach's stormpetrel (*Oceanodroma leucorhoa*), double-crested cormorant (*Phalacrocorax auritus*) and black guillemot (*Cepphus grille)* are the most effective bioindicators of Hg (Goodale et al. 2008). These authors have also demonstrated that seabird blood could be an effective method for using seabirds as bioindicators of Hg in nondestructive ways and suggest that eggs are preferred for long-term Hg monitoring since they are easy to collect. Seabird eggs were also used as bioindicators by other authors; thus Cienfuentes et al. (2003) found that *Sterna trudeaui* eggs are useful bioindicators for Hg, but they were rare and inaccessible in the sampling area; and Burger and Gochfeld (2004) explained that *Sterna hirundo* eggs can serve as effective bioindicators of temporal trends in exposure to metals (Cd, Cr, Pb, Mn, Hg, Se, and As). Penguin species were widely used as metal bioindicators. Feathers from different penguin species (*Aptenodytes patagonicus*, *Eudyptes chrysolophus*, *Eudyptes chrysocome filholi* and *Pygoscelis papua, Pygoscelis antarctica, Spheniscus humboldti, Eudyptula minor)* proved to be useful to demonstrate metal accumulation, including Hg (Carravieri et al. 2013; Metcheva et al. 2006; Squadrone et al. 2019). Little Penguin blood (*Eudyptula minor*) was also used to analyze trace metals and metalloids (Finger et al. 2015) describing this species as an efficient bioindicator with concentrations linked to industrialisation levels from adjacent to the foraging zones, and a clear correlation between blood and feathers for mercury, lead, and iron levels. Thus, there is extensive use of feathers as bioindicators; however, a work that analysed feathers with synchrotron radiation X-ray fluorescence (SR-XRF) microanalysis in snow petrel (*Pagodroma Nivea*) showed external contamination of Fe, barium (Ba), Pb, Zn and Hg suggesting that feathers could be suitable bioindicator only of external contamination (Xie et al. 2008).

Twelve percent of the reviewed papers used fish as metal bioindicators (Figure 4). Thus, because many fish species have the required criteria as bioindicators for aquatic ecosystems assessment and they are considered one of the best organisms to study bioaccumulation characteristics and pollutants effects on ecosystems (Tsygankov et al. 2017). Additionally, metal bioaccumulation has been described in their tissues, particularly in the liver where they are bio-transformed and excreted or passed over to consumers through the food chain (Mehana et al. 2020). In estuarial environments, two species (*Micropogonias furnieri* and *Mugil liza)* were described as proper bioindicators for Hg, Cd and Zn by Marcovecchio (2004), while six species (*Brevoortia aurea, Odontesthes argentinensis, Micropogonias furnieri, Cynoscion guatucupa, Mustelus schmitti* and *Paralichthys orbignyanus*) were described as useful bioindicators of metal pollution by La Colla et al. (2017; 2018). Benthic fish are also suitable bioindicators because they have relatively low mobility and are present in the sediment where the bioavailability of contaminants is typically higher (Azevedo et al. 2012), such as *Salaria basilisca* that was described for Cd accumulation (Barhoumi et al. 2009), *Cathorops spixii* and *Genidens genidens* were described as effective metal bioindicators including for trace levels (Azevedo et al. 2009; 2012). Other benthic and pelagic fish species (*Arius heudelotii, Mullus barbatus, Merlangius merlangus*) were used as metal bioindicators, finding significant differences between species probably due to variances in diet or trophic level (Fonge et al. 2011; Fındık and Cicek 2011; Storelli and Marcotrigiano 2005).

Marine mammals were used in 9% of the reviewed works (Figure 4). Marine mammals have demonstrated high potential as bioindicators since they accumulate metals due to their position at the top of the marine food web and long life-span (Lemos et al. 2013). The skin of Commerson's dolphins (*Cephalorhynchus commersonii*) was proposed as a useful bioindicator for Hg taking into account its correlation with internal tissues concentrations such as lung, liver, kidney and muscle (Cáceres-Saez et al. 2015). The Guiana dolphin (*Sotalia guianensis*) was also used as a bioindicator for Hg, and even positive correlations with body length were found (de Moura et al. 2012). High concentrations of total-mercury, organic mercury, and Cd were found in the melon-headed whale (*Peponocephala electra*), and levels of other 10 elements (V, Cr, Mn, Co, Cu, Zn, Sr, molybdenum-Mo, and cesium-Cs) presented seasonal variations (Hirata et al. 2010). As part of a program monitoring the cetacean contamination by heavy metals, striped dolphins (*Stenella coeruleoalba*) stranded dead on the beach between 1996 and 1997 were compared to those between 1990 and 1991. As a result, a significant decrease in Cu, Hg, Ni and Pb concentrations was shown, but a slight decrease in the concentrations of Cd, and Zn levels remained high. This was in response to clean up efforts the zone coast, which corroborates the use of cetaceans as reliable bioindicators (Augier et al. 2001). Similarly, the sperm whale (*Physeter macrocephalus*) proved to be a proper metal bioindicator, but high variability between individuals and tissues was found. High metal concentrations were found in pregnant oldest females, warning the necessity to assess the impact of these pollutants on vulnerable individuals since pregnant females and younger individuals have low or altered detoxification capacity (Squadrone et al. 2015). Multiple cetaceans were used as bioindicators by Chen et al. (2017) *Grampus griseus*, *Kogia simus*, *Lagenodelphis hosei* and *Stenella attenuate* demonstrating marked Ag and Cd pollution in the western Pacific Ocean in the last two decades. Moreover, Lemos et al. (2013) analysed essential (Cu, Mn, Se and Zn) and non-essential (Cd and Hg) elements in *Feresa attenuate*, *Orcinus orca*, *Pontoporia blainvillei*, *Sotalia guianensis*, *Stenella frontalis*, *Steno bredanensis*, *Tursiops truncates*, observing bioaccumulation variations between species probably due to the preference for certain preys and their bioavailability in the environment. All these studies demonstrate cetaceans as effective bioindicators, however metals bioavailability must be also considered to fully understand the accumulation mechanisms.

Gastropods have been widely used as metal bioindicators due to their biological characteristics of sedentary and thus representativity of the study area, they are hardy and tolerant to high levels of metals, abundant in coastal environments, easy to identify and collect and provide sufficient tissue for analysis of metal concentrations (Ramirez 2013). Eight percent of the studies reviewed in this chapter used gastropods as effective bioindicators (Figure 4). *Monodonta turbinata* was used as a bioindicator of Fe, Zn, Cd, Cu, Co, Ni, Al, Mn, Pb and Cr; and although accumulations of all elements were affected from seasonal changes, this gastropod was a very efficient heavy metal accumulator and, therefore, a valuable bioindicator (Duysak and Ersoy 2014). It has been shown that variations of antioxidant parameters such as reduced glutathione (GSH), malondialdehyde (MDA), glutathione S- transferase (GST) and catalase (CAT) in *Stramonita haemastoma* could be used as prospective biomarkers of metals toxicity; demonstrating that this specie could be a useful bioindicator although seasonal variations were also found (Bouzahouane et al. 2018). Besides, *Osilinus atrata* presented great potential as a bioindicator of heavy metals (Cd, Cu, Pb and Zn), however, intraspecific variations were observed (Ramirez 2013). Gastropod gills (*Cerithium scabridum*) were also successfully used as metals bioindicators with seasonal variations, with significant correlations between metal concentrations in gills and sampling sites (Bu-Olayan and Thomas 2001). Finally, *Patella caerulea* was used by two authors who observed that shells and soft tissue were useful bioindicators of Cd, Pb, Cu, Fe, Ni, Mn, Zn, Hg, and Cr (El-Damhogy et al. 2019; Storelli and Marcotrigiano 2005).

Parasites have been shown to be proper bioindicators of essential and nonessential metals (7%, Figure 4) due to the number of parasitic species that exist compared to free-living species. Also, with their complex life cycles, the numbers of potential indicators increase with the number of different developmental stages, and some parasites are highly sensitive to heavy metal pollution (Malek et al. 2007; Mehana et al. 2020). The cestode/seabird system (*Tetrabothrius bassani*/*Morus bassanus*) was considered a promising bioindicator to monitor environmental Cd and Pb pollution in marine ecosystems (Mendes et al. 2013). Also, shark parasites proved to be suitable PB and Cd bioindicators, such as *Anthobothrium sp*. and *Paraorigmatobothrium sp*. cestodes in the shark *Carcharhinus dussumieri*; while *Gyrocotyle plana* infecting the spiral intestine of *Callorhinchus capensis* shark was a useful bioindicator for As, Mn, Pb, Ti and Zn. These organisms were extremely sensitive as early warning bioindicators, particularly in environments under threat but where pollution levels are presently low (Malek et al. 2007; Morris et al. 2016). Finally, for fish parasites, *Siganus rivulatus*/*Sclerocollum rubrimaris* system, and nematodes in the fish *Dicentrarchus labrax* demonstrated their sustainability as bioindicators of metal pollution (Al-Hasawi 2019; Morsy et al. 2012).

Crustaceans are generally excluded as possible bioindicators due to their ability to metabolically regulate essential metals (Simonetti et al. 2013). Nevertheless, the bioaccumulation of non-essential metals has been described and different crustaceans showed to be suitable bioindicators (5%, Figure 4). The crab, *Neohelice granulate*, was an appropriate candidate for bioindication of Ni and Pb pollution. However, seasonal variations and gender differences were found, therefore these factors must be considered (Simonetti et al. 2013). Besides, the benthic crustacean *Melicertus plebejus* was an effective bioindicator of some trace elements such as Pb and Cu (Munroe et al. 2018) and the isopod crustacea *Ligia italica* described as a reliable and representative bioindicator of Hg pollution (Longo et al. 2013) where ultrastructural alterations in the hepatopancreas epithelium were found. Finally, a study

compared the metal bioaccumulation of barnacles, ghost shrimps, polychaetes, and bivalves. The barnacle, *Amphibalanus amphitrite*, was the most suitable bioindicator. Also, barnacles are sessile or at least show restricted mobility, are available in all seasons, and can be easily sampled (Amoozadeh et al. 2013).

Sea urchins are suitable bioindicator organisms for their wide distribution, easy collection, filter-feeding habits, and good tolerance to pollutants (Salvo et al. 2014) and were used in 4% of the reviewed works (Figure 4). For Pb and Cd metals, *Diadema antillarum* proved to be an excellent bioindicator, and concentrations of metals in tissue and shell were positively correlated with the sample size (Dolores Hernández et al. 2009). *Paracentrotus lividus* was a suitable organism to be used as a bioindicator for different metals in situ and in bioassays (Salvo et al. 2014, Soualili et al. 2008).

Sponges are promising bioindicators because they process large amounts of water, show a wide distribution and year-round availability, are abundant in sublittoral areas, and can accumulate a wide range of metals from both the suspensions and dissolved phases. Additionally, sponges submitted to metal contamination experience morphological, biological, physiological, and biochemical responses, which can be easily monitored (Cebrian et al. 2007; Venkateswara et al. 2009). These organisms have been used as metal bioindicators in the 4% of the revised works (Figure 4). A comparative study on metal bioaccumulation by four widespread sponge species (*Crambe crambe*, *Chondrosia reniformis*, *Phorbas tenacior*, and *Dysidea avara*) showed that *Crambe crambe* provide accurate information on the background levels of metals in the area, and it reflected fluctuations of the bioavailable metals (Cebrian et al. 2007). *Haliclona tenuiramosa* was also a suitable bioindicator for As, Cd, Co, Cu, Fe, Mn, and Ni with positive correlations between concentration levels in water and bioaccumulation in tissues (Venkateswara et al. 2009). It has been demonstrated that the sponge *Hymeniacidon perlevis* closely reflected the heterogeneous distribution of metals in the environment (Mahaut et al. 2013) and that it can accumulate *in situ* more contaminants than the blue mussel *M. edulis,* meeting all the requirements of a proper bioindicator for integrated monitoring programs (Mahaut et al. 2013).

Sharks and ascidians were scarcely used as metal bioindicators among the reviewed works, with only 1% each. The blue shark, *Prionace glauca*, showed great potential as a bioindicator of Al, Cr, Mn, Fe, Ni, Cu, Zn, As, Se, Ag, Cd, Pb, and Hg (Alves et al. 2016). On the other hand, two invasive ascidian species, *Phallusia nigra* and *Microcosmus exasperates*, could be effective as heavy metal bioindicators due to high levels of bioaccumulation coupled with changes in the hepatosomatic index (Tzafriri-Milo et al. 2019).

# **BIOINDICATORS OF PERSISTENT ORGANIC POLLUTANTS (POPS)**

In marine environments, persistent organic pollutants (POPs) are of great environmental and health concern**.** POPs are toxic chemicals resistant to chemical and biological degradation, characteristics that make them have a global distribution and be persistent in the environment. Furthermore, due to their fat solubility, POPs ingestion by organisms leads to bioaccumulation throughout their lives, generally in fatty tissues, and to biomagnification in the food chain (Luzardo et al. 2014; Noventa et al. 2011). Among POPs, organochlorine

pesticides (OCs), polychlorinated biphenyls (PCBs), polychlorinated dibenzofurans (PCDFs), dioxins, polybrominated diphenyl ethers (PBDEs), brominated flame retardants (BFRs), and perfluorinated compounds (PFCs) have been found in marine organisms and environments (Alves et al. 2016; Luzardo et al. 2014). Strictly speaking, polycyclic aromatic hydrocarbons (PAHs) cannot be considered POPs since they are easily metabolized by some organisms, however, due to their high prevalence in the environment and lipophilicity, these compounds are usually considered as POPs being the most frequently found in marine coastal areas (Luzardo et al. 2014). All POPs arrive in the marine environment from anthropogenic sources and have significant detrimental effects on wildlife and humans, including carcinogenesis, mutagenesis, endocrine disruption, and immunotoxicity (Batista et al. 2013; Noventa et al. 2011).

To monitor the contamination status of POPs in marine ecosystems, sophisticated and highly sensitive techniques of chemical analyses are required. Marine organisms have been commonly used as bioindicators to assess regional/global contamination by POPs as possible integrators of these contaminants (Ueno et al. 2003b). According to reviewed works in this chapter and considering POP pollution, invertebrates were the preferred organisms for biomonitoring these compounds (63.2 %; Figure 5A), probably due to the higher capability to bioaccumulate contaminants than vertebrates. Within the invertebrate group, mollusc bivalves were the most widely used (58.3%; Figure 5B). This is because, in addition to the characteristics mentioned above, bivalves have been used as marine indicator organisms in national and international monitoring studies, such as Mussel Watch Program, U.S. National Oceanic and Atmospheric Administration (NOAA), Status and Trends Program (NS&T), Exxon Valdez contamination monitoring and Gulf of Mexico Produced Water Bioaccumulation Study (Francioni et al*.* 2005; Kimbrough et al. 2008). In Brazil, the mussel *Perna perna* is the main species used as a bioindicator for PAHs due to its economic importance and wide geographical distribution (Batista et al. 2013) being a reliable bioindicator for monitoring coasts and estuaries (Francioni et al. 2005). This species is also able to bioaccumulate PAHs, and physiological and biochemical biomarkers were subsequently demonstrated to be sensible (Pereira et al. 2007; 2010). Other mussel species were described as suitable bioindicators of PAHs such us *Brachidontes rodriguezii* and *Tagelus* sp. in Argentina (Arias et al. 2009; Oliva et al. 2015); and *Sanguilonaria (Soletellina) acuminate* in India (Zuloaga et al. 2009).

On the other hand, for organochlorine pesticides (OCs) *Mytilus galloprovincialis* was used as bioindicator in Spain and the Adriatic Sea (Campillo et al. 2017; Carro et al. 2014; Giandomenico et al. 2013). A correlation with effects on physiological parameters, such as lipid content and shell length were demonstrated (Carro et al. 2014). The brown mussel (*Perna perna*) was used as a sentinel species for OCs and dioxins, and bioaccumulation of these compounds was demonstrated without seasonal variation (Galvao et al. 2015); *Perna viridis, Mytilus gallorovincialis* and *Crenomytilus grayamus* from Asia waters were shown to be suitable bioindicators of OCs (Monirith et al. 2003); and *Perna viridis* proved to be a useful bioindicator of PCBs and PBDEs in Singapore's marine environment (Bayen et al. 2003). Wang et al. 2008 compared seven bivalves and gastropods species for using as OCs, PBDEs and PCBs bioindicators proving that *Crassostrea talienwhanensis* and *Mytilus edulis* bivalves were the most sensitive bioindicators among those selected in the Chinese Bohai Sea. *Mytilus edulis* was also described as a very sensitive bioindicator for PAHs and PCBs during a bioremediation process (Walker et al. 2013), and for PBDEs, HBCDs, PCBs and

OCs in Korea coastal waters (Ramu et al. 2007). Bivalves from other families such us *Polymesoda arctata, Anadara tuberculosa and Larkinia grandis* were also suitable POPs bioindicators used in Nicaraguan coasts to detected PAHs, PCBs, PBDEs, OCs, and organophosphorus pesticides (Aguirre-Rubí et al. 2019).

Figure 5. Bioindicators used for Persistent Organic Pollutants (POPs). A: Proportion of vertebrate and invertebrate organisms, B: Invertebrate bioindicators (%), C: Vertebrate bioindicators (%).

Gastropods were the second group of invertebrates most used as bioindicators (16.7%; Figure 5B). These have been used for years as effective bioindicators of tributyltin (TBT) due to their propensity to develop the imposex and intersex phenomena in which superimposition of male sexual organs onto females concentration-dependent occurs, resulting in infertility and population declines in extreme cases. TBT is an organotin compound (OTCs) and is not strictly considered as POP but has been banned and regulated along with them (Noventa et al. 2011). It has been demonstrated in West Africa that *Gemophos viverratus* is sensitive to TBT since imposex could be artificially induced by injecting very small doses of TBT into females (Lopes-Dos-Santos et al. 2014). In Venezuela three species of gastropods, *Chicoreus brevifrons*, *Chicoreus (Phylonotus) margaritensis* and *Leucozonia nasa* were used as TBT bioindicators, but their concentrations were not determined (Miloslavich et al. 2007). In Canada, *Nucella lapillus* proved to be a useful TBT bioindicator with high correlations between imposex and their concentrations (Titley-O'Neal et al. 2011). *Littorina littorea* was described as an effective PAHs and organotin compounds (OTCs) bioindicator along the southwestern English coast, verifying the bioaccumulation of both compounds and strong correlations between PAHs concentrations and DNA damage, as well as OTC levels and Intersex development (Noventa et al. 2011).

Sponges (Porifera Phylum) have been proposed as deep waters bioindicators where mussels are not found. They are also among the most abundant benthic animals colonizing consolidated substrates in tropical zones, coral reefs, rocky shores and many artificial

structures. They are widely distributed in marine systems and have high filtration rates (Batista et al. 2013; Mahaut et al. 2013; Perez et al. 2003). *Hymeniacidon heliophile* was described as a suitable deep-water PAHs bioindicator since having desirable characteristics such as wide distribution, easily identified in the field, encrusting massive sponge with a large amount of soft tissue and petrogenic and pyrolytic PAHs effective accumulation (Batista et al. 2013). *Spongia officinalis* and *Hymeniacidon perlevis* proved also to be useful PCBs and PAHs bioindicators, respectively, being able to concentrate these contaminants in higher proportions than bivalves (Mahaut et al. 2013; Perez et al. 2003).

Another invertebrate, the squid *Todarodes pacificus* has been described as an effective POPs bioindicator in offshore waters. This species has a wide distribution with a minimal migration and it has been considered as an important commercial food item which ecology and biology have been extensively studied. These organisms have been partly used in ''Squid Watch'' Program as a pollution bioindicator for monitoring (Ueno et al. 2003a). *T. pacificus* proved to be a proper OCs bioindicator (Ueno et al. 2003A; Wong et al. 2009), PBDEs and HBCDs (Kim and Stapleton 2010).

The characteristics that make fish suitable bioindicators have been mentioned in the previous section (Metal pollution bioindicators). Among vertebrates, fish were preferred with a 66.7% (Figure 5C). Four species of Pacific salmon (*Oncorhynchus gorbuscha, O. keta, O. nerka, and O. tshawytscha*) were successfully used as OCs bioindicators in the Sea of Okhotsk and the Western Bering Sea (Tsygankov et al. 2017). On the other hand, a fish species of widespread distribution and high abundance in near-shore seawaters (*Trematomus bernacchii*) was considered a useful bioindicator of PCBs, PBDEs, HCBs compounds and changes in the Antarctic ecosystem quality and temporal trends (Cincinelli et al. 2016). The piscivorous young of year bluefish (*Pomatomus saltatrix*) has a high lipid content and has been described as an effective bioindicator of PCBs, PBDEs and OCs in estuaries since it has been shown greater sensitivity to contaminants than other estuary-resident fish, being their residence in this environment during the critical life stages (Smalling et al. 2016). The fish *Boops boops* have been successfully used as a bioindicator of PCBs, OCs, BDEs, and PAHs since significant pollutant concentrations differences between wild fish compared to farmed fish were found (Heriquez-Hernandez et al. 2018). On the other hand, as an offshore waters bioindicator, skipjack tuna fish (*Katsuwonus pelamis*) was shown to have desirable qualities such as it is an important commercial fish, its ecology and biology have been well studied, it is widely distributed and OCs accumulation suggests that their concentrations rapidly reflect pollution levels of this compound in seawaters (Ueno et al. 2003B). The same fish species has been used as a bioindicator of dibenzo-p-dioxins (PCDDs), PCDFs, PCBs (Ueno et al. 2005) and hexabromocyclododecane (HBCD; Ueno et al. 2006). In estuarial environments, *Ramnogaster arcuata* has been suggested as a bioindicator of PAHs due to its short life cycle and its completion within estuaries. Additionally, *R. arcuata* showed significant correlations of PAH concentrations with metabolic enzymes, proteins and lipid peroxidation (Ronda et al. 2018). Similarly, *Cynoscion guatucupa* juveniles, residents of estuarine environments during their first year of life, proved to be suitable bioindicators of PAHs, showing changes in the metabolic enzyme activities, lipid peroxidation and condition factor in response to PAH concentrations (Recabarren-Villalón et al. 2019). Finally, the seahorse (*Hippocampusreidi reidi*) was described as an excellent bioindicator for PAHs. This neo-tropical fish has low mobility and does not migrate from contaminated areas being a proper bioindicator for oil spills (Delunardo et al. 2015).

At higher trophic levels, organisms are more exposed to pollutants by bioaccumulation and biomagnification processes through the food web. Elasmobranchs, such as sharks are ideal marine pollution bioindicators because they are also widely distributed and are important in the ecosystem. The blue shark (*Prionace glauca*) is one of the most frequently caught shark species all over the world, particularly in Portugal where it was demonstrated to be an effective bioindicator for BFRs and PFCs with high correlations between chemical analysis and biochemical responses such as DNA damage and lipid peroxidation (Alves et al. 2016).

Figure 6. Bioindicators for each POP (in percentage of reviewed works).

Seabirds are especially prone to POP accumulation due to their high position on the food chain, food consumption high rates and rapid responses to contamination events. Nonmigrating birds can reflect the background contamination of their habitat and if there are no local pollution sources, birds reflect the global pollution resulting from the pollutants transboundary transport (Cienfuentes et al. 2003; Tsygankov et al. 2017). Five species of seabirds (*Larus schistisagus, Aethia cristatella, Aethia pusilla, Fulmarus glacialis, and Oceanodroma furcate*) were used as useful bioindicators of OCs in Okhotsk and Western Bering seas (Tsygankov et al. 2017). Bird eggs have also been demonstrated to be excellent bioindicators because during the breeding season energy reserves are mobilized and females consume large quantities of food. The assimilated proteins and fat, as well as the pollutants bound to them, are transferred into the eggs (Cienfuentes et al. 2003). In Cienfuentes et al. 2003 seabird eggs of five species (*Larus maculipennis, Larus dominicanus Sterna trudeaui, Phalacrocorax brasilianus, and Puffinus creatopus*) were used as bioindicators of OCs pollution. However, based on their abundance and sampling ease, only *Larus dominicanus* and *Larus maculipennis* eggs proved to be suitable bioindicators of OCs. Petroleum products are toxic to seabirds and their characteristics make them particularly vulnerable to oil pollution. They spend much of their lives on the ocean's surface and their populations
concentrate in habitats prone to high oil exposure. Nevertheless, because of their great ability to metabolize PAHs, seabirds are not commonly used as PAHs bioindicators, being necessary to develop alternative techniques for the use of these organisms as bioindicators. The analysis of PAHs in the *Larus michahellis* blood turned out to be a promising method for the use of seabirds as bioindicators of PAHs in a non-mortal way (Pérez et al. 2008).

Marine mammals are considered key species for monitoring of POPs in the marine environment all over the world. Thus, they can be used as bioindicators of global pollution. The grey whales (*Eschrichtius robustus*) and Pacific walrus (*Odobenus rosmarus divergens*) have been successfully used as bioindicators of OCs (Tsygankov et al. 2017).

Finally, from the reviewed works, it was observed that among the different POPs, the greatest attention has been focused on OCs, with a wide range of bioindicators described, followed by PAHs, PCBs, PBDEs and BFRs summarized in the Figure 6. Other pollutants such as dioxins, PCDFs and PFCs are still receiving little attention regarding bioindicators, so they still represent a challenge for research and environmental monitoring.

### **PLASTIC POLLUTION BIOINDICATORS**

Marine pollution due to plastic is a global threat widely recognized by policymakers, the scientific community and citizens (Bonanno and Orlando-Bonaca 2018). Plastics are persistent pollutants, lasting hundreds to thousands of years; therefore, they accumulate over time and the fate and consequences are just beginning to be understood (Santana et al. 2016). Depending on their size, plastic debris can be classified as macro-, meso-, micro and nanoplastics. Its widespread use and persistent nature have made that especially the microplastics (MPs) were ubiquitous in marine waters, sediments, organisms and even sea salts (Li et al. 2016). MPs are particles less than 5 mm of diameter that could be intentionally produced in this small size (primary microplastics used in products such as abrasive products and exfoliating creams) or originated from the fragmentation of larger plastic (secondary microplastics). Additionally, they represent a special threat to marine ecosystems due to their high bioavailability, persistence and capacity to be toxic by themselves or adsorb other pollutants in their surfaces (Santana et al. 2016). In the marine environment, plastic debris is exposed to a combination of chemical and physical agents that lead to a degradation process producing potentially harmful and toxic chemicals, such as organic pollutants and chemical additives (Khoironi et al. 2018). Therefore, the biomonitoring of plastic pollution is necessary to generate appropriate and tailored actions of prevention and mitigation, for better sea ecosystems protection. Although the ingestion of plastic has been documented in more than 300 species, the use of plastic bioindicators is still at a preliminary stage, with few documented monitoring campaigns in the marine environment. The need to identify potential useful bioindicators is thus urgent given the ever-increasing impact of plastic debris on the sea (Bonanno and Orlando-Bonaca 2018; Lim et al. 2020). The species that have been evaluated, used, and/or recommended as bioindicators of plastic contamination have been summarized in Table 1, with bivalves, fish, and seabirds as the preferred organisms.

Regarding bivalves, multiple works point to their suitability as MPs bioindicators (Digka et al. 2018; Khoironi et al. 2018; Li et al. 2016; Lim et al. 2020; Santana et al. 2016). Brate et al. (2018), described the ingestion of small particles suggesting that *Mytilus* spp. is a suitable bioindicator of small MPs (<1mm). An experiment with transplanted mussels proved that a balance between intake and defecation/egestion reached in approximately 6 weeks being this information adequate to reflect the native mussel's ingestion. However, a study evaluated the use of two bivalve's specie (*Mytilus edulis* and *Crassostrea virginica*) demonstrating that these organisms are not robust indicators of MPs pollution because they only ingest the smallest spheres and microfibers. The authors strongly recommend searching for new marine bioindicators for MPs (Ward et al. 2019). Consequently, bivalves could be proper MPs bioindicators, but it is necessary to continue their study because microplastic monitoring is complex and it is in its initial phase (Kazour and Amara 2019).

Most of the reviewed works evaluated the use of fish as bioindicators through MPs ingestion (Bray et al. 2019; Digka et al. 2018; Garcia-Garin et al. 2019; Giani et al. 2019; Lopes et al. 2020; Possatto et al. 2011; Tsangaris et al. 2020). Of relevance, a significant correlation was described between the frequency of MPs ingestion with fish condition factor (Sbrana et al. 2020) and hepatosomatic index (Arias et al. 2019).

Various species of seabirds were described as effective MPs bioindicators (Codina-García et al. 2013; Phillips and Waluda 2020; Cartraud et al. 2019; van Franeker and Lavender 2015); besides, Provencher et al. (2018) suggested that seabirds could also act as microplastic vectors, bioaccumulating MPs in their colonies through the faeces.

For crustaceans, five species are suitable bioindicators of MPs pollution (Table 1; Cau et al. 2019; Cau et al. 2020; Lopes Costa et al. 2019; Villagran et al*.* 2019). It has been demonstrated that the Atlantic ghost crab was a indicator but only qualitatively since MPs prevalence in the gut content of this organism did not follow the constant MP density in the sediment at spatial-temporal scales. Therefore, the authors warn about the need of searching for other beach bioindicators and agree with the assumption that plastics biomonitoring in marine ecosystems is complex, and should rely on the combination of several indicator species with distinct characteristics, particularly feeding habitats and/or mobility (Lopes Costa et al. 2019). Also, it is important to highlight that Cau et al. (2020) documented the occurrence of MPs biological fragmentation in the crustacean *Nephrops norvegicus*, but future studies are necessary to better understand this process.

Other organisms have been related to MPs pollution studies. Cultivation of Nori algae releases large amounts of microplastics that are trapped in the algae for human consumption (Feng et al. 2020). Possible adverse effects of MPs were also described for sponges (Girard et al. 2020); and corals (Rotjan et al. 2019), demonstrating capability of these organisms to be MPs bioindicators, although more studies are necessary to elucidate this.

## **BIOINDICATORS OF EMERGING POLLUTANTS (EPS)**

Emerging pollutants (EPs) or contaminants of emerging concern (CECs) encompass a wide range of chemicals that have been released into the environment and only recently detected in the environment, or they are present in the environment and have become of recent concern, or well-recognized contaminants for which new information on

environmental risk has become available. For most of these, there are no current regulations (Kroon et al. 2019; Tang et al. 2019). EPs can be categorized in multiple ways depending on their chemical structure and/or mode of action. The US EPA lists cover pharmaceuticals and personal care products (PCPs), veterinary medicines, endocrine-disrupting chemicals (EDCs) and some persistent organic pollutants (POPs). Other studies also contemplate lifestyle compounds, such as caffeine and nicotine, drugs and more recently MPs (Kroon et al. 2019). POPs and MPs have already been mentioned above in this chapter and are widely studied. However, the rest of the EPs are not commonly monitored in the environment and have the potential to enter to the diverse environmental compartments and cause adverse ecological and human health effects (Cunha et al. 2017). They are persistent, bioactive, bioaccumulative, and endocrine-disrupting being their effects not fully elucidated (Horricks et al., 2019; Rzymski et al., 2017). Sources of these compounds are diverse and include urban and industrial wastewater and diffuse runoff from agricultural land uses (Kroon et al. 2019).

Emerging pollutants are currently the newest and most serious challenges to natural resources, ecosystems and human health. Scientifically validated processes and tools are necessary to address this problem leading to future regulations (Gavrilescu et al. 2015). To overcome these challenges, mussels (*Mytilus galloprovincialis and Mytilus edulis)* and macroalgae (*Laminaria digitata*) were used for diclofenac (a nonsteroidal anti-inflammatory drug) monitoring. Levels of this compound in mussels were closely related to the environmental contamination turning them as potential bioindicators of diclofenac contamination in coastal environments (Cunha et al. 2017). For other pharmaceutical products such as carbamazepine, ibuprofen, fluoxetine, 17α-ethynylestradiol and propranolol, the marine bioindicator *Hediste diversicolor* (polychaete) has been used in bioassays and *in situ*. Analyses of antioxidant system (glutathione peroxidase-GPX and glutathione reductase-GR), neurotoxicity (acetylcholinesterase-AChE) and oxidative effects (lipidperoxidation-LPO and DNA damage *strand breaks*) comprised the battery of biomarkers recommended to evaluate in this bioindicator the environmental evaluation of pharmaceutical contamination (Maranhoet al. 2014; Pires et al., 2016). Marine macroalgaes *Pterocladia capillacea*, *Ulva lactuca* and *Sargassum hornschuchii* turned out to be suitable bioindicators of pharmaceutical contamination through measurements of fatty acid contents (Mohy El-Din 2017). Moreover, antibiotic resistant bacteria were used as bioindicators by several authors either, in effluents (Al-Bahry et al. 2012), as in organisms such as sea turtles (*Chelonia mydas*) through a noninvasive procedure (Al-Bahry et al. 2011) or the fish *Sparus aurata* (Barros et al. 2011).

Regarding personal care products (PCPs), those using organic ultraviolet (UV) filters such as oxybenzone, 4-methylbenzylidene camphor, Padimate-O or octyl methoxycinnamate were evaluated on muscle and stomach content from the invasive Pacific lionfish (*Pterois volitans*) showing that this organism may be bioaccumulating their residues and could be a useful bioindicator for such compounds (Horricks et al. 2019). Seaweeds specially *Asparagopsis taxiformis*, were proper bioindicators of benzotriazole ultraviolet stabilisers (BUVSs; Pacheco-Suárez et al. 2019) and *Boops boops* an aquaculture-associated fish, proved to be an effective bioindicator of chemical sunscreens (UVFs; Henriquez-Hernandez 2016). Also, *Artemia salina* and *Allium cepa* were used as bioindicators of cosmetics with hormonal composition (Viega et al. 2019).

Finally, rare earth elements (REEs) of anthropogenic origin are also contaminants of emerging concern. Feathers of the Humboldt penguin (*Spheniscus humboldti*) showed to be suitable as bioindicators of 16 REEs (Squadrone et al. 2019).

### **ACOUSTIC POLLUTION BIOINDICATORS**

Marine noise pollution is a relatively recent development and is now recognized as a worldwide problem (Williams et al. 2015). It is introduced intentionally and incidentally into the oceans through human activities. Sound waves can differ in frequency (measured in hertz [Hz] or cycles per second), in wavelength and amplitude (generally measured in decibels [dB]) (Harm and Oude 2000). Anthropogenic noises vary significantly in terms of frequencies and intensities and can be categorized into two main types: high-intensity impulsive noise and low-frequency stationary noise. High-intensity noise can be produced by pile driving, underwater blasting, seismic exploration and active sonar application. Low-frequency stationary noise can be generated by various ships and vessels (Peng et al. 2015).

Assessing the impacts of noise pollution is complex and expensive. There is limited information on sound processing in marine organisms or the role that plays in populations balance and development, and up to what sensory and systemic levels the impact can reach is still unknown, being an effect not immediately observed but in the medium or long term. Also, there are no well-defined protocols to measure the noise pollution impacts, which lead to heterogeneous and fragmented results, useless to guide management actions (Andre et al. 2009).

As top predators with vital dependence and an almost exclusive relationship with sound, cetaceans are the best bioindicators of marine acoustic pollution. They depend on acoustic exchange for a great number of activities and vital behaviours such as communication, geographical orientation, habitat use, feeding and a wide range of endeavours within the broader social group (cohesive action, warnings and maternal relationships), which makes them especially sensitive to acoustic pollution (Andre et al., 2009). The effects can be physical, physiological and behavioural and therefore, different actions have been recommended to determine acoustic contamination impact such as the detection of cetacean strandings and mortalities along with noise events worldwide that should be disclosed and documented. Moreover, post-mortem inspection to determine injuries into the acoustic reception channels and lesions in "non-acoustic" organs have been carried out as well as studies of noise effects on ecological processes, population dynamics, patterns of distribution and behaviour, stress hormones levels (e.g., in faeces) in noisy and quiet areas, and hearing studies in high-noise areas compared with suitable controls (Andre et al. 2009; Weilgart 2007).

Currently, there is still uncertainty and many questions regarding noise pollution since many species have not been studied, such as fish that seem quite vulnerable, and bivalve "can sessile marine species adapt to non-lethal noise environments?" (Peng et al. 2015; Weilgart 2007).

## **CONCLUSION**

A wide range of pollutants that affect marine environments have been reviewed in this chapter. All these pollutants can severely alter both the marine world stability and biodiversity. Therefore, constant monitoring and identification of impacts in time are essential to avoid irreparable damage. The use of bioindicators has proven to be reliable tools for

constant monitoring of marine environments through the evaluation of qualitative and quantitative responses. Organisms of different taxonomic groups, from microorganisms to marine mammals have been described. Bivalve molluscs were the preferred bioindicators while fish were widely used for POPs, metals, and plastic pollution. The use of algae specie as bioindicators were useful for metals and nutrients, and seabirds were frequently used for metal and plastic pollution. Many other promising bioindicators were described for particular environments or pollutants, such as marine mammals, marine sponges, gastropods, crustaceans, parasites, plankton, bacteria, among others, although these were less frequent.

Among the newest challenges, the use of bioindicators for some pollutants such us plastic, emerging pollutants, acoustic pollution, and some POPs, is still in the preliminary stage, and the need to identify useful bioindicators is urgent, considering the increasing impacts that these entails. Furthermore, it is important to note that some authors suggest a multi-species approach as a more effective monitoring method; and non-invasive methods have been explored, such as the use of faeces or blood in seabirds, the use of shells or blood in bivalves, non-invasive methods in sea turtles, and behavioural studies in cetaceans. Finally, there are still many considerations that must be evaluated in the use of bioindicators, advantages, disadvantages and techniques according to the objectives sought. However, its use is currently essential for obtaining representative data that can support decision-making and regulations for environmental preservation and human health.

## *BIOGRAPHICAL SKETCH*

### *Tatiana Valentina Recabarren Villalón*

**Affiliation:** Instituto Argentino de Oceanografía (CONICET-UNS)

### **Education:**

- Bachelor's degree in Marine Biology, Department of marine sciences and natural resources, Universidad de Valparaíso, Chile
- Professional Marine Biologist, Department of marine sciences and natural resources, Universidad de Valparaíso, Chile
- PhD in Biology, Instituto Argentino de Oceanografía/Universidad Nacional del Sur, Argentina (In progress)
- **Business Address:** Florida 8000 (Camino La Carrindanga km 7,5); CCT-CONICET Complex Bahía Blanca, building E1, Bahía Blanca, Argentina. Postal code: B8000FWB

### **Research and Professional Experience:**

My research areas are Environmental Sciences and Ecotoxicology focused mainly on aquatic environments. My research is based on the determination of occurrence, accumulation patterns, and possible sources of persistent pollutants, and the assessment of biomarkers for the early detection of their effects on organisms.

### **Professional Appointments:** Doctoral Fellow

## **ABSTRACT**

Since the banning of popular organochlorine pesticides in 1970s, organophosphorus pesticides (OPPs) started to be widely used throughout the world for agricultural purposes. With an increasing popularity since the 1980s, they were simultaneously applied with organochlorine pesticides for several years. OPPs represent the most used pesticides around the world, to protect agricultural crops against pests, private houses, gardens and in veterinary practices.

Chemically, although they have a lower half-life in the environment than organochlorine pesticides, a moderate persistence and ecotoxicological effects on nontarget species like invertebrates, fish, birds, and even humans have been proved. OPPs resistance to degradation leads to a half-life ranging from hours-at elevated temperature, extreme pH, or high radiation to more than 6 months in the marine environment.

They commonly enter to the marine environments transported by river runoff from the continent in dissolved phase or sorbed to particulate matter. Once in the water, they can enter the trophic network causing damage to the biota; in simultaneous, they can undergo chemical, photochemical and biological degradative processes which could result in more toxic metabolites than the parental compounds.

## **1.INTRODUCTION: HISTORY, CHEMISTRY AND USES OF ORGANOPHOSPHORUS PESTICIDES**

At the present time, many chemical compounds are widely dispersed in the environment. Frequently, the sea is the destination of the contaminants such as sewage, oils, metals, radioactive isotopes, plastics, and synthetic organic compounds after their use in industrial, agricultural, and urban activities (Serrano et al. 1995). Coastal marine environments are some of the most anthropogenically-stressed environments in the world and are known to receive copious amounts of hazardous organic chemicals. These organic chemicals include carcinogenic and toxic polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), pesticides, and among others. These chemicals can not only adversely benthic and pelagic organisms but also accumulate to higher trophic levels, ultimately affecting humans (Smith 1987).

Pesticides, because of their widespread distribution, physicochemical properties, and toxic nature, have become an important class of aquatic pollutants, and so have been the focus of intense research (Jun et al. 2001; Serrano et al. 1995). In many countries, restrictions have been imposed on the use of organochlorine pesticides; and this has shifted the use patterns away from organochlorine toward organophosphorus and carbamate pesticides (Jun et al. 2001).

Organophosphorus are the most widely used pesticides in most countries around the world to protect agricultural crops against pests and also elimination of ectoparasites of animal husbandry (Kazemi et al. 2012). OPPs have become increasingly popular for both agricultural and home use because their unstable chemical structure leads to rapid hydrolysis and little long-term accumulation in the environment (Kumar et al. 2010).

Because of the extensive use of organophosphorus pesticides, the risk of contamination affects different types of aquatic environments, namely rivers, estuaries, lagoons, shallow waters, and wetlands (Barceló et al. 1990). Although they have lower persistence in the environment than organochlorine pesticides, their moderate persistence, toxicity, and bioaccumulation in different species have been reported in many scientific articles (Mercado-Borrayo et al. 2015, Giesy et al. 2014, Klosterhaus et al. 2003, Varó et al. 2002, Escartín and Porte 1996, Keizer et al. 1991).

### **1.1. History and Evolution of Organophosphorus Compounds and Opps**

In order to describe the history of organophosphorus pesticides (OPPs), it is necessary to mention the events that made the development of this type of compound possible and also the difference between organophosphorus compounds and organophosphorus pesticides. Organophosphorus compounds are used as insecticides, nematicides, acaricides, fungicides, herbicides, defoliants, fire retardants, solvents, plasticizers, drugs, and chemical warfare nerve agents (Bey et al. 2001). Thus, OPPs (insecticides, nematicides, acaricides, molluscicides, fungicides, and herbicides) are a particular type of organophosphorus compounds, however in this review article herbicides would not be considered. The synthesis of the first organophosphorus compound and even the development of chemical warfare agents were very important developments for evolution in the synthesis of OPPs and these made possible large-scale production for agricultural purposes in the following years.

The systematic study of organophosphorus compounds began in the  $19<sup>th</sup>$  century, by Jean Louis Lassaigne –a French scientist- in 1820, with the esterification of acid phosphoric that resulted in the obtaining of triethyl phosphate (TEP), (Dos Santos et al. 2007, Chambers 1992). However, the first organophosphorus compound acetylcholine esterase inhibitor (anti-AChE) was produced by Philippe de Clermont, another French scientist, and it was the tetraethyl pyrophosphate (TEPP) in 1854. Then in 1873, Von Hofmann synthesized an organophosphorus compound called methyl phosphoryl chloride (Balali-Mood and Saber 2012). Methyl phosphoryl dichloride is the first example of the C-P linkage and is one of the important steps in the synthesis of modern C-P compounds (Holmstedt 1963).

By the end of the nineteenth century, Carl Michaelis – a german chemist, professor at the University of Rostock- reported a compound with a P-CN bond, diethylamidoethoxy phosphoryl cyanide. This was an important contribution that later led to the synthesis of very important insecticides and the nerve gas, Tabun (Holmstedt 1963).

On the other hand, a few decades later, in 1932, Willy Lange and Gerda Von Krueger, at the University of Berlin, synthesized some compounds containing the P-F linkage -dimethyl fluorophosphates and diethyl fluorophosphates- and noticed that these compounds have strong odor and after inhaling for a few minutes cause difficulties in breathing, loss of consciousness and painful sensitivity to sunlight (Popov and Popov 2009).

Two years later, Dr. Gerhard Schrader, a German chemist at I. G. Farbenindustrie, was given the task to develop a pesticide (Soltaninejad 2014). However, it was not until 1936, that he turned his interest to the phosphorus compounds (Holmstedt 1963). The organophosphorus compounds are highly toxic substances with effect on the nervous system (Popov and Popov 2009). Indeed, in 1937 Schrader synthesized secret compounds bearing the code names Sarin, Tabun and Gelan. Their high volatility and toxicity made them potentially suitable as chemical warfare agents (CWA). These compounds have been called "nerve gases," because their effects are predominantly on the nervous system (Costa 1988). These three nerve gases were known as "G agents," the G letter means German. Seven years later Schrader synthesized Soman and thionophosphorus esters including parathion and its oxygen analog paraxon, two well-known pesticides. Till the end of the war, Schrader and his coworkers developed about 2000 organophosphorus compounds (Soltaninejad 2014). The formulas of Tabun and Sarin were published in 1948 by Valade and Sallé who also reported some preliminary pharmacological experiments in the same year (Holmstedt 1963).

After the WWII, American companies gained access to information from Schrader's laboratory, and began to develop OPPs in copious quantities. Hence, in 1950 the American Cyanamid Company began to produce malathion, an extremely low human toxicity pesticide that become the most popular pesticide worldwide for more than half a century (Soltaninejad 2014; Gupta et al. 2011).

### **Table 1. Chronology of the synthesis and development of organophosphorus compounds**

In 1951 Schrader and Lorenz developed a new type of sulfur- having OPPs, including Systox (demeton or mercaptophos, a mixture of the thiono- and thioloisomers of O, Odiethyl-2-ethylmercaptoethyl phosphorothioate).

In 1952 occurred three notable events for the evolution and development of organophosphorus compounds and so of OPPs too. First, British scientists in the United Kingdom produced CWA known as "V agents" – "V" for "Victory" after WWII- which were sulfur-containing organophosphorus compounds (Balali-Mood and Balali-Mood 2008). These compounds are ten-fold more toxic than sarin (Soltaninejad 2014). Secondly, Russian chemists developed a similar nerve agent, variably referred to as VR or "Russian VX" (N, Ndiethy-2-methyl-2-methylpropoxy phosphorylsulfanylethanamine, Popov and Popov 2009; Mikler et al. 2011). Finally, the Perkow reaction was discovered, and many important vinyl phosphate esters –as dichlorvos and trichlorfon- begun to be introduced as practical insecticides (Eto 1979). In the latest years of the 1950s, chlorthion, fenthion and fenitrothion were also synthesized (Eto 1979).

Therefore, the use of OPPs peaked in the 1970s when most widely used organochlorine insecticides where phased out or banned (Costa 2018). While there has been a considerable increase in the annual use of organophosphorus insecticides for crop protection since 1970, the overall increase has been less since the early 1980s. However, new uses and formulations have been introduced and the use of OPPs is still high in most developing countries, particularly because of the low cost of these chemicals compared to newer insecticides (Costa 2018; WHO 1986).

#### **1.2. Chemistry**

Organophosphorus pesticides are normally esters, amides, or thiol derivatives of phosphoric, phosphonic, phosphorothioic, or phosphonothioic acids and are currently used in agriculture or animal husbandry for crop protection and/or elimination of ectoparasites (Sud

and Kaur Sidhu 2012). The general formula of organophosphorus is presented in Figure 1, where  $R_1$  and  $R_2$  are usually simple alkyl or aryl groups, both of which may be bonded directly to phosphorus (in phosphinates), or linked via -O-, or -S- (in phosphates and phosphorothiolates, respectively), or  $R_1$  may be bonded directly and  $R_2$ , bonded via one of the above groups (phosphonates, WHO 1986).

Figure 1. General formula of organophosphorus pesticides.

Main groups of OPPs	Chemical structure	Examples
Phospate	OR <sub>3</sub> $R_1O$ $R_2C$	Dichlorvos, Diazoxon, Dicrotophos, Mevinphos, Monocrotophos, Naled, Phosphamidon, Tetrachlorvinphos
Phosphorothiolate	SR <sub>3</sub> $R_1O$ R <sub>2</sub> O	Demeton-S, Oxydemeton-Me
Phosphorothioate	$R_1$ O OR <sub>3</sub> R <sub>2</sub> O	Chlorpyrifos, Chlorpyrifos-Me, Demeton-O, Diazinon, Fenitrothion, Fensulfothion, Fenthion, Isazofos, Methyl- Parathion, Parathion, Pirimiphos-Me, Pirimifos-Ethyl, Temephos, Tolclofos-Me
Phosphorodithioate	SR <sub>3</sub> $R_1C$	Azinfos-Me, Carbophenothion, Dimethoate, Disulfoton, Malathion, Phorate, Phosmet, Terbufos, Thiometon

**Table 2. Chemical structures of main groups of OPPs**

The double-bonded atom may be oxygen or sulfur and related compounds would, for example, be called phosphates or phosphorothioates (WHO, 1986). In phosphoramidates, carbon is linked to phosphorus through an -NH group. The X group can be diverse and may belong to a wide range of aliphatic, aromatic or heterocyclic groups linked to phosphorus via a bond of some lability (usually -O- or –S-). The X group is also known as a leaving group because on hydrolysis of the ester bond it is released from phosphorus (Singh and Walker 2006).

Organophosphorous pesticides vary in chemical structures and toxicities. For instance, a phosphorthioate compound such as Parathion is much more toxic than a phosphorodithioate compound like Malathion (Balali-Mood and Saber 2012).

Based on the molecular structures, OPPs are typically categorized into four subgroups: phosphates, phosphorothioates, phosphorodithioates, and phosphorothiolates (Pehkonen and Zhang 2002).

### **1.3. Uses of OPPs**

Organophosphorus pesticides include not only insecticides, but also fungicides, herbicides, molluscicides, nematicides and others. They are used to protect crops and improve agricultural production by controlling insects, diseases, fungi, and other pests. OPPs are wide spectrum pesticides, not only used for field crops, fruits, vegetables, ornamental plants, trees, horticulture, cattle parasites and, pet ectoparasites, but also in public health for disease vector control. For instance, azinphos methyl is frequently used for cotton, apples, pears, citrus crops, and blueberries, whereas chlorfenvinphos is used as pesticide to control root flies, root worms and other soil insects in vegetables; foliar application on potatoes; scale insects and tick eggs on citrus fruit; stem borers and leafhoppers on rice, corn and sugar cane; and white flies on cotton; aside from control of mosquito larvae, acaricide and animal ectoparasiticide (Mackay et al. 2006).

### **1.4. Currently Used OPPs, Quantities and Restricted Compounds**

The population explosion and resulting increased demand for agro-products have resulted in such an increase in the consumption of pesticides worldwide. The U.S. Environmental Protection Agency (USEPA) had registered about 23.400 different pesticide products by the year 1991 (Kumar et al. 2018). The top five highest pesticide-consuming countries globally (tonnes per year) are Italy (63.305), Turkey (60.792), Colombia (48.618), India (40.379), and Japan (36.557, Verma et al. 2014).

Currently, organophosphorus pesticides are the most commercially favored group of pesticides, with large application areas all over the world (Kumar et al. 2018). Out of 2.300.000 tonnes of pesticides which are used worldwide every year, organophosphosphorus pesticides (mostly insecticides) constitute 20-38%, and the main candidates are chlorpyrifos, dichlorvos, diazinon, dimethoate, fenitrothion, methyl parathion, monocrotophos, malathion, and profenophos (Mahajan et al. 2019).

According to Pesticides Industry Sales and Usage 2008 – 2012 USEPA report, the amount of OPPs used in the United States OPPs usage as a percentage of total insecticide use has decreased from 71% in 2000 to 33% in 2012 and the most usage include acephate, chlorpyrifos, malathion, naled, phorate, dicrotophos, phosmet, dimethoate, terbufos, ethoprophos, and tetrachlorvinphos. The decrease in OPPs usage reflects a shift in usage to other classes of pesticides (i.e., pyrethroids, neonicotinoids, and other new formulations) because of the phasing out and use restrictions placed on OPPs.

In the case of the European Union, over the period 2011-2018 (EU agri-environmental indicator consumption of pesticides 2020), the sales of pesticides remained stable at around 360.000 tonnes per year. Particularly, in 2018 total pesticides sales were of 428.800 tonnes, of which 12.52% were insecticides and acaricides. From that insecticides and acaricides 11.7% were insecticides based on organophosphorus, constituting 6.286 tonnes. However,

organophosphorus pesticides also include acaricides, fungicides, and molluscicides, therefore the number of total organophosphorus pesticides should be higher.

As for other continents, there is only few data on South and Central America (Argentina, Belize, Panama, Paraguay and Suriname) of total organophosphorus pesticides use of 2.908 tonnes in year 2017 (FAOSTAT, Pesticides use 2020) and Asia (Bangladesh, Cyprus, Japan, Maldives, Myanmar and Sri Lanka) of 5.591 tonnes in the same year. No data of Africa, and Oceania were found in the FAOSTAT Pesticide use registers.

Regarding international conventions on organophosphorus pesticides, Annex III of the Rotterdam Convention include pesticides and industrial chemicals that have been banned or severely restricted for health or environmental reasons by two or more parties. The Annex III includes: azinphos-methyl, metamidophos (severely hazardous pesticide formulations), monocrotophos, parathion, phorate, trichlorfon, methyl-parathion and phosphamidon. Moreover, fenthion is recommended for list in Annex III.

On the other hand, the European Union for instance recently banned chlorpyrifos, because it is linked to health problems in children, but the U.S. has allowed its use because the USEPA did not agree with the assessment in Europe (Topping et al. 2020).

## **2. CHEMICAL PROPERTIES OF OPPS AND ENVIRONMENTAL BEHAVIOR**

### **2.1. Physical- Chemical Properties of OPPs: Structures and Related Parameters of 28 Compounds**

After organophosphorus pesticides are deposited on or incorporated into the soil matrix, they distribute between the air, soil air, soil water and soil solid phases (Pedersen and Suffet 2002). The major differences between behavior profiles of organic chemicals in the environment are attributable to their physical-chemical properties (Mackay et al. 2006).

A comparison of the octanol-water partition coefficients,  $K_{ow}$ , reveals the role the leaving group (X) plays in determining compound hydrophobicity and provides a direct estimate of partitioning tendency from water to organic media such as lipids, waxes and natural organic matter such as humin or humic acid (Mackay et al. 2006; Pedersen and Suffet 2002). Thus, it is used in environmental fate studies and large values (+4 or higher) are regarded as an indicator that a substance will bio-accumulate according to the Pesticide Properties DataBase website from University of Hertfordshire (https://sitem.herts.ac.uk/aeru/ppdb/).

Furthermore, the differences between the  $K_{ow}$  coefficients are mostly due to the leaving group of the molecule. For instance, the high  $K_{ow}$  value of chlorpyrifos (log  $K_{ow} = 4.70$ ) is due primarily to the hydrophobic 3,5,6-trichloro-2-pyridinyl X group, while the low  $K_{ow}$ value of dimethoate ( $log Kow = 0.50$ ) is due to the polar 2-mercapto-N-methyl acetamide X group (Pedersen and Suffet 2002).

Another important property is the water solubility, which is the mass of a given substance (the solute) that can dissolve in each volume of water (Pesticide Properties DataBase website from University of Hertfordshire). In addition to this, water solubility values above 500 mg/L means compounds with high solubility and below 50 mg/L low solubility. Acephate (818000 mg/L at 25ºC), Dicrotophos (1000000 mg/L at 25ºC), and Monocrotophos (1000000 mg/L at 25<sup>o</sup>C) have high solubility in water, while Ethion (1 mg/L at 25<sup>o</sup>C), and Chlorpyrifos (2 mg/L at 25ºC) have extremely low solubility in water.

Instead, to analyze the pesticide volatilization process, the vapor pressure property of each compound must be reported. This is the pressure at which a liquid is in equilibrium with its vapor at 20ºC (Pesticide Properties Data Base website from University of Hertfordshire). Besides, it is a measure of the tendency of a material to vaporize, hence can be viewed as a "solubility in air" (Mackay et al. 2006). According to the interpretation of parameters provided by the Pesticide Properties Data Base website from University of Hertfordshire; vapor pressure values above  $1x10^{-2}$  Pa means highly volatile compounds; and values below  $5x10^{-3}$  means low volatility compounds. Therefore, Dichlorvos (1.60 Pa at 20 $^{\circ}$ C) is one of the most volatile OPPs and by contrast Temephos  $(9.5 \times 10^{-6} \text{ at } 20^{\circ}\text{C})$  is one of the less volatile compounds. Volatilization of soil and foliar applied pesticides reduces the amount available for transport with runoff water (Pedersen and Suffet 2002). Volatilization depends on the vapor pressure and water solubility of the compound. Partitioning between the water and vapor phases is expressed by the Henry's law constant,  $K_H = C_a/C_w$ , where  $C_a$  and  $C_w$  are the air, and water phase concentrations, both expressed in mol/L (Pedersen and Suffet 2002). Henry's law constant supplies a sign of the preference of a chemical for air compared to water i.e. its volatility (Mackay et al. 2006). Table 3 displays physicochemical properties of representative organophosphorus pesticides.

Figure 2. Distribution pathways of OPPs in the environment. Adapted from WHO 2001.
Table 3. Physical- chemical properties and related parameters of 28 organophosphorus pesticides **Table 3. Physical- chemical properties and related parameters of 28 organophosphorus pesticides**

2.2 Environmental behavior. Distribution pathways. Persistence. Half-lives.

\* Parameters were selected from Mackay et al. (2006), Lacorte et al. (1995) and from Lattigues y Garrigues (1995).<br>DA: Disappearance after, VFD: Very fast degradation. \* Parameters were selected from Mackay et al. (2006), Lacorte et al. (1995) and from Lartigues y Garrigues (1995).

DA: Disappearance after, VFD: Very fast degradation.

The OPPs enter the environment (target soil or air or surface water) through different pathways after their application onto crops (by spraying) or into the soil (as seed treatment). These routes include emissions, leakage, drainage, and volatilization (Mahajan et al. 2019). These kinds of pesticides are applied to crops via a variety of methods. Malathion is often applied from low-flying airplanes in agricultural as well as urban areas while fenamiphos is applied as a spray or in granular form to the soil surface and incorporated post application (Pedersen and Suffet 2002). On the other hand, phorate is an example of a soil pesticide that is applied as granules on the land where the protected crop is cultivated, while chlorpyrifos belongs to a group of OPPs that are applied directly to the fruit and/or leaves (Pehkonen and Zhang 2002).

Regarding transport through the air, except for dichlorvos, most organophosphorus pesticides show low volatility. Dispersion of spray dew by wind is possible, but, in general, only insignificant amounts are likely to be distributed in this way (WHO 1986). From the soil, the OPPs residues can enter either surface water or groundwater via drainage or leakage.

As a result of the movement of the OPP residues in different environmental components, several non-target species are adversely affected. These non-target species range from microorganisms in the soil to aquatic and terrestrial organisms (Mahajan et al. 2019).

Factors controlling the distribution of organophosphorus pesticides discharged to marine environment are the degree of natural degradation and the extent of adsorption onto particulate matter while moving toward the offshore area (Stoker and Seager 1976). In addition to this, temperature, pH, contributions from microorganisms, and levels of suspended solids in seawater are also important (Paris et al. 1975).

The half-life of a chemical in the environment depends not only on the intrinsic properties of the chemical, but also on the nature of the environmental compartments. Factors such as sunlight intensity, hydroxyl radical concentration and the nature of the bacterial community, as well as temperature, affect the chemical's half-life so it is impossible (and misleading) to document a single reliable half-life (Mackay et al. 2006). Several works concerning the persistence of OPPs in the aquatic environment have been carried out; however, the most of them were studied in freshwater environments. In 1995 Lartigues and Garrigues, studied the degradation kinetics of a mixture containing 19 organophosphorus (OP) and organonitrogen (ON) pesticides at ppb level was studied over a 6-month period in different water types (ultrapure water, natural seawater -from Arcachon Bay, France-, river water, filtered river water) and under various conditions (Lartigues and Garrigues 1995). The mixture was analyzed by gas chromatography coupled with a nitrogen phosphorus detector (GC/NPD) and the half-lives times of the OPPs were decided (Lartigues and Garrigues 1995).

In the same year, Lacorte et al. studied the degradation of 10 organophosphorus pesticides in natural estuarine waters. The estuarine water samples of Ebro River in Spain were placed in Pyrex flasks, spiked with OPPs 50 µg/L and exposed outdoor to ambient sunlight and temperature from January to march (Lacorte et al. 1995). The analytical determinations were performed by solid phase extraction (SPE) followed by GC-NPD and GC-MS (Lacorte et al. 1995). As a result, five OPPs were stable for less than 1 week (disulfoton, fenamiphos, fenthion, malathion, and temephos), others had a half-life of ca. 1 week (chlorpyrifos-methyl, methidathion, and diazinon), and the rest showed a half-life of ca.10 days (isofenphos and pyridafenthion, Lacorte et al. 1995). The half-life of three pesticide transformation products: disulfoton sulfoxide, disulfoton sulfone, and fenthion sulfoxide varied from 7 to 12 days (Lacorte et al. 1995).

#### **2.2. OPPs Mechanisms of Degradation and Sorption in Estuaries and Oceans**

In the aquatic environment, the survival time in water may be influenced by light intensity, oxygen concentration, salinity, and pH. Most OPPs are more stable in the pH range that may be met in the environment ( $pH: 3 - 6$ ), than at neutral  $pH$  (WHO 1986). Consequently, in the marine environments –usually with alkaline pH- the OPPs tend to be degraded faster. In addition to this, the influence of microbiological factors in the degradation of these pesticides in water may be considerable. Different climatic conditions, especially temperature and humidity, before, during, and after application may influence the survival time of OPPs markedly before reaching to the marine ecosystem (WHO 1986).

Organophosphorus pesticides in water can suffer different process of degradation, such as oxidation –can occur in a biotically way by ozone, dissolved oxygen and radical mechanisms, and in biotically way by specific enzymes-, photolysis - by direct or indirect ways- and hydrolysis, which seems to be the principal route of degradation in the environment and the most studied. Abiotic and biotic transformation processes reduce the amount of parent compound available in the environment. Transformation products call for concern, however, when they show significant toxicity (Pedersen and Suffet 2002). Therefore, identification of metabolites after their release into the environment is necessary for the evaluation of the OPPs toxicity to the biota (Battala et al. 2012).

#### *2.2.1. Hydrolysis*

All organophosphorus pesticides are subject to degradation by hydrolysis yielding watersoluble products that are believed to be non-toxic at all practical concentrations. The toxic hazard is therefore essentially short-term, in contrast to that of the persistent organochlorine pesticides, though the half-life at neutral pH may vary from a few hours for dichlorvos to weeks for parathion (WHO 1986). In addition to this, half-lives studies are often carried out in "model" environments and conditions, making extremely complicated to predict the results in the natural marine environments and at natural conditions.

The mechanism of hydrolysis plays a critical role in the overall degradation process of OPPs, which accounts for the cleavage of P–S or P–O bonds (Mahajan et al. 2019). Despite of hydrolysis is the most common route of degradation of OPPs in natural waters, the rate of hydrolysis depends of the type of OPP, for instance phosphorothioate pesticide hydrolysis is typically less than that of the corresponding phosphate compounds because the greater electrophilicity of the oxon renders it more susceptible to nucleophilic attack (Schwarzenbach et al. 1993). Hydrolysis can occur by a concerted mechanism, where H2O and HO (H<sup>+</sup> catalysis is less common) act as nucleophiles in an  $SN_2$  mechanism (Pehkonen and Zhang 2002). It is important to realize that nucleophiles can attack either the phosphorus atom (with an alcohol or thiol residue being the leaving group) and the carbon atom bound to the oxygen or sulfur of an alcohol or thiol moiety respectively (with one of the the diester being the leaving group, Hong and Pehkonen 1998). For organophosphorus pesticides, HO is a better nucleophile than  $H_2O$ . The base-catalyzed reaction results in detachment of the best leaving group from the phosphorus atom (Pedersen and Suffet 2002). In most cases, acid-catalyzed hydrolysis is unimportant unless the leaving group holds a basic functional group that enhances reactivity when protonated (Schwarzenbach et al. 1993).

Moreover, constituents of soil, sediments of surface water may themselves catalyze degradation of OPPs (WHO 1986). Hydrolysis of organophosphorus pesticides can be catalyzed by dissolved metal ions -particularly  $Cu^{2+}$  for Diazinon or H $g^{2+}$  for malathion, fenitrothion, fenthion and parathion methyl- and constituent or exchangeable metal ions in aluminosilicate minerals -e.g., montmorillonite-*.* (Pedersen and Suffet 2002; Smolen and Stone 1997; Wan et al. 1994; Pehkonen and Zhang 2002).

Hong an Pehkonen (1998) studied the hydrolysis of phorate under simulated environmental conditions and with several metal oxides –like aluminum hydroxide, hematite, goethite and ferrihydrite- as solid phase in natural aquatic systems, although this four metal hydroxide or oxides (the most common in natural environments) did not seem to have significant influence on the half-life of phorate, under the experimental conditions employed in the study, i.e. no statistically significant catalytic effect was observed (Hong and Pehkonen 1998). They also found that abiotic hydrolysis of phorate under alkaline conditions produces diethyl disulfide, hydrogen sulfide, and formaldehyde, all of which are toxic compounds (Hong and Pehkonen 1998). In addition to this, Battala and co-workers studied the degradation of phorate in different water types –well water, Penna river water and seawater of Nellore, Bay of Bengal, India- and found that this pesticide had degraded at faster rates in sea water compared to river and well water. This shows that the hydroxide-catalyzed hydrolysis is a major pathway for the degradation in marine systems (Battala et al. 2012).

Batalla and co-workers (2012) studied the degradation of malathion in seawater of Bay of Bengal in India. They figured out that malathion had a half-life of 2 days in the seawater/sediment system -pH 7.3 to 7.7- (Battala et al. 2012). This half-life time value is in agreement with what was studied earlier by Cotham and Bidleman in 1989 at the same pH ranges for the seawater obtained from North Inlet estuary, Georgetown County, USA (Cotham and Bidleman 1989).To conclude, for malathion hydroxide-catalyzed hydrolysis, as well as in the case of phorate, is a major pathway for their degradation in marine systems, and is regulated by the pH of water (increase with alkaline pH) and salinity (faster degradation with increase of salt content, Cotham and Bidleman 1989; Lartigués and Garrigués 1995). Speedup of the reaction in saltwater is attributed to the higher ionic strength which influences hydrolysis through primary and/or secondary salt effects (Weber 1976).

On the other hand, Lartigués and Garrigués (1995) studied the degradation kinetics of several OPPs for a 6-month period in different water types, included natural seawater, under various conditions. Quite different degradation behavior with respect to physicochemical conditions and molecular structures of the pesticides was seen (Lartigués and Garrigués 1995). Moreover, the authors determined half-life times  $(t_{1/2})$  of the pesticides in seawater. For phosmet, a very fast degradation in seawater at  $(T = 6^{\circ}C, pH = 8.1)$  was observed due to a rapid hydrolysis, whereas t<sub>1/2</sub> for dimethoate were 219 day (T = 6°C, pH = 8.1) and in the case of azinphos-ethyl ( $T = 6^{\circ}C$ , pH = 8.1) no degradation at all was observed (Lartigués and Garrigués 1995).These experiments confirm that half-lives of OPPs can be more than several months and consequently lead to lasting environmental pollution. It is worth mentioning that there are marine environments that may present conditions that do not favor degradation. In this case, it was evaluated for seawater, in the dissolved fraction and with controlled conditions –pH and temperature-. Thus, in natural marine environments, there are multiple factors that influence the behavior of OPPs and it is not possible to generalize what may occur in a natural environment from a laboratory study.

#### *2.2.2. Oxidation*

The oxidation of OPPs can occur by a direct absorption of light, by an attack of photoproduced radicals, or by aqueous oxidants such as dissolved oxygen, aqueous chlorine, or by enzymatic reagents such as oxygenases (Pehkonen and Zhang 2002). The possible mechanisms include oxidation of the  $P = S$  bonds or the isomerization (Mahajan et al. 2019). Oxidation of OPPs to the corresponding oxons, sulfones, and sulfoxides has been reported widely (Pehkonen and Zhang 2002). Oxidation of OPPs by ozone produces oxons -where a sulfur atom from the thioate group is substituted by an oxygen atom- and sulfates due thiophosphorile bonds were oxidized by ozone into phosphorile bonds (Ohashi et al. 1994).

Lacorte and co-workers (1997) studied the oxidation with N-bromosuccinimide (NBS) of fenthion and temephos in water. In the case of fenthion the products were fenthion oxon (from the replacement of the doubly bonded sulfur with oxygen), fenthion sulfoxide (from the oxidation of the sulfur in one of the ester side chains), fenthion oxon sulfoxide (from the combination of the above two), and finally the S-methyl isomer of fenthion (changes the sulfur of the dimethyl-phosphorotioate group with the oxygen of the methoxy group) (Lacorte et al. 1997). Moreover, another oxidation product whose formation is possible is sulfone –is formed when sulfoxide in the ester side chain is further oxidized to yield two  $S = O$  bonds on a single sulfur atom- (Lacorte et al. 1997). Likewise, in the case of temephos similar products than fenthion were founded. The main difference is that temephos has two  $P = S$  bonds, thus dioxon can also be formed (Pehkonen and Zhang 2002). In the next figure are shown all degradation products of oxidation of fenthion with NBS.

Figure 3. Structural formula of fenthion and its degradation products and schema of the oxidative pathways after oxidation of fenthion with NBS. Adapted of Lacorte et al. 1997.

#### *2.2.3. Biodegradation*

Pesticides are degraded in the environment principally by the action of indigenous microorganisms, a process termed as biodegradation, which is defined as the breakdown of a substance to small inert end products (Aislabie and Lloyd-Jones 1995). According to Kumar et al. 2018 most organophosphate pesticides are degraded by microorganisms in the environment as a source of their limiting nutrients, carbon (C) and/or phosphorus (P). The principal reactions involved in the degradation process are oxidation, hydrolysis, alkylation, and dealkylation (Singh and Walker 2006).

As cited Kumar (2018) different species of *Pseudomonas* isolated from agricultural soils and contaminated effluents throughout different regions have proven to be very efficient in the biodegradation of chlorpyrifos.

Wang and Hoffman (1991) studied the persistence and degradation of parathion in the Indian River estuary, which is found along the east coast of Florida. Test water was put into a 1 L borosilicate glass bottle and was spiked with 2.5 mL of 200 ppm pesticide solution. As a result of the study, the most significant pathway for parathion degradation was biological interaction (Wang and Hoffman 1991). After 30 days in sterilized water, 64%, 57%, and 49% of initial parathion in pH 6, 7, and 8.16 respectively was still present (Wang and Hoffman 1991). By contrast, persistence in nonsterile water after 30 days revealed that only 21%, 14%, and 6% were present in pH 6, 7, and 8.16, respectively. Both alkaline hydrolysis and sunlight photolysis of parathion occurred, but they were not as competitive as the biological degradation pathway, i.e. both are secondary pathways of degradation (Wang and Hoffman 1991).

#### *2.2.4. Photodegradation*

Photodegradation can occur either by a direct photolysis of OPPs, which have an absorption spectrum overlap with the solar spectrum or by indirect photodegradation, whereby dissolved humic and fulvic acids can act as a sensitizer or when particles can lead to semiconductor promoted photodegradation (Pehkonen and Zhang 2002).In static water, in a simulated aquatic environment, there is evidence of the contributions of light, suspended particulates, and bacteria to degradation. Thus, the degradation of fenitrothion in lake water under illumination occurred with a half-life of about 2 days, compared with 50 days in the dark (Greenhalgh et al. 1980).

Lacorte and Barceló (1994) were the first ones who studied the degradation of fenitrothion at environmental conditions in estuarine water. Fenitrothion was applied in the irrigation ditches of the Ebro Delta in Spain at a concentration of 200 and 20 µg/L to eliminate the American crab (Lacorte and Barceló 1994). The transformation products (TPs) formed 4 days after its application were 3-methyl-4-nitrophenol, fenitrooxon, and S-methyl isomer of fenitrothion (Lacorte and Barceló 1994). The concentration of fenitrothion decayed sharply in 2 h to less than 10% of the initial amount and reached a steady state within 10 h, while TPs were at a very low 0.01 µg/L level. Half-life of fenitrothion was of 13 h, with a disappearance rate of 0.053 and photolysis being the main pathway (Lacorte and Barceló 1994).

#### *2.2.5. Sorption*

Adsorption to soil solids, sediments, and plant cuticular material represents an important process influencing the chemodynamic behavior of insecticides, including their transport in surface runoff. Sorption phenomena affect the volatilization, hydrolysis, photolysis, and microbial transformation of organophosphorus insecticides (Pedersen and Suffet 2002). The degree of adsorption and the rate and extent of ultimate degradation are influenced by many

factors, which include solubility, volatility, charge, polarity, molecular structure, and the size of the pesticides (Kumar et al. 2018).

As cited Pedersen and Suffet (2002) sorption of organophosphorus insecticides to soil particles depends primarily on compound hydrophobicity and the fraction of natural organic matter (NOM) in the soil. This is because the particles of organic matter or clay provide soils and sediments with an increased number of adsorptive sites onto which pesticides molecules can bind. In the case of chlorpyrifos, its strong association with suspended sediments presents a potential migration route unique to aquatic environments and may explain reported detections of chlorpyrifos in water wells and marine sediments (Gebremariam et al. 2012).

Readman and co-workers studied the presence of OPPs in sediments of tropical marine environments -coastal areas of Central America and Mexico-. In sediments from the areas chosen for study, chlorpyrifos was found to be the most widely distributed compound. Traces of parathion and methyl-chlorpyrifos were, however, also encountered (Readman et al. 1992). However, the physical chemistry of chlorpyrifos differs to that of most other organophosphorus pesticides. Not only is generally less soluble in water (2.0 mg/L compared to, for example 145 mg/L for malathion and 24 mg/L for parathion) but also the log  $K_{ow}$  of 4.70 contrasts those for malathion (2.36) and parathion (3.83) and approaches that of pp'- DDT (6.39) (Chiou et al. 1977, Mackay et al. 2006). Whilst this would enhance partitioning of chlorpyrifos onto sediments compared to most other organophosphorous compounds, it is likely that the identification of primarily chlorpyrifos in the sediments is also a function of rapid degradation as well as solubilization of the others (Schimmel et al. 1983; Readman et al. 1992).

#### **3. CURRENT OPP LEVELS IN MARINE ENVIRONMENTS**

Scientific articles of organophosphorus pesticides in marine environments – in water and sediments- around the world in the last decade (2010-2020) were reviewed. Despite of being harmful pesticides for aquatic biota very few information was found about research conducted in marine environments. The compounds reviewed were: azinphos methyl, chlorfenvinphos, chlorpyrifos, chlorpyrifos methyl, diazinon, dichlorvos, dimethoate, disulfoton, ethion, fenitrothion, iprobenfos, malathion, parathion, parathion methyl, Terbufos and triazophos.

Regarding the detection limits (LOD) of the reviewed works, a disparity was seen in them. It is hard to get a wide interpretation of a ND (Not detected) or below the detection limit (<LOD) value; if this is a high LOD, since is possible that there are organophosphorus pesticides but they are below this limit of detection. Therefore, the finding of pesticides may be because the LOD was low and in other cases where no compounds are found it is because the LOD is high. The above explained complicates the item QA/QC because for the comparison of works the harmonization of LODs is necessary; setting a limit as a minimum and standardizing a common protocol. LODs of OPPs in seawater ranged from 0.001 pg.  $L^{-1}$ to 3.3 ng. L<sup>-1</sup> and in sediments from 0.067 pg  $g^{-1}$  dw to 10 ng  $g^{-1}$  dw. In the particular case of chlorpyrifos in seawater, as an example, its LOD were 0.4 ng.L-1 for Moreno-González and coworkers (Moreno-González et al. 2013) using capillary gas chromatography coupled to mass spectrometry (SBSE- GC- MS);  $(0.20 - 1 \text{ ng.L}^{-1})$  for Montuori and coworkers using gas chromatography coupled to nitrogen-phosphorus detector (GC-NPD) (Montuori et al. 2015;

Montuori et al. 2016); (0.001  $pg.L^{-1}$  - 2  $pg.L^{-1}$ ) for Zhong and coworkers using GC-MS in the German Bight, North sea (Zhong et al. 2012);  $0.06$  pg. L<sup>-1</sup> for the same author from East China to high Artic Ocean (Zhong et al. 2011) and 1  $ng.L^{-1}$  for Harino and coworkers using GC-MS (Harino et al. 2013).

On the other hand, in order to determine the ecotoxicological risk associated with de presence of OPPs in sediments and water, the mean levels found of OPPs in the marine environments in the reviewed articles were compared with the benchmarks proposed by the SQuiRTs (Screening Quick Reference Tables) of the NOAA (National Oceanic and Atmospheric Administration) from USA (Buchman 2008); the Australian and New Zealand Guidelines for Fresh and Marine Water Quality, 2000 and the Environmental Quality Guidelines of Canadian Council of Ministers of the Environment (CCME 2002).

#### **3.1. OPPs in Marine Sediments**

In the case of sediments, the studies reviewed were from research in Europe, Asia and North America. No research studies of OPPs in marine environments from Central and South America, Oceania, or Africa for the last decade were found; fourteen scientific articles were reviewed. By contrast, several works for freshwater sediments were found, like determination of OPPs in the Zio River, Togo, África by Mawussi et al. 2014; in the Guan River, China by He et al. 2014; in the Lake Zumpango, Mexico by Dzul-Caamal et al. 2014; and in the Llobregat River, Spain by Masiá et al. 2015.

Furthermore, the only guidelines applicable to levels in sediments are those corresponding to SQuiRTs of NOAA. However, in these tables the only OPPs with benchmarks for sediments are azinphos methyl, diazinon, and parathion. For diazinon and parathion the benchmark is Ecotox Thresholds (ETs) -defined as media specific contaminant concentrations above which there is sufficient concern regarding adverse ecological effects to warrant further site investigation- whereas for azinphos methyl are target benchmark meaning that analyte concentrations in the sediment matrix are set such that they should not contaminate another matrix above risk- and intervention benchmark –meaning risk that the analyte may migrate to other matrix-.

The current environmental mean concentration of OPPs in sediments range from ND to  $311.81$  ng.  $g^{-1}$  dw (Table 7). On one hand chlorpyrifos was the most studied and quantified pesticide in sediments, and its general mean for the reviewed sites in the world is 9.60 ng.  $g^{-1}$ dw. On the other hand, the highest concentration of pesticide found in sediments was for iprobenfos with a mean concentration of 331.81 ng.  $g^{-1}$  dw in the East China Sea, reported by Lan et al. 2019.

**Table 5. Benchmarks for OPPs given in SQuiRTs tables from NOAA. Parameters were selected from (Buchman 2008)**

Organophosphorus Pesticides	Target (ppb or $ng. g-1$ )	Intervention (ppb or $ng. g-1$ )	EcoTox (ppb or $ng. g-1$ )
Azinphos Methyl	0.05	$2000 S*$	
Diazinon			
Malathion			0.67

\*S: Serious contamination.

ND: Not detected. Mean ± SD, or Mean if it is only one value; Range is expressed with a hyphen between and in some case in the study was only informed the maximum. S: Summer, 5 ццкі á A: Autumn.  $\frac{81}{2}$ 

# Table 6. (Continued) **Table 6. (Continued)**

#### **Table 7. Benchmarks for OPPs in marine surface water given in SQuiRTs tables from NOAA (Buchman 2008), CCME (2002) and Australian and New Zealand Guidelines (2000)**

When comparing levels of OPPs in the sediments with the international guidelines on ecotoxicological risk proposed by SQuiRTs tables of NOAA, it was observed that in the case of diazinon in the three places – Mar Menor coastal Lagoon, Spain in summer and autumn studied by Moreno-González et al. 2017; Tiber river Estuary in Italy, studied by Montuori et al. 2016 and Maizuru Bay, Japan studied by Harino et al. 2013- detected the mean concentration levels found of this compound indicate there is sufficient concern regarding adverse ecological effects to warrant further investigation of the sites and it can cause damage to marine biota.

Meanwhile, malathion was only detected in Vistula lagoon, Baltic Sea, Poland (Staniszewska et al. 2013) where the mean concentration exceeds EcoTox threshold of SQuiRTs tables meaning, like diazinon, there is sufficient concern regarding adverse ecological effects to warrant further investigation of the sites.

#### **3.2. OPPs in Seawater**

To analyze the current levels of OPPs in seawater, eleven articles were reviewed, all from Europe, Asia, and North America. No available studies were found for other continents. It is remarkable that the number of studies available on OPPs in seawater is much lesser than in freshwater (e.g., Shaw et al. 2010; Polidoro et al. 2017; Bonansea et al. 2013; Phillips et al. 2012; Mamta et al. 2018).

Guidelines applicable to levels in marine water are those corresponding to SQuiRTs of NOAA, trigger values of Australian and New Zealand guidelines and Canadian guidelines for the protection of aquatic life. For the NOAA tables the benchmarks are marine surface water acute effects (health effects usually develop rapidly after a short-term exposure to hazardous chemicals) and chronic effects (health effects become apparent and/or continue for some time after exposure to hazardous chemicals). Meanwhile, Canadian water quality guidelines for the protection of aquatic life help to protect species that live oceans by establishing acceptable levels for substances that affect water quality. As long as conditions are within the levels

established by the guidelines, one would not expect to see negative effects in the environment. Finally, in the Australian and New Zealand guidelines the benchmark is a trigger value for marine biota, which represents either bioavailable concentrations or unacceptable levels of contamination.

The current environmental mean concentration of OPPs in seawater range from ND to 19.37  $\mu$ g. L<sup>-1</sup> (Table 8). The most studied pesticides in seawater were chlorpyrifos and diazinon. In the same way that happened in the sediments, iprobenfos was the pesticide with the highest mean concentration detected; 19.37  $\mu$ g. L<sup>-1</sup> in the East China Sea, reported by Lan et al. 2019.

OPPs levels in seawater where compared with the international guidelines on ecotoxicological risk proposed by the SQuiRTs tables from NOAA. From this, it was observed that azinphos-methyl mean concentrations did not exceed the benchmark proposed for marine surface waters, meaning there would not be adverse effects on biota in none of the three places where it was detected –in coastline of Catalonia in Spain, Sarno river Estuary in Italy and in German Bight in the North Sea (Köck- Schulmeyer et al. 2019, Montuori et al. 2015, Mai et al. 2013)-. Meanwhile, the mean levels of chlorfenvinphos, in seawater of the Catalan, German Bight and Portuguese coasts (Köck- Schulmeyer et al. 2019, Mai et al. 2013, Sousa et al. 2020) were below the SQuiRTs benchmark, however the maximum concentration in the Portuguese coast was extremely close to the benchmark, meaning it would be adverse effects to marine biota. By contrast, diazinon was detected in six places –coastline of Catalonia, Mar Menor coastal lagoon, Tiber river Estuary, Sarno river Estuary, German Bight and Maizuru Bay- but in none of them the mean concentration were higher than the benchmark for surface marine water (Köck- Schulmeyer et al. 2019, Moreno- González et al. 2013, Montuori et al. 2015, Montuori et al. 2016, Mai et al. 2013, Harino et al. 2013); whereas the same happen with Malathion concentrations in the Sarno river Estuary, Tiber river Estuary, and in the German Bight (Montuori et al. 2015, Montuori et al. 2016, Mai et al. 2013). From this, no adverse effects would be expected to marine biota of the places diazinon and Malathion were detected.

On the other hand, chlorpyrifos were detected in seven of eleven studied places. The maximum concentrations found along the Portuguese coast and in the Mar Menor coastal lagoon (Moreno- González et al. 2013) exceeded the benchmarks proposed by NOAA –both acute and chronic adverse effects-, the trigger value for marine water of Australian and New Zealand Guidelines and also the marine concentration long term of Canadian Guidelines for the protection of aquatic life. This means that in both places are unacceptable levels of contamination by this pesticide, and there would be acute and chronic adverse effects on marine biota. While, in the Sarno River Estuary and in the Maizuru Bay (Montuori et al. 2016, Harino et al. 2013) the mean concentrations of chlorpyrifos were higher than the benchmarks of Australian-New Zealand -and Canadian guidelines, whereas the mean concentration in the Tiber River Estuary (Montuori et al. 2015) only exceeded the Australian-New Zealand benchmark, meaning there were unacceptable levels of contamination and it would expect to see negative effects on the marine biota. Instead, the mean concentrations in the German Bight, North Sea and from the East China Sea to the high Artic (Zhong et al. 2012, Zhong et al. 2011), did not exceed any of the benchmarks mentioned before, meaning it would not pose an ecotoxicological risk to marine biota.

### **4. ORGANOPHOSPHORUS PESTICIDES TOXICITY ON NON-TARGET ORGANISMS**

OPPs are one of the two major classes of cholinesterase-inhibiting pesticides. The main mode of action of the OPPs is inhibition of acetylcholinesterase, the enzyme that ends the action of acetylcholine neurotransmitter, which is released by nerve stimulation, on postsynaptic cholinergic receptors in the nervous system. OPPs produce an irreversible inhibition of acetylcholinesterase, in contrast to the carbamates (the second major class) that produce a reversible inhibition (WHO 2001).

#### **4.1 Mode of Action of OPPs**

The primary biochemical effect associated with toxicity caused by organophosphorus pesticides is inhibition of acetylcholine esterase (AChE, WHO 1986). AChE is an enzyme that catalyzes the breakdown reaction of Acetylcholine –a neurotransmitter which is required for the transmission of nerve impulses in the brain, skeletal muscles, and other areas (Toole and Toole 1995). OPPs inhibit the normal activity of the AChE by covalent bonding to the enzyme, thereby changing its structure and function. The leaving group is replaced –by nucleophilic substitution- by the oxygen of serine in the AChE active site (Elersek and Filipic 2011). Then, the leaving group binds to the positive hydrogen of His 447 and breaks off the phosphate, leaving the enzyme phosphorylate (Singh and Walker 2006).The rate of AChE inhibition depends on the leaving group; higher tendency of leaving results in higher affinity of the inhibitor to the enzyme (Elersek and Filipic 2011). Loss of AChE activity may lead to a range of effects resulting from excessive nervous stimulation, convulsion, paralysis and finally death for insects and mammals and culminating in respiratory failure and death (WHO 1986; Ragnarsdottir 2000).

#### **4.2. Bioaccumulation and Bioconcentration of OPPs in Marine Biota**

Aquatic organisms may absorb dissolved chemicals directly from water through respiratory organs (e.g., gills), through the body surface, or may ingest chemicals through intake of contaminated sediments or prey (Katagi 2010). Uptake of the OPPs from the water may occur across the gills, through the skin, and by intestinal adsorption. This process is known as bioaccumulation and is affected by different factors (Serrano et al. 1995). It is primarily controlled by the physico-chemical properties of the chemicals involved  $(K_0w,$ water solubility, molecular weight, and size), the physiological disposition of each organism (lipid content is considered the most important determinant for bioaccumulation), and the surrounding environmental conditions (Katagi 2010). This process includes uptake of dissolved pesticides from water, pesticides sorbed to particulate components in water or sediments, and also trough dietary. Bioaccumulation is the net result of competing processes of chemical uptake into the organism at the respiratory surface and from the diet and chemical elimination from the organism including respiratory exchange, fecal egestion, metabolic biotransformation of the parent compound and growth dilution (Arnot and Gobas 2006).

Serrano et al. studied the bioconcentration of selected OPPs in *Mytilus galloprovincialis and Venus gallina* at different concentrations and found that dimethoate presented low concentrations in mollusc tissues, while chlorpyrifos was bioconcentrated by molluscs at high levels (1995). Moreover, phosmet was not detected at any of the pesticide exposure concentrations. This is in accordance with Log  $K_{ow}$  partition coefficients of the OPPs studied; chlorpyrifos can be considered a fat-soluble pesticide due to its high Log  $K_{ow}$  of 4.70. Instead, dimethoate has a Log  $K_{ow}$  of 0.50, and perhaps it causes low concentration of this pesticide in the mollusk tissues.

In more recent research, bioaccumulation of fenitrothion was demonstrated in different marine species in Seto Inland Sea in Japan by Kaonga et al, 2015. In that study, the animals with the higher bioaccumulation factors were mollusks, followed by fish, plankton, crustaceans, and sea cucumber, with mean of 0.313, 0.250, 0.189, 0.149 and 0.089  $\mu$ g. g<sup>-1</sup> dw respectively.

Besides, bivalves are one of the most widely used animals to study the bioaccumulation of pesticides due to their high lipid content, feeding by water filtration, and presence worldwide. This is the case of the study carried out by Harino et al. (2013) in Maizuru Bay, Japan and by Dodder et al. (2014) in California coast, USA. On the one hand, Harino and coworkers studied bioconcentration of diazinon, iprobenfos, fenitrohion and chlorpyrifos in *Mytilus galloprovincialis;* and the range concentrations of diazinon, iprobenfos and fenitrothion in mussel samples were 4.3–25, 22–60 and 9.2–13 mg.kg<sup>-1</sup> ww respectively, however chlorpyrifos was only detected at the concentration of  $1.0 \text{ mg}$ .kg<sup>-1</sup> ww in one sample station (Harino et al. 2013). On the other hand, Dodder and coworkers studied the occurrence of contaminants of emerging concern in mussels (*Mytilus spp*.) along the California coast and found a maximum concentration of chlorpyrifos of 0.036 mg.kg-1 dw (Dodder et al. 2014). Hence, it can be stated that certain marine species, with a particular focus on bivalves, are capable of bioaccumulating OPPs and this can lead to a risk for these species, the ecosystem in general and even for human beings who usually include this type of mollusks in their diet.

#### **4.3. Common Effects and Toxicity on Marine Biota**

These chemicals are neurotoxic that act by inhibiting acetylcholine esterase in the central and peripheral nervous system, resulting in choline and acetate formation (Elersek and Filipic 2011). The inhibition of this enzyme results in a continuous binding of acetylcholine to the receptor, leading to an overstimulation of this cholinergic receptors, which may result in alterations in behavior, potentially reducing the organism's ability to move, eat, and reproduce (Azevedo-Pereira et al. 2011). This suppression leads to convulsion, paralysis, and lastly death for insects and mammals (Ragnarsdottir 2000). The degree of brain AChE inhibition has often been used to distinguish OPPs related adverse effects from exposure. For example, an inhibition of brain AChE activity greater than 20% in birds is generally accepted as an index of exposure, whereas an inhibition exceeding 50% is a sufficient cause of adverse effects (Ludke et al. 1975). In mammals, inhibition of brain AChE greater than 50% has been suggested for sublethal exposure and inhibition exceeding 80% as a cause of death (Walker 1998).

Additionally, OPPs also bear the potentiality to cause genotoxic and carcinogenic effects (Kaushik and Kaushik 2007).

Reductions in cholinesterase (ChE) activity have been widely used to indicate exposure to OPPs in vertebrate and invertebrate species (Cooper and Bidwell 2006). Silva and coworkers (2019) studied the results of sublethal concentrations of chlorpyrifos in cholinesterases (ChE) in the marine snail *Gibbula umbilicalis* and determined that this inhibition cause an alteration on its behavior, capacity to turn over, lead to increased drift and disruption in their escape reaction from predators, feed, or even reaction (Silva et al. 2019).

Ferrero and coworkers (2001) studied acute toxicity of malathion in *Chasmagnathus granulata*, a crab present in Bahía Blanca Estuary, Argentina (Ferrero et al. 2001). In that study, only adult male crabs, with mean carapace width of  $20.9 \pm 0.73$  mm and  $33.0 \pm 2.94$ mm, were used and the estimated LC50 (concentration of a substance that can be expected to cause death, during exposure or within a defined period after it, of 50% of the population exposed to that substance during a given period) values to malathion were 13  $\mu$ g.L<sup>-1</sup> and 19  $\mu$ g. L<sup>-1</sup> respectively. Marine crustaceans are particularly vulnerable, as they tend to be highly susceptible to the toxic effects of OPPs (Johnston and Corbett 1985) and estuaries serve as critical feeding and nursery grounds for many aquatic organisms, including commercially and recreationally important fish and shellfish species. These productive, diverse ecosystems are particularly vulnerable to pollution because they serve as repositories for pollutants from upland sources (De Lorenzo et al. 2001).

On the other hand, acute toxicity of several OPPs in two marine species (*Artemia sp* and *Brachionus plicatis)* was studied by Guzella et al, 1997. Comparisons of the EC50 (concentration of a compound in which 50% of its maximum effect is seen) values show that chlorpyrifos was the most toxic OPP to both species. In order of toxicity decreasing in both the marine organisms tested azinphos-ethyl was the second compound followed by fonofos while diazinon, parathion-methyl, azinphos-methyl showed a lower toxic response (Guzzella et al. 1997).

#### **4.4. Effects on Human Health**

These compounds can also cause a high toxicity to humans. In occupational and nonoccupational poisonings, exposure to these pesticides may occur via oral, inhalation or dermal route. But the majority of studies available in the literature involve the oral route (Gupta et al. 2011). Therefore, not only the application of pesticides in agricultural activities but also the consumption of marine organisms inhabiting pesticides polluted areas are a serious threat to people (Serrano et al. 1995). In general, following oral exposure, these pesticides are rapidly absorbed, widely distributed, metabolized in the liver, and eliminated in the urine (Gupta et al. 2011).

OPPs phosphorylate acetylcholinesterase in an irreversible reaction that inhibits the activity of cholinesterase to hydrolyze the neurotransmitter at the nerve synapse. The accumulation of acetylcholine results in continuous nerve firing and eventual failure of nerve impulse propagation (Smith 1987). Bronchial constriction and increased bronchial secretions are characteristic signs of OPPs poisoning (Serrano et al. 1995). Consequently, respiratory paralysis is generally the immediate cause of death (Murphy 1975). Brain cholinesterase activity is used in the diagnosis of OPPs poisoning in humans, with a reduction of 20 % of normal activity indicating exposure while a cholinesterase inhibition of 50% or more is considered the diagnostic threshold for determining the cause of death (Smith 1987).

Once entering the body, OPPs can be enzymatically converted to their oxon form, which then inhibits the enzyme acetylcholinesterase (AChE) responsible for the breakdown of the neurotransmitter acetylcholine (Prapamontol et al. 2014). The oxon also can be enzymatically or spontaneously hydrolyzed to form a dialkyl phosphate (DAP) metabolite and an organic molecule specific to the pesticide. If the pesticide is not converted to its oxon form, it can hydrolyze similarly to form its specific and dialkylthionate metabolites (Barr et al. 2004). Thus, quantification of these metabolites in human urine offers information on cumulative exposure of this class of pesticides and the data are used in several epidemiological studies for the health outcome assessment (Prapamontol et al. 2014).

Absorption following inhalation is also rapid. Dermal absorption varies depending on the site of application and dose. Compared to many OPPs, dermal absorption of chlorpyrifos is low (Gupta et al. 2011). Chlorpyrifos is moderately toxic to human beings; however, there are reports of genotoxic and mutagenic effects of chlorpyrifos in human beings and rat (Mulla et al. 2019).

Moreover, OPPs occupational exposure was associated with an elevated risk of breast cancer ( $RR = 1.20$ , 95% CI 1.01–1.43); one of the most commonly used OPPs, malathion was associated with the elevated risk of thyroid cancer and whereas diazinon was positively associated with increased risk of ovarian cancer (RR=1.87, 95% CI 1.02–3.43) (Lerro et al. 2015). According to the IARC (International Agency for research on Cancer, WHO 2020); malathion and diazinon are assigned to Group 2A (*probably carcinogenic to humans*), and tetrachlorvinphos and parathion are assigned to Group 2B (*possibly carcinogenic to humans*) based on epidemiological and experimental evidence of carcinogenicity and mechanistic and other relevant data.

#### **CONCLUSION**

Currently, organophosphorus pesticides are used worldwide; however, these pesticides are being replaced by new formulations as carbamates, neonicotinoids and pyrethroids, most recently developed and less harmful for the environment.

Despite of their extensive use trough the last decades, there is a lack of data on the behavior of organophosphorus pesticides in the marine environment; hence it is probable that potential impacts on marine ecosystems have been substantially underestimated. On the contrary, in freshwater environments, toxicity, behavior and current levels in different matrices are well known and studied.

In what refereed to current levels in different countries in the reviewed period, most of studies have been performed in Europe and Asia; there are a few studies in North America; and no research in Central and South America, Africa or Oceania marine environments was found. It is notable that are just a few studies focused on developing countries, in which legal OPPs are often applied in large amounts. The most extensively studied matrix is sediments.

Although everything seems to indicate that chlorpyrifos is the most toxic pesticide (a bias can be posed since it is the most studied congener in the marine environments), iprobenphos and triazophos exhibited the highest mean concentrations in the studied matrices.

Another output to consider is that despite their rapid environmental degradation, there are no recent OPP degradation research studies tracking metabolites in marine environments. This is not a minor aspect since some metabolites are more toxic than the parent compounds and may represent a higher ecotoxicological risk for the marine biota.

On the other hand, regarding the OPPs detection limits (LOD), a high disparity was seen which difficult comparisons and data interpretation. There is a general need for OPPs method´s harmonization.

The scarcity of studies on OPPs bioaccumulation and ecotoxicity in marine environments during the last ten years does not allow us to affirm whether the present OPPs levels represent a risk for humans; however, they do represent a risk for the marine biota, with ability to cause chronic and acute adverse effects on it.

Finally, considering that the oceans and seas are the ultimate sink for all kinds of pollutants, including organophosphorus pesticides, apart from the already internationally regulated, there is a need for global regulation for OPPs in sediments and waters of the oceans, estuaries, and seas.

### *BIOGRAPHICAL SKETCH*

#### *Cristian A. Vitale*

#### **Affiliation:**

- Instituto de Química del Sur (INQUISUR) Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET) and Universidad Nacional del Sur (UNS)-, Bahía Blanca, Provincia de Buenos Aires, Argentina.
- Organic Chemistry Area of the Chemistry Department of the National South University (Argentina).

#### **Education:**

- PhD in Chemistry. 1995. National South University, Argentina.
- Bachelor's Degree in Chemistry. 1989. National South University, Argentina.
- Chemist. 1988. National South University, Argentina.

#### **Business Address:**

National South University | Avda. Alem 1253 B8000FWB Bahía Blanca | Argentina.

**Research and Professional Experience**: My area of expertise is the synthesis and characterization of bioactive compounds with phosphorous functional groups, with particularly focused experience in polymers, anticancer and neuroactive substances. My main interests are to explore other fields such as Persistent Organic Pollutants (POPs) and microplastics, and their impact in the environment.

**Professional Appointments:** At present, Adjunct Professor Exclusive Dedication at the Chemistry Department of the National South University. Organic Chemistry A (6386), Organic Chemistry B (6387) and Fundamentals of Organic Chemistry (6117).

#### **ABSTRACT**

Sulfate radical-based advanced oxidation processes (AOPs) have become emergent technologies for the destruction of emerging organic pollutants (EOPs) in water and soil. UV activation of persulfate generates both sulfate and hydroxyl radicals (SO<sub>4</sub><sup>•</sup>, <sup>•</sup>OH) which are the most oxidizing species researched for water treatment. These radicals work together to make the destruction of EOPs very easy. The efficiency and, accordingly, the success of AOPs have generally been evaluated on the basis of degradation kinetics. In practice, chloride in saline wastewater is often found to inhibit degradation processes. Therefore, it is highly desirable to develop more effective processes which are not affected by chloride.

We herein show the potential application of UV/persulfate process for the degradation of EOPs in seawater, taking chlorazol black (CB) as a substrate model. CB is very persistent azo dye that is not only refractory to biodegradation but also toxic and mutagenic. This compound constitutes a factor of risk for the marine life. Firstly, the fast conversion of  $SO_4^{\bullet-}$  and  $\bullet$ OH into dichlorine radical anion  $(Cl_2^{\bullet-})$  has been proven experimentally through radical probes technique.  $Cl_2^{\bullet-}$  was found to be the main oxidant implicated in the degradation of CB in seawater. Secondly, the impact of influencing

 $\overline{a}$ 

<sup>\*</sup> Corresponding Author's Email: aharias@criba.edu.ar.

factors such as initial persulfate and pollutant concentrations and solution pH was clarified. Besides, the influence of several surfactants on the process efficiency was elucidated. The process performance was found to be more efficient in acidic and neutral pH under relatively high concentration of persulfate (< 5 mM) and low concentration of CB. More interestingly, there was no significant difference between the degradation rate of CB in seawater and deionized water, meaning that  $Cl_2^{\bullet-}$ , although less reactive than SO<sup>4</sup> ●– and ●OH, may has other promising properties that make its performance comparable to those of  $SO_4^{\bullet-}$  and  $\bullet$ OH. In fact,  $Cl_2^{\bullet-}$  is more selective and has much longer lifetime than  $SO_4^{\bullet-}$  and  $\bullet$ OH.

**Keywords:** seawater, emerging organic pollutants (EOPs), advanced oxidation processes (AOPs), UV/persulfate process, degradation, Cl<sub>2</sub><sup>•-</sup> radical

#### **INTRODUCTION**

The sea is usually the receptor of discharges and dumping wastes containing high concentrations of persistent organic pollutants (POPs) produced from the diverse anthropogenic and human industrial activities [1, 2]. Polychlorinated biphenyls, polycyclic aromatic hydrocarbons, endocrine disrupting chemicals and synthetic dyes are among the various kinds of POPs detected in different marine environments [3–5]. Azo dyes are among the most notorious and widespread environmental pollutants associated with textile, food, cosmetic and leather industries [6]. They are characterized by an -N=N- azo bond in their molecular structure. Due to their high water solubility, their facile transportability and their high persistence [6], these compounds are of potential risks on human health and aquatic ecosystems. Dyes interfere with penetration of sunlight into seawater, retards photosynthesis, inhibits the growth of aquatic biota and interferes with gas solubility in water bodies [7]. Moreover, these contaminants are known or suspected as mutagenic and carcinogenic [8].

In situ chemical oxidation (ISCO) technologies utilizing persulfate have been increasingly applied for the remediation of contaminated soil and groundwater [9–11]. There are several techniques for persulfate activation into reactive  $SO_4$ <sup> $-$ </sup> radicals including heat,  $Fe<sup>2+</sup>$ , UV, basic conditions (pH > 11), metal oxides, zerovalent metals, sonolysis, radiolysis, microwaves and organic compounds (e.g., quinones and phenols), and all these techniques were extensively employed in both laboratory research and field applications [12, 13, 22–29, 14–21]. However, each activation method has its pros and cons. For example, heat is an effective method for persulfate activation, but this technique suffers from potential high costs as the treated soil and groundwater must be heated continuously [30].  $Fe<sup>2+</sup>$  activation suffers from pH limitation as the process could be operated at low pH to prevent iron precipitation as hydroxides [30]. Basic activation operates with high pH level, which required higher quantity of bases and subsequent neutralization step.

UV light with  $\lambda$  < 400 nm is one of the most effective activators of persulfate for the remediation of soil and groundwater heavily contaminated by organic pollutants [18]. This technique is relatively low-cost and environmentally friendly, specifically when solar irradiation is employed [31, 32]. UV activation of persulfate has been found to provide an alternative for the destruction of organic contaminants including phenols [33, 34], perfluorocarboxylic acids [35, 36], dyes [37, 38] and endocrine disruptor chemicals [39]. A summary of the persulfate activation chemistry is given below [30, 40, 41]:

$$
S_2O_8^{2-} \xrightarrow{\quad \text{hv} \quad} 2SO_4^{\bullet-} \qquad k_I = 1 \times 10^{-7} \,\text{s}^{-1} \tag{1}
$$

$$
SO_4^{\bullet-} + H_2O \to {}^{\bullet}OH + H^+ + SO_4^{2-} \qquad k_2 = 660 s^{-1}
$$
 (2)

$$
SO_4^{\bullet-} + HO^- \to \bullet OH + SO_4^{2-} \qquad k_3 = 7 \times 10^7 \text{ M}^{-1} \text{s}^{-1}
$$
 (3)

$$
SO_4^{\bullet-} + S_2O_8^{2-} \rightarrow S_2O_8^{\bullet-} + SO_4^{2-} \qquad k_4 = 6.5 \times 10^5 \,\mathrm{M}^{-1}\mathrm{s}^{-1} \tag{4}
$$

$$
{}^{\bullet}OH + S_2O_8{}^{2-} \rightarrow S_2O_8{}^{\bullet-} + OH^- \qquad k_5 = 1.2 \times 10^7 \,\mathrm{M}^{-1}\mathrm{s}^{-1} \tag{5}
$$

$$
SO_4^{\bullet-} + SO_4^{\bullet-} \to S_2O_8^{2-} \qquad k_6 = 7 \times 10^8 \,\mathrm{M}^{-1} \mathrm{s}^{-1} \tag{6}
$$

$$
{}^{\bullet}OH + {}^{\bullet}OH \to H_2O_2 \qquad k_7 = 5.5 \times 10^9 \,\mathrm{M}^{-1}\mathrm{s}^{-1} \tag{7}
$$

The degradation process proceeds with production of the sulfate and hydroxyl radicals, which is demonstrated experimentally by ESR spin trapping technique [42]. Sulfate ion will be generated as the end-product, which is practically inert and not considered to be a pollutant.

Although persulfate photochemistry in pure water has been widely investigated and has been relatively well elucidated, there are, until now, scarce data on the applicability of this technique in seawater contaminated with POPs, where the high salinity ( $\sim$ 35 g/L) may inhibit or suppress the reaction of free radicals with target contaminants [43]. Also, the seawater may completely change the radicals distribution due to its high content of chloride.

The present investigation deals with the application of UV/persulfate process for the degradation of organic pollutants in seawater, taking chlorazol black (CB) dye, as substrate model of POPs. The specific physicochemical properties of chlorazol black are available in refs. [5, 44]. Chlorazol black is a highly water soluble azo dye which is widely used for various applications like dyeing of fabric, leather, cotton, cellulose materials and plastic [45]. It is an eye irritant chemical and is moderately toxic by inhalation and ingestion [46]. The carcinogenic and mutagenic effects of the dye towards humans and animals have been experimentally confirmed [46]. Additionally, laboratory experiments showed that CB is very persistent to direct oxidation with  $H_2O_2$ , persulfate and periodate oxidants [5]. Therefore, any presence of this dye in seawater would have detrimental effects on aquatic life. Before proceeding, a succinct view on previous works conducted on the effect of chloride ions on the performance of the persulfate photoactivated process is given in the following section.

## **EFFICIENCY OF SO<sup>4</sup> ●– -BASED AOPS IN SALINE WATERS**

In sulfate radical-based AOPs, both <sup>•</sup>OH and SO<sub>4</sub><sup>•–</sup> coexist. These processes have been successfully applied for the degradation of recalcitrant contaminants in industrial wastewaters [30, 47]. However, as known, industrial effluents may contain large amount of mineral salts, specifically chloride ions (Cl<sup>-</sup>), which are known as radical scavengers [48]. Chloride ions upon reactions with SO<sub>4</sub><sup> $\bullet$ </sup> and  $\bullet$ OH may induce a radical-based chain reactions (Eqs. 8-20)

allowing to form reactive chlorine species RCS, mainly Cl<sup>•</sup>, HClO<sup>•−</sup> and Cl<sub>2</sub><sup>•</sup><sup>−</sup>, which may have a significant influence on the overall treatment efficiency of AOPs [40, 49–53].

$$
Cl^{-} + SO_{4}^{\bullet-} \rightleftharpoons SO_{4}^{2-} + Cl^{\bullet} \quad k_{8} = 4.7 \times 10^{8} \text{ M}^{-1} \text{s}^{-1}, k_{8} = 2.5 \times 10^{8} \text{ M}^{-1} \text{s}^{-1}
$$
(8)

$$

Previous investigations have focused on the influence of Cl<sup>−</sup> on the performance of UV/persulfate process. In most cases, the applicability of the process was evaluated by assessing the degradation efficiency in saline wastewater. Since the resulted RCS from the reaction of chloride ions with  $\text{°OH}$  or SO<sub>4</sub><sup> $\text{–}}$ </sup> are less reactive than the primary radicals, the involvement of Cl<sup>−</sup> would mostly inhibit the radical reaction chains, thus significantly reducing the overall efficiency of the selected treatment process [30,54]. Chen and Chu [55] have studied the degradation of atrazine by the activation of peroxymonosulfate, and found that Cl<sup>−</sup> exhibited inhibitory effects in the process; they deduced that the reason was likely due to the scavenging of SO<sub>4</sub><sup>•−</sup> and the formation of weaker radical species such as Cl<sup>•</sup> and Cl<sup>2</sup> ●−. Fang et al. [56] have reported insignificant effect of chloride addition for up to 300 mM on the degradation of four monochlorophenols by persulfate photoactivated, but several chlorinated aromatic intermediates were identified confirming the involvement of chlorine reactive radicals in the degradation pathway. Fang et al. [40] showed that the presence of chloride ions at 20 mM greatly inhibited the degradation of polychlorinated biphenyls; transformation by-products were monitored, confirming that Cl<sup>−</sup> can react with SO<sub>4</sub><sup>•−</sup> to produce chlorine radicals, which react with biphenyl to generate chlorinated compounds.
Additionally, a significant reduction in the degradation of 1,1,1-trichloroethane by heated activated persulfate was reported by chloride addition at 100 mM [54]. Merouani et al. [15] found that the effect of Cl<sup>−</sup> on the degradation of safranin O in heated persulfate system was not significant when Cl<sup>−</sup> concentration was below 50 mM.

In contrast, Anipsitaki et al. [23] observed faster degradation rate of phenol and 2,4 dichlorophenol due to the low amount of Cl<sup>−</sup> in the cobalt/persulfate system. Yang et al. [37] reported that the destruction of an azo dye can be enhanced by Cl<sup>−</sup> without catalyst, possibly resulting from the activation of persulfate with unsymmetrical structure.

Besides, a dual role of chloride ions has been recently reported. Wang et al. [57] found that the degradation of azo dyes by sulfate radical was significantly inhibited in the presence of Cl<sup>−</sup> (0-10 mM), while the degradation of the dye was significantly enhanced for higher chloride ions concentration  $(>100 \text{ mM})$ . The same trend has been reported by Yuan et al. [58,59] for the degradation of acid orange 7 by UV/persulfate and Co/persulfate processes.

Therefore, the different reported observations on the effect of Cl<sup>−</sup> revealed that the importance of converting SO<sub>4</sub><sup>•–</sup> and <sup>•</sup>OH into Cl<sub>2</sub><sup>•–</sup> depend on the concentration and reactivity of  $Cl_2^{\bullet-}$  toward the target contaminant. If  $Cl_2^{\bullet-}$  is not reactive toward the pollutant, the effect of Cl<sup>−</sup> addition is detrimental toward the degradation process. If Cl<sup>2</sup> ●− is reactive with the target substrate, the additions of low Cl<sup>−</sup> concentration could reduce the degradation process via reducing the concentration of SO<sub>4</sub><sup>•–</sup> and <sup>•</sup>OH which are more reactive than Cl<sub>2</sub><sup>•–</sup>. However, using higher concentration of Cl<sup>−</sup> could generate higher concentration of Cl<sub>2</sub><sup>•-</sup> which may compensate of the loss in  $SO_4^{\bullet-}$  and  $\bullet$ OH level in the solution.

# **RADICALS DISTRIBUTION IN SALINE WATERS: KINETICS MODELING DATA**

To better understand the underlying mechanisms of radical generation and distribution in SO<sub>4</sub><sup>•-</sup>-based AOPs in the presence of chloride, many authors have developed many kinetic models as a tool for predicting the effect of chloride ion on the types of radical species and their distributions.

The results of Fang et al. [40], reported in Figure 1, showed that chloride ion could influence the selectivity of radical species and their distribution, and increase the concentration of the sum of radical species. In the absence of Cl<sup>−</sup> , SO<sup>4</sup> ●− was the main radical species for pH < 10; above which  $\bullet$ OH was predominated (Figure 1a). In the presence of Cl<sup>−</sup> at 100 mM,  $Cl_2^{\bullet-}$  was the predominate radical species for pH < 9, while both  $\bullet$ OH and ClOH<sup>•−</sup> coexist at alkaline conditions, i.e.,  $pH > 10$  (Figure 1b). Besides, distribution percentage of Cl<sub>2</sub><sup>•−</sup> increased rapidly as Cl<sup>−</sup> concentration increased, while that of SO<sub>4</sub><sup>•−</sup> decreased substantially (Figure 1c). When Cl<sup>−</sup> concentration reached 100 mM, most of SO<sub>4</sub><sup>•-</sup> was converted to  $Cl_2^{\bullet-}$ . The results suggested the rapid conversion of  $SO_4^{\bullet-}$  to  $Cl_2^{\bullet-}$ . Even in the presence of 10 mM Cl<sup>-</sup>, approximately 40% of  $SO_4$ <sup>•–</sup> was converted to  $Cl_2$ <sup>•–</sup>.

The total radical concentrations (TRC) were calculated in the presence and absence of chloride ion. As shown in Figure 1d, the TRC in the presence of 100 mM Cl<sup>−</sup> was significantly higher than that without Cl<sup>−</sup>(Figure 1d). As pH < 6, the TRC in the presence of Cl<sup>−</sup> was fifty times larger than that in the case of absence of Cl<sup>−</sup> , and the TRC values with and without Cl<sup>-</sup> ion were  $8.8 \times 10^{-12}$  and  $1.6 \times 10^{-13}$  M, respectively. This is ascribed to reactions

(8) and (10) which favored the conversion of  $SO_4^{\bullet-}$  into  $Cl_2^{\bullet-}$  in the presence of Cl<sup>-</sup>, and increased the TRC.

Figure 1. Effects of pH on the distribution of radical species in the absence (a)/presence (b) of Cl–  $([S_2O_8^2]_0 = 16.8$  M;  $[Cl^-]_0 = 100$  mM;  $25^{\circ}$ C), effects of Cl<sup>-</sup> concentration on the distribution of radical species (c) and calculated total radical concentration (TRC) in the absence/presence of  $\text{[CI]}_0 = 100$ mM) (d). Reprinted with permission from [40].

In contrast, most of SO<sub>4</sub><sup>•−</sup> in the absence of Cl<sup>−</sup> was scavenged by reactions (4) and (6), resulting in reducing the TRC. When pH increased from 6 to 8, the TRC decreased rapidly in the absence of Cl<sup>−</sup>. As discussed in Figure 1a, the concentration of SO<sub>4</sub><sup>•−</sup> decreased as pH increased to 8.0 due to reactions (4) and (6), while the TRC slightly changed in the presence of Cl<sup>−</sup> . This suggests that reactions (6) and (8) are not only related to their reaction constants, but also to their concentration, although the reaction rate constant of  $SO_4^{\bullet-}$  with  $SO_4^{\bullet-}$  (Eq. 6) is slightly higher than that with Cl<sup>−</sup> (Eq.8). The concentration of Cl<sup>−</sup> was 100 mM, which was far greater than  $SO_4^{\bullet-}$  concentration. Thus, the slight change in  $SO_4^{\bullet-}$  had limited effects on reaction (8), and the TRC slightly changed as pH increased. At  $pH > 8$ , the TRC decreased rapidly in the presence of Cl<sup>−</sup> due to reactions (12) and (17).

Similar radical distribution has been reported by Yuan et al. [58] whose used a kinetics model consisting in 76 reactions for simulating the degradation of acid orange 7 by UV/persulfate system in the presence of chloride ions for up to 500 mM.

The finding in Figure 1b indicated that the TRC was greatly increased in the presence of Cl<sup>−</sup> , which can explain some experimental results reported in previous studies. For example, Wang et al. [57] found that the degradation of azo dyes was greatly enhanced in the presence of high concentration of Cl<sup>−</sup> (> 50 mM), and attributed this to a dual effect of chlorine and sulfate radicals for azo dyes degradation. Theoretically, if SO<sub>4</sub><sup>•−</sup> is completely converted to Cl<sup>2</sup> ●−, the degradation of organic pollutants should be inhibited due to the lower reactivity of Cl<sup>2</sup> ●−. However, in Wang's study, they observed that the degradation of azo dyes was enhanced in the presence of high  $Cl^-$  concentration (> 50 mM). This is due to the fact that the total radical concentrations increased in the presence of Cl<sup>−</sup> . Although its reactivity is less than that of sulfate radical, its concentration was greatly increased under these conditions. Thus, the degradation rate of organic pollutants increases in the presence of high concentration of Cl<sup>−</sup> . Similarly, the results presented in Figure 1 could also explain Yuan's experimental results [59].

#### **EXPERIMENTAL**

Seawater of the Mediterranean Sea (collected from the north-East of Algeria in the autumn of 2019) has been used as water matrice. Its salinity was of  $\sim$  35.7 g L<sup>-1</sup>, distributed as  $\text{Na}^+ \approx 11 \text{ g } L^{-1}$ ,  $\text{Mg}^{2+} = 1.3 \text{ g } L^{-1}$ ,  $\text{Ca}^{2+} \approx 0.4 \text{ g } L^{-1}$ ,  $\text{Cl}^- \approx 20 \text{ g } L^{-1}$  and  $\text{SO}_4^{2-} = 3 \text{ g } L^{-1}$ . Chlorazol black degradation experiments were conducted in the setup described early [60]. It consists in a cylindrical water-jacketed glass cell of 500 mL. The operating solution volume was 250 mL. A low-pressure mercury lamp (Oriel 6035, 15 mW cm−2) emitting maximum irradiation at 253.7 nm was mounted in a quartz tube and submerged vertically in the center of the solution. A thermocryostat (RC6 Lauda) has been used to maintain the temperature of the treated solution at  $25\pm1\textdegree C$  through flowing water at  $23\textdegree C$  in the jacket surrounding the cell.

During irradiation, the temperature of the magnetically stirred solution, was displayed by a thermocouple submerged in the solution. A pH-meter Jenway 3505 was used to measure and adjust the solution pH. The dye concentration was determined spectrophotometrically at  $\lambda_{\text{max}}$  = 578 nm as described in refs. [5, 60]. Runs were repeated at least 3 times and averages values were plotted (error bars ensuring the maximum deviation of the means were inserted in plots).

# **EFFICIENCY OF UV/PERSULFATE PROCESS IN SEAWATER: CB DEGRADATION**

CB degradation runs in seawater upon UV and UV/persulfate treatments have been conducted at pH 3 and ambient temperature of about 25 °C, for various initial persulfate dosages in the range of 0.1 to 5 mM. The degradation results, reported in Figure 2a, obviously demonstrated the super advantage of the combined process against the treatment with the UV sole. Complete removal of CB was achieved after 20 min with UV irradiation in the presence of 5 mM of persulfate; the time at which only 22% of CB was removed with the sole UV irradiation. The degradation rate increased with increasing initial persulfate loading in the solution. At 20 min, the removal efficiency increased from 29% for 0.1 mM of persulfate to 55%, 76%, 90% and 100% for 0.5, 1, 2 and 5 mM of persulfate, respectively. Note that there was no CB removal with persulfate in the absence of UV over the same concentration range of persulfate, i.e.,  $0.1-5$  mM. Therefore, the rise in the persulfate dosage could increase the RCS concentration, which makes the degradation faster.

Many studies conducted in deionized water have reported the existence of certain optimum persulfate dosage above which the degradation rate was detrimentally affected by persulfate due to the radicals-quench by the excess of persulfate (Eqs. 4 and 5) or by the radicals quench by themselves (Eqs. 6 and 7) at higher RCS concentration in the solution [15– 17]. This scenario was not obtained for the case of seawater, which is may be attributed to the fact that (i) the maximum dosage of persulfate in Figure 2a did not yet achieving a higher level for becoming a radicals-quencher in the solution or (ii) the reaction of persulfate with RCS is not efficient as those of persulfate with  $\text{O}-OH$  and  $SO_4^{\bullet-}$  which diminishes the impact of higher persulfate dosage on radicals consumption. On the other hand, the radical-radical recombination reactions are too fast for  $\text{O}-H$  and  $SO_4\text{O}-$  (Eqs. 6 and 7) than those of RCS (Eqs. 17 and 20). Therefore, the detrimental concentration of persulfate in deionized water could be much lesser than that required in seawater.

Figure 2. (a) CB degradation kinetics for various PS dosages and (b) radical scavenger tests for 0.5 mM persulfate using Benzoic acid (BA), tert-butanol (t-BuOH) and phenol (Ph) (conditions  $-C_0 = 25.5 \mu M$ , pH 3,  $[t-BuOH]_0 = 100$  mM,  $[BA]_0 = [Ph]_0 = 1$  mM,  $\sim 25 \pm 1^{\circ}$ C).

## **EVIDENCE OF RCS IMPLICATION**

As illustrated early, the reactive species <sup>•</sup>OH, SO<sub>4</sub><sup>•−</sup> and RCS (Cl<sup>•</sup>, HOCl<sup>•−</sup> and Cl<sub>2</sub><sup>•−</sup>) may all be formed in seawater irradiated by UV light in the presence of persulfate. The contribution of these radicals in the overall CB degradation rate was evaluated using some specific radical scavengers, namely, benzoic acid (BA), *tert*-butanol (*t*-BuOH) and phenol (Ph). Table 1 shows the reactivity of these three scavengers with SO<sub>4</sub><sup>•–</sup>, <sup>•</sup>OH, Cl<sup>•</sup> and Cl<sub>2</sub><sup>•–</sup>. Ph can scavenge all radicals; it has been used for confirming the radical pathway for CB

degradation in seawater. *t*-BuOH can scavenge *●*OH and Cl*●* but its scavenging effect on SO<sub>4</sub><sup>•–</sup> and Cl<sub>2</sub><sup>•–</sup> is negligible. *t*-BuOH was used for appreciating the global role of SO<sub>4</sub><sup>•–</sup> + Cl<sub>2</sub><sup>•−</sup>. BA can efficiently scavenge <sup>•</sup>OH, SO<sub>4</sub><sup>•−</sup> and Cl<sup>•</sup> but its scavenging effect on Cl<sub>2</sub><sup>•−</sup> is negligible. It has been then used to determine the contribution of the sole Cl<sub>2</sub><sup>•−</sup>.

Radicals	Benzoic acid (BA)	<i>t</i> -butanol (t-BuOH)	Phenol (Ph)
$\cdot$ OH	$1.8\times10^9$ M <sup>-1</sup> s <sup>-1</sup>	$6\times10^8$ M <sup>-1</sup> s <sup>-1</sup>	$6.6\times10^{9}$ M <sup>-1</sup> s <sup>-1</sup>
$SO_4$ <sup>*</sup>	$1.2\times10^9$ M <sup>-1</sup> s <sup>-1</sup>	$8.9\times10^5$ M <sup>-1</sup> s <sup>-1</sup>	$8.8\times10^{9}$ M <sup>-1</sup> s <sup>-1</sup>
$Cl^{\bullet}$	$1.8\times10^{10}$ M <sup>-1</sup> s <sup>-1</sup>	$3\times10^8$ M <sup>-1</sup> s <sup>-1</sup>	$(0.8-2.5)\times10^9$ M <sup>-1</sup> s <sup>-1</sup>
$Cl2$ <sup><math>\bullet</math>-</sup>	$(0.2-1.8)\times10^6$ M <sup>-1</sup> s <sup>-1</sup>	$0-700 M^{-1} s^{-1}$	$(2.5-5)\times10^8$ M <sup>-1</sup> s <sup>-1</sup>

**Table 1. Second-order rate constant between scavengers and radicals in the UV/persulfate system [30,61,62]**

Figure 2b shows the influence of the three radical scavengers on the removal kinetics of 25.5 µM of CB in seawater. The initial concentrations of scavengers were 100 mM for *t*-BuOH and 1 mM for BA and Ph. These doses were selected to ensure high excess of these scavengers against the dye pollutant, i.e.,  $[t-BuOH]_0 / [CB]_0 \sim 3920$  and  $[Ph]_0 / [CB]_0 \sim 40$ . Phenol addition drastically inhibits the CB removal; i.e., more than 90% of CB was remained in the solution for up to 40 min of reaction. Thus, CB degradation happens mainly through radical pathway. Besides, *t*-BuOH addition reduces the dye removal after 40 min by only about 10%, revealing that both  $SO_4^{\bullet-}$  and  $Cl_2^{\bullet-}$  can take place in the degradation of CB by the UV/persulfate in seawater. However, the dye removal was totally unaffected by BA addition, meaning that Cl<sub>2</sub><sup>•−</sup> plays the dominant role in the degradation of CB by the UV/persulfate in seawater. This distribution of radicals consists with that furnished by the simulation results of Figure 1b where the concentration of Cl2<sup>•</sup> is dominated over all other radicals in saline water containing 100 mM of chloride ions, i.e., the typical concentration in seawater is 565 mM.

For deionized water, Liang and Su [63] have researched active radical species formed by thermally activated persulfate in deionized water under various pH conditions using a chemical probe method. Their results revealed that  $SO_4$ <sup> $\text{-}$ </sup> is the predominant radical oxidant at  $pH < 7$ . Both  $SO_4$ <sup>--</sup> and  $O$ <sup>+</sup> OH are present at neutral  $pH$ , and  $HO$ <sup>\*</sup> is the predominant radical at more basic pH (pH  $> 9$ ). Alternative spectroscopic method (ESR spin trapping) [64] also demonstrated that the predominant radical species at different pH conditions in the persulfate activated system are similar to those reported by the chemical probe method. Therefore, when Cl<sup>-</sup> is present at huge quantity as in seawater, i.e., 565 mM, the rate of  $SO_4^{\bullet-}$  consumption by Cl<sup>-</sup> to yield Cl<sup>•</sup> (Eq. 8) could be several orders of magnitude higher than that of SO<sub>4</sub><sup>\*</sup> reaction with the dye pollutant, specifically at pH 3. Thus,  $SO_4$ <sup> $\text{-}$ </sup> could have a low chance to react with CB.

Besides, the resulted Cl<sup>•</sup> radical may conduct four main reaction pathways: (i) fast reaction with Cl<sup>-</sup> to produce Cl<sub>2</sub><sup>•</sup> (Eq. 10), (ii) rapidly hydrolyzed to generate the HClO<sup>•</sup> radical anion (Eq. 11), (iii) radical recombination with them self (Eq. 20) or (iv) reaction with CB to induce degradation. The rate constant of pathway (i), i.e.,  $8.5 \times 10^9$  M<sup>-1</sup> s<sup>-1</sup>, is much higher than those of all other pathways  $[2.5 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$  for pathway (ii) and  $8.8 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ for pathway (iii)], assuming that its rate constant with CB is of the order of  $10^9$  M<sup>-1</sup> s<sup>-1</sup> [50]. Therefore,  $Cl^{\bullet}$  could principally be consumed via pathway (i) and, hence, its implication in the degradation process is insignificant. In fact, a lifetime of less than 5 µs was estimated for

Cl<sup>•</sup>, against fractions of milliseconds for Cl<sub>2</sub><sup>•–</sup> [65]. Accordingly, the contribution of HClO<sup>•–</sup> can also be neglected, as it is unreactive with synthetic dyes [58].

Consequently, the present radical scavengers studies revealed that CB degradation by UV/persulfate in seawater was mainly driven by Cl<sub>2</sub><sup>•−</sup>, generated from reactions associated to the photolysis of persulfate in seawater.

# **ROLE OF BROMIDE IONS**

Seawater contains bromide ions at  $\sim 1$  mM, wich means that bromide reaction chain may also be produced from reactions of bromide-containing seawater with SO<sub>4</sub><sup>\*-</sup>/\*OH and their associate reactions (Eqs. 21-37), where many brominated reactive species, i.e., BRS: Br<sup>o</sup>, Br<sub>2</sub><sup>•–</sup> and HBrO<sup>•–</sup>, and other Cl-Br mixed radicals have been suspected to be generated [41, 51, 66–68]. However, given that the Cl– concentration in seawater is 565 folds much higher than that of Br<sup>-</sup> (565 mM for Cl<sup>-</sup> against 1 mM for Br<sup>-</sup>), the Br-radical pathway is not suspected as all of SO<sub>4</sub><sup>+-</sup>/\*OH radicals would be scavenged by chloride, favoring the predominance of CRS instead BRS. Besides, reactions between RCS and Br<sup>-</sup>, i.e., like those of Eqs. 26-28, are also possible but their happening in seawater is also unsuspected due the same previous reason; RCS could preferably react with the Cl<sup>-</sup> rather than with Br<sup>-</sup> due to the high excess of the former.

## **OVERALL EFFECT OF SEAWATER SALINITY**

To appreciate the overall impact of the seawater salinity on the process performance, CB degradation runs upon UV and UV/persulfate processes was assessed in two matrices: deionized water and seawater, and the results are shown in Figure 3. The photochemical removal of the dye was appreciably reduced in seawater, as compared to the pure water; i.e., a 15% of reduction was remarked. This is in fact due to the salts-induced light attenuation, in which the seawater acts as light screens, thus reducing the photon receiving efficiency and, subsequently, shrinking the degradation rate of the pollutant [69]. However, for UV/persulfate process, the difference in the removal yields is much lower, i.e.,  $\sim$  7%, than that obtained by the photochemical treatment. This means that the generated RCS, although less reactive than SO<sup>4</sup> , can compensate of the lower UV treatment in the seawater via the generation of high concentration of  $Cl_2^{\bullet-}$ , which has a longer lifetime than  $SO_4^{\bullet-}$ . Thanks to these benefic specifications of Cl2<sup>•</sup>, the seawater can be regarded as a strong oxidation environment of organic pollutants when applying UV/persulfate as a decontamination process. Consequently, the higher concentration of salts containing in seawater, i.e., mainly Cl<sup>−</sup> , could be helpfully for oxidizing persistent organic pollutants in marine media.

Figure 3. CB degradation kinetics in seawater (SW) and deionized water (DW) upon sole photolysis (UV) and UV/PS system (conditions  $-C_0 = 25.5 \mu M$ ,  $[S_2O_8^{2-}]_0 = 0.5 \text{ mM}$ , pH 3,  $\sim 25 \pm 1^{\circ}\text{C}$ ).

# **IMPACT OF SOLUTION pH AND POLLUTANT CONCENTRATION**

A series of degradation experiments in seawater has been conducted by varying pH from 3 to 9 and initial CB concentration in the range of  $3.37-63.75 \mu M$ . The application of UV/persulfate process for decontaminating seawater was not affected by pH elevation in the range of 3 to 7, while a reduction in the degradation rate is looked at pH 9, but only after an advanced reaction period of 10 min (Figure 4a). This latter reduction was due to an observed precipitation phenomenon, which was taken place at basic medium.

Figure 4. CB degradation kinetics for different pH (a) and various initial CB concentration (b) (conditions  $-C_0 = 25.5 \mu M$  for (a), pH 3 for (b),  $[S_2O_8^2]_0 = 0.5 \text{ mM}, \sim 25 \pm 1^{\circ}\text{C}$ ).

In deionized water, the solution pH affects the radicals distribution in the reacting medium [42,63]. ESR spin trapping studies during photolysis of persulfate showed that  $SO_4^{\bullet-}$ is the main product species at pH  $< 8.5$ . For pH  $> 8.5$ , SO<sub>4</sub><sup> $-$ </sup> decays rapidly into  $\cdot$ OH via reaction (2) and only **OH** was detected for  $pH > 10.8$  [42]. Alternative chemical probes method in heat activated persulfate system revealed that  $SO_4$ <sup> $\text{-}$ </sup> is the predominant radical oxidant at  $pH < 7$ ; both  $SO_4^{\bullet-}$  and  $SO_4^{\bullet-}$  and represent at neutral pH, and  $SO_4^{\bullet-}$  is the predominant radical at more basic pH ( $pH > 9$ ) [63]. However, the above distribution was completely modified in seawater as stated in Figure 1, where the  $Cl_2$ <sup>+-</sup> becoming the dominant radical species in the solution for pH 1–9. Therefore, as  $Cl_2^{\bullet-}$  was the sole radical oxidant implicated in the degradation of CB, the pollutant removal rate could insignificantly be changed with the solution pH in the interval of 3-8. Consequently, the photoactivated persulfate process could be efficiently operable for seawater treatment under acidic to neutral pH-conditions.

On the other hand, the efficiency of CB removal at 20 min decreased from 100% for 6.37  $\mu$ M of initial CB concentration to 80% for 12.75  $\mu$ M, 55% for 25.5  $\mu$ M and 27% for 63.75 µM, as reported in Figure 4b. The process is then more efficient for low pollutant concentration in which a shorter treatment time is required. Meanwhile, the initial degradation rate increased from 0.77  $\mu$ M min<sup>-1</sup> for 6.37  $\mu$ M of CB to 1.1  $\mu$ M min<sup>-1</sup> for 12.75  $\mu$ M, 1.27  $\mu$ M min<sup>-1</sup> for 25.5  $\mu$ M and 1.4  $\mu$ M min<sup>-1</sup> for 63.75  $\mu$ M. These results are in good agreement with those reported in deionized water for several SO<sub>4</sub> • based AOPs [15–17]. The rise of initial degradation rate with initial CB concentration is not linear, as expected for a first order kinetics law. Therefore, the degradation of organic pollutants in seawater with the UV/persulfate could not be represented with a pseudo-first order kinetics law, as reported for many cases of SO<sub>4</sub><sup>\*-</sup>-based AOPs conducted in deionized water [21, 54, 70, 71].

The augmentation of the degradation rate with augmenting the initial pollutant concentration could be associated to the following reasons: at fixed irradiation intensity and initial persulfate dosage, the overall production rate of reactive radicals, i.e.,  $Cl_2^{\bullet-}$ , could be constant. Hence, with increasing the initial pollutant concentration, the portion of radicals that could be scavenged by the pollutant molecules increases, thereby accelerating the destruction rate of contaminants [5, 7, 15, 17, 60, 72, 73].

## **IMPACT OF SURFACTANTS**

Surfactants are usually used as additives in dyeing processes and are widely discharged along with the dye effluents [15]. It is of practical point to test their impact on the efficiency of UV/persulfate process in seawater. The effect of four surfactants (SDS 'sodium dodecyl sulfate', Tween 20, Tween 80 and Triton X-100) on the degradation of CB by photoactivated persulfate in seawater was investigated at pH 3 by fixing persulfate dosage at 0.5 mM. SDS, Tween 20, and Tween 80 did not affect the CB degradation rate, whereas the process losses more than 50% of its efficiency in the presence of Triton X-100, as highlighted in Figure 5. The dye removal after 40 min of treatment decreased from 73% without surfactant to 55% and 38% in the presence of Triton  $X-100$  at 20 and 80 mg  $L^{-1}$ , respectively. It seems that the reactivity of Cl2<sup>•</sup> radical is strongly affected by this type of surfactant. This radical is very selective for olefins and aromatics containing hydroxyl or amino groups [61, 74, 75].

Figure 5. Effect of different surfactants on the removal kinetics of CB in seawater upon UV/persulfate treatment (conditions – C<sub>0</sub> = 25.5 µM, pH 3,  $[S_2O_8^2]_0 = 0.5$  mM, ~ 25 ±1<sup>o</sup>C).

Conversely to these results, Tween 20 and Tween 80 at 80 mg  $L^{-1}$  have reduced the dye elimination in deionized water by about 10-15%, while Triton X-100 accelerated the process performance by about 15%, both as compared to runs performed without surfactants. Thus, the water matrix affects sensitively the performance of the UV/persulfate process through changing the radicals distribution in the reacting system. In general, surfactants can scavenge both SO<sub>4</sub><sup> $-$ </sup> and <sup>•</sup>OH, thereby decelerating the process efficiency in deionized water [17, 76– 79]. However, the Cl<sub>2</sub><sup>•−</sup> radical is strongly affected by the nature of the surface-active solute [5, 61, 75, 80].

#### **CONCLUSION**

Sea has historically been subject to high anthropogenic weights of direct and indirect discharges of persistent organic pollutants (POPs) from exhaustive industrial and agricultural activities. The findings of this study showed that UV/persulfate oxidation process can supply a good performance toward the degradation of POPs in seawater. The high quantity of chloride ions existing in seawater exerts a conversion of radicals, in which SO<sub>4</sub><sup>+-</sup> and <sup>•</sup>OH were totally converted into Cl<sub>2</sub><sup>•</sup><sup>−</sup>, which has a longer life time than the primary radicals formed during persulfate photoactivation. The degradation rate of CB by UV/persulfate was drastically improved as compared to the sole UV irradiation, due to the involvement of free radical pathway. The degradation rate increased with the increase in persulfate dosage whereas low dye concentrations favor a quick removal rate. UV/persulfate process can be practicable in seawater for up to pH 7. Interestingly, many surfactants did not affect the degradation of the dye, making persulfate photoactivated treatment a promising method for treating seawater contaminated with emerging organic pollutants.

# *BIOGRAPHICAL SKETCHES*

## *Slimane Merouani*

**Affiliation:** Department of Chemical Engineering, Faculty of Process Engineering, University Salah Boubnider Constantine 3, Constantine, Algeria

**Education:** PhD, chemical Engineering

**Business Address:** Department of Chemical Engineering, Faculty of Process Engineering, University Salah Boubnider Constantine 3, Constantine, Algeria

**Research and Professional Experience:** Advanced oxidation processes

**Professional Appointments:** Associate professor of chemical engineering

#### **Honors:**

- Major of promotion, State Engineer in Chemical Engineering, University of Constantine, 2006.
- Major of promotion, Certificate of success first year Magister in chemical engineering of separation, University of Annaba, 2008
- Best publishing researcher of the university of Constantine 3, edition 2019

#### **Publications from the Last 3 Years:**

## **ABSTRACT**

This chapter summarizes the diversity of dinoflagellates divided into several groups: basal dinoflagellates (i.e., Syndineans and Noctilucales), unarmored dinokaryotes and thecate forms such as Prorocentrales and Dinophysales, Gonyaulacales, Peridiniales, thinwalled dinoflagellates and unclassified taxa. The morphology of the main representatives are illustrated, phylogenetic trees of each group and a scheme on the tentative evolution are provided. The trends on dinoflagellate biodiversity research, problematic and unresolved issues (i.e., biases in the availability of molecular markers for the less accessible taxa, recent proposals on nomenclature, etc.) are outlined. A classification scheme for dinoflagellate levels above genus is proposed within a context of unresolved relationships of higher ranks in the molecular phylogenies.

**Keywords**: Dinoflagellata biodiversity, Dinophyta classification, Dinophyceae systematics, alveolate evolution, protist diversity

# **INTRODUCTION**

Dinoflagellates (Alveolata, Dinophyceae) are protists with a truly remarkable diversity in lifestyles (free-living, parasites and mutualistic symbionts), habitats (marine, freshwater, plankton, benthos), and trophic modes (heterotrophic, chloroplast-containing) (Gómez 2012a). Dinoflagellates and ciliates are the most diverse groups of alveolates. About ~2400 species of dinoflagellates are currently accepted (Gómez 2012b), several tens of new species are described every year, and the environmental molecular surveys reveal numerous lineages

 $\overline{a}$

of basal dinoflagellates that has not been documented yet (Guillou et al. 2008). This chapter summarizes the main groups of dinoflagellates and its classification, with illustrations of the diversity, and some brief notes on ecological aspects and problematic issues.

A first issue is to delimitate what a dinoflagellate is. In a strict sense, a dinoflagellate is a dinokaryote which is characterized by a peculiar nucleus, the dinokaryon, devoid of histones and with permanently condensed chromosomes, and a huge genome with peculiar characteristics (Lin 2011). Most of these biflagellate cells have a wavy transversal flagellum, although this character is missing in the desmokont (prorocentroid) dinokaryotes. The cingulum or girdle, a groove that encircles the cell harboring the transversal flagellum, is not only missing in prorocentroids. It is also apparently absent in planktonic (*Podolampas*) or benthic species (*Adenoides*) that have the wavy transversal flagellum. Alternatively, if the cingular plates are not in a depressed or sunken groove, they can be mistaken for the precingular or postcingular plate series (Gómez et al. 2015c).

## **BASAL DINOFLAGELLATES**

Unexpectedly, the earlier molecular studies reveal the phylogenetic relationship between the dinoflagellates and the apicomplexans that include agents of human diseases (*Plasmodium*, *Toxoplasma*; Gunderson et al. 1987). Since then, the molecular phylogeny has placed numerous lineages between the apicomplexans and the dinokaryotes (Figure 1). Among these groups of basal dinoflagellates are parasites such as the perkinsids (*Dinovorax*, *Parvilucifera*, *Perkinsus*, *Snorkelia*; Figure 2A; Goggin and Barker 1993, Nóren et al. 1999, Reñé et al. 2017), the ellobiopsids (*Thalassomyces*, *Ellobiopsis*, Figure 2B; Silberman et al. 2004, Gómez et al. 2009a) and the free-living heterotrophic genus *Oxyrrhis* (Figure 2C, Saldarriaga et al. 2003a). The nuclei of the syndineans have intermediate characteristic between the typical eukaryotic and dinokaryotic nucleus (Ris and Kubai 1974). The syndineans are divided into two groups: the euduboscquellids with *Ichthyodinium*, a parasite of fish eggs (Figure 2D–E), and *Euduboscquella*, a parasite of ciliates (Figure 2F–G; Yuasa et al. 2007, Harada et al. 2007, Coats *et al*. 2010, Gómez and Gast 2018) and the Syndiniales with the parasites of crustaceans *Hematodinium* and *Syndinium* (Figure 2H, Skovgaard et al. 2005) and the dinophagous parasite *Amoebophrya* (Figure 2I–K, Gunderson et al. 1999). The genera *Syndinium*, *Hematodinium* and *Amoebophrya* can be placed in the Syndiniales or Syndinea, and *Euduboscquella* and *Ichthyodinium* can be placed in the family Euduboscquelliaceae or alternatively in the order Coccidiniales following Cachon and Cachon (1987). These basal dinoflagellates remain unreported in epicontinental waters, and they have an important role in the marine ecosystems, including the control of the proliferations of harmful dinoflagellates (Chambouvet et al. 2008). The molecular data reveal a huge genetic diversity of basal dinoflagellates (Guillou et al. 2008). The lack of distinctive characters, even in the dinospores, make difficult the species characterization. In the past, the species names were proposed citing the host as the species epithet. This could be interpreted as a high host-specificity. Further studies have revealed that the relationship between host and parasite is not often species specific, and a single parasitic species may infect different species of hosts, and a host species may be infected by different syndinean parasites (Salomon et al. 2003).

Figure 1. The phylogenetic position of dinoflagellates and other alveolate lineages based on Maximum Likelihood analysis inferred from SSU rRNA gene sequences. Bootstrap values  $\geq$ 70 are noted to the left of internodes. The stramenopile *Bolidomonas pacifica* was used as outgroup. Scale bar = 0.05 substitutions site<sup>-1</sup>.

The Noctilucales are the basal dinoflagellates closer to the dinokaryotes, and have dinokaryotic characteristics in some life stages*. Noctiluca scintillans* was the first observed dinoflagellate because it is the biggest species, bioluminescent and common in coastal temperate waters. The other noctilucaceans have received less attention and numerous species remain undescribed (Gómez 2010). *Noctiluca scintillans* (Figure 2L) and *Spatulodinium* spp. are closely related in the molecular phylogenies (Gómez et al. 2010a), and they share a tentacle-like extension used for feeding. In some tropical areas, *Noctiluca* may harbor a freeswimming chlorophyte, *Spatulodinium* possesses chloroplasts of an unknown nature (Figure 2O), and *Pomatodinium* possesses a photosynthetic endosymbiont (Figure 2P). A close relative is *Kofoidinium*, which possesses an extracellular dome as well as *Spatulodinium* used for prey capture (Figure 2M–N). The members of the Leptodiscaceae are even less known due to their fragility. These heterotrophic species have highly flattened cell bodies and able of fast changes of shape. *Leptodiscus* (Figure 2Q) and *Cymbodinium* (Figure 2R) swim like a medusa, and *Abedinium* and *Scaphodinium* (Figure 2S) are also able of sudden contractions. The molecular data on the Leptodiscaceae are restricted to partial ribosomal RNA gene sequences of *Abedinium* (Gómez et al. 2010a). The phylogenetic position is instable, being more distantly related to the other noctilucaceans (Figure 1). The Noctilucales are

#### 3422 *Fernando Gómez*

characterized by sequences with long branches in the ribosomal RNA gene phylogenetic trees. This is associated with the long-branch attraction artefact that is a form of systematic error where distantly related lineages with long branches appear closely related in the phylogenetic trees (Philippe et al. 2005).

# **UNARMORED DINOFLAGELLATES (GYMNODINIPHYCIDAE)**

The dinoflagellates have been traditionally classified as armored (thecate) and unarmored dinoflagellates (athecate or naked dinoflagellates). As all the known basal dinoflagellates are unarmored, we could speculate that this is an ancestral trait and the thecate dinoflagellates constituted the most derived forms. Recent data based on dinoflagellate transcriptomes confirmed this view and placed the unarmored dinoflagellates as a basal group among the dinokaryotic dinoflagellates (Janouškovec et al. 2017).

 $\mathbf{1}$ 

Figure 3. The phylogenetic position of dinoflagellates based on Maximum Likelihood analysis inferred from SSU rRNA gene sequences, with especial focus on the unarmored forms. Bootstrap values ≥70 are noted to the left of internodes. The syndinean *Syndinium turbo* was used as outgroup. Scale bar = 0.02 substitutions site<sup>-1</sup>.

There is an important gap in the knowledge between unarmored and armored dinoflagellates due to practical reasons. When compared to the thecate dinoflagellates, the naked forms are easily damaged by net sampling, cells lysis or the morphology is distorted due to the manipulation and common fixatives. Modern methods such as the cultures provide abundant material fresh material that allow reducing the gap of knowledge between naked and thecate species. Although the bias remains for the heterotrophic species that predominate in the open oligotrophic ocean (Gómez 2014). In the earlier studies, most of the free-living unarmored dinoflagellates were placed in the genus *Gymnodinium*, and later new genera were

proposed based on characters such as the degree of cingular displacement (*Gyrodinium*), number of turns of the cingulum (*Cochlodinium*), or the relative height of the cingulum (*Amphidinium*, *Torodinium*) (Kofoid and Swezy 1921). The molecular data revealed that genera such as *Gymnodinium*, *Amphidinium* or *Cochlodinium* were not monophyletic, and these classical diagnostic criteria were not supported (Daugbjerg et al. 2000, Jørgensen et al. 2004a, Gómez et al. 2017a). The modern generic diagnoses are based on a combination of features with an especial relevance of the shape of the apical groove (Takayama 1985, Daugbjerg et al. 2000).

Figure 4. Light micrographs of unarmored dinoflagellates: Amphidinioids and Gymnodiniales *sensu stricto*. A. *Amphidinium* (photosynthetic). B. *Amphidinium* (heterotrophic). C. *Testudodinium*. The unarmored dinoflagellates with a very anterior cingulum have been placed under the genus *Amphidinium* (Kofoid and Swezy 1921). The earlier life stages of *Kofoidinium*  (Figure 2N) and *Spatulodinium* (Figure 2O) resemble species formerly placed in the genus *Amphidinium* (Figure 4D–F), and we could speculate that the amphidinioids represent the most ancestral morphology of the dinokaryotes. In the earlier evolutionary schemes, *Amphidinium* was placed as a basal dinoflagellate after the prorocentroids (Kofoid and Swezy 1921, p. 86). Based on the ribosomal DNA such as the SSU rRNA gene, the sequences of the clade of the type species *Amphidinium operculatum* are characterized by long branches, and often clusters closer to the basal dinoflagellates that have also long branches, raising the question of whether *Amphidinium* is really a basal group among the dinokaryotes or its position is artificial due to the long-branch attraction (Figure 3). Based on multigene (Zhang et al. 2007) and transcriptome phylogenies (Janouškovec et al. 2017), *Amphidinium* is considered as the most basal lineage of the dinokaryotes clustering between the Noctilucales and the other dinokaryotes. As occurred with other earlier genus of naked dinoflagellates, under the genus *Amphidinium* were placed unrelated genera of unarmored dinoflagellates that share a very anterior cingulum and consequently a small episome (Jørgensen et al. 2004a) (Figure 3). The clade *Amphidinium sensu stricto* (Figure 4A–B) is a basal group, and species such as *Gymnodinium venator* (Figure 4K) belongs to the Gymnodiniales or other former members of *Amphidinium* are currently placed in new genera such as *Testudodinium* (Figure 4C), Togula (Figure 4D), *Ankistrodinium* (Figure 4E), Apicoporus (Figure 4F), and new amphidinioid genera have been proposed (i.e., *Bispinodinium*). Other species of *Amphidinium* still needs a new generic placement (Figure 4G) (Jørgensen et al. 2004b, Sparmann et al. 2008, Hoppenrath et al. 2012, Horiguchi et al. 2012, Yamada et al. 2013). According to Janouškovec et al. (2017) *Amphidinium sensu stricto* is the most basal lineage of the dinokaryotes, and Togula is a sister group of clade of Gymnodiniales *sensu stricto*. There are no transcriptome sequences of the other amphidinioid genera that in the SSU rRNA gene phylogenies are dispersed in the dinokaryote core without a clear relationship with other dinoflagellates to establish a suprageneric classification (Figure 3).

The order Gymnodiniales is restricted to the clade that contains the type species of *Gymnodinium*, *G. fuscum* (Figure 3, Daugbjerg et al. 2000). This is the most specious, and morphologically and ecologically diverse clade of unarmored dinoflagellates. Blooms of the colonial species *Gymnodinium catenatum* have received attention as responsible of Paralytic Shellfish Poisoning (Figure 4H), and sometimes confused with other colonial non-toxic species such as *G. impudicum* (Figure 4I). In addition to the typical peridinin-containing chloroplast, other species possess a chloroplast derived from a chlorophyte with chlorophyll *b* (*Lepidodinium*, Figure 4J), and the members of the family of *Nusuttodinium* and *Spiniferodinium* (Figure 4L) have a chloroplast derived from a cryptophyte. The polykrikoid dinoflagellates are constituted of multinucleate 'pseudocolonies' of zooids (Figure 4M–P). *Polykrikos* possesses two nuclei and the species are heterotrophic (Figure 4M, R) or with chloroplasts (Figure 4O–P). All the species have ejectile organelles or extrusomes with analogies to the nematocyst found in metazoans such as the cnidarians (Figure 4N; Gavelis et al. 2017). Other genus constitutes by zooids is *Pheopolykrikos* that possesses an equal number of nuclei and zooids (Figure 4Q). The warnowiids possess an elaborate photoreception organelle with analogies the ocelloid of pluricellular organisms (Figure 4R–U; Gómez et al. 2009b, Gavelis et al. 2015). The described species are heterotrophic, but at least one species may contain chloroplasts (Figure 4R). The highest degree of ultrastructural sophistication is

#### 3426 *Fernando Gómez*

found in *Erythropsidinium* that also has a piston (Figure 4T–U, Gómez 2017). Among the symbiotic forms, *Gymnoxantella* lives in symbiosis with pelagic radiolarians and it was overlooked with the thecate dinoflagellate *Zooxanthella* (Figure 4V, Yuasa et al. 2016). The members of the family Chytriodiniaceae are parasites of copepod eggs (*Dissodinium*, Figure 4W; *Chytriodinium*, Figure 4X; *Syltodinium*, Figure 4Y; Gómez et al. 2009c, 2019a), and *Myxodinium* (Figure 4Z) that feeds on the microalgae *Halosphaera*, probably as an alternative host in absence of eggs. The rRNA gene sequences of parasitic forms have often longer branches than the free-living relatives. This results in unstable topologies in the phylogenetic trees as often occurs with the sequences of *Chytriodinium* (Figure 3). Mixotrophic species such as *Gymnodinium aureolum* are closely related to the Chytriodiniaceae (Figure 3).

Based on currently available transcriptome phylogeny, the brachidiniaceans (Brachidiniales) are placed between the Amphidiniales and the Gymnodiniales *sensu stricto* (Janouškovec et al. 2017). The members of the Brachidiniales are photosynthetic species containing fucoxanthin, a typical accessory pigment of haptophyte. Recently, a new genus, *Gertia*, with a chloroplast containing peridinin and lacking fucoxanthin has been described (Takahashi et al. 2019). The brachidiniaceans cluster into two groups in the SSU rRNA gene phylogenies (Figure 3). One group for the species which apical groove is linear straight such as *Asterodinium* (Figure 5A), *Brachidinium* and *Karenia* (Figure 5B; Daugbjerg et al. 2000, Gómez et al. 2005, Benico et al. 2019), and other group for species with a sigmoidal apical groove such as *Karlodinium* and *Takayama* (de Salas et al. 2003). The order Ptychodiscales was a catch-all of species with a supposed strongly developed cell covering or pellicle, pooling thecate forms such as *Kolkwitziella*, unarmored forms such as *Balechina* and *Ceratoperidinium*, the Brachidiniales, and species with a endoskeleton such as *Monaster* (=*Achradina*) (Fensome et al. 1993). The order Ptychodiscales remains only for *Ptychodiscus*  (Figure 5C–D), with straight apical groove and yellow pigmentation, tentatively with fucoxanthin-containing plastids, that suggests an affinity with the Brachidiniales that is not well supported in the molecular phylogenies (Figure 3; Gómez et al. 2016a).

The family Ceratoperidiniaceae contains up to date species with a circular apical groove, which is also present in other lineages of unarmored dinoflagellates (*Cochlodinium*, *Cucumeridinium*). All the described species of the Ceratoperidiniaceae are photosynthetic with the typical peridinin-containing plastids, a smooth cell surface, and the cells are often enclosed in a hyaline membrane. There are species with the typical gymnodinioid outline, *Kirithra*, and cells with body extensions and ventro-dorsally compressed (*Ceratoperidinium*, Figure 5E), laterally compressed (*Gynogonadinium*, Figure 5F) or slightly or non-compressed such as *Pseliodinium* (Figure 5G–I) (Reñé et al. 2013, Boutrup et al. 2017). The torsion or the cingular displacement, features traditionally used for the diagnoses, have low diagnostic value for the generic split as evident for two closely related species such as *Pseliodinium fusus* (Figure 5G–H) and *P. pirum* (Figure 5I) (Gómez 2018). The latter species was placed in the new genus *Torquentidium* using as diagnostic character that the cingulum encircled the cell 1.5 times (Shin et al. 2019). The use of this arbitrary numeric morphometric character, also found in *Polykrikos geminatum* or the warnowiids, is not supported by the molecular data. This new genus proposal only contributes to the excessive proliferation of new genera of dinoflagellates.

Figure 5. Light micrographs of unarmored dinoflagellates. A. *Asterodinium*. B. *Karenia*. C–D. *Ptychodiscus*. E. *Ceratoperidinium*. F. *Gynogonadinium*. G–H. *Pseliodinium fusus*. I. *Pseliodinium pirum*. J. *Akashiwo*. K. *Levanderina*. L. *Margalefidinium*. M*–*N. *Gyrodinium*. O. *Cochlodinium*. P. *Cucumeridinium*. Q. *Torodinium*. R*–*S. *Lebouridinium*. T. *Kapelodinium*. U. *Kapelodinium* and '*Amphidinium*' sphenoides. V. *Balechina*. W*–*X. Actiniscus. Y. Dicroerisma. Z*–*AA. Monaster. Scale bar = 20 μm.

Other species that were first described as members of the genus *Gymnodinium* or *Cochlodinium* constitute independent lineages of photosynthetic species with a smooth cell surface such as *Akashiwo* (Figure 5J), *Levanderina* (Figure 5K) or *Margalefidinium* (Figure 5L, Gómez et al. 2017a). Based on the available transcriptome phylogenies, *Akashiwo* is the closer relative to the thecate dinoflagellates (Janouškovec et al. 2017). Longitudinal striae in the cell surface and encapsulated nucleus are common features in several heterotrophic genera. This could be an adaptation to engulf large preys. We have to be cautious to consider the surface striation as a diagnostic character for a clade. For example, nearly all the members of the Gymnodiniales *sensu stricto* have a smooth surface, while *Erythropsidinium*, able to ingest large preys, has reinforcements of the cell surface that can be interpreted as longitudinal striae (Figure 4U, Gómez 2017). Longitudinal striae are found in *Gyrodinium*  (Figure 5M–N), *Cochlodinium* (Figure 5O), *Cucumeridinium* (Figure 5P), and taxa with a reduced episome such as *Torodinium*, that also have chloroplasts (Figure 5Q), and *Lebouridinium* for the species previously known as *Katodinium*/*Gyrodinium glaucum* (Figure

5R–S) (Hansen and Daugbjerg 2004, Takano and Horiguchi 2004, Gómez et al. 2015a,d). Boutrup et al. (2016) proposed *Kapelodinium vestifici* for the cold water species *Gymnodinium vestifici* (Figure 5T–U), and they considered that *Katodinium*/*Gyrodinium glaucum* and *Amphidinium extensum* as synonyms. The synonymy of *Gymnodinium vestifici*  and *Katodinium/Gyrodinium glaucum* (now *Lebouridinium*) is unsupported*. Gymnodinium vestifici* is an amphidinioid cell, with a small episome and missing the cap-like structure, fine longitudinal striation and closely related to species such as '*Amphidinium*' *extensum* or '*Amphidinium*' *sphenoides* (Figure 5U). The cells of *Katodinium*/*Gyrodinium glaucum* have a small hyposome, an apical cap-like structure, and coarse longitudinal striation (Figure 5R–S). The true *Gymnodinium vestifici* has not been investigated by modern methods and the molecular data labelled as *Kapelodinium vestifici* correspond to *Lebouridinium glaucum* (Figure 3). The longitudinal striation is not the exclusive of the phagotrophic species. The genus *Balechina* (=*Gymnodinium gracile*) possesses a thick and smooth cell covering that is able to sudden changes of shape (Figure 5V, Gómez et al. 2015d).

Other unarmored dinoflagellates have an internal skeleton. *Actiniscus* possesses a pair of endoskeletal elements of silicate (Figure 5W–X), *Dicroerisma* has an inverted Y-shaped endoskeleton of unknown nature (Figure 5Y), and *Monaster* (=*Achradina*) has as endoskeleton of celestite, strontium sulfate. This type of skeleton is only known in Acantharia and some radiolarians, opening the hypothesis of a gene transfer as numerous Rhizaria live in symbiosis with dinoflagellates (Figure 5Z–AA; Gómez et al. 2017b). The cell covering of *Monaster* may contain thin thecal plates, and it may constitute other group of the so-called thin-walled dinoflagellates among the thecate dinoflagellates.

# **THECATE DINOFLAGELLATES (PERIDINIPHYCIDAE)**

#### **Prorocentroids and Dinophysoids**

One century ago, the prorocentroids were considered as the most primitive forms of dinoflagellates, even more basal dinoflagellates than *Noctiluca* and *Amphidinium* (Kofoid and Swezy 1921, p. 86). The most typical armored and unarmored dinoflagellates are dinokonts, in which the two flagella are inserted ventrally, and the wavy transversal flagellum is usually placed in the cingulum, and the smooth longitudinal flagellum is placed in the sulcus. In contrast, the prorocentroid dinoflagellates are desmokonts, with both smooth flagella and inserted anteriorly. The grooves such as the sulcus or cingulum are not evident. This configuration is closer to some flagellate groups (e.g., Cryptophyta) suggesting that *Prorocentrum* could constitute the most basal group representing the ancestral morphology of the dinoflagellates (Kofoid and Swezy 1921). However, in the ribosomal RNA gene phylogenies, *Prorocentrum* is well-placed among the dinokaryotic core (Figure 6), and in the transcriptome phylogenies is, together with the dinophysoids, a basal group of the thecate dinoflagellates (Janouškovec et al. 2017).

The theca of prorocentroids is composed of two large plates joined by a sagittal suture, and numerous tiny plates near the flagellar pore (periflagellar platelets). In molecular phylogenies based on a single ribosomal RNA gene marker, the prorocentroids clustered into three clades within the dinokaryotic core (Figure 6), while the monophyly appears using several genes (Zhang et al. 2007, Murray et al. 2009). We have to take into account that these multigene phylogenies are built with a less taxonomically representative dataset of different species of other dinoflagellates. The clade of Prorocentrales *sensu stricto* with the type species, *P. micans*, contains planktonic or tychoplanktonic species taxa, often with an apical spine or tooth (Figure 7A–C). Benthic or epiphytic species (Figure 7D–E), often with toxic species (i.e., *Prorocentrum lima*) constitute a second clade. The third clade also contains several benthic species, which first described member was *P. panamense* (Grzebyk et al. 1998).

Figure 6. The phylogenetic position of dinoflagellates based on Maximum Likelihood analysis inferred from SSU rRNA gene sequences, with especial focus on prorocentroids and dinophysoids. Bootstrap values ≥70 are noted to the left of internodes. The basal dinoflagellate *Amoebophrya* was used as outgroup. Scale bar =  $0.02$  substitutions site<sup>-1</sup>.

The dinophysoid dinoflagellates possess prorocentroid organization because the theca is fundamentally divisible into two halves by a sagittal suture, but they have a cingulum separating the epitheca and hypotheca, with the typical wavy flagellum that corresponds to the dinokont organization. Consequently, the dinophysoids could be regarded as morphologically intermediate between the desmokonts and dinokonts (Figure 7). In the rRNA

gene phylogenies, the dinophysoids cluster into three clades. The Dinophysales *sensu stricto*  comprised the most specious and ecologically diverse group. The genus *Dinophysis* (Figure 7F) comprises numerous toxic species that are responsible of Diarrhetic Shellfish Poisoning. These species contains chloroplasts with a controversy on whether they are permanent or kleptoplastids that need a periodical replacement. Other species of *Dinophysis* in a more basal position are heterotrophic and have an antapical spine (Figure 7G). Several oceanic taxa such as *Citharistes* (Figure 7H), *Histioneis* (Figure 7I–J) and *Ornithocercus* (Figure 7K) survive to the prevailing oligotrophic conditions in circumtropical seas with ectosymbiotic bacteria in the 'phaeosome' chamber or attached to the cingular or sulcal lists. The family Oxyphysiaceae is highly diverse with most of the species placed in the genus *Phalacroma*, mainly composed of heterotrophic and some species with plastids of different origins (Figure 7L–O). The most basal group contains the highly elongated cells of *Triposolenia* (Figure 7P) and *Amphisolenia* (Figure 7Q) with a much reduced epitheca, and endosymbionts in numerous taxa. A second clade of dinophysoids contains the planktonic heterotrophic genera *Metaphalacroma* (Figure 7R) and *Pseudophalacroma* (Figure 7S), and the third clade contains the benthic heterotrophic species of *Sinophysis* (Figure 7T–U) that in some species may also harbor photosynthetic endosymbionts (Gómez et al. 2011b, 2012b).

Figure 7. Light micrographs of thecate dinoflagellates: prorocentroids and dinophysoids. A. *Prorocentrum micans* (dissociated valves). B. *P. gibbosum* (dissociated valves). #### **Gonyaulacales**

The most evolved dinoflagellates lack the two large valves, and the theca shows latitudinal series of plates (apical, anterior intercalary, precingular, cingular, postcingular, posterior intercalary, antapical) that reach a higher number of series >10 in the so-called thinwalled dinoflagellates. The number of plates is variable, and we can observe a high plate multiplication or fragmentation of plates in *Pyrophacus* (Figure 9L). The Gonyaulacales is the more recently proposed classical order, previously considered as a peridinioid family (Taylor 1980, Fensome et al. 1993). It should be noted that *Pyrocystis* is the type of the order Pyrocystales Apstein 1909 that was proposed before the Gonyaulacales Taylor 1980. The article 11.3 of the I. C. N. states that the correct name is the earliest legitimate, but from family to genus. The type genus of the Gonyaulacales is *Gonyaulax* that shows a marked asymmetry due to the left-handed torsion of the epitheca as well as an asymmetrical first apical plate (Figure 9M), while the Peridiniales tend to show a bilateral symmetry, with a more-or-less symmetrical first apical plate (Figure 11A). Among other characteristics, the Peridiniales have additional plates such as the canal plate near the apex that is missing in the gonyaulacoids (Fensome et al. 1993).

Up to date, the Gonyaulacales is the only classical major order that is monophyletic, although species such as *Peridiniella catenata* with a gonyaulacoid appearance clusters within the short-branching dinokaryotic core together with peridinioid taxa (Daugbjerg et al. 2000). In the molecular phylogenies, the rRNA gene sequences of the Gonyaulacales are characterized by long branches, especially for the genera *Pyrophacus*, *Ostreopsis* and *Gambierdiscus*. This problem is evident in the case of *Pyrophacus* and *Ostreopsis* that artificially cluster together due to the long-branch attraction artefact (Figure 8). If *Ostreopsis* is removed, *Pyrophacus* clusters with *Fragilidium* and *Pyrocystis*. The most diverse clade of gonyaulacoids includes *Centrodinium* (Figure 9A) that is a tropical open ocean form of the best known genera *Alexandrium*, *Gessnerium* and *Protogonyaulax* (Figure 9B). Contrary to all previous taxonomical schemes, Gómez (2012b) placed *Centrodinium* in the same subfamily of the toxicologically important genus *Alexandrium.* The morphological and molecular data of *Centrodinium punctactum* (Li et al. 2019), and typical species of *Centrodinium* such as *C. eminens* (Figure 8) evidended that *Alexandrium* is not monophyletic, and the need of the re-instatement of the genera *Protogonyaulax* and *Gessnerium*, and a new genus for the clade of *Alexandrium affine* (Gómez and Artigas 2019). Within the family Ostreopsidaceae, these planktonic genera are closely related to benthic genera also associated with harmful events such as *Coolia* (Figure 9C) and *Ostreopsis* (Figure 9D). Other clade contains the planktonic and benthic genera such as *Pyrrhotriadinium* (nom. illeg.) [formerly *Goniodoma* (nom. rejic.)] (Figure 9E), *Psammodinium* (Figure 9F), *Fukuyoa* (Figure 9G), *Gambierdiscus* (Figure 9H), and the more distantly related bioluminescent *Pyrodinium* (Figure 9I) that may be also placed in the Ostreopsidaceae or an independent family (Gómez et al. 2015b, Reñé and Hopperanth 2019). Family names such as Goniodomataceae or Triadiniaceae are not considered valid because they are based on a peridinioid type (Kretschmann et al. 2015). *Pyrocystis* (Figure 9J) is other bioluminescent genus closely related to genera with an exceptional multiplication/fragmentation of thecal plates such as *Fragilidium* (Figure 9K), and very especially *Pyrophacus* (Figure 9L).

Figure 8. The phylogenetic position of dinoflagellates based on Maximum Likelihood analysis inferred from SSU rRNA gene sequences, with especial focus on gonyaulacoid dinoflagellates. Bootstrap values ≥70 are noted to the left of internodes. The apicomplexan *Eimeria* was used as outgroup. Scale bar =  $0.02$  substitutions site<sup>-1</sup>.

Figure 9. Light micrographs of gonyaulacoid dinoflagellates. A. *Centrodinium.* B. *Protogonyaulax*. C. *Coolia*. D. *Ostreopsis*. E. *Pyrrhotriadinium*. F. *Psammodinium* G. *Fukuyoa*. H. *Gambierdiscus*. I. *Pyrodinium*. J. *Pyrocystis*. K. *Fragilidium*. L. *Pyrophacus*. M. *Gonyaulax*. N. *Spiraulax* (*ecdysis).* O. *Lingulodinium* (ecdysis). P. *Ceratium*. Q. Two species of *Tripos*. R. *Schuettiella*. S. *Protoceratium*. T. *Ceratocorys*. U–V. Two species of *Thecadinium*. Scale bar 20 μm.

The second main group of gonyaulacoids contains the type *Gonyaulax* (Figure 9M), and *Spiraulax* (Figure 9N) and generic names based on fossils such as *Ataxiodinium*, *Bitectatodinium*, *Impagidinium* or *Spiniferites*. It should be noted that the fossil names have not priority if a name of an extant taxa is available (I. C. N. Art. 11.8). Other closely related clade is composed of *Lingulodinium* (Figure 9O) and *Amylax* that could be placed in the family Lingulodiniaceae or alternatively also placed in the Gonyaulacaceae (Figure 8). Based on the molecular data, other lineages are *Dapsilidinium*, the Ceraticeae for *Ceratium* (Figure 9P) and *Tripos* (Figure 9Q), and in a more divergent position the Protoceratidaceae with *Schuettiella* (Figure 9R), *Protoceratium* (Figure 9S), *Pentaplacodinium* and *Ceratocorys* (Figure 9T). The placement of the benthic genus *Thecadinium* (Figure 9U–V) among the Gonyaulacales is unstable (Figure 8). In some phylogenies, the genera *Amphidiniella* or *Halostylodinium* may cluster among the basal gonyaulacoids, but this is uncertain whether this reflects a real phylogenetic relationship or more likely an artefact of long-branch attraction as also occurred between *Protoperidinium* and the long-branch group of the Gonyaulacales.

## **Peridinioids**

A more restricted tabulation scheme for the Peridiniales is an epitheca with seven precingular plates  $(7'')$ , several anterior intercalary plates  $(1-3a)$ , four apical plates  $(4')$ , and often additional plates such as the canal plate or ×-plate near the apical pore. This is the most extended scheme for planktonic peridinioids that shows a more or less globular cell shape with an equatorial cingulum. When the cell is compressed and the cingulum is more anterior, as usual in benthic forms, this pattern is altered and the interpretation of the tabulation is more difficult. The Peridiniales are polyphyletic, and we must restrict the Peridiniales *sensu stricto* to the clade that contains *Peridinium* (Figure 11A), a clade of freshwater photosynthetic taxa with few species (*P. cinctum*, *P. bipes*, *P. willei*), and tentatively we can add other freshwater genera such as Glochidinium, Palatinus, Parvodinium or Thompsodinium (Figure 10). The marine species of *Peridinium* were placed in the genus *Protoperidinium*, being the most specious genus that was inflated to over 200 described species (Figure 11B–D). Most of the species of *Protoperidinium* cluster together, with the exception of several species such as *P. depressum* (section Oceanica) that cluster with the members of the *Diplopsalis*-group (Figure 11E), the latter also divided into two groups (Figure 10). The members of the *Diplopsalis*group show variations in the number of hypothecal and epithecal plates that have resulted on the description of numerous genera (*Diplopsalis*, *Gotoius*, *Huia*, *Niea*, *Preperidinium*, *Qia*, etc.). The nomenclature of the diplopsalid genera is also complicated because sometimes a genus has been proposed with different names under the Botanical and Zoological Codes of Nomenclature. Other species of *Protoperidinium* such as *P. americanum*, *P. monovellatum* and *Archaeperidinium* (*P. minutum*) cluster with benthic genera such as *Amphidiniopsis*  (Figure 11F–G) and *Herdmania* (Figure 11H) that can be placed in the Amphidioniopsidaceae (Figure 10; Gómez et al. 2011a, Yamaguchi et al. 2011). All the members of the Protoperidiniaceae are heterotrophic forms known as pallium-feeders (Figure 11B), and at least one species, *Protoperidinium* cf. *diabolum* possesses photosynthetic endosymbionts with similar morphology to those in *Podolampas* (Figure 11I–J).

The shape of *Podolampas* (Figure 11I–J) reminds some species of *Protoperidinium*, but with an important difference because *Podolampas* and its relatives **(**Gaarderiella, Lissodinium, Mysticella, *Heterobractum*, *Blepharocysta*; Figure 11K) lack of a series of depressed or sunken plates that harbor the transversal flagellum that could be interpreted as the cingulum, although the transversal flagellum encircles the cell at the position where is expected to find the cingulum. As occurred with *Herdmania* or *Amphidiniopsis*, the molecular phylogenies have unexpectedly revealed a relationship of the pelagic podolampadaceans and the benthic genera *Roscoffia* (Saldarriaga et al. 2003b; Gómez et al. 2010b). The available sequences of the sand-dwelling dinoflagellate *Cabra* (Figure 11L) are highly divergent and it is not easily to confirm the affinity with the Podolampadaceae proposed by Yamaguchi et al. (2018). The sequences of other sand-dwelling genera such as *Planodinium* (Figure 11M), *Plagiodinium* and *Chrysodinium* have similarities with the Podolampadaceae, but this feature is poor supported in the molecular phylogenies (Figure 10, Gómez et al. 2019b). *Lessardia*, with a fusiform antero-posteriorly elongated cell (Figure 11N), was related to the Podolampadaceae in the earlier phylogenies (Saldarriaga et al. 2003b), but more complete phylogenies support the placement in its own family as suggested by Carbonell-Moore (2004). It is not common to find highly antero-posteriorly elongated cells in the planktonic peridinioids such as in some species of *Oxytoxum* (Figure 11O), that together with *Corythodinium* (Figure 11P) conforms the family Oxytoxaceae (Gómez et al. 2016b).

Figure 10. The phylogenetic position of dinoflagellates based on Maximum Likelihood analysis inferred from SSU rRNA gene sequences, with especial focus on peridinioid dinoflagellates. Bootstrap values ≥70 are noted to the left of internodes. The apicomplexan *Eimeria* was used as outgroup. Scale bar =  $0.02$  substitutions site<sup>-1</sup>.

Other peridinioids with endosymbionts are the members of the Kryptoperidiniaceae, the so-called 'dinotoms' because they contains a diatom as endosymbiont (Yamada et al. 2017). Up to date this family remains unrepresented in the open ocean, all the known members live in coastal, brackish or freshwater environments such as the genera *Blixaea* (Figure 11Q), *Dinothrix*, *Durinskia* (Figure 11R), *Galeidinium*, *Kryptoperidinium* and *Unruhdinium.* One of the most specious and ecologically diverse clade of peridinioid dinoflagellates are the members of the family of *Scrippsiella* (Figure 11S) that is able to produce calcareous cysts that have been described as different genera names (*Calcigonellum*, *Pernambugia*, *Leonella*, *Posoniella*). The whole family and order is placed in the Thoracosphaerales, based on *Thoracosphaera heimii* that was first described as a coccolithophorid. In addition to the freeliving planktonic photosynthetic species (*Scrippsiella*), there are other planktonic forms **(**Apocalathium, Caladoa, *Calcicarpinum*, Chimonodinium, *Fusiperidinium*, *Laciniporus*, Naiadinium, Speroidinium, *Stoeckeria*, Theleodinium, Tyrannodinium), and also heterotrophic benthic forms (*Aduncodinium*, Figure 11T). Many of new planktonic genera derived from freshwater taxa first described as species of *Peridinium*, *Peridiniopsis*, *Glenodinium* or *Glenodiniopsis*. An important group of species is the pfiesterids (*Pfiesteria*, *Pseudofiesteria*, *Luciella*, *Cryptoperidiniopsis*) (Figure 11U) that cause fish mortalities in estuaries (Steidinger et al. 1996). The Thoracosphaerales also includes parasitic forms, such as parasites of diatoms (*Paulsenella*, Figure 11V), parasites of ciliates (*Duboscquodinium*, *Tintinnophagus*, Figure 11W; Coats et al. 2010) and fishes (*Amyloodinium*, Figure 11X; Levy et al. 2007, Gómez and Gast 2018). In a more basal position of the Thoracosphaerales are marine species *Pentapharsodinium* and *Ensiculifera*, but the phylogenetic position is unstable.

In the classical taxonomic schemes, most of parasitic dinoflagellates were placed in the orders Syndiniales and Blastodiniales, placing the dinokaryotic parasites in the latter order. Currently, the Blastodiniales must be restricted to the clade that contains the type species of *Blastodinium*, *B. pruvotii*, and even the monophyly of the genus is not always evident (Figure 10, Skovgaard et al. 2007). Nearly all the species of *Blastodinium* contain chloroplasts and carry out the photosynthesis inside the copepod hosts (Figure 11Y). The members of the Heterodiniaceae are free-living heterotrophic species that live preferentially in deep waters of warm oceans, and the most distinctive species are characterized by highly flattened cell body as typical in other members of the 'shade flora' (Figure 11Z, Gómez et al. 2012a). The order Heterocapsales was proposed for the genus *Heterocapsa* (Figure 11AA; Fensome et al. 1993). Based on the combination of several genes, *Heterocapsa* was placed as a basal dinoflagellate, a sister group of *Amphidinium* (Zhang et al. 2007), but recent analyses based on dinoflagellate transcriptomes placed *Heterocapsa* within the Peridiniales *sensu lato* (Janouškovec et al. 2017).

The nomenclatural issues also affect *Symbiodinium*, a dinoflagellate genus with a high ecological interest for the functioning of the coral reefs that have recently split in several genera (LaJeunesse et al. 2018). The symbionts of the coral reefs invertebrates are commonly referred as zooxanthellae, and this is source of confusion with the genus name *Zooxanthella*. The type of the genus *Zooxanthella*, *Z. nutricula*, is a symbiont of pelagic radiolarians such as *Collozoum* (Figure 12A; Gast and Caron 1996). *Zooxanthella nutricula* is a thecate dinoflagellate, and it was unnecessarily transferred to *Scrippsiella* and *Brandtodinium* (nom. illeg.) (Probert et al. 2014). Planktonic radiolarians may also contain an unarmored dinoflagellate symbiont such as *Gymnoxanthella* (Figure 3V). The genus *Zooxanthella* has been placed among the Thoracosphaerales, but this is not well supported in the molecular phylogenies (Figure 10). In that case, the order Zooxanthellales proposed in 1970 and Thorascophaerales in 1982 may have the priority, although the article 11.3 of the I. C. N. states that the correct name is the earliest legitimate, but from family to genus. The type species of *Symbiodinium* was already transferred into *Zooxanthella* (Loeblich and Sherley 1979), and more recently all the species of *Symbiodinium* have been placed into *Zooxanthella* (Guiry and Andersen 2018). *Zooxanthella* is a thecate genus that lives in pelagic radiolarians (Figure 12A), and *Symbiodinium* is a thin-walled dinoflagellate that live in benthic invertebrates (Figure 12M). The species of these unrelated genera are placed together (Guiry and Andersen 2018) although there is no a morphological or phylogenetic relationship (Figure 13). The parasites of fishes *Amyloodinium* (Figure 11V) and *Piscinoodinium* have been placed in the family Oodiniaceae (Cachon and Cachon 1987, Fensome et al. 1993), but they are members of the order Thoracosphaerales and Symbiodiniales, respectively (Levy et al. 2007). The Oodiniaceae is restricted to the type *Oodinium*, an ectoparasite of appendicularians (Figure 12B, Gómez and Skovgaard 2015). The rRNA gene sequences of *Oodinium*, as occurred with other parasites, have long branches in the phylogenetic trees, which resulted in unstable topologies, often clustering in basal positions.

Scale bar = 20 μm.

Since the proposal of the genus *Azadinium* (Tillmann et al. 2009), more than 10 new species have been added. The species *Amphidoma caudata* (Figure 12C) was transferred into *Azadinium*, and more recently new of species of *Amphidoma* have been proposed, placing *Amphidoma* and *Azadinium* in the Amphidomataceae. A genus and family is defined by the type species, and *Amphidoma nucula* (Figure 12D) has not been investigated by modern methods. Although *A. nucula* and *A. caudata* showed a superficial resemblance (Figure 12C– D), they are unrelated species, and *Azadinium* and the recently described species of *Amphidoma* do not belong to the Amphidomataceae. The members of the Cladopyxiaceae have been classified among the Gonyaulacales (Fensome et al. 1993). Molecular data are missing of genus such as *Clapopyxis* (Figure 12E) with abundant information in the fossil records. Numerous genera of thecate dinoflagellates cluster as independent lineages within the dinokaryotic core, especially benthic dinoflagellates. Clear affinities with pelagic genera have been found for *Amphidiniopsis*, *Herdmania* or *Roscoffia*, but numerous benthic genera cluster as independent lineages of uncertain suprageneric classification (Figure 10). Some species have more typical peridinioid morphology with an median cingulum such as *Bysmatrum* (Figure 12F) and *Rhinodinium* (Figure 12G), while other have an anterior cingulum that remind the dinophysoids such as *Sabulodinium* (Figure 12H), and a very reduced episome (*Pseudadenoides*, Figure 12I), and without an apparent cingulum such as *Adenoides* (Figure 12J) that reminds the prorocentroids. Other thecate dinoflagellates, even with distinctive morphology, remain unreported since the original description such as *Thaumatodinium* (Figure 12K) or undescribed (Figure 12L).

#### **Thin-Walled Dinoflagellates**

A thecate life stage has been reported in the life cycle of the unarmored dinoflagellate *Margalefidinium polykrikoides* (Kim et al. 2007), but this supposed thecate life stage is a misidentification for an *Alexandrium* species. It is common to observe how armoured dinoflagellates leave behind the theca and continue as unarmored forms (i.e., Figure 9N–O), but from a phylogenetic point of view armoured and unarmoured dinoflagellates are distinct groups. At a first sight, the so-called 'thin-walled' dinoflagellates could be considered as intermediate between unarmored and thecate dinoflagellates, and consequently showing the characteristics of the hypothetical ancestor of the thecate dinoflagellates. The recent transcriptome phylogenies suggest that the thin-walled dinoflagellates such as *Symbiodinium* have evolved from thecate dinoflagellates (Janouškovec et al. 2017). This could be interpreted as that the thin-walled dinoflagellates are thecate dinoflagellates that have reduced the thickness of the thecal plates, and the plate multiplication or fragmentation resulted in numerous latitudinal plate series. The proliferation of plates also occurs in other thecate dinoflagellates such as *Pyrophacus* (Figure 9L). If the thecal plates are considered as defensive structures, thick thecal plates are not necessary when living as an endosymbiont, but not all the genera of the thin-walled dinoflagellates are endosymbionts. The thin-walled dinoflagellates are not a monophyletic group (Figure 13), suggesting that the loss of the thick thecal plates that are replaced by more numerous delicate plates have occurred independently several times in the evolution.

The symbiotic *Symbiodinium* and its recently derived new genera are essential for the life of the coral reefs (LaJenneuse et al. 2018). It has been intensively investigated by ecologists, more interested on aspects as the host specificity than in the morphological differences among the species. *Symbiodinium* has been recently split into several genera (*Breviolum*, *Durusdinium*, *Effrenium*, *Fugacium*, *Gerakladium*; Figures 12M–N) based on molecular data (Figure 13) and ecological aspects such as the type of host or geographical information, and missing information on the morphology such as the plate arrangement in the generic diagnoses (LaJeunesse et al. 2018). The ecologists do not always know or respect the rules of the Nomenclature, and the species of *Symbiodinium* have experienced a convulse history of typifications and validations, and finally the generic name *Symbiodinium* have been attributed to three different authorities. The recent proposal by Guiry and Andersen (2018) placing all the species of *Symbiodinium* into the distantly related thecate genus *Zooxanthella* is other source of confusion. The family Symbiodiniceae also contains *Pelagodinium*, a symbiont of pelagic Foraminifera, parasites of fishes such as Haidadinium and Piscinoodinium, free-living species such as *Polarella*, *Protodinium* and numerous new genera have been recently added (*Ansanella*, *Asulcocephallum*, *Biecheleria*, *Biecheleriopsis*, *Dactylodinium*, *Leiocephalium*, *Yihiella*). This clade is often reported as the Suessiaceae, based on a fossil genus *Suessia*. The article 11.8 of the International Code of Nomenclature (I. C. N) reports that fossil type has no priority over names of extant species, and at the family level the use of Symbiodiniaceae seems to be more coherent because we cannot verify with molecular data the relationship of these taxa with the extinct *Suessia*. Other thin-walled dinoflagellate clades are mainly freshwater taxa placed in recently erected families as the Borghiellaceae (*Baldinia*, *Borghiella*) and the Tovelliaceae/Tovelliales (*Bernadinium*, *Esoptrodinium*, *Jadwigia*, *Tovellia*) (Moestrup and Calado 2018). Nearly all these families and orders are based on species described from accessible localities in Europe, but new names that can be superfluos

are proposed without a re-investigation of the type of other existing suprageneric names (Cystodiniaceae, Desmomastigales, Dinamoebidiales, Dinamoebales, Dinococcales, Dinotrichales, Dinosphaeraceae, Hemidiniaceae, Glenodiniopsidaceae, Lophodiniales, Phytodiniales, Woloszynskiaceae). The thin-walled dinoflagellates are often named woloszynskioid dinoflagellates, being based on species that were previously described as *Woloszynskia*, *Gymnodinium* or *Glenodinium*. New genera, families and even orders are proposed without a re-investigation of the genus *Woloszynskia*, type of the family *Woloszynskiaceae*.

Figure 13. The phylogenetic position of dinoflagellates based on Maximum Likelihood analysis inferred from SSU rRNA gene sequences, with especial focus on thin-walled dinoflagellates. Bootstrap values ≥70 are noted to the left of internodes. The syndinean *Syndinium* was used as outgroup. Scale bar =  $0.01$  substitutions site<sup>-1</sup>.

# **CURRENT ISSUES**

The most important advances in our knowledge of the dinoflagellate classification are due to the molecular phylogeny that has allowed to test the hypotheses in the evolution and the morphological characters of diagnostic value. Since the surprising relationship between dinoflagellates and human parasites such as the apicomplexans (Gunderson et al. 1987), the molecular phylogenies have modified the diagnostic criteria used for the classification (Saldarriaga et al. 2004). The examples are evident in the unarmored dinoflagellates with split of the genera *Gymnodinium*, *Amphidinium* and *Cochlodinium* (Daugbjerg et al. 2000, Jørgensen et al. 2004a, Gómez et al. 2017a). Among the thecate dinoflagellates, the tabulation is considered a stable diagnostic character, but again we fail in the interpretation of the tabulation when the species have lost the typical globular morphology with an equatorial cingulum of the pelagic species. The cell compression and the small epitheca, as usually occurred in the benthic species, is associated with a re-arrangement of the thecal plates. Only with the aid of the molecular phylogeny, we are able to relate *Roscoffia* and *Podolampas* (Saldarriaga et al. 2003b, Gómez et al. 2010b) or *Herdmania* and *Amphidiniopsis* with species of *Protoperidinium* (Gómez et al. 2011a, Yamaguchi et al. 2011). The use of molecular markers (SSU-, LSU- and ITS rRNA genes) is unable to resolve the evolution and suprageneric classification of dinoflagellates, although the resolution is slightly better in a few groups (Gymnodiniales *sensu stricto*, Thoracosphaerales, Gonyaulacales). Sequences of transcriptomes are a promising tool to resolve the deep branching relationships, but at the present the number of available sequences of different species is low (Janouškovec et al. 2017). As usual, the application of the new tools shows a strong bias towards the cultivable species or easily accessible coastal species (Gómez 2014). The open ocean is mainly studied with techniques such as the metabarcoding (Le Bescot et al. 2016). These short environmental sequences allow a view of the relative abundance of groups of dinoflagellates, but the studies are not accompanied with microscopic observations. The microscope is an instrument to banish together with the taxonomists. Research and academic positions are offered for molecular biology and bioinformatics. Beyond the research groups focused on the monitoring of the harmful algae blooms, the general taxonomy of dinoflagellates persists in a few groups in Denmark, Germany and Japan, and as it occurs in other research fields such as the ciliates with an important increase of the taxonomical studies in China.

There are no significant advances on several topics. The molecular phylogeny reveals a huge diversity of syndinean dinoflagellates (Guillou et al. 2008), but in the last decade there is no advance because the sequences are not identified at the species level, and the syndineans remains restricted to five genera. Other tentative syndinean genera such as *Actinodinium*, *Atlanticellodinium*, *Caryotoma*, *Coccidinium*, *Dogelodinium*, *Keppenodinium*, *Merodinium* or *Sphaeripara* do not receive the amount of attention that they deserve. Coats et al. (2012) proposed the transfer of the species associated with the sequences previously identified as *Duboscquella* in the new genus *Euduboscquella*, but they did not solve the identity of the dinokaryotic genus *Duboscquella*. Coats et al. (2012) proposed the family *Euduboscquellaceae*, but this clade of *Euduboscquella* and *Ichthyodinium* needs to be ranked at least at the order level. We can use the order Coccidinales following Cachon and Cachon (1987), although cautiously because *Coccidinium* has not been investigated by modern methods. Our knowledge on the phylogeny of Noctilucales remains limited to the few partial sequences in Gómez et al. (2010a). It is uncertain if the leptodiscaceans are really basal dinoflagellates or they should be placed among the dinokaryotic dinoflagellates (Figure 1). The nature of chloroplasts of *Spatulodinium* or the endosymbionts of *Pomatodinium* remain unknown.

In the last two decades, there is an increase of the descriptions of new taxa, mainly of unarmored and thin-walled dinoflagellates, while numerous species described by Wołoszyńska, Skvortsov, van Goor, van Meel, Conrad & Kufferath, or Schiller remains in most of the cases restricted to the original descriptions (Thessen et al. 2012). The proposals of new genera, often based on a single species, have largely increased, revealing the inability to relate the morphology of the new taxa with other existing species. In other cases, superflous new genus names are proposed without molecular support such as the case of Torquentidium (Shin et al. 2019). Several attempts have tried to propose new genus names for species such as *Gymnodinium catenatum* and other species of *Gymnodinium* just only based on the distance in the molecular phylogenies to the type species *G. fuscum*. The question could be the reverse, why to place all the species of the Gymnodiniaceae into *Gymnodinium*? Similarly, we could place the species of the genera Alexandrium, Episemicolon, Gessnerium and Protogonyaulax into *Centrodinium*. On the other hand, numerous benthic species of *Prorocentrum* have been described in the last two decades, but many of them should be placed into another genus because they are distantly related to the type species, the spine-bearing planktonic *Prorocentrum micans*. Sometimes, we are splitters in the Gymnodiniaceae, *Alexandrium*/*Centrodinium* or the Pfiesteriaceae (*Pfiesteria*, *Pseudofiesteria*, *Luciella*, *Cryptoperidiniopsis*), while lumpers in *Prorocentrum*. This is the dilemma of being a splitter or a lumper taxonomist.

New species are described from coastal isolates or germination of cysts that are able to grow well with the standard culture media. In contrast, most of the oceanic species are uncultivable with the current methods, and the studies must be based on the few cells available. This paucity of material renders the detailed studies that are not comparable to the morphological, ultrastructural and molecular studies when billions of cells are available in a culture. Unfortunately, this limitation is not well understood, and the requirements for publication discourage researchers to study the heterotrophic species that predominates in the open ocean (Gómez 2014). It is embarrassing that we have not solved classical issues such as whether *Pronoctiluca* is or is not a dinoflagellate and the molecular affiliation of *Cladopyxis*.

In addition to the excessive proliferation of new genus names (i.e., *Torquentidium*), there is an increase of the proposal of suprageneric names, families and orders, based on the characteristics of a single genus. If we are unable to find relatives based on the ribosomal RNA gene sequences, it does not mean that each taxon constitutes a new family or even order. Moestrup and Calado (2018) proposed new families (Gyrodiniaceae, Amphidiniaceae, Sphaerodiniaceae) or even an order (Amphidiniales) based on a single genus. If this practice extends, new suprageneric names will appear everywhere. Several new families or even orders of freshwater taxa have been proposed such as Borghiellaceae, Sphaerodiniaceae or Tovelliales (Moestrup and Calado 2018). Tens of new taxa of the so-called 'woloszynskiods' are proposed without a study of the identity of *Woloszynskia*. The detail of the earlier species descriptions is not comparable to the current description, but we have the option of the typification.

The consideration of the earlier descriptions is important, but sometimes they have scarce detail that may result in subjective interpretations. Gottschling and collaborators have recently re-interpreted the identity of species illustrated by Ehrenberg in the 1830's that are the

basionyms of the Stein's genera *Goniodoma*, *Heterocapsa* or *Blepharocysta* (Stein 1883). Proposals appears such as the consideration that the description of *Peridinium splendormaris*  in the Mediterranean Sea, basionym of the type of the genus *Blepharocysta*, corresponds to an earlier description of *Alexandrium balechii*, a species that lives in the mangroves of the Caribbean Sea. Ehrenberg's *Peridinium splendormaris* looks like *Lingulodinium polyedra*, a common bioluminescent dinoflagellate in the Mediterranean Sea. Gottschling et al. (2019) considered that the basionym of the type species of *Heterocapsa*, *Peridinium triquetrum*, is a species of the genus *Kryptoperidinium*. There is no a phylogenetic relation between *Kryptoperidinium* and the species that we know as *Heterocapsa* (Figure 10). Then, the genus, family and order of Heterocapsales is dismantled when the type is placed in another genus. Kretschmann et al. (2015) re-interpreted that the basionym of the type of *Goniodoma* is a peridinioid cell of the genus *Scrippsiella* instead of a gonyaulacoid dinoflagellate. The genus named *Goniodoma* is rejected, as well as related families such as Goniodomatadaceae or Triadiniaceae (Prud'homme van Reine 2017), without reporting an alternative because *Pyrrhotriadinium* is an illegitimate name. The changes may not stop here. The most common species of *Scrippsiella*, *S. trochoidea*, is now *S. acuminata* (Kretschmann et al. 2015). In the molecular phylogenies, *Duboscquodinium* is very closely related to the type species of *Scrippsiella*, *S. sweeneyae* (Figure 10). In case of congenerity, *Duboscquodinium* Grassé 1952 has the priority over *Scrippsiella* Balech 1959. There is no molecular data of *Duboscquella*, type genus of the Duboscquellaceae, which could be closely related to *Duboscquodinium*. Then, the family name Duboscquellaceae has the priority over the Thoracosphaeraceae. As consequence of nomenclatural changes, the free-living genus *Goniodoma* traditionaly used for gonyaulacoid dinoflagellates is a posterior synonym of a peridinioid parasite of ciliates. Other studies are not good examples of the observance of the recommendations in the Nomenclature. Gottschling et al. (2017) proposed *Blixaea* and *Unruhdinium* for species of the family Kryptoperidiniaceae, when other tentative related taxa such as *Dinothrix* have not been investigated. According the Recommendation 20A of the I. C. N.: "Not dedicate genera to persons quite unconnected with botany, mycology, phycology, or natural science in general". *Blixaea* and *Unruhdinium* are in honor of musicians. At least, I will prefer the use of the orthography '*Unruhidinium*'. Based on an inexistent proposal to reject the name *Zooxanthella*, Probert et al. (2014) proposed the new name *Brandtodinium* to replace *Zooxanthella*, the thecate endosymbiont of pelagic radiolarians. The conflicts on nomenclature must be solved by the Committee for Algae of International Association for Plant Taxonomy. Most of the members of the Committee that vote the recommendation or rejection of proposals are not experts on taxonomy of dinoflagellates and decision remains in the hands of a few people. The decision to recommend or to reject a proposal may delay for several years being associated with uncertainty during that period. John et al. (2014) proposed to reject the *Gonyaulax catenella*, basionym of an important toxicologically species of *Protogonyaulax*. In the decision, Prud'homme van Reine (2017) reported "*Alexandrium fundyense* and *A. catenella* are certainly conspecific, and then 'catenella' has nomenclatural priority". Is it really the same species responsible of the blooms in the Canadian Atlantic and California? Members of the Committee placed all the species of *Symbiodinium* into *Zooxanthella* (Guiry and Andersen 2018), when the morphology and molecular phylogeny evidence that *Zooxanthella* and *Symbiodinium* are independent genera (Figure 13).

## **CLASSIFICATION**

The names that we use for the classification of dinoflagellates are in continuous evolution due to the new taxonomical innovations, re-classifications based on the molecular data, and the nomenclatural changes. There is nothing more risky for an author than to propose a suprageneric classification when the evolutionary relationships of numerous dinoflagellates remain unresolved yet. With the exception of some groups (Gymnodiniales *sensu stricto*, Thoracosphaerales, Gonyaulacales), the words -*incertae sedis*- are everywhere, and we cannot propose a new family or order for each independent lineage of dinoflagellates. A principle that I follow in the classifications is to avoid adding taxonomical innovations, or suprageneric new names and using the existing published names (Fensome et al. 1993). New terminology can be found in other classifications (Hoppenrath 2017). The next classification is an updated version of that in Gómez (2012b), but in this case from genus to class because the citation of all species names needs more than 100 pages. A tentative scheme that summarises the dinoflagellate evolution is proposed in the Figure 14.

Figure 14. Tentative evolutionary relationships of dinoflagellates.

Infraregnum Alveolata, Phyllum Dinoflagellata Class Ellobiopsea / Ellobiophyceae Order Thalassomycetales: Ellobiopsidae / Thalassomycetaceae: Ellobiocystis, Ellobiopsis, Parallobiopsis, Rhizellobiopsis, Thalassomyces Class Oxyrrhea Order Oxyrrhida / Oxyrrhinales Oxyrrhinaceae: Oxyrrhis Class of Pronoctiluca, incertae sedis. The affinity with the dinoflagellates needs molecular data. Protodiniferaceae: Pronoctiluca Class of Coccinidiales (Marine Alveolate Group I) Order Coccinidiales: Coccidinium, Dogelodinium, Euduboscquella, Ichthyodinium, Keppenodinium Class Syndinea/Syndiniophyceae (Marine Alveolate Group II) Order Syndiniales Syndiniaceae: Actinodinium, Caryotoma, Merodinium, Syndinium, Hematodinium Sphaeriparaceae: Atlanticellodinium, Sphaeripara Amoebophryidae / Amoebophryaceae: Amoebophrya Class Noctilucea / Noctiluciphyceae (Dinokaryota) Order Noctilucales Noctilucaceae: Noctiluca, Pomatodinium, Spatulodinium Kofoidiniaceae: Kofoidinium Order of Leptodiscaceae Leptodiscaceae: Abedinium, Cachonodinium, Craspedotella, Leptodiscus, Petalodinium, Scaphodinium Class Dinoflagellata / Dinophyceae (Dinokaryota) Subclass Gymnodiniphycidae Order Amphidiniales Amphidiniaceae: Amphidinium s.s., Schillingia, Trochodinium Order Brachidiniales Brachidiniaceae: Asterodinium, Brachidinium, Gertia, Karenia, Karlodinium, Microceratium, Takayama Order Ptychodiscales Ptychodiscaceae: Ptychodiscus Order Haplozooidea / Haplozoonales Haplozoonaceae: Haplozoon Order Gymnodiniales Gymnodiniaceae: Barrufeta, Gymnodinium, Gymnoxantella, Lepidodinium, Paragymnodinium, Polykrikos, Spiniferodinium, Nussuttodinium, Pellucidodinium, Wangodinium Chytriodiniaceae: Chytriodinium, Dissodinium, Myxodinium, Schizochytriodinium, Syltodinium, Gymnodinium s.l. Warnowiaceae: Erythropsidinium, Nematodinium, Nematopsides, Proterythropsis, Warnowia Gymnodiniales sensu stricto, incertae familiae: *Gyrodiniellum*, Pheopolykrikos

Torodiniales Torodiniaceae: *Torodinium* Family of *Lebouridinium*: *Lebouridinium* Order Amphilothales Amphilothaceae: Monaster Order Actiniscales Actiniscaceae: Actiniscus Subclass Gymnodiniphycidae, incerti ordinis. Dicroerismataceae: Dicroerisma Apodiniaceae: Apodinium, Parapodinium Ceratoperidiniaceae: Ceratoperidinium, Gynogonadinium, Kirithra, Pseliodinium Kapelodiniaceae: Kapelodinium Gyrodiniaceae: Ceratodinium, Gyrodinium, Plectodinium, Sclerodinium Gymnodiniphycidae, incerti ordinis, incertae familiae: Akashiwo, Ankistrodinium, Apicoporus, Balechina, Bispinodinium, Cachonella, Cochlodinium, *Cucumeridinium*, *Filodinium*, *Grammatodinium*, Levanderina, Katodinium, *Margalefidinium*, Moestrupia, Testudodinium, Togula Subclass Peridiniphycidae Order Prorocentrales Haplodiniaceae: Haplodinium Prorocentraceae: Prorocentrum s.s., Mesoporos Family of Prorocentrum lima: Exuviaella, Prorocentrum s.l. Family of Prorocentrum panamense: Genus of Prorocentrum panamense Order Dinophysales sensu stricto Amphisoleniaceae: Amphisolenia, Triposolenia Oxyphysaceae: Dinofurcula, Latifascia, Phalacroma, Proheteroschisma Dinophysaceae: Citharistes, Dinophysis, Histioneis, Histiophysis, Metadinophysis, Ornithocercus, Parahistioneis Order Dinophysales sensu lato Family of Pseudophalacroma: Metaphalacroma, Pseudophalacroma Family of Sinophysis: Sinophysis Order Gonyaulacales / Pyrocystales Ostreopsidaceae: Alexandrium, Centrodinium, Coolia, Episemicolon, Gambierdiscus, Gessnerium, Fukuyoa, *Goniodinium*, Ostreopsis, Pachydinium, Protogonyaulax, *Psammodinium*, Pyrodinium, Pyrrhotriadinium Pyrocystaceae: Fragilidium, Pyrocystis, Pyrophacus Gonyaulacaceae: Gonyaulax, Spiraulax Lingulodiniaceae: Amylax, Lingulodinium Ceratiaceae: Ceratium, Tripos Protoceratidaceae: Ceratocorys, Pentaplacodinium, Protoceratium, Schuettiella Thecadiniaceae: *Thecadinium*  Order Gonyaulacales, incertae familiae: *Dapsilidinium*, *Halostylodinium*, *Pseudothecadinium*, Thecadiniopsis

Order Peridiniales *sensu stricto*

Peridiniaceae: Peridinium, Bagredinium, Glochidinium, Palatinus, Parvodinium, Staszicella, Thompsodinium

Order Peridiniales sensu lato

Perinidiniopsidae: Peridiniopsis

Glenodiniopsidaceae: Glenodiniopsis

Protoperidiniaceae: Kolkwitziella, Matvienkodinium, Protoperidinium s.s.

Diplopsaliaceae: Boreadinium, Diplopelta, Diplopsalis, Diplopsalopsis, Dissodium, Gotoius, Huia, Lebouraia, *Niea*, *Qia*, Preperidinium, Protoperidinium depressum-group

Amphidiniopsidaceae: Amphidiniopsis, Archaeperidinium, Herdmania, Protoperidinium s.l.

Podolampadaceae: Blepharocysta, Gaarderiella, *Heterobractum*, Lissodinium, Mysticella, Podolampas, Roscoffia. The genera Cabra, Chrysodinium, Plagiodinium and Planodinium may be related, but the placement in this family needs further research.

Lessardiaceae: Lessardia

Heterodiniaceae: Dolichodinium, Heterodinium

Oodiniaceae: Oodinium

Heterocapsaceae: Heterocapsa

Oxytoxaceae: Oxytoxum, Corythodinium

Amphidomataceae: Amphidoma s.s.

Cladopyxidaceae: Cladopyxis, Palaeophalacroma

Endodiniaceae: Endodinium

Family of *Azadinium*: *Azadinium*, *Amphidoma s.l*.

Crypthecodiniaceae: Crypthecodinium

Order Blastodiniales

Blastodiniaceae: Blastodinium

Order Thoracosphaerales or Duboscquellales?

Apocalathium, Amyloodinium, Caladoa, Cachonella, Calcigonellum, Chalubinskia, Chimonodinium, Crepidoodinium, Cryptoperidiniopsis, Cystodinedria, Duboscquodinium, Duboscquella, Ensiculifera, *Fusiperidinium*, Lebessphaera, Leonella, Luciella, Naiadinium, *Oodinioides*, Paulsenella, Pentapharsodinium, Pernambugia, Pfiesteria, Protoodinium, Pseudopfiesteria, Scrippsiella, Theleodinium, Tyrannodinium, Speroidinium, Staszicella, Stylodinium, Stoeckeria, Tintinnophagus, Thoracosphaera

Order Dinotrichales

Dinotrichaceae/Kryptoperidiaceae: *Blixaea*, Dinothrix, Durinskia, Galeidinium, Kryptoperidinium, *Unruhdinium*

Order Symbiodiniales/Dinococcales

Symbiodiniaceae: Ansanella, Asulcocephallum, Aureodinium, Biecheleria, Biecheleriopsis, Breviolum, Dactylodinium, Durusdinium, Effrenium, Fugacium, Gerakladium, Haidadinium, Leiocephalium, Pelagodinium, Piscinoodinium, Polarella, Protodinium, Symbiodinium, Yihiella

Order Phytodiniales

Phytodiniaceae: Baldinia, Borghiella, Cystodinium, Dinamoebidium, Dinastridium, Dinoclonium, Dinococcus, Hypnodinium, Manchudinium, Phytodinium, Prosoaulax, Sphaerodinium, Tetradinium Order Tovelliales

Woloszynskiaceae/Tovelliaceae: Bernardinium, Esoptrodinium, Jadwigia, Opisthoaulax, Tovellia, Woloszynskia

Peridiniphycidae, incerti ordinis

Dinosphaeraceae: Dinosphaera

*Hemidiniaceae:* Hemidinium, *Nottbeckia*

Glenodiniaceae: Glenodiniopsis, Nephrodinium

Peridiniphycidae, incerti ordinis, incertae familiae: Adenoides, Amphidiniella, Archaeosphaerodiniopsis, Berghiella, Bysmatrum, *Grammatodinium*, Halophilodinium, Laciniporus, *Madanidinium*, Micracanthodinium, Peridiniella, *Pileidinium*, Pseudoactiniscus, Pseudadenoides, Pyramidodinium, Rhinodinium, Sabulodinium, Stylodinium, Vulcanodinium, Thaumatodinium

<sup>1</sup>Mareas Rojas y Fitoplancton Tóxico, Instituto Español de Oceanografía (IEO), Vigo, Spain <sup>2</sup>Fotobiología y Pigmentos de Fitoplancton, Instituto de Investigaciones Marinas (CSIC), Vigo, Spain <sup>3</sup>Department of Biosciences, College of Science, Swansea University, Swansea, United Kingdom

## **ABSTRACT**

Dinoflagellates exhibit the richest pigment composition among microalgae. Their diverse trophic modes and evolutionary histories, with multiple losses and acquisition of plastids, turn them into a sample book of many other protist, and even prokaryote, pigment suites. Unfortunately, pigment analyses have not always been documented, either due to the lack of cultures or the opportunity in obtaining them as a complementary information in addition to morphological and molecular characters. Here we review the major pigment groups previously reported in dinoflagellates, and also discuss the plastid types found within them (with or without pigment data), described as obligate endosymbionts fully integrated in the host, temporary kleptochloroplasts or in endo/ectocytobionts of eukaryotic and prokaryotic nature.

**Keywords**: carotenoids, chlorophylls, chloroplast, dinoflagellates

## **INTRODUCTION**

Dinoflagellates are an abundant and diverse group of protists in freshwater and marine ecosystems, with a cosmopolitan distribution from polar to tropical latitudes. There are approximately 2,400 named extant species (Gómez, 2012). They display three major trophic modes: (primarily) photoautotrophic, mixotrophic and heterotrophic (Jeong et al. 2010).

Parasite forms include both photosynthetic (order Blastodiniales) and heterotrophic members (Stoecker 1999).

A comprehensive review of their lifestyle, habitat and trophic modes (Gómez, 2012) states that most species can be found in marine waters (82%). Overall, photosynthetic dinoflagellates account for ~50% of the described species so far, with a vast predominance of the photosynthetic component in the freshwater environment.

From the available literature, it becomes evident that relative proportion of dinoflagellates having permanent/constitutive plastids (either autotrophic or mixotrophic species) is considerably larger than mixotrophic ones with non-permanent temporal organelles that need to be replenished during feeding (Stoecker 1999; Stoecker et al. 2017).

With that in mind, five plastid types were described by various authors based on their pigment types (Dodge 1989; Jeffrey et al. 2011; Egeland 2016). These authors considered fucoxanthin-type, peridinin-type, 19'-hexanoyloxyfucoxanthin-type, phycobilin-type and chlorophyll (Chl) *b*-type pigment groups. Zapata et al. (2012) refined this classification introducing an additional sixth group (Table 1) splitting those having 19'-acyloxifucoxanthins using different Chl *c* compounds and the presence/absence of gyroxanthin-diesters. The six groups as a whole represent the highest diversity among algal classes.

The latter study stands out as the most comprehensive review on photosynthetic pigments in dinoflagellates up to date. Since then limited information on pigment patterns have been accumulated from the already known or newly described species. Our aim here is to provide an updated overview of pigment composition in dinoflagellates, expanding as much as possible the data provided by Zapata et al. (2012).

# **CHLOROPHYLLS AND CAROTENOIDS DESCRIBED IN DINOFLAGELLATES**

Plastids found in dinoflagellates are overwhelmingly dominated by those belonging to the red lineage. In consequence, pigment composition is characterized by the presence of chlorophylls (Chls) *c* and associated carotenoids distributed among diverse microalgal groups. Given the promiscuous nature of several dinoflagellate genera that have acquired their plastids from secondary algae, a wide array of pigment suites can be found in them.

However, most plastid-containing dinoflagellates display the canonical pigment type including peridinin (Per) as main accesory carotenoid, considered to be ancestral to all photosynthetic members of the group (Delwiche, 2007). It is not the purpose of this chapter to discuss the evolutionary relationships within dinoflagellates and the putative ancestral or derived state of Per-containing organisms, but it must be kept in mind that actual pigment composition in dinoflagellates reflects both the origin of their plastids and the transformations and new pigments then synthesized by the host that integrated these plastids as permanent organelles during evolution.

#### **Chlorophylls in Dinoflagellates**

Table 1 summarizes the actual chlorophylls found in dinoflagellates. Besides the constant presence of Chl *a* and the widespread occurrence of its biosynthetic precursor Magnesium-2,4-Divinylpheoporphyrin a<sub>5</sub> monomethyl ester (MgDVP), the Chl  $c$  family compounds are frequent and very diverse. For instance, among the polar Chls *c* with known structure, only monovinyl-Chl *c*<sup>3</sup> has not been recorded in dinoflagellates. This compound is restricted to some haptophytes from the genera *Emiliania*, *Imantonia* and *Prymnesium* (Zapata et al. 2004) but it has never been observed in dinoflagellates with tertiary plastids from haptophyte origin.

Several additional polar Chls *c* with unknown nature, whose UV-VIS absorption properties match those of Chl *c*1, *c*<sup>2</sup> and *c*3, have been also found in dinoflagellates, although these are not exclusive from this group (Zapata et al. 2012). However, we will not cover here these compounds that are minor and still pending of deeper studies to reveal their structure and putative functions in the photosynthetic machinery.

Non-polar Chls *c* (i.e., those with a galactolipid moiety containing two fatty acid chains, Garrido et al. 2000, Zapata et al. 2006, Porra et al. 2011), which are characteristic from haptophytes, display a wide distribution in dinoflagellates as discussed hereafter. Two nonpolar Chls *c* have been characterized until date in haptophytes (Garrido et al. 2000; Zapata et al. 2001), that can be found also in dinoflagellates (Table 1). Additionally, a third non-polar unknown Chl *c* has been also detected in *Takayama* and *Karlodinium* (Zapata et al. 2012).

Chl *b*-containing dinoflagellates are represented by two unique -and very distinctexamples to our knowledge. First, *Lepidodinium chlorophorum*, originally described as *Lepidodinium viride* (Watanabe et al. 1990), later emended as *L. chlorophorum* by Hansen et al. (2007) on the basis of its identical ultrastructure and phylogenetic characterization to *Gymnodinium chlorophorum* (Elbrächter & Schnepf, 1996). Second, the green form of *Noctiluca scintillans* containing endocytobionts that mainly occurs in tropical waters in Southeast Asia (see below).

Regarding Chls *a* and *b* the unique variations of these compounds are their divinylic counterparts (DV Chl *a* and *b*) found in the cyanobacteria *Prochlorococcus marinus*. Both pigments were considered since their discovery as exclusive markers for prochlorophytes (Goericke and Repeta, 1992). Nevertheless, it was recently detected the presence of DV Chl *a* in a Per-containing species, *Alexandrium ostenfeldii* from the Baltic Sea (Rodríguez et al. 2016). These authors suggested that a mutation and/or epigenetic change in the expression of divinyl reductase gene/s could explain this altered pigment composition. DV mutants of *A. ostenfeldii* exhibited reduced fitness in comparison to normally pigmented cultures, due to a slower growth and stronger sensitivity to high irradiance (evidenced from pulse amplitude modulated fluoresence (PAM) measurements), and lower <sup>14</sup>C assimilation rates.

This fact, together with the gradual loss of DV-chl *a* content, made necessary to continuously isolate and raise new clonal cultures from the mutant lineage to avoid losing high DV Chl *a*/ Chl *a* ratios. In any case, not a single mutant was found to lack Chl *a* and the loss of DV Chl *a* proceeded irreversibly in every case.

Last, Yamada et al (2014) reported the presence in six species of benthic dinoflagellates of 13<sup>2</sup> ,17<sup>3</sup> -cyclopheophorbide *a* enol (cPPB-aE), a chlorophyll catabolite derived from Chl *a* previously found in heterotrophic protists and in marine and lacustrine sediments. This non fluorescent compound was later found in shrunken/abnormal zooxanthellae (symbiotic algae harbored by reef-building corals) where its formation was considered as a mechanism for

avoiding oxidative stress (Suzuki et al. 2015). Further chlorophyll catabolites have been reported in cultures of *Prorocentrum micans* and *Amphidinium tamarense* with the detection of cPPB-aE in *A. tamarense* in a culture exposed to copepod grazers supporting a possible stress response mechanism (Talbot et al. 2000).

#### **Carotenoids in Dinoflagellates**

The main carotenoids found in dinoflagellates are summarized in Table 1. In addition to most of those already known in diatoms, haptophytes and cryptophytes, dinoflagellates display exclusive pigments both in Per-type organisms and those with tertiary plastids.

Among the first, dinoflagellate exclusive carotenoid compounds are peridinol, peridinin, cis-peridinin, dinoxanthin and pyrroxanthin (Zapata et al. 2012; Egeland 2016). Also, the unique carotenoid lactoside, P457, was characterized from Per-containing dinoflagellates, namely a *Symbiodinium* sp. strain isolated from a sea anemone, two strains of *Amphidinium carterae* and *Prorocentrum triestinum*, as well as in many other *Symbiodinium* strains, reefbuilding corals and other cnidarians harbouring dinoflagellate symbionts in their tissues (Wakahama et al. 2012).

In addition, a new unknown carotenoid has been detected in a recently described Suessial species, *Biecheleria tirezensis* (Raho et al. 2018), which was not mentioned in that study, as shown in the corresponding HPLC pigment analyses in Figure 1A. The UV-VIS properties and chromatographic behaviour of this compound do not coincide with those of any known carotenoid and suggest that its molecule could harbor some very polar group and have a reduced conjugated system (around eight double bonds) restricted to the aliphatic part of the molecule.

Among dinoflagellates with "non-canonical" peridinin plastids, a special mention must be given to the presence of the acetylenic allenic gyroxanthin-diesters. Gyroxanthin-diesters are present in those organisms with tertiary plastids and haptophyte (also possibly pelagophyte) pigment signature. Gyroxanthin-diester was first characterized in *Gymnodinium galatheanum* (at present *Karlodinium veneficum*) by Bjørnland et al. (2000), then detected, together with two new different forms, in other members of the genera *Karenia* and *Karlodinium*, but not in *Takayama* (Bjørnland et al. 2003; Zapata et al. 2012). This structural diversity can be explained by the different chain lengths of the fatty acids (e.g., lauric, myristic, Bjørnland et al, 2000) that are part of the molecules.

Regarding Chl *b*-containing dinoflagellates of the genus *Lepidodinium*, their plastid was initially attributed to a prasinophyte endosymbiont, as prasinoxanthin was tentatively identified (Elbrächter and Schnepf 1996). Further studies demonstrated that *Lepidodinium chlorophorum* contains permanent plastids acquired by serial endosymbiosis from green algae (core chlorophytes; Matsumoto et al. 2011). Later, these were traced to the pedinophyte *Pedinomonas minor* (Kamikawa et al. 2015), the occurrence of prasinoxanthin was dismissed and the expected carotenoid profile of a chlorophyte (excepting lutein) was confirmed (Matsumoto et al. 2012; Gavalás-Olea et al. 2016).

*L. chlorophorum* has been recently demonstrated to contain a new carotenoid, lepidoxanthin (Gavalás-Olea et al. 2016), with a unique 19,19′-diacyloxy structure ((3S,5R,6S,3′R,6′R)-5,6-epoxy-19-(2-decenoyloxy)-19′-acetoxy-4′,5′-didehydro-5,6,5′,6′-

tetrahydro-β,ε-carotene-3,3′-diol), absent from parallel pigment analyses in *Pedinomonas minor*.

## **Table 1. Distribution of chlorophylls (chl) and carotenoids among pigment-based chloroplast types in Dinophyta. Black circle: consistent occurrence; white circle: occasional occurrence**

\*Up to three different compounds detected in dinoflagellates from types 2 and 3. Modified from Zapata et al. (2012).

In the case of the green form of *Noctiluca scintillans*, this heterotrophic species harbours endosymbiotic populations constituted by free-swimming phototrophic endocytobionts of *Protoeuglena noctilucae* (Chlorophyta, Pedinophyceae; Wang et al. 2017). Those green *Noctiluca* are responsible of massive outbreaks (green tides) in the open ocean (Gomes et al. 2014). Pigment composition of *Protoeuglena noctilucae* (as *Pedinomonas noctilucae* in

Furuya and Lirdwitayaprasit, 2000) showed a typical pigment pattern in Chl *b*-containing algae, matching previous analyses from *Pedinomonas* as mentioned herein.

Finally, in a recent study relating pigment composition and habitats in benthic dinoflagellates, Yamada et al. (2015) reported the occurrences of various sets of unknown carotenoids either in some peridinin-containing and certain fucoxanthin-bearing dinoflagellates. Carotenoids are highly prone to isomerisation and oxidation indicating the possibility of carotenoid catabolite production within benthic dinoflagalles. Further detailed analyses of carotenoids in benthic dinoflagellates is required to determine phylogenetic distribution and the functional role of such undetermined carotenoids.

# **CHLOROPLAST PIGMENT TYPES AND DINOFLAGELLATE TAXA**

Zapata et al. (2012) defined six types of chloroplasts in dinoflagellates, depending on their pigmentary composition (Tables 1 and 2). Since then, some additional pigments have been detected in a few cases but in general, they do not imply in our opinion essential modifications as to vary the number of types proposed. These pigmentary types are constructed according to a presence/absence criterion, since the relative contents of the different compounds vary depending on environmental and physiological conditions (Kana et al. 1997, Brunet et al. 2011, Islabão, 2016). Dinoflagellates may benefit from photosynthesis by three groups of associations (Schweikert and Elbrächter 2004): obligate endosymbionts (i.e., permanent plastids), kleptochloroplasts (temporal organelles acquired by feeding) and endo/ectocytobionts (where symbionts are identical to their free-living counterparts and are separated from the host cytoplasm). The following pigmentary types belong to the first and second groups.

### **Type-1: Peridinin-Containing**

In the last years numerous studies have dealt with the characterization of dinoflagellate species harbouring typical type 1 chloroplasts. These plastids are characterized by the constant presence of peridinin and dinoxanthin, and occasionally of peridininol, phyrrhoxanthin and P457, all of them being dinoflagellate-exclusive carotenoids. Additional compounds are the xanthophylls diadinoxanthin and diatoxanthin (implied in photoprotection mechanisms), diadinochrome and  $\beta$ ,  $\beta$ -carotene.

Accessory chlorophylls in this pigmentary type are chlorophyll *c*<sup>2</sup> (major) and MgDVP at trace level. Chlorophyll *c*<sup>1</sup> appears occasionally in this pigmentary type (Zapata et al. 2012, Yamada et al 2015). An interesting example is the recently described *Pentaplacodinium saltonense* (Mertens et al. 2018; =*Ceratocorys mariaovidiorum*, Salgado et al. 2018), with appreciable amounts of chlorophyll  $c_1$  (this work). It has been suggested that chlorophyll  $c_1$ can be produced from chlorophyll *c*<sup>2</sup> whenever the latter is present, although the amount of chlorophyll *c*<sup>1</sup> is variable and frequently it cannot be detected (Yamada et al. 2015).

Pigment type 1 is the most frequently found among photosynthetic dinoflagellates, comprising the orders Amphidiniales, Gonyaulacales, Gymnodiniales, Peridiniales, Prorocentrales, Suessiales and Thoracosphaerales (Zapata et al. 2012). In that study HPLC analyses of any member of the order Suessiales were not detailed, but these authors proposed the extension of chloroplasts with peridinin within them by generalizing the composition described for *Polarella glacialis* by Montresor et al. (2003). In an attempt to add information about this order, in this work we have analyzed *Symbiodinium natans* (Class Symbiodiniaceae), *Biecheleriopsis adriatica* and *Biecheleria tirezensis* (Class Biecheleriaceae), and the chromatographic traces of these additional species are similar (Figure 1A) and support the presence of type 1 chloroplasts in Suessiales. Furthermore, the genera *Amphidoma* and *Azadinium*, which have not been adscribed to any extant order, also appear to display type 1 plastids (Tillmann et al. 2010, 2012, 2014, this study).

Figure 1. A) HPLC chromatogram of a pigment extract from *Biecheleria tirezensis* (BEA 1549B). The insert shows the VIS spectrum of an unknown carotenoid. B) HPLC chromatogram of *Azadinium poporum* (UTH D4). Peak identification: 1) peridininol, 2) chlorophyll *c*2, 3) peridinin, 4) diadinochrome, 5) diadinoxanthin, 6) dinoxanthin, 7) diatoxanthin, 8) chlorophyll  $a$ , 9)  $\beta$ , $\beta$ -carotene.

The descriptions of *Azadinium spinosum* (Tillman et al. 2009) and *A. obesum* (Tillmann et al. 2010) reported a peridinin-containing profile which surprisingly included prasinoxanthin in minor amounts. *A. caudatum* was also shown to bear type 1 chloroplasts with no prasinoxanthin but minor amounts of violaxanthin (Tillmann et al. 2014). However, the HPLC profiling of *A. poporum* performed for this work yielded the typical type 1 pigment suite without any additional carotenoid (Figure 1B).

Interestingly, a new and minute Kareniaceae species displaying a Per-containing plastid, belonging to a new genus (*Gertia stigmatica*) has been recently discovered (Takahashi et al. 2019). To our knowledge, this is the only exception within such family characterized by permanent plastids of tertiary origin acquired from haptophytes (Type-2, see below). These authors suggested that this undescribed kareniacean replaced the former acyloxifucoxanthincontaining chloroplast by a Per-type one.

#### **Type-2: 4-Keto-Acyloxifucoxanthin-Containing**

The maximum diversity of carotenoids related to fucoxanthin has been detected in certain dinoflagellates, constituting type 2. In this type, restricted to the genus *Karenia*, six of these xanthophylls characteristically appear: fucoxanthin itself, 19'-hexanoyloxyfucoxanthin, 19' butanoyloxyfucoxanthin, 19'-hexanoiloxy-4-keto-fucoxanthin, and three unidentified carotenoids (as far as we know, restricted to members of the genus *Karenia*) with identical absorption spectrum to the latter (Zapata el al. 2012). The different proportions of these fucoxanthin-related carotenoids seems to be very influenced by the culture irradiance as it has been observed in the coccolitophoride *Emiliania huxleyi* (Garrido et al. 2016). Work on this topic in several *Karenia* species is currently under progress (Barreiro et al. *in preparation*).

Diadinoxanthin (and diatoxanthin at high irradiances) appear as main photoprotective carotenoids. In addition, various forms of gyroxanthin have been detected in different species of the genus *Karenia* (Zapata et al. 2012). Accompanying these xanthophylls, several chlorophyll *c* compounds (chlorophyll *c*3, chlorophyll *c*2, MgDVP and MGDG-chlorophyll *c*2-*Chrysochromulina polylepis*-type) complete the pigment suite of type 2 (Zapata et al. 2012).

#### **Type-3: Acyloxifucoxanthin-Containing**

Type 3 chloroplasts, contained in species of the *Asterodinium*, *Karlodinium* and *Takayama* genera, lack the acyloxy derivatives of 4-keto-fucoxanthins. The major carotenoids in this pigment type are fucoxanthin, 19'-acyloxifucoxanthin derivatives, a fucoxanthinrelated compound of unknown structure and the diadinoxanthin and diatoxanthin pair. The occurrence of 19'-butanoyloxyfucoxanthin cannot be generalized in this Type after the recent finding that *Asterodinium gracile* lacks this pigment (Benico et al. 2019). Although absent in *Takayama* cf. *helix*, gyroxanthin derivatives are abundant in species of the genus *Karlodinium* analyzed in Zapata et al. (2012) and in *Asterodinium gracile* (Benico et al. 2019). The composition in chlorophylls is very similar to type 2, with chlorophylls  $c_2$ ,  $c_3$  and MgDVP always present, while MGDG-chlorophyll *c*2-like pigments have not been always detected (Zapata et al. 2012). Recent analyses in new *Karlodinium* species raised a very first contradiction in the pigment composition of members of that genus. *K. gentienii* (Nézan et al. 2014) could be classified as a type 3 member as it contains acyloxy fucoxanthins, despite it lacks gyroxanthin derivatives and MGDG-chlorophylls. However, *K. zhouanum* (Luo et al. 2018b) contains fucoxanthin but lacks its acyloxy derivatives, thus placing this species into chloroplast type 4 (see below).

## **Type-4: Fucoxanthin-Containing**

The dinoflagellates with chloroplast type 4, coming from a tertiary endosymbiont derived from a diatom (the so-called "dinotoms" due to the early stage of integration of their endosymbiont, Imanian et al. 2010), display fucoxanthin without any acyloxyderivatives. The monophyletic "dinotoms" harbor a chloroplast of diatom origin, but their chloroplasts are polyphyletic belonging to one of four genera: *Chaetoceros*, *Cyclotella*, *Discostella*, or *Nitzschia* (Yamada et al. 2017). It is worth highlighting the characteristical presence in this group of  $\beta$ ,  $\psi$ -carotene (Zapata et al. 2012; Yamada et al. 2015) that, together with diadinoxanthin and diatoxanthin, complete the set of carotenoids. On the composition of chlorophylls there is a certain discrepancy: although the presence of chlorophylls  $c_2$  and  $c_1$  in all the species examined has been detected in several studies, Zapata et al. (2012) found chlorophyll *c* type pigments characteristic of the haptophytes *Pavlova gyrans* and *Exanthemachrysis gayraliae* in *Durinskia dybowskii* (*=D. baltica*) and *Kryptoperidinium foliaceum*. Moreover, Yamada et al. (2015) reported the occurrence of chlorophyll  $c_3$  in the sand-dwellers *Galeidinium rugatum* and *Durinskia* cf. *baltica*. Yamada et al. (2017) also described *D. kwazulunatalensis*, that had been analyzed as *Durinskia* sp. in their previous work, showing a type 4 pattern without chlorophyll *c*<sup>3</sup> (Yamada et al. 2015).

#### **Type-5: Alloxanthin-Containing**

Type 5 is composed of mixotrophic dinoflagellates that harbor heterotrophically acquired temporal cryptophyte chloroplasts (kleptoplastids). Among them, *Dinophysis* is the most studied and representative example, whose chloroplasts were traced to a cryptophyte by pigment and ultrastructural analyses (e.g., Schnepf and Elbrächter 1988, Meyer-Harms and Pollehne 1998) long before confirming their identity by molecular means (Hackett et al. 2003) and the establishment of cultures (Park et al. 2006). Their temporary or permanent nature held a long debate, now settled in favor of the first hypothesis due to the evidences accumulated from culture and field studies (see Reguera et al. 2012). In the field, photosynthetic species of *Dinophysis* display kleptoplastids from cryptophyte origin (typically *Teleaulax* spp.), most probably obtained from the ciliate *Mesodinium rubrum*. This specific food chain is the unique identified so far to grow *Dinophysis* spp., but plastids from multiple origins have been also retrieved in the field suggesting occasional feeding on other preys (Kim et al. 2012a).

In the genus *Dinophysis*, HPLC pigment data from cultures (fed with the *Teleaulax/ Mesodinium* food chain) have become available for *D. acuminata, D. acuta, D. caudata* and *D. tripos* (Zapata et al. 2012, Rial et al. 2013, García-Portela et al. 2018) with alloxanthin and crocoxanthin as the characteristic carotenoids, accompanied by chlorophyll *c*2, MgDVP and biliproteins (Jeffrey et al 2011, Zapata et al., 2012, Egeland 2016). Cryptophytes also contain the pigment-protein phycobilin complex, phycoerythrin. All these pigments are contained in the engulfed plastids originating from cryptophytes, that undergo important structural modifications in *Dinophysis* (Kim et al. 2012b).

But neither all the members of type 5 are Dinophysiales nor all of them show kleptochloroplasts of cryptophyte origins (Qiu et al. 2011, Nishitani et al. 2012), as it will be discussed afterwards.

There are other taxonomic groups of dinoflagellates having kleptoplastids from cryptophyte preys which are temporary and photosynthetically active. Members of the genera *Amphidinium* (*A. poecilochroum, A. latum*), *Amylax* (*A. buxus, A. triacantha*), *Gymnodinium* (*G. aeruginosum, G. acidotum, G. eucyaneum, G. gracilentum*), *Cryptoperidiniopsis* and *Pfiesteria* (*P. piscicida*) have been reported (see refs. in Nishitani et al. 2012, Onuma et al. 2013).

In the case of the genus *Amylax*, *A. triacantha* cultures were established feeding the ciliate *Mesodinium rubrum* (Park et al. 2013) and its pigment composition is expected to be identical to *Dinophysis*. Although no pigment data are available in the literature, *A. busus and A. triacantha* are known to contain cryptophyte kleptochloroplasts of *Teleaulax amphioxeia* (Koike and Takishita 2008).

Similarly, within the order Gymnodiniales, the recently described genus *Nusuttodinium*  that comprises both freshwater and marine species retains plastids from cryptophyte origin (Takano et al. 2014).

Order		Pigment type					
	Representative species			3	4	5	6
Amphidiniales	Amphidinium carterae <sup>a</sup>	●					
Dinophysiales	Dinophysis acuminata						
Gonyaulacales	Alexandrium minutum						
	Amylax triacanthab						
	Pentaplacodinium saltonense <sup>c</sup>						
	Tripos fusus <sup>c</sup>						
Gymnodiniales	Bispinodinium angelaceum <sup>d</sup>						
	Gymnodinium catenatum						
	Nusuttodinium myriopirenoidese						
	Paragymnodinium shiwhaense <sup>f</sup>						
	Spiniferodinium galeiforme <sup>s</sup>						
	Wangodinium sinense <sup>h</sup>						
	Karenia mikimotoi						
	Karlodinium veneficum						
	Takayama helix						
	Karlodinium zhouanum <sup>i</sup>						
	Lepidodinium chlorophorum						
Peridiniales	Heterocapsa triquetra						
	Durinskia baltica						
	Galeidinium rugatum <sup>i</sup>						
	Kryptoperidinium foliaceum						
Prorocentrales	Prorocentrum lima						
<b>Suessiales</b>	Biecheleria tirezensis <sup>c</sup>						
	Symbiodinium natans <sup>c</sup>						
Thoracosphaerales	Ensiculifera loeblichii <sup>c</sup>						
	Thoracosphaera heimii						
<b>Tovelliales</b>	Tovellia diexiensis $k$						
(freshwater)	Woloszynskia coronata <sup>l</sup>						
Dinophyceae ordo	Azadinium poporum <sup>c</sup>						
incertae sedis	Amphidoma languida <sup>m</sup>						
	Levanderina fissa $c$						

**Table 2. Distribution of pigment-based chloroplast types across Dinophyta taxa**

Data from Zapata et al. (2012) and other authors (for superscripts see references): "Haxo et al. (1976), "Based on kleptoplast origin by Koike and Takishita (2008), 'This study, <sup>d</sup>Yamada et al. (2013), 'Based on kleptoplast origin by Yamaguchi et al. (2011), <sup>f</sup>Kang et al. (2010), <sup>g</sup>Takano et al. (2014), <sup>h</sup>Luo et al. (2018a), <sup>i</sup>Luo et al. (2018b), <sup>j</sup>Tamura et al. (2005), <sup>k</sup>Zhang et al. (2016), also reported high amounts of astaxantin and astaxanthin diester in a natural bloom, <sup>1</sup> Lindberg et al. (2005), "Tillmann et al. (2012).

#### **Type-6: chl** *b***-Containing**

Type 6 chloroplast, restricted to the genus *Lepidodinium*, shows pigments characteristic of green algae, including chlorophyll *b*, and the carotenoids 9'-*cis*-neoxanthin, violaxanthin, antheraxanthin and  $\beta$ ,  $\beta$ -carotene, together with a new major carotenoid, lepidoxanthin, unique in this type of chloroplast (Gavalás-Olea et al. 2016). Lepidoxanthin coeluted with lutein found in *Pedinomonas minor* in the Zapata et al. (2000) method, although both carotenoids displayed different UV-VIS properties. The chromatographic method proposed by Sanz et al. (2015) achieves good separations of lutein from lepidoxanthin.

### **Kleptoplasts and Endo/Ectocytobionts from Multiple Origins**

The organisms considered below could provide, in some instances, additional pigment types in dinoflagellates. These would originate from their kleptoplasts acquired by feeding or through their association with endo/ectocytobionts from different phytoplankton groups.

It must be kept in mind that the nature and origin of these associations remains fairly unknown and *pigment data have not been reported*, to our knowledge, due to the absence of cultures or their scarce abundance in field samples (excepting, as described above, the green forms of *Noctiluca* that develop extensive blooms).

Some examples of Dinophysiales that retain plastids not only from cryptophyte origin are *Dinophysis mitra* (haptophytes, Nishitani et al. 2012), *D. miles* (cryptophyte, haptophyte and cyanobacteria, Qiu et al. 2011), and species of the genera *Sinophysis* (cyanobacterial endosymbionts, Escalera et al. 2011, García-Portela et al. 2017), *Amphisolenia* and *Triposolenia* (cyanobacterial and eukaryotic endosymbionts, Tarangkoon et al. 2010), *Citharistes, Histioneis, Parahistioneis* and *Ornithocercus* (cyanobacterial ectosymbionts like *Synechococcus* and *Synechocystis*, Ossipov et al. 1997, Tarangkoon et al. 2010).

In the order Peridiniales plastids of Dictyochophycean origin have been detected in *Podolampas bipes* (Schweikert and Elbrächter 2004).

Finally, this group of dinoflagellates that retain the photosynthetic machinery from other organisms is completed with the already mentioned green forms of *Noctiluca* which enclose intact cells of *Protoeuglena noctilucae* (Wang et al. 2017).

The systematic pigment analysis of all these species is still needed to contribute to tracing the exact origin of the foreign plastids and cyanobionts.

## **LINKING PIGMENT AND PLASTID DIVERSITY**

Despite the evolutionary and ecological importance of dinoflagellates, their morphological diversity and complicated genetics has made phylogenic resolution highly challenging. This is compounded by the ability of dinoflagellates to lose, replace or gain new plastids. However rapid advances have been made in recent years. This has been made possible with the availability of genome and transcriptome sequencing data resulting in a clearer understanding of dinoflagellate phylogeny, plastid diversity, endosymbiosis and evolutionary trends (Bachvaroff et al. 2015, Janouškovec et al. 2017, Waller and Koreny

2017; Gornik et al. 2019). However, as highlighted by Hoppenrath (2017) natural classification reflecting evolutionary processes and phylogenetic relationships for dinoflagellates whilst on a promising path is still at an extremely early stage.

Figure 2. Mapping and comparing pigment types with plastid diversity and phylogeny: A. Taken from Zapata et al. (2012). Numbers indicate chloroplast types (1-6). B. Adapted from Waller and Korĕný (2017).

Historical chemotaxomic pigment analysis spearheaded by the seminal work of Jeffrey and Zapata appears remarkably consistent with this more recently emerging understanding on dinoflagellate phylogenomics and plastid diversity. In Zapata et al. (2012), pigment based chloroplast types were mapped to a proposed evolutionary history based on molecular data scheme by Saldarriaga et al. (2004) (Figure 2A). This can be compared to a more recent schematic (Figure 2B) where current knowledge on plastid diversity has been mapped onto a phylogenomic tree (Waller and Korĕný, 2017) derived using protein transcript information (Janouškovec et al. 2017).

As dinoflagellate phylogeny is still fluid detailed comparisons are challenging. Four pigment plastid types plus kleptoplasty are presented by Waller and Korĕný (2017). Detailed pigment analysis can help discrimate further plastid diversity patterns. One example being for the alloxanthin containing, classified as Type 5, derived from cryptophyte plastids (also containing phycoerythrin) present within the Dinophysiales and Gonyaulacales clades. Another example being the gyroxanthin diesters, possibly derived from coccolithophytes and or pelagophytes, and the acyloxyfucoxanthin (excluding keto-derivatives typical of haptophytes) grouped as Type 3 as discussed in this chapter within the Kareniaceae clade. In addition a peridinin-containing plastid has also been reported for the first time within Kareniaceae, as mentioned before (Takahashi et al. 2019).
Further detailed analysis of pigments in now required in conjunction with recent molecular data to gain further insight into phylogenic diversity and evolutionary and ecological adjustment of dinoflagellates. This could be further developed to incorportate understanding on dinoflagellate metabolome with wider metabolomic analysis including at the single cell level. The ability to discriminate physiological status using metabolomic analysis at the single cell level in diatoms and chlorophytes has recently been achieved (Baumeister et al. 2019).

## **PIGMENT COMPOSITION AND HABITAT TYPES**

Studying pigment profiles of 40 dinoflagellate species (45 strains) isolated from three habitat types (sand-dwelling benthic forms, tidal pool inhabitants and planktonic species), Yamada et al. (2015) proposed that far greater diversity of pigments are produced by the dinoflagellates living in sand regardless of chloroplast types relative to those of planktonic and tidal pool forms.

In sand-dwellers with type-1 chloroplasts a set of minor unidentified carotenoids, together with cPPB-aE, were found in addition of the common pigment profile. Also, sanddwellers with type-4 chloroplasts showed a characteristic set of unknown carotenoids and chl *c*3. These results were claimed by Yamada et al. (2015) as a link between pigment profile and habitat types, but given that these pigments have not been reported elsewhere, further work would be needed to confirm the native occurrence of these compounds.

## **A BRIEF METHODOLOGY OF PIGMENT ANALYSES**

Analytical methods for pigment analysis date back from colorimetric techniques like the Forel Ule scale, employed since the last decade of s. XIX to build up maps of water color, still useful at present, such as those of the Atlantic Ocean during the Plankton Expedition (1889). Further methodological developments enabled to quantify the absorption and fluorescence signals of pigment mixtures (both in natural samples and organic extracts), by means of spectrophotometric and fluorometric methods (e.g., Lorenzen, 1967, Jeffrey and Humphrey, 1975; Neveux and Lantoine, 1993). These approaches provided complementary results and, with proper data processing, good estimates of main carotenoids and chlorophyll forms (total chls *a*, *b*, *c* and phaeopigment derivatives) in aquatic ecosystems.

However, the precise calculation of individual compounds in phytoplankton field samples and cultures, such as those detailed in the previous sections, were only acquired after the implementation of modern chromatographic techniques. These evolved from thin-layer chromatography (e.g., Jeffrey 1968) towards more resolutive and quantitative methods like HPLC and UPLC incorporating diode-array and fluorescence detectors, which streamlined with mass-spectrometry analysis allow to gain further insights on the nature of unknown pigments (Airs and Garrido 2011).

Since the pioneer work of Mantoura and Llewellyn (1983), many HPLC methods were developed and applied for the quantitation and estimation of pigments both in laboratory cultures and phytoplankton populations in the field. It is not our task here to provide a comprehensive overview of these methods: these have already been compiled by other authors (Garrido et al. 2011, Sanz et al. 2015). Nevertheless, it must be stressed that the chemotaxonomic application of pigments –and its utility to characterize the composition of phytoplankton groups– required (as cited in the case of spectrophotometric and fluorometric methods), the application of mathematical tools to extract additional information from HPLC data to reconstruct phytoplankton groups by means of marker pigments.

These tools include five methods (Higgins et al. 2011), among which multiple linear regression and CHEMTAX software, based on iterative adjustments of pigment ratios (Mackey et al. 1996), have been widely applied in the last twenty years. To give an idea, only HPLC combined with CHEMTAX data processing accounts for around 300 studies, increasing steadily in number since 1997.

In parallel, the fast development of molecular tools and high-throughput sequencing provided more "meticulous" ways (both in qualitative and quantitative terms) to scrutinize the taxonomic composition of aquatic microorganisms, including dinoflagellates (e.g., Stern et al. 2010, Le Bescot et al. 2016), superseding the dominant place of pigments in previous decades.

The chemotaxonomic characterization by pigments (whichever the mathematical approach used) is mostly restricted in dinoflagellates to illustrate a single pigmentary group (type-1), based on the exclusive carotenoid marker, peridinin (characteristic of pigmentary type-1, found in most photosynthetic dinoflagellates). Notwithstanding, additional pigmentary groups, built up on the presence of fucoxanthin-related compounds and gyroxanthin-diester have been also considered in some studies (Örnólfsdóttir et al. 2003, Rodríguez et al. 2003), although these do not fit always to the pigment types shown herein and can integrate mixed contributions from other groups (mainly diatoms and haptophytes). The reverse situation frequently occurs when pigments shared by a certain dinoflagellate type and other algal groups are attributed to the latter (this being the case of type-4 dinoflagellates and diatoms or type-5 and cryptophytes). This stresses the relevance of other methods, such as microscopic cell counts, to discern the dominant taxa in natural samples minimizing misidentification of pigment patterns originating from tertiary dinoflagellates (Irigoien et al. 2004).

CHEMTAX calculations require the input of pigment ratios (accessory marker pigments to chl *a*) in order to estimate the relative contribution of defined pigment groups to total chl *a*. In this sense, the availability of pigment ratios for each pigmentary type is needed and those from organisms isolated in the study area was originally suggested by Mackey et al. (1996) as an adequate strategy to gain a more accurate approach. In addition, splitting data prior to CHEMTAX processing has been also employed to reconstruct pigment groups and adjust pigment ratios following geographical areas or depth (light) ranges (e.g., Llewellyn et al. 2005, van De Poll et al. 2016, Araujo et al. 2017).

In this sense, despite the relative paucity of data about the influence of distinct environmental factors on dinoflagellate pigments, there exists at least a review about the effects of variable light conditions on the ratios of accessory pigments to chlorophyll *a* (Higgins et al. 2011). Namely, these authors compiled field and culture data about pigment:chl *a* ratios at low, medium and high light for type-1 and type-2 dinoflagellates, which provide good estimates of initial pigment ratios to reconstruct these groups by means of CHEMTAX processing of HPLC data.

## **STRATEGIC UTILITY OF PIGMENTS**

The quantitative estimation of the contribution of a certain dinoflagellate (group) to the planktonic biomass can be a crucial information when studying the onset, development and decline of a bloom, specially if it involves species with negative effects towards the marine fauna, public health and/or human activities. If a pigment can be employed as a proxy for the causative organism, this compound has a strategic utility, facilitating the detection and monitoring of the bloom. This approach usually relies on the previous knowledge of the recurring proliferations in a region that can be linked to the presence of a marker pigment reasonably attributable to a given species (Johnsen et al. 2011).

The most remarkable example is the use of gyroxanthin diester for quantifying the abundance of *Karenia brevis* in natural waters, either HPLC measured (Örnólfsdóttir et al. 2003, Richardson and Pinckney, 2004) or *in situ* detected through optical sensors exploiting the unique absorption characteristics that this pigment confers (Johnsen et al. 2011). In this sense, satellite techniques have been successfully applied to monitor not only *K. brevis* (Stumpf et al. 2009) but also other species such as *K. mikimotoi* (Kurekin et al. 2014) and even, but with a lower specificity, the proliferations of the chl *b*-containing species *Lepidodinium chlorophorum* (Sourisseau et al. 2016).

The main drawback of this approach could be the presence of other algal groups that contain the same reference pigments. For example, gyroxanthin diester has been detected in other dinoflagellates (genus *Karlodinium*, type-3) and certain haptophytes and pelagophytes (Bjørnland et al. 2003, Zapata et al. 2005). The quest for other pigments with such strategic utility in dinoflagellates should consider compounds with appropriate marker quality, in amount enough to be easily detected even at low cell abundances. Among the different pigments found in dinoflagellates, only a few can heretofore be unequivocally assigned to a certain type: peridinin and dinoxanthin for type-1, keto-acyloxy-fucoxanthins for type-2 and lepidoxanthin for type-6.

The separation of these pigments in field samples and their use as chemotaxonomic markers of dinoflagellates requires highly resolution HPLC methods. The discrimination of peridinin and dinoxanthin is achieved by most methods but the separation of fucoxanthin from all its related acyloxy- and keto- derivatives in the genus *Karenia* (as described in Zapata et al. 2012) is difficult for methods focused on the analysis of gyroxanthin diester (Örnólfsdóttir et al. 2003). On the other hand, lepidoxanthin is hard to differentiate from lutein except with certain specialized methods (Sanz et al. 2015)

### **CONCLUSION**

As highlighted the pigment diversity in dinoflagellates is the widest across any group of microalgae reflecting the complexity of plastid endosymbiosis. It is clear that whilst there have been detailed studies of carotenoids and chlorophylls across the dinoflagellates, the systematic data collection across more species would be advantageous. This should be combined with on-going advances in transcriptomic and genetic research and with improved resolution in dinoflagellate phylogeny. Single cell analysis techniques provide exciting opportunities and will be particularly important in determining physiological response of dinoflagellates to environmental variables such as light and nutrients. Combining knowledge on pigment distribution and function with a systems biology approach will help build deeper understanding on this important and amazingly diverse and beautiful group of microorganisms.

#### **ACKNOWLEDGMENTS**

We thank U. Tillmann for providing the strain of *Azadinium poporum* (UTH D4). This work is a contribution of the Unidad Asociada IEO-CSIC Microalgas Nocivas.

# **SPECIES ASSEMBLIES AND SEASONAL SUCCESSION OF DINOFLAGELLATES**

## *Karin Rengefors\**

Department of Biology, Lund University, Lund, Sweden

## **ABSTRACT**

Seasonality of dinoflagellate blooms and dinoflagellate assemblies are not random. Yet, bloom events and the specific appearance of species is difficult to predict and sometimes appears stochastic. Nevertheless, it has been established that both abiotic and biotic factors determine species assemblies, as well as the available species pool. The physical environment, especially nutrients and mixing/light depth largely determines when and where dinoflagellates are present. As a response to the environment, adaptive strategies (C,S,R) have evolved, allowing different species to be favored in different conditions. Based on functional traits, with cell size being a so called master trait, species can be categorized into different life-forms, which in turn can be predicted for different conditions. Among biotic factors, mortality due to natural enemies, including both grazers and parasites are involved in species succession. In addition both competition among dinoflagellates and with other phytoplankton groups can determine which species occur. Finally, life-cycle transitions, especially for cystproducing (meroplanktonic) species can be used to explain fine-scale species replacement. The latter together with species-specific parasite infections provide promise to untangle the processes behind apparently stochastic events.

### **INTRODUCTION**

Years of monitoring dinoflagellates in limnic and marine environments have revealed that there is a pattern to the seasonal occurrence of certain taxa and of bloom events. However, to the frustration of ecologists and managers, the timing of blooms, as well as the specific species that will dominate are not entirely predictable. By identifying controlling factors, relevant traits, and the processes involved, it is possible to develop concepts and build models to better understand and predict dinoflagellate occurrence.

The dinoflagellate species present at any given point of time in a specific aquatic habitat, form a species assembly or community. This assembly of species is the result of various factors and processes including the physical environment, interactions among the biota, inherent traits of the present species, as well as stochastic processes. The change of species assemblies with time throughout a year, and the yearly reoccurrence of specific taxa, is what here is loosely referred to as seasonal succession. Thus, both shifts due to physical alterations as well as true ecological succession due to species replacement (Odum 1969), as determined by community-driven processes, will be included in this chapter.

In the following paragraphs I will discuss the concepts and theory regarding how dinoflagellate species assemblies are formed. This includes the abiotic and biotic factors that determine the community compositions, and the mechanisms involved in species replacement with time. In relation to these, I will describe the different adaptive strategies and the role of functional traits. Finally, I will also include examples of the patterns observed in different habitats.

## **SPECIES ASSEMBLY**

#### **Species Do Not Assemble Randomly**

Species assemblages or communities have been widely studied in terrestrial plants, and much of the conceptual basis can be found in this literature (e.g., Kraft and Ackerly 2014). The two overarching concepts are that of a "species pool," which contains the suite of potential species that can colonize a habitat, and a "filter," the abiotic and biotic barriers to establishment (Figure 1). Overall, species communities are considered to be formed by deterministic processes, such as environmental and biotic filtering, and stochastic processes, such as dispersal, which regulates the species pool (Cornell and Harrison 2014). In contrast to perennial terrestrial plants, phytoplankton have a generation time that is very short and they must remain in suspension. In addition, the pelagic zones of aquatic habitats are highly dynamic, and vary rapidly both spatially and seasonally. As a consequence plankton communities change frequently throughout a year. Since the biotic and abiotic filters change with time, some species will disappear (die or encyst), while other species will be recruited from the species pool (Figure 1). The replacement of species will result in new assemblies, thereby generating a succession pattern.

Thus, to understand dinoflagellate succession, I will first focus on species assembly, regardless of whether differences are due to spatial or temporal factors. The major ecological filters to consider that define when and where dinoflagellates will be present in the water column are the physical environment, resources and resource competition (both abiotic and biotic factors), and natural enemies as well as positive interspecies interactions (biotic interactions).

Figure 1. Schematic view of species assembly and seasonal succession of phytoplankton species. Abiotic and biotic conditions will change with time, and some species will be replaced, resulting in a seasonal succession of different taxa.

#### **The Species Pool**

The species compositions of a specific habitat will be determined by the pool of species available, on which the environmental filtering acts. Dinoflagellate species may originate from three main sources; (1) from holoplanktonic species, i.e., those present in the water column all the time, (2) from meroplanktonic species, which alternate growing in the water column and resting on the sediments, and provide an inoculum when cysts germinate or (3) species derived from stochastic introduction by advection (in marine habitats) (Anderson and Rengefors 2006) or other means of dispersal (marine and inland waters). As for dispersal to freshwater environments, dinoflagellates can potentially disperse by water (e.g., streams and rivers), air, or by animal vectors, likely as resting cysts (Kristiansen 1996, Tesson et al. 2016, 2018). In addition, cysts can be dispersed as resting cysts by ballast water and other human introduction (Hallegraeff and Bolch 1992, Lilly et al. 2002, Bolch and de Salas 2007, Briski et al. 2013).

#### **Functional Traits and Seasonal Succession**

While abiotic and biotic factors can be viewed to shape when and where which type of dinoflagellate communities form, species have responded by evolving a variety of functional traits. Functional traits are features that can be measured and influence processes such as growth and reproduction (Weithoff 2003). The fundamental traits that affect fitness can be categorized as life history-related, behavioral, physiological, and morphological (e.g. Litchman et al. 2006). These in turn have a function related to reproduction, resource acquisition, or predator avoidance (Litchman and Klausmeier 2008). In dinoflagellates, these traits include traits such as motility, resting cysts, mixotrophy, and toxin production, where cell-size is considered a master trait that affects several other traits (Litchman and Klausmeier 2008). For instance, small dinoflagellates tend to have higher growth rates but be more susceptible to grazing. Smayda and Reynolds (2001, 2003), also recognized cell size as the master trait, that could be related to dinoflagellate species assembly. By categorizing dinoflagellates (and other phytoplankton) by functional traits (as in Smayda and Reynolds 2001, 2003), models for assembly, dynamics, and succession can be tested.

## **THE ROLE OF ABIOTIC FACTORS IN SPECIES ASSEMBLY**

#### **Filtering by the Physical Environment**

For planktonic assemblages, Margalef was among the first to argue that it is the physical environment, i.e., advection and turbulence, which controls plankton communities. Water movement, he reasoned, in turn affects light climate, suspension, and nutrient availability. Margalef developed a a model that became known as *Margalef's Mandala* that utilizes habitat mixing and nutrient concentration to explain selection of taxa and their seasonal succession (Figure 2) (Margalef et al. 1978). Based on this model, Margalef predicted round-shaped dinoflagellates in high nutrient – high stability habitats, and flattened dinoflagellate species in oligotrophic high stability habitats.

Figure 2. Margalef's Mandala, modified from Margalef et al. (1978). This conceptual model utilizes habitat mixing and nutrient concentrations to explain the presence of taxa and their seasonal succession. *K* refers to *K*-strategists and *r* to *r*-strategists, the former indicating species that are slow growers but good competitors, and the latter, species with fast growth rates.

Figure 3. *Reynolds´ Intaglio*, redrawn from figure 6 in Smayda & Reynolds (2001), shows species selection based on nutrient accessibility and mixing/light depth. The year-long trace of the selective trajectory imposed by temperate seasonal habitats is added on top of the intaglio. C, S, and R refer to the primary adaptive life-cycle strategies. C-strategist are competitors or opportunistic colonists, S-strategists are nutrient stress-tolerant, while R-strategists are disturbance-tolerant.

However, while Margalef's Mandala predicted the presence of "red" rounded bloomforming dinoflagellates in high-nutrient, low turbulence environments, this was contradicted by many coastal and freshwater harmful algal bloom (HAB) events, appearing in oligotrophic oceans or relative turbulent conditions (Reynolds 1988a, Smayda 2000, Steidinger et al. 1998). Reynolds resolved this by showing that nutrients and turbulence act independently and further developed Margalef's concept into *Reynolds' Intaglio*, with nutrient accessibility on one axes, and light/mixed depth on the other axis (Reynold 1998a) (Figure 3). Later, Smayda and Reynolds (2001) reasoned that the importance of turbulence is the degree of vertical structure it offers, rather than direct effect on nutrients, which allows the flagellated dinoflagellates to utilize their ability to swim to exploit light and nutrients. The current understanding is thus that the abiotic factors that shape dinoflagellate communities are centered around mixing-irradiance-nutrients.

#### **Dinoflagellate Adaptive Strategies in Response to the Physical Environment**

In order to predict and explain which dinoflagellates will occur in different physical environments, a first step is to consider which type of adaptive strategy will be favored in the different environments. Reynold's reasoned that phytoplankton are adapted to survive prolonged periods of suboptimal conditions. He hypothesized that (freshwater) phytoplankton have evolved three types of adaptive strategies based on Grime's C, S, R-strategists (Grime 1979, Reynolds 1988a) (Figure 3). Dinoflagellates exploit all three of these basic adaptive strategies: C-strategist are competitors or opportunistic colonists, S-strategists are nutrient stress-tolerant, while R-strategists are disturbance-tolerant. Within each, both r- (high growth rates) and K-selected (good competitors in crowded niches) species occur (Reynolds 1988a).

### **Life-Forms Based on Functional Traits and the Physical Environment**

Based on Margalef's and Reynold's models, Smayda and Reynolds (2001) could group assemblages of marine dinoflagellates on a continuum from the shore to the open ocean. This continuum involves a gradient of decreasing nutrient levels, reduced mixing, and a deepening euphotic zone, and is based on morphotype and habitat preference (Figure 4). The general trend is for an increase in cell size along this gradient, with classical eridinoid/gymnoid/prorocentroid forms in high nutrient high mixing environment, towards more attenuated and chain-forming, and with the most elongated and elaborated in low nutrient highly stratified water masses (Smayda and Reynolds 2001). Within each sub-group of life-forms (nine types) species thus have a similar size/shape. Also, there is a general decrease of surface area to cell volume in each life-form type with reduced nutrients, mixing, and a deepened euphotic zone. Consequently, depending on the conditions, which can vary both spatially and temporarily, one of the nine different type communities will form.

Figure 4. Smayda & Reynold's life-form types displayed on a schematic matrix of pelagic marine habitats. The marine habitats (numbers 1-10, see below), are defined by nutrient accessibility (y-axis) and turbulence/light climate (x-axis). *I\** refers to the irradiance level that reaches cells, and *Hm* is the depth of the mixed layer. Smayda & Reynold's life-form types (roman numerals I-IX) are represented in colored boxes. Types I-II represent Reynolds' C types, i.e., invasive, small fast growing, requiring high nutrients. Types IV-VI are R-strategists, which are adapted to moderate shear stress and have efficient light harvesting ability. Types VIII-IX are typically large, ornamented species, often with endosymbionts, highly mixotrophic, and with high motility. Type III encompasses mainly C, but also S and R-strategists. The marine pelagic habitats are;  $1 =$  increasingly eutrophic coastal waters,  $2 =$ shallow shelf waters,  $3 =$  frontal zones,  $4 =$  off-shore currents,  $5 =$  major upwelling,  $6 =$  temperate ocean (spring),  $7 =$  temperate ocean (winter),  $8 =$  post upwelling relaxation,  $9 =$  highly stratified tropical ocean. Redrawn and combined from Smayda & Reynolds (2001) Figures 4 & 5.

Smayda and Reynolds (2001, 2003) categorized their different dinoflagellate life-form types into the C, S, R adaptive strategies. In habitats that are relatively shallow and are high nutrient-enriched, C-strategists dominate. These include types I and II, and are invasive, small, fast growing species that thrive in high nutrient conditions. The species assemblages are composed of small to intermediate-sized gymnoid (Type I) and peridinoid (Type II) species (Figure 4). Habitats such as frontal zones, upwelling relaxation, and coastal currents are instead dominated by R-strategists. The latter are dinoflagellates adapted to elevated shear stress (but vulnerable to turbulence) and effective light harvesting. Many are strong vertical migrators and resting cyst-producers. They encompass types IV, V, VI. Type IV include typical frontal zone species that require high nutrients but are adapted to entrainment in coastal currents. Type V are adapted to upwelling habitats and bloom during upwelling relaxation, and have high tolerance to elevated shear. Type VI, in turn, are coastally entrained, and tolerate the shear/stress of coastal currents. Some examples are *Karenia mikimotoi* (IV), *Gymnodinium catenatum* (V), and *Karenia brevis* and *Alexandrium fundyense* (VI). Finally, towards the off-shore, with reduced mixing, low nutrients, and deep euphotic zones, types VII-IX are found, which are classified as S-strategists. Most are large and ornamented, highly motile, have endosymbionts, and are mixotrophic. These includes *Dinophysis* spp. (VII) and tropical flora, e.g., *Ceratium* spp. (VIII) and *Pyrocystis* spp. (IX).

## **DINOFLAGELLATE ASSEMBLY RULES**

The life-form classification model allowed Smayda and Reynolds (2003) to propose five rules of assembly that govern marine dinoflagellate communities. These can be summarized as follows:

- 1. Specific habitat conditions select for specific life-forms, i.e., assemblages are not random, and all species are not capable of sustaining growth everywhere/all the time.
- 2. Life-forms are selected primarily on a physical-chemical habitat template of turbulence-irradiance-nutrients.
- 3. Dinoflagellates employ the C-, S- and R- strategies to exploit abiotic habitat conditions, with r-(fast-growing) and K-selected species (slow-growing, resource tolerant) within each strategy
- 4. Selection follows the pathway: phylogenetic to genera to species. In other words, it may be uncertain whether diatoms or flagellates will bloom, or which flagellates. But if it is dinoflagellates, the candidate genera are known.
- 5. Selection of species within a life-form is stochastic.

Currently, there are few studies that thoroughly test the Rules of Assembly. However, in a study of dinoflagellates in an estuary, Anderson and Rengefors (2006) concluded that the dominant species were those predicted by the Rules of Assembly, but also that the seasonal succession of cyst-forming species was not stochastic, thereby challenging Rule 5.

## **DINOFLAGELLATE SPECIES ASSEMBLY IN FRESHWATER LAKES**

For freshwater dinoflagellates, there is no equivalence to the Smayda and Reynolds model and Assembly rules. However, Reynolds's classification system with C, S, R strategies and more fine-scaled subdivisions can, and has to a limited extent been applied to freshwater dinoflagellate species (Reynolds et al. 2002). Moreover, for temperate lakes, there is a general model for phytoplankton seasonal succession. The PEG (Plankton Ecology Group)-model (Sommer et al. 1986, 2012), predicts a high contribution of dinoflagellates in late summer when the water column is stratified and both silica and orthophosphate has decreased down below levels of detection. The large dinoflagellates that dominate have a low growth rate, but are considered to have a selective advantage due to high grazer resistance and their ability to migrate vertically to retrieve nutrients in the meta/hypolimnion. Built on the PEG model, the Lake Erken model (Blomqvist et al. 1994) describes a similar situation in late winter/early spring, when the column stability is high due to ice-cover in high latitude/altitude lakes, and dinoflagellates can form blooms under ice. Nevertheless, finer-scale models are lacking.

## **BIOLOGICAL FACTORS SHAPING DINOFLAGELLATE COMMUNITIES**

While Reynolds and Smayda proposed that selection of species within a dinoflagellate life-form type is stochastic (see above), there is evidence that deterministic biotic factors play an important role. Although the physical environment explains much of general phytoplankton assembly and succession, biotic interactions perhaps are more important in determining the specific dinoflagellate species replacement. The biotic filtering factors include natural enemies (grazers and parasites), but also resource competition (with other phytoplankton, including other dinoflagellates). These processes, similar to the abiotic filters, have resulted in the evolution of different adaptive traits.

## **COMPETITION**

#### **Resource Competition**

Resource competition occurs when reproduction is limited by consumption of a commonly needed resource (Tilman 1981). For dinoflagellates (and other phytoplankton) these include light, inorganic carbon, phosphorus, nitrogen, silica (not all), trace elements, and vitamins. Dinoflagellates are generally considered poor competitors for phosphorus and have low maximum uptake ( $V_{\text{max}}$ ) rates and high half-saturation ( $K_s$ ) constants. For example, the freshwater *Peridinium* sp. had a  $V_{\text{max}}$  of 0.11 compared to green algae that range from 5-25 in  $V_{\text{max}}$ , and a  $K_s$  of 6.3 compared to cyanobacteria that have  $K_s$  of 0.2-0.3 µmol phosphorus  $L^{-1}$  at half  $V_{\text{max}}$  (Reynolds 1988a). Likewise, marine dinoflagellates also generally have high  $K_s$ , ranging from 0.01 to 2.7 (Cembella et al. 1984). Interestingly, in a natural freshwater community bioassay, the dinoflagellates were not nutrient-resource limited in 54% of the cases, or else only slightly limited. When limited, *Ceratium hirudninella* was usually nitrogen limited, while *Peridinium bipes*, *P. cinctum*, *P. umbonatum*, and

*P. inconcpicuum* were more often P-limited (Sommer 1988). These findings illustrate that dinoflagellates have other nutrient acquisition strategies.

Because they are poor competitors for nutrient assimilation, dinoflagellates have evolved a number of adaptations to compete. These include luxury storage (polyphosphates) (Cembella et al. 1984), use of alkaline phosphatase (AP) to utilize organically bound phosphorus (Cembella et al. 1984, Dyhrman and Palenik 1999, González-Gil et al. 1998), vertical migration to access nutrients in the meta- and hypolimnion (Heaney and Eppley 1981, James et al. 1992), and mixotrophy (Stoecker 1999). Together, these adaptations allow dinoflagellates to flourish when nutrient conditions are limiting phytoplankton growth.

#### **Diatom-Dinoflagellate Competition**

Because of their generally low competiveness for nutrients, dinoflagellates usually do not dominate during seasons characterized by relatively high nutrient conditions, often coupled to high turbulence (see figure 4 for marine species). In temperate lakes, they tend to dominate during periods of high water column stability (under-ice later winter or summer stratification) when nutrients are low in the epilimnion but available at depth (e.g. Sommer et al. 1986, Rengefors 1998, Heaney et al. 1988, Kremp et al. 2005). On the other hand, diatoms dominate during spring and fall turnover, when turbulence is and nutrients are high (Sommer et al. 1986, Blomqvist et al. 1994). In tropical lakes, dinoflagellates are often abundant during the dry season, when turbulence is low (Meyer et al. 1997).

In the field it is, however, difficult to tease apart column stability from nutrients. In the Baltic Sea for instance, recent evidence indicates a trend of an increased proportion of dinoflagellates relative to diatoms (Klais et al. 2011), which was originally suggested to be coupled to a reduction of silica. Nevertheless, in a mesocosm experiments, changed nutrient ratios of N, P, and Si did not lead to dinoflagellate dominance (Kremp et al. 2008). Instead, the dinoflagellate dominance depended mainly on the size of the inoculum (from cysts), suggesting that bloom initiation strategies and initial conditions were more important (Tesson et al. 2018, Klais et al. 2011, Kremp et al. 2008).

In another study, observations together with numerical modelling indicated that phosphate, but not light, temperature, silicate or nitrate, is critical in seasonal succession from diatoms to dinoflagellates in the China Sea (Zhou et al. 2017). While not important for species replacement, nitrate was implicated as important in determining the intensity and duration of the dinoflagellate bloom.

Mutshinda et al. (2016) analyzed a set of dinoflagellate and diatom species during seven consecutive years and found repeated seasonal patterns, where biomass was mainly explained by temperature and irradiance. While the diatoms had a higher growth rate, the dinoflagellates responded more to increased temperature, and dominated during warmer stratified conditions (Mutshinda et al. 2016). However, the sequence of particular species was not predictable, suggesting again that stochastic variation governs species dynamics.

#### **Interference Competition – Alleopathy**

While dinoflagellates can compete by exploitative competition, as described above, they can also compete by interference competition. The latter refers to when the competitor growth is inhibited, for instance by chemical interference, aka allelopathy (Lampert and Sommer 1997). It is likely that allelopathy may also contribute to seasonal succession, by reducing competitor density, and increasing nutrient availability. Keating (1977,1978) was the first to provide some evidence that algal succession may be connected to allelopathic interactions. Many dinoflagellates have been shown to produce allelochemicals that suppress other competitor species, including members of diatoms, dinoflagellates, and cyanobacteria (see reviews by Gross 2003, Legrand et al. 2003). For example, *Karenia brevis*, produces allelopathic compounds that inhib many co-occurring species (Prince et al. 2008), and which could help explain its dominance. However, microcosm studies show that the allelopathic effect on co-occurring natural assemblies is species-specific and dependent on conditions of cells (Poulson et al. 2010). While recent modelling efforts demonstrate that certain phytoplankton communities are susceptible to allelochemicals, and that alleopathy can help explain species replacement (Muhl et al. 2018), studies from the natural communities are still largely lacking.

#### **Dinoflagellate – Cyanobacteria Competition in Lakes**

In temperate lake ecosystems, dinoflagellates and cyanobacteria often occupy the same niche during late summer stratification (Sommer et al. 1986). For instance, in both Rostherne Mere, England, and Lake Erken, Sweden, the late summer bloom altered between dinoflagellate (*Ceratium* sp.) and cyanobacterial dominance (Blomqvist et al. 1994, Reynolds and Bellinger 1992). Also in the oligotrophic Lake Njupfatet, Sweden, dominance switched between the cyanobacterium *Merismopedia tenuissima* and the dinoflagellate *Peridinium inconspicuum* (Blomqvist et al. 1994). Evidence from mesocosm experiments show that this competition is driven by nutrients, with cyanobacteria being favored by ammonium-nitrogen and dinoflagellates by nitrate-nitrogen (Blomqvist et al. 1994). Similarly, in subtropical Lake Kinneret (Sea of Galilee), Israel, there is a strong negative correlation between the bloomforming *Peridinium gatunense* and the cyanobacterium *Microcystis* sp. (Vardi et al. 2002). However, here experimental studies show that this interaction is likely due to densitydependent allelochemical cross-talk, where each species' allelochemicals can inhibit or lyze the other (Susenik et al. 2002, Vardi et al. 2002). To summarize, the evidence to date suggests that both resource availability and intereference competition plays a role in the dynamics of dinoflagellate-cyanobacteria competition.

## **NATURAL ENEMIES**

#### **Grazing by Metazoan Zooplankton**

Another biotic interaction that has a very strong effect on phytoplankton is grazing by zooplankton, both as a selective force leading to adaptations to minimize losses due to grazing, and by affecting seasonal succession (Sommer et al. 1986). In freshwater, the PEGmodel (Sommer et al. 1986, 2012) predicts and explains the dominance of large dinoflagellates (and other canopy species) as a response to high water-column stability, low nutrient conditions, and high predation due to metazoans (mostly calanoid copepods). Modelling by Scheffer et al. (1997) was able to explain seasonal patterns in phytoplankton biomass using predator-prey models. Klausmeier and Litchman (2012) were subsequently able to model species replacement of an edible species leading to a grazer-induced clearwater phase, followed by the dominance of an inedible species. They also found that nutrients and the length of the season could influence the trajectories, and that a bimodal seasonality of inedible species before and after the grazer peak, could be modelled. These models suggest that grazing can have a significant effect on dinoflagellate succession, potentially including species-specific dynamics.

Predation occurs to some extent all year round and in all habitats, but the composition of predators varies, as do the numbers. For instance, zooplankton abundance is very low in lakes under the ice during winter, a time period when round peridinid dinoflagellates flourish (Rengefors 1998). Rengefors et al. (1998) showed that *Peridinium* (now *Apocalathium*) *aciculiferum* cyst germination was reduced by zooplankton exudates, and suggested that growth during winter was a temporal escape from predation. In a marine estuary, the decline of *Alexandrium tamarense*, *Gonyaulax verior*, and *Scrippsiella* spp due to cyst formation, occurred when nutrients and temperature were conducive of growth, but grazers increased (Anderson and Rengefors 2006) . Other correlative evidence shows high dinoflagellate biomass when calanoid population numbers are low, and vice-versa (e.g. Calic et al. 2013). In Vancouver Lake, the cyploid copepod *Diacyclops thomasi* grazed selectively on dinoflagellates, reducing the standing stock by 30% per day (Rollwagen-Bollens et al. 2013), and likely contribute to take-over by other phytoplankton.

#### **Predation by Dinoflagellates and Mixotrophy**

A large percentage of dinoflagellates have been shown to be mixotrophic, and to a lesser or larger extent photoautrophic (see Chapter 7, Hansen & Tillmann). Given that constitutive and non-constitutive mixotrophic dinoflagellates (see chapter 7) can have the role as grazers on autotrophic species, there is also a complex correlation and interrelationship between dinoflagellates taxa, which affects seasonal succession. Hansen (1991) found that large heterotrophic dinoflagellates coincided with, and fed on large dinoflagellate species in late summer (August/September). The small heterotrophs, in contrast, dominated in the summer (May to July) when nanoplankton were most abundant. Nevertheless, it is difficult to unravel whether the system is top-down or bottom-up governed.

In a modelling study, Berge et al. (2017) proposed that there is a seasonal aspect to the degree of mixotrophy in dinoflagellates. In the spring, mixotrophic populations are more photoautorophic, i.e., invest in photosynthesis and resource uptake, while in the summer populations have a higher investment in phagotrophy (Berge et al. 2017). Based on modelling and experimental studies with *Karlodinium armiger* and *K. veneficum*, Berge et al. (2017) constructed a seasonal cycle with high nutrients in the spring and recycled nutrients in the summer. *K. armiger* which has invested mostly in phagotrophy was favored in the summer,

when optimal investment in photosynthesis and nutrient uptake was low, while *K. veneficum* (high investment in inorganic resource uptake) was favored in the spring and end of summer.

#### **Parasites and Dinoflagellate Dynamics**

Microparasites, including viruses, bacteria, fungi, and protists, have long been known to infect dinoflagellates. However, their importance in dinoflagellate population dynamics and succession is still not fully understood. Because of the species specific nature of many microparasites, this may explain some of the variation which has been attributed to stochasticity.

Zoosportic parasitoids, are aquatic parasites which produce numerous asexual spores, kill their hosts and have a significant top down effect (Jephcott et al. 2016). These include several protist groups, and but especially fungi and alveolates are parasitic on dinoflagellates. Fungal parasites (chytrids) were described in freshwater dinoflagellates early on (Canter 1968), and were shown to be involved in the dynamics of *Ceratium* spp. (Canter and Heaney 1984, Heaney et al. 1988, Sommer et al. 1984) . A long-term data set shows that periods of high infections were associated with marked decreases in *Ceratium* populations, and in addition affected next year's inoculum as they infected resting cysts (Heaney et al. 1988, Sommer et al. 1984). Thus, if losses to parasites are large, this will help end the boom of the infected species, while stimulating the replacement of another. In marine dinoflagellates, a chytrid parasite (*Dinomyces*) was isolated and described in *Alexandrium minutum*, and was shown to preferentially infect *Alexandrium* species, but also strains of *Heterocapsa*, *Ostreopsis*, and *Scrippsiella* (Lepelletier et al. 2014). While mortality was high in some strains, their role in the population dynamics of these species remain to be explored.

In marine dinoflagellates, the taxa *Parvilucifera* (Perkinsea, Alveolata) and *Amoebophrya* (Syndiniales, Alveolata) are the most dominant and well studies parasitoids (Jephcott et al. 2016). Because each infection generates hundreds of spores, these parasitoids have the potential to control the sizes of host populations, and thereby affect seasonal succession. In a study of the dinoflagellate succession in Chesapeake Bay, USA, Coats et al. (1996) showed that the species *Gymnodinium sanguineum*, *Gyrodinium uncatenum*, and *Scrippsiella* sp. showed temporal differences in peaks during the summer season. Infection of the parasite *Amoebophrya ceratii* in these species, showed similar fluctuations, and high infection levels were often followed by a population decline in the host. Consequently, the authors postulated that the parasites were the main drivers of species succession. Similarly, Chambouvet et al. (2008) investigated the seasonal succession of dinoflagellates in an estuary in Brittany, France. Here *Heterocapsa rotundata* typically blooms at the end of May, and is followed by *Scippsiella trochoidea*, *Alexandrium minutum*, and *H. triquetra*. While population dynamics were not correlated to physical-chemical parameters, each species was infected by a speciesspecific parasitoid (Syndiniales), and the decline of each population preceded by high infection rates and subsequently high number of parasite spores. Montagnes et al. (2008) next constructed a mathematical model that could predict the decline of dinoflagellate populations due to microparasites. Likewise, *Parvilucifera* parasitoids appear to be involved in bloom termination of *Alexandrium minutum*, as they regularly peaked in abundance after the dinoflagellate bloom peak, and were shown to contribute with up to 18% of the mortality (Alacid et al. 2017).

Many bacteria have been shown to be algicidal to a number of dinoflagellates but their role in natural populations are still unclear (reviewed in Meyer et al. 2017). For example, it has been shown that associated alpha, beta and Gammaproteobacteria can inhibit growth the dinoflagellate *A. tamarense* (Hu et al. 2015). However, the importance and role of bacteria in seasonal succession has not been established.

Lytic viruses have been found to control phytoplankton either by causing population decline or by preventing populations from reaching high densities (Brussard 2004). It is also known that algal viruses are very host specific (Short 2012). As such, viral-mediated mortality can affect both interspecific and intraspecific phytoplankton succession. One example of viruses that are thought to be able to control the biomass of dinoflagellate populations, is the RNA-virus HcRNAV in *Heterocapsa ciruclarisquama* (Nakayama and Hamaguchi 2016, Nagasaki et al. 2004, Tarutani et al. 2001).

## **THE ROLE OF LIFE-CYCLE TRANSITIONS IN SEASONAL SUCCESSION**

While most functional traits have been treated above in relation to environmental factors determining species assembly, a remaining trait, unrelated to cell size, but closely coupled to seasonal succession, is life-history traits.

The bloom dynamics of many dinoflagellates are regulated by the transition between resting cysts and motile planktonic cells (Anderson et al. 1983, Rengefors 1998, Bravo et al. 2010, Krempand Heiskanen 1999, Kremp and Anderson 2000). In other words, life-cycle events determine the seasonal occurrence of cyst-forming (meroplanktonic) dinoflagellates. The two main events framing the seasonal occurrence of meroplanktonic species are cyst germination (excystment), providing the population inoculum, and cyst formation (encystment) determine the end of the planktonic phase (Anderson et al. 1983). Early studies addressing the role of life cycle transitions in bloom initiation and termination were on *Ceratium hirundiella* in freshwater (Chapman et al. 1982, Heaney et al. 1983) and *Alexandrium tamarense* (Anderson et al. 1983). The timing of these events have been shown to depend on a combination of inherent traits of individual species, and external environmental cues (Anderson 1980, Binder and Anderson 1987, Rengefors and Anderson 1998). Reliance on these cues is necessary to avoid periods that are generally unfavorable to growth.

Studies on the role of life-history stages on succession are mostly focused on single species, although there are a few examples of multiple species, addressing species replacement. For example, the summer bloom sequence of six taxa of cyst-producing dinoflagellates in Perch Pond, USA, could be explained by the length of the cyst dormancy period and the temperature window in which they could germinate (Anderson and Rengefors 2006) (Figure 5). Similarly, the timing of excystment was described for the brackish water species *Scrippsiella hangoei* (now *Biecheleria baltica* and *Apocalathium malmogiense*), which germinate and grow during the winter. In freshwater, the appearance of *Ceratium hirundinella* in early summer and the growth of *Apocalathium aciculiferum* (previously *Peridinium aciculiferum*) during winter was explained by cyst dormancy, together with an endogenous clock timing excystment together with a germination temperature window (Rengefors and Anderson 1998).

Figure 5. Seasonal succession of six cyst-forming dinoflagellate species in Perch Pond, USA. Note the sequential biomass peaks (n.b. species with \* are plotted against the Y2-axis). The seasonal appearance of each species could be explained by dormancy period, temperature window for germination, and threshold for germination. Data replotted from Anderson & Rengefors (2006).

Figure 6. Illustration of data from a dinoflagellate bloom and a model of the same species, with and without the inclusion of life-cycle events. Panel (a) shows cell biomass concentrations in moles nitrogen (converted from cell numbers) from field observations of the brackish-water dinoflagellate *Bicheleria baltica*. The different colored lines represent vegetative cells (black), gametes (blue), and planozygotes (red). Panel (b) displays model results of the same system showing dinoflagellate cells in the water with and without including life-history events. These results illustrate that the timing, magnitude, and duration of a bloom is affected by life-cycle events, and the that by including the lifecycle the model is much improved. Re-printed from Warns et al. 2013, Figure 8a and 7a, with permission from the authors.

The end of the bloom, on the other hand, is usually controlled by cyst formation in these species. Encystment has been shown to be important in bloom termination in a number of marine dinoflagellate species (e.g. Anderson et al. 1984, Kremp and Heiskanen 1999, Garces et al. 2004, Wang et al. 2007). In laboratory experiments, encystment can usually be induced by nutrient stress (von Stosch 1973, Anderson and Lindquist 1985, Figueroa et al. 2005), while lower nutrient conditions are typically not associated with cyst formation in the field, neither in marine or freshwater habitats (Anderson et al. 1983, Kremp and Heiskanen 1999, Rengefors 1998). Instead, Kremp et al. (2009) provided data that indicated that dinoflagellates utilize reliable token cues (in this case temperature), even if the ultimate causes may be nutrient depletion.

Some efforts have been made at modelling population dynamics based on life-cycle transitions. For example, Yamamoto et al. (2002) used both encystment and excystment to model the population dynamics of *Alexandrium tamarense* in Japan. Similarly, based on cyst distribution and germination, McGillicuddy and colleagues have developed a model explaining the temporal (and spatial) distribution pattern of *Alexandrium fundyense* (Stock et al. 2005, McGillicuddy et al. 2005). Warns et al. (2013) modeled the seasonality of the coldwater brackish species *Biecheleria baltica* based on the whole life cycle (germination, encystment, growth rates) and temperature and nitrogen concentrations, resulting in seasonal patterns similar to those observed in the field. When the removed life cycle transitions from the model, they could demonstrate that the life cycle affects the timing, magnitude and duration of the bloom (Figure 6). On the other hand, Estrada et al. (2010) found in a simulation study that excystment rates were only important in the beginning of the bloom, but failed to affect final bloom magnitude. Also, fieldwork on the lake-dwelling *Ceratium hirundinella*, indicated that the size of the germinating inoculum did not correlate with the final maximum bloom densities (Rengefors 1998). Nevertheless, overall it can be concluded that species with resting cysts are more likely to re-occur at specific sites, less prone to stochastic processes compared to non-cyst producers.

## **CONCLUSION**

General models for dinoflagellate succession are largely lacking, but the building blocks are there, based on functional traits, knowledge of seasonal changes in the physical environment, species pools, and the factors determining assembly. From these building blocks, and models produced so far, it should be possible to make better predictions in other systems. Although conclusions to date indicate that the succession patterns of specific species are difficult to predict, and that stochastic events rule these, there is some promise of improving the resolution. In my opinion, this lies in improved incorporation of mainly the biological factors in conceptual and mathematical models. These include species-specific lifecycle transitions, better understanding of species-specific mortality due to natural enemies, and allelopathic interactions. Moreover, by utilization of molecular tools it should be easier to better establish the potential species pool in an area.

## **ABSTRACT**

In this chapter, following a brief historical review of dinoflagellate cultures, methods of culturing athecate, thecate, toxic dinoflagellates and composition of 22 media are presented. About a total of 100 species of photosynthetic, heterotrophic, mixotrophic and symbiotic dinoflagellates are amenable for culturing. Division rates of natural assemblages of dinoflagellates, and as well as those cultured reported from various publications are summarized. In general, dinoflagellates have lower division rates compared to several other microalgae. The impact of salinity, temperature, and light, nutrients such as phosphate, nitrate, ammonia and iron on division rates is discussed. Mixotrophy appears to be common amongst dinoflagellates and resulted in higher growth rates than cells grown as autotrophs. The lower division rates in dinoflagellates are possibly due to channelling of much energy into the production of cellulose skeleton and toxins; this needs to be substantiated with detailed observations on the Carbon: Nitrogen dynamics in a variety of dinoflagellate cultures.

**Keywords:** growth, media, nutrients, divison rates

## **INTRODUCTION**

Culturing marine microalgae dates to 1893 [1]. Since culturing the photosynthetic diatom *Thalassiosira gravid* in artificial seawater as a feed for animal life [2], interest has grown in culturing microalgae in nutrient media as feed for invertebrates and commercially important

organisms.The pioneering contributions of Pringsheim [3] in establishing pure cultures of algae and usage of soil extract for enrichment, Venkataraman [4] on culturing and cultivation of tropical algae, Provosoli [5] in developing artificial culture media and treatment with antibiotics to obtain bacteria free cultures, Tamiya [6] in developing synchronous cultures for investigating individual life cycles and Burlew [7] in developing pilot plant cultures gave rise to several interesting culture studies. Studies of Stein [8], Fogg [9] and Richmond and Hu [10] provide an excellent introduction to algal culturing, metabolism and growth. Results obtained on algal cultures established from various geographical regions have been utilized for various purposes including scientific enquiry, to advance our knowledge on their structure and physiological functioning in relation to their environmental conditions, wastewater treatment, enhancing primary production in oligotrophic ocean expanses by ocean fertilization with nitrogen or iron, providing microalgal feed for animal husbandry, specifically in aquaculture, and in discovering natural bioactive compounds and nutraceuticals that will advance microalgal biotechnology and biomedicine [11-13]. This increase in interest in culturing microalgae has reflected in worldwide institutionalized culture centers (Table 1). These centers are engaged in the collection of microalgae, isolation and maintenance, characterization of algal strains from all over the world, from polar to tropical waters, marine, freshwater, brackish, and hypersaline environments and supply of strains for scientific research, teaching, and biotechnology development.

**Table 1. Microalgal culture collection centers**

This paper summarizes information on the sources of athecate, thecate, toxic dinoflagellate cultures, culturing methods and division rates of natural assemblages of dinoflagellates, as well as those of cultured photosynthetic, heterotrophic, mixotrophic and symbiotic dinoflagellates. Further, a brief discussion on the factors regulating their growth is provided. Dinoflagellates have lower division rates compared to other microalgae such as diatoms and flagellates and studies on the carbon: nitrogen dynamics in a variety of dinoflagellate cultures would be instructive.

The Centre of Excellence for Dinophyte Taxonomy (CEDIT), part of the herbarium Senckenbergianum of the Senckenberg Research Institute and Natural History Museum, located in Wilhelmshaven (curator Dr. Mona Hoppenrath - mhoppenrath@senckenberg.de) is a source of information on dinoflagellates but does not handle live cultures. It is an excellent source for taxonomic knowledge of 2500 living dinoflagellate species and for holotypes, epitypes and isotypes. It maintains checklists, descriptions of taxa, type collection reference material, literature, Max Taylor library, identification keys, photocollections and video clips.

## **BRIEF HISTORY OF DINOFLAGELLATE CULTURES**

There are 2377 dinoflagellate species belonging to 259 genera [14] with diverse nutritional requirements. A large number of species are autotrophic (photosynthetic) while a few are heterotrophic (holozoic) and symbiotic species. Küster [15] made the first successful attempts to grow the colorless heterotrophic dinoflagellate *Gyrodinium fucorum* isolated from rotting *Fucus* in simple artificial seawater but could not obtain pure cultures. He concluded *G. fucorum* was osmoheterotrophic and assimilated carbon through its cell membrane. *G. fucorum,* now revised as *Crypthecodinium cohnii* (Seligo) [16], is widely cultured for commercial production of polyunsaturated fatty acids. *Gloeodinium montanum* an autotrophic freshwater dinoflagellate was the first to be cultured [17]. For culturing marine autotrophic dinoflagellates i.e., *Prorocentrum micans*, *P. gracile*, *Exuviella* sp. *Gonyaulax* species, *Ceratium* sp., *Dinophysis,* Barker [18] utilized enriched aged seawater and, to culture the holozoic *Oxyrrhis marina,* used the diatom *Nitzschia* sp. as feed and studied their physiology. A detailed historical review of the importance of microalgae and techniques in algal culturing utilized in the 19th and  $20<sup>th</sup>$  centuries is given by Anderson [12]. Today there are 97 species of dinoflagellates cultured in about 22 media (Table 2) and most of the efforts are on toxigenic harmful dinoflagellates.

# **PROTOCOL FOR CULTURES**

For culturing dinoflagellates, in general, the protocol detailed for microalgal culture can be used. Excellent step-by-step guides describing in detail the sterilization techniques, cleaning the culture ware, preparation of the nutrient media, inoculations and precautions for maintenance of culture facilities are provided [12, 19-24]. Also, Lavens and Sorgeloos [25] discussed culture production schemes for batch cultures, carboy cultures, mass production of micro-algae in 20,000 liter tanks and 150 liter cylinders and 40 liter continuous cultures techniques. These are not repeated here but based on our experience a few helpful pointers for culturing dinoflagellates are given below.

Figure 1. Serial dilution method to isolate single cells for cultures.

Figure 2. Scaling up stock cultures to 200 liter cultures.

Marine dinoflagellate cultures are grown in suitably enriched seawater. To avoid batch to batch variations in the composition of sea water, it is best to obtain offshore seawater in bulk and age it in plastic barrels. Aged seawater filtered through Glass fibre filter (GF/F) and steam sterilized at 125ºC for 20 minutes is enriched with nutrients. Nutrients are refrigerated individually in Teflon bottles and added aseptically.

To establish cultures from cysts of *Gonyaulax tamarensis*, Anderson et al. [26] used extensive precautions to avoid precipitation, adsorption, desorption or chemical contamination. All plastic and Pyrex glassware was washed with Micro detergent, rinsed several times, soaked in 2N HCl, rinsed again with deionized distilled, UV –irradiated water. Glassware was coated with Surfasil (Pierce Chemical Co) and recoated after 3 or 4 washings.

Local seawater was filtered through Gf/f filters, and was autoclaved in Teflon bottles. After depressurization, the bottles were recapped and cooled immediately and cooled for more than 24 hours. Nutrients, except the iron/chelator kept in separate autoclaved Teflon, were used aseptically for enrichment. Pyrex tubes (25x 150 mm), with the 25ml f/2-Si medium, were used. Following greater than 30 days of growth, vegetative cells were destroyed by sonication of the culture (Branson S-75) for 1min at a 1.4 setting and the cysts were counted. In another experiment [27] such cysts were incubated in medium without silicate, phosphate, nitrate and vitamins with chelator ranging from 0 to  $10^{-4.3}$  M EDTA.

Most investigators used f/2 medium without silicate enrichment. Anderson et al. [26] using f/2 –Si medium reported the lowest cyst yield in *Gonyaulax tamarensis*; the yield dropped to 41% of the control when the inocula and media were prepared in glass containers. Because of suspected leaching of silica from borosilicate culture ware, and because of no apparent requirement of silica by dinoflagellates, the investigators used inert tissue culture ware (Table 3) i.e., polyethylene [28], polycarbonate bottles [29-31], microplate wells [32] and polystyrene tissue culture ware [33]. Guillard and Keller [19] reported more reliable survival of *Ceratium tripos* cultures over a number of years in f/2 media in polycarbonate rather than in glass. For culturing dinoflagellates, the LATZ Laboratory (Scripps Institution of Oceanography) uses sterilized glassware if autoclave is available, otherwise uses disposable tissue culture flasks and Guillard's (f/2) marine medium with macro- and micronutrients, but without silicate.

Enrichment	Range $\mu$ M
Phosphorus	5.74-28.70 x10 <sup>6</sup>
Nitrogen	$1 \times 10^2 - 2.47 \times 10^3$
Silica	$3.52 \times 10^2 - 5.04 \times 10^2$
Iron	$4.0 \times 10^{-1}$ -11.70
Copper	$1.00 \times 10^{-2} - 1.00 \times 10^{4}$
Cobalt	$9.24 \times 10^{-7} - 5.00 \times 10^{-1}$
Zinc	$7.97 \times 10^{-2} - 8 \times 10^{4}$
Manganese	$5 \times 10^{-2} - 9.10 \times 10^{5}$
Vitamin $B_{12}$	$9.22 \times 10^{-5} - 3.69 \times 10^{-4}$
Thiamine hydrochloride	49.42 x $10^{-1}$ -30.0
Thiamine	$6.30 \times 10^{-1} - 3.00$
<b>Biotin</b>	$1.0 \times 10^{-3} - 1.78 \times 10^{-2}$

**Table 3. Range of nutrient enrichment in media utilized for culturing dinoflagellates**

Composition of various media is given in Table 2. Selected major nutrient enrichments in 22 media (Table 3) show a wide range for phosphate and nitrogen. Trace elements Fe, Co, Cu and Zn varied over several orders of magnitude thus suggesting certain dinoflagellates grow in a wide range of nutrients.

Although several investigators used media without silicate [24], a few others used media enriched with silica: for example f [35], f/2 [36], Aquil [37], ESAW [38], ASP [39] and NH [19, 40] and optimal medium [41] (Table 2). Loeblich [42] used GPM medium enriched with 15 ml  $1<sup>-1</sup>$  soil extract which has an unknown composition but fortified with 4.0 g NaNO<sub>3</sub> and 0.6 g Na2HPO<sup>4</sup> 12H2O per liter.

#### **Categories of Cultures**

Cultures are grown either indoor under controlled conditions of light and temperature and outdoors under ambient light and temperatures. Based on their sterility they are axenic (sterile/xenic) and non-axenic cultures. It is best that cells in the exponential growth phase are used as inocula and the inoculum is 2-10% of the final volume. Sub-culturing is done once a week and parent cultures are retained for 30 days as a fallback. Cotton gauze plugs are used as stoppers.

1. Sterile medium reservoir 2. Medium pump 3, Culture vessel 4. Temperature regulated bath

5. Light source 6. Magnetic stirrer 7. Collecting receptacle 8. Measuring cylinder

9. Inflow of fresh sterile air 10. Water bath 11. Air flow meter 12. Cotton filter 13. Regulatory valve

Figure 3. Continuous culture set up.

There are 3 types of cultures 1. Batch cultures, 2. Continuous cultures 3. Semi-continuous cultures.

- 1) In batch culture, cells are inoculated and as the culture grows the nutrients in the medium change. Considered as the most reliable method, cells go through lag, accelerated, exponential, retardation, stationary and decline phases. Cells use up the nutrients and produce their own waste products. Batch cultures can be scaled from test tubes to 250 ml- 500ml-1000ml flasks to 5 and 20 liter carboys, 160 liter indoor cylinders to 5000 liter to 25,000 liter outdoor tanks.
- 2) In continuous culturing, the cells are kept growing indefinitely by supplying fresh nutrient medium and automatically an equal volume of the culture is removed. The steady supply of nutrients maintains the cells at their maximum growth rate. Two categories of continuous cultures can be recognized a) Turbidostat and b) Chemostat. .In the former, fresh medium is added at a predetermined turbidity point of the culture determined by the extinction of light passing through the culture. In the chemostat, fresh medium is added to the culture at a steady predetermined rate. The level of biomass is adjusted by an inflow of fresh sterile medium; the growth rate is equal to the dilution rate. When the algal cell density of the culture is held constant the culture is designated as a steady state culture.
- 3) In semi-continuous cultures, a predetermined volume of fresh nutrient flows into the culture vessel and an equal volume of culture flows out.

### **Photobioreactors**

When massive algal biomass is required for biotechnological production of high-value products, photobioreactors are utilized. There are excellent reviews on the current status, recent developments and detail designs of photobioreactors for different microalgae, both labscale and upscale [43, 44]. However, not many dinoflagellates were cultured in photobioreactors. For culturing benthic dinoflagellates, *Amphidinium carterae* (JHWAC), *Prorocentrum rhathymum* (JHWPMX1) and *Symbiodinium* sp. (JHLSD1) Shah et al. [45] used a photobioreactor. It had two rows of 6 columns each, placed adjacently. The towers were 35cm diameter, 160 cm high (#1 to 6) and 145 cm high (#7-12) and were connected at the bottom for circulation of the medium through aeration. Cool-white fluorescent lights (38W) provided 40-50 µmol photons  $m^{-2}$  sec<sup>-1</sup> with a 12:12 h light/dark (L/D) cycle. The water used for culturing was 30PSU, UV treated, heat sterilized at  $110^{\circ}$ C, cooled and filtered through 0.2 μm. For 20 L carboy cultures, water was chemically sterilized with sodium hypochlorite solution containing 9%active chlorine for 30min followed by neutralization with sodium thiosulphate  $(0.12g \mid l^{-1})$  seawater). Exponentially growing stock cultures were incrementally scaled up from 30ml -300ml-1L-3Land 20L. Each tower contained 60L of the medium. Two media, f/2 and IMK, were used as needed. Twenty liters of exponentially growing culture was introduced in tower 1 and filtered air (0.2 μm) was used for aeration. Cultures were grown at  $20 \pm 1^{\circ}$ C.

*Protoceratium reticulatum* cultures raised in a 15L semicontinuous perfusion photobioreactor were more productive with 5228 cell mL−1 day−1 similar to those obtained in a 2L stirred tank [41]. For *Karlodinium veneficum* mass culture two types of photobioreactors

with a working volume of 80 liters were used [46]: a bubble column and a rectangular flatpanel device. The bubble column consisted of clear plastic (polymethyl methacrylate) cylindrical tube; cell production was more in a semi continuous operation in a bubble column photobioreactor [47].

## **Turbulence: Photobioreactors**

Cultures raised in Photobioreactors experience turbulence which inhibits growth. Sullivan and Swift [48] investigated the impact of high turbulence ( $\epsilon$ ~10<sup>-4</sup> m<sup>2</sup>.S<sup>-3</sup>), low turbulence  $(E~10^{-8} \text{ m}^2 \text{.} \text{S}^{-3})$ , and unstirred cultures on cell growth. Of the 10 species tested, in *Lingulodinium polyedrum, Gymnodinium catenatum* and *Alexandrium fundyense* division rates increased in high turbulence while *Alexandrium tamarense, Pyrocystis fusiformis, Alexandrium catenella* and *Gymnodinium* species were unaffected. Shaking of cultures affected growth rate in *Amphidinium klebsii*, lowered the division rate in *Scripsiella trochoidea* from 0.53 to 0.35 div d-1 and even killed *Gyrodinium aureolum* cells [49]. Growth of dinoflagellates is inhibited by shear forces and turbulence shear rate of about 0.3 s<sup>-1</sup> for 24h resulted in an elevation in the levels of chlorophyll *a*, peridinin and dinoxanthin in *Protoceratium reticulatum* [50].

Though the response of dinoflagellates in photo bioreactors is relatively unknown, a few advancements have been made. Gallardo-Rodríguez et al. [51] evaluated growth kinetics, micronutrient requirements and toxin production in two strains of *Protoceratium reticulatum;*  in low-shear stirred tank photobioreactors quite different quantities (ranging from 0 to 34 pg cell-1 ) of yessotoxins (YTX) are produced. Results of Garcia-Camacho et al. [23, 24] with a semi-continuous perfusion culture of *Protoceratium reticulatum* in a 15 L photo bioreactor yielded 5228 cell mL<sup>-1</sup> day<sup>-1</sup>, or about 3.7 times more than the best attainable cell density in static flask cultures; however, the productivity of yessotoxin was 9.16 μg  $L^{-1}$  day<sup>-1</sup> comparable to that obtained in a 2L stirred tank. López-Rosales et al. [52] designed and utilized a bubble column photobioreactor to culture the shear-sensitive marine dinoflagellate *Karlodinium veneficum*. To prevent the damage of the cells, López-Rosales et al. [46] designed a photobioreactor (80L) with a transparent methyl methacrylate tube (internal diameter 0.242m, with a gas-free liquid height of 1.85 m). Red, green, blue and warm white light emission-diodes provided light spectrally similar to sunlight in the photosynthetically active (PAR) range. Nearly  $12x \ 10^5$  cells ml<sup>-1</sup>, similar to densities in laboratory cultures, were sustained. Further, López-Rosales et al. [46] modelled the impact of turbulence caused by the nozzle sparger diameter, air flow. Because of its potential to yield several high-value metabolites, *Amphidinium carterae* was cultured in a 5cm light path, a 320 L photobioreactor [53] and obtained a growth rate (0.29 d<sup>-1</sup>), and dry biomass productivity (78 mg L<sup>-1</sup> d<sup>-1</sup>). An indoor LED-lighted raceway photobioreactor was used for long-term culture of the marine dinoflagellate microalga *Amphidinium carterae for* production of carotenoids and fatty acids [54]. Biomass productivity was 2.5 g m−2 day−1 and carotenoid peridinin was 19.4 ± 1.35 mg m−2 L−1, nearly 1% of the biomass dry weight. Additionally, these cells had several polyunsaturated fatty acids. Continuous cultures of the toxigenic *Alexandrium ostenfeldii* grown in a100 liter photobioreactor in L1 medium fortified with soil extract had a division rate of  $0.16 \text{ day}^1$  [55].

## **Isolation of Cells**

Cells are isolated with a modified one ml plastic disposable syringe; the needle is removed and the needle hub is suitably modified (with a neoprene O ring) to accommodate a finely drawn haematocrit capillary (0.11 to 0.12cm diameter) pipette. Single cells or cysts are isolated under a bright field microscope from natural assemblages of phytoplankton or directly from seawater and transferred to polycarbonate tubes with sterile media. To avoid osmotic shocks to cells and to avoid a high nutrient concentration shock, media are diluted (50, 25, 10 and 2%) and used. The seeded cultures are incubated in a temperature controlled facility under light 3-10% of full daylight or  $\sim$  <170  $\mu$  mol m<sup>-2</sup> s<sup>-1</sup> supplied by daylight fluorescent lights. Light and dark cycle of 12: 12 or 14: 10 and 16:8 h are maintained. The time-honoured serial dilution (1:10) technique was used successfully to isolate algal cells.

As selection of cells manually is labor intensive, multiparametric flow cytometry is used successfully to sort out cells [56] and to establish axenic cultures of *Karenia brevis* from a bloom sample [57].

Cellamare et al. [58] discussed the utility of flow cytometry to sort freshwater phytoplankton.Trauma to electronically sorted cells was not a limiting factor, as fragile dinoflagellates, such as *Karenia brevis* (Dinophyceae), survived electronic cell sorting to yield viable cells. However, one of the disadvantages of electronic cell sorting is the need for manual post-sort culture maintenance and assessment of a large number of isolated cells. The rapidity of cell sorting would potentially accelerate the discovery of new algal strains [57].

## **Antibiotics**

Complex bacterial flora is associated with harmful algae and is known to form an intrinsic component of phytoplankton physiology and ecology. Growth of *Gymnodinium catenatum* was modified by a complex of one, two, or three-bacterial associates. The microbial community induced up to four-fold changes in the dinoflagellate growth rate and a three-fold change in stationary phase cell concentration and death rate, probably mediated by cell lysis [59]. Hence, dinoflagellate cells are washed several times usually in penicillin and streptomycin [19]. Tropical and temperate species are exposed for 18-36 hours and 36-72 hours for cold water species. In general penicillin G (K or Na salt), streptomycin  $(SO<sub>4</sub>)$  and chloramphenicol are used. To eliminate gram-positive bacteria broad spectrum antibiotics i.e., erythromycin, novobiocin are used and for gram-negative bacteria streptomycin and polymixin B are effective. Other antibiotics (ampicillin, kanamycin and neomycin) were also used to reduce the bacterial activity in *C. polykrikoides* cultures [60]. Su et al. [61] developed a method to obtain axenic cultures of *Alexandrium tamarense* in sterile f/2 medium without antibiotics; cells were repeatedly washed in lysozyme/SDS and antibiotic treatment with a mixture of gentamycin, streptomycin, cephalothin and rifampicin. Sterility tests were carried out on *Cochlodinium polykrikoides* cultures using the f/2pm medium [62] and fluorochrome 4′, 6-diamidino-2-phenylindole staining [63]. As treatment with antibiotics may alter the cell physiology, maintaining the cultures in active exponential phase is recommended.

Bacterial involvement in toxicity has been hypothesized in the dinoflagellate *Alexandrium tamarense* [64]. A great diversity of bacterioplankton, either attached or intercellular, is usually associated with dinoflagellates. Based on pure cultures obtained by repeated streaking on nutrient seawater agar, from the benthic toxic dinoflagellates, *Ostreopsis lenticularis* and *Gambierdiscus toxicus*, six bacterial genera- *Nocardia, Pseudomonas, Vibrio, Aeromonas, Flavobacterium,*and *Moraxella-* were isolated in addition to coryneform bacteria but extracts of dinoflagellate-associated bacteria grown in pure culture were not toxic [65].

From *A. tamarense* culture, bacteria were cultured in Zobell 2216E medium based on aged seawater enriched with GSe trace elements and vitamins [66]. Using DNA extraction and PCR amplification, 17 bacteria were identified i.e., *Paracoccus* sp. zao 3-3,*P*. sp 3-6, *P*.sp. 3-10, *P.homiensis* DD-R11, *Roseibacteriuim* sp. Zao 3-2, *R.elongatum* DSM, *Nitratireductor* sp. Zao 3-1, *N.basaltis* J3(T)'Amorphus sp. Zao 3-6'A.sueedae'Marinobacter sp. Zao3-5'M. algicola DG893'M.sp Zao3-7, *M.adhaerens* HP15(T), *M*.sp. zao 3-4, *M*.sp.zao 3-B' and *Arthobacter* sp. Zao 3-A members of *Roseobacter* and *Alteromonas* clades, associated with *A. tamerense* [66].

Earlier methods employed to test the bacterial toxicity hypothesis were time consuming or imprecise and involved extraction of DNA, followed by sequencing and dot blot hybridization [67]. Molecular studies on cultures of toxic and non-toxic dinoflagellates, *Alexandrium* spp. and *Scrippsiella trochoidea* [68] showed that the phylogenetic diversity of the bacteria was limited to the Proteobacteria and the Cytophaga-Flavobacter-Bacteroides (CFB); while some bacteria were common, some were unique to a particular dinoflagellate.

Several advanced techniques such as double hybridization (TSA-FISH) using monolabeled probes and confocal microscopy were developed to identify the bacteria [69]. In the non-thecate dinoflagellate *Gyrodinium instriatum,* endocytoplasmic and endonuclear bacteria were successfully identified but in either toxic or nontoxic strains of the thecate *Alexandrium* spp intracellular bacteria were not observed. There are 3 main constraints to establish the bacterial involvement of toxicity: 1. Establish whether the intercellular and those attached bacteria are the same 2. Establishing culturability of these bacteria and 3. Screening these bacterial cultures for toxins.

# **MEDIA FOR AUTOTROPHS**

Most media (Table 2) used for dinoflagellate cultures are based on enrichment of sea water (ESAW) and f/2 [70]. Derivatives of f/2 have been used for a long time in several laboratories but the National Center for Marine Algae and Microbiota (CCMP) is using L1 and L1 derivatives. There have been several versions for preparation of media using artificial seawater [39, 71]. An artificial seawater medium tested on 83 strains of phytoplankton represented by 11 algal classes [39] resulted in reduced final cell yields of Prymnesiophyceae and Dinophyceae compared to those grown in enriched natural seawater. The Aquil medium [37] and ESAW medium [72], unlike other media, are based on enrichment of artificial seawater water and are therefore highly useful in critical evaluation of specific nutrient requirements on the growth of dinoflagellates. More attention is paid to culturing toxin producing dinoflagellates due to their importance as constituents of algal blooms and producers of harmful phycotoxins with consequential impact on commercial fisheries and the consumers.

Dinoflagellate cultures go through an initial lag phase; a log phase with exponential growth, a stationary phase after attaining a maximum, followed by a senescent phase as in *Karlodinium micrum* [73], *Dinophysis caudata* [74], *Alexandrium tamarense* [75], and *A. fundyense* [33].

To suit individual experimental needs such as nutrient uptake studies, perturbation (spiking) techniques are used [76]. Several media including medium *f* are enriched to evaluate the impact of nutrients on growth and include carbon dioxide [77], phosphate [78], nitrogen compounds [49, 51], ammonia [79], NaNO3, urea, glycerophosphate [80], lipoperoxides, ascorbic acid [78] and iron [81].The medium utilized seems to affect the toxin profile as in *Alexandrium ostenfeldii* [82], and in *A. Tamarense* [75] and the production of bioactive compounds in several strains of *Protoceratium reticulatum* [51].

Several media contain a wide range of micronutrients, trace elements and a vitamin mix consisting of cyanocobalamin (vitamin  $B_{12}$ ), thiamine hydrochloride  $(B_1)$  and biotin (H) as in medium f [35], f/2 [36], Aquil [37], ESAW [38], ASP [39], Optimal Culture medium [80], IMK [83-85], GPM [42], NH15 [40], MLH medium [86] (Table 2). The vitamin concentrations in these media vary widely, *ca*. 3.7 pM - 7.4 nM, 0.3 nM - 3 mM and 3.27 nM to 0.2  $\mu$ M for B<sub>1</sub>, B<sub>12</sub> and H, respectively (Table 2). Growth of axenic dinoflagellate *Lingulodinium polyedrum* cultures in L1medium was studied at different vitamin concentrations ranging from 3.33×10<sup>-2</sup> to 3.33×10<sup>1</sup> pM of B<sub>1</sub> thiamine and 5.25×10<sup>-2</sup> to 5.25×10<sup>1</sup> pM of B<sub>12</sub> cobalamin (0.033 pM [83]. In their lowest range, 0.033 pM of B<sub>1</sub> and 0.053 pM of  $B_{12}$ , cell growth was limited. When co-cultured with the bacterium *Dinoroseobacter shibae*, a known B<sub>1</sub> and B<sub>12</sub> producer, *L. polyedrum* grew at the same rate as in culture media supplemented with  $B_1$  and  $B_{12}$ .

# **CULTURING MIXOTROPHS**

The history of culturing the toxic mixotrophic dinoflagellate *Dinophysis* was elusive and fascinating [88]. It was done in two steps. First, the marine ciliate *Myrionecta rubra* isolated from the bay is cultured. The salinity of the local water from Inokushi Bay, Japan was adjusted to 30PSU to grow *M. rubra* in f/2 medium [36], modified with 1/3 nitrate, phosphate, and metals and 1/10 vitamins [89]. Polycarbonate Erlenmeyer flasks were incubated under  $100-150$  µmol m<sup>-2</sup> s<sup>-1</sup> light provided by cool-white fluorescent lamps with a 12: 12 h L: D cycle. Next, *M. rubra*, in turn, was fed with the cryptophyte *Teleaulax amphioxeia* (3,000 cells) maintained similarly as *M. rubra*. *D. caudata* were isolated from the bay and maintained as a clonal culture and 150μl (2,500-3,000 cells) were added to 750 μl of *M. rubra* but incubated at 25<sup>0</sup>C. The growth rate of *D. caudata* was 1.03 kd<sup>-1</sup>. A mix of both *M.rubra* and *Teleaulax amphioxeia* was essential to sustain *D. caudata* culture.

For culturing mixotrophic dinoflagellates, media f/2 without silica, ES, L1 and SWM are utilized supplemented by a variety of microalgal flagellates, diatoms, dinoflagellates, the ciliate *Mesodinium rubrum* and the blue green *Synechococcus* as feed. Several autotrophic dinoflagellates were cultured in a mixotrophic mode using the ciliate *Mesodinium rubrum* and the blue green *Synechococcus* as feed.

A review by Jeong et al. [90] listed 29 dinoflagellate species feeding on a variety of prey including heterotrophic bacteria, autotrophic bacteria, pico-eukaryotes, Cryptophytes, Haptophyta (Prymnesiophyta), Ciliates, Chlorophytes (Dunaliella), Prasinophytes, Euglenophytes, Raphidophytes, Bacillariophytes, Dinoflagellates, Heterotrophic nanoflagellates, Ciliates, Naupliar stages of metazoans, Bloods of metazoans and flesh of metazoans. The feed included *Pseudomonas, Alteromonas, Acinetobacter, Teleaulax amphioxieia, Rhodomonas salina, Chroomonas*, *Pyramimonas* sp*, Myrionecta rubra (Mesodinium rubrum)* and *Thalassiosira.* Of interest are the other feed organisms i.e., dinoflagellates *Ostreopsis* cf. *ovata*. *Alexandium lucitanicum*, *A.tamarensis, Heterocapsa rotundata. H. triquerea, Heterocapsa* sp*, Scripsiella trochoidea, Margalefidinium (Cochlodinium) polykrikoides, Dinophysis accuminata, D. caudata* and *Ostreopsis* cf. *ovata, Heterosigma akashiwo, Amphidinium carterae* and the ciliate *Mesodinium rubrum.* Blood cells of the perch *Lateolabrax japonicus* served as feed for *Stoeckeria changwonensis* [91].

Unlike most heterotrophic dinoflagellates which play a significant role in the transfer of organic matter, the predatory dinoflagellate *Pfiesteria* has unique nutritional preferences. Skelton et al. [92] cultured 3 strains of *Pfiesteria shumwayae* monoxenically on fish cells [93] and then axenically in a biphasic culture medium containing chicken egg yolk as a major component [94]. The development of a semi-defined culture medium (PSD) is a significant step as it facilitates understanding the biochemical requirements of this heterotrophic dinoflagellate [94]. PSD is a mix of Instant Ocean (75%, v/v; Aquarium Systems, Atlanta, GA), Medium 199 (25%, v/v; Sigma-Aldrich), amicase (0.5 g/L; Sigma-Aldrich), soy lecithin (0.5 g/L; MP Biomedicals, Solon, OH, #102147), L1 trace metals and  $2 \times L1$  vitamins [95].

# **DIVISION RATES**

### **Monophasic**

Division rates are calculated when the cells are in their exponential growth phase. The exponential increase of cell numbers in a population  $(N_0)$  to a proportionally  $(N_t)$  is expressed as:

Nt= N0e *k*t

where  $k$  is the specific growth rate and t is the time period expressed in days. The growth coefficient (*k*) is calculated from changes in cell numbers over a period of days as:

 $k (day^{-1}) = [ln(N_t/N_0)]$  [96] (Furnas, 2002)

Growth of culture is usually monitored by determining changes in biomass measured in terms of cell numbers and pigments [97]. Cells are examined under a microscope. Cell enumeration is done using a Sedgwick Rafter cell, or Utermohl sedimentation chamber or using an electronic particle counter .The initial numbers( $N_0$ ) increase exponentially ( $N_1$ ) over a generative period (t); the cell growth rate( $\mu$ ) is calculated [96], i.e.,

G=  $24/((\ln(Nt/N0))/\delta t)/0.693$ 

```
derived from k (\text{day}^{-1}) = [\ln(Nt/N0)]/\delta t\mu (divisions day<sup>-1</sup>) = k (day<sup>-1</sup>)/ln 2
= k \, (day^{-1})/0.693G = 24/u
```
where G is generation time,  $n_1$  and  $n_2$  represent cell numbers corresponding to day1 (t<sub>1</sub>) and day 2 (t<sub>2</sub>) and k is the doubling time day <sup>-1</sup>. Division rates ( $\mu$  divisions day<sup>-1</sup>) reported by the authors are used in this study.

Doblin et al. [98] used fluorescence yield of cells to calculate division rates as:

k (day<sup>1</sup>)=ln (F<sub>1</sub> / F<sub>0</sub>)/(t<sub>1</sub>- t<sub>0</sub>)

where  $F_1$  and  $F_0$  are fluorescence reading at each time period  $t_1$  and  $t_0$  were corrected for fluorescence of control tubes at the same time. It should be noted that fluorescence depends on the past growth history (temperature and light) of the algal cells.

### **Bayesian Generalized Logistic Model**

The effects of temperature and light on the comparative growth kinetics of five strains of cultured dinoflagellate *Symbiodinium*, *S*. *microadriaticum* (cp-type A194; strain 04–503), *S*. *microadriaticum* (cp-type A194; strain CassKB8), *S*. *minutum* (cp-type B184; strain Mf 1.05b.01.SCI.01), *S*. *psygmophilum* (cp-type B224; strain Mf 11.05b.01) and *S*. *trenchii* (cptype D206; strain Mf 2.2b were studied [99]. Cultures were grown in medium f/2, 38 PSU at 26°C under 14:10 light: dark70–90  $\mu$ mol photons m<sup>-2</sup> s<sup>-1</sup> light. Results of growth modelled using Bayesian generalized logistic model showed faster growth reaching a higher asymptote at 26°C than at 18°C.

Klueter et al. [99] formulated the biphasic model to simultaneously estimate growth parameters and quantify the uncertainty of monophasic or biphasic growth with a binary switching parameter, *w*, similar to the model averaging method described by Carlin and Chib [100].

The likelihood of observing a given cell density,  $D$  (x  $10^4$  cells ml<sup>-1</sup>), *n* days after the experiment began was defined as:

$$
D \sim Poisson(\mu \cdot \rho)^{\mu} = 1 + \frac{K_1 - 1}{1 + e^{-B_1(n - M_1)}} + w \left(\frac{k}{1 + e^{-B_2(n - M_1 - m)}}\right) \rho \sim Gamma(\alpha, \alpha)
$$

where (prior distributions in parentheses):

- 1)  $\mu$  = Expected density,
- 2)  $K_I =$  Asymptotic density of the first curve (*Uniform*(1, 800)),
- 3)  $k =$  Increase in the density of the asymptote of the second curve above  $K_I$ (*Uniform*(1, 500)),
- 4)  $B_1$ ,  $B_2$  = Logistic growth rates of the first and second curves respectively (*Uniform*(10−1, 1)),
- 5)  $M_1$  = Number of days to the maximum growth rate of the first curve (*Uniform*(2,  $40$ )).
- 6)  $m =$  Number of days to the maximum growth rate of the second curve above  $M_1$ (*Uniform* (2, 40)),
- 7)  $w = A$  switching parameter determining if the model describes a monophasic logistic (= 0), or biphasic logistic (= 1) curve (*Bernoulli* (0.5),
- 8)  $\rho =$  Gamma distributed error term,
- 9)  $\alpha = \text{Gamma shape}$  and scale parameters (*Lognormal* ( $\mu = 0$ ,  $\tau = 10^{-4}$ )).

Biphasic growth was especially evident for *S*. *minutum* and *S*. *psygmophilum* across all treatments. When the cell density was  $\sim 200$  million cells ml<sup>-1</sup>, monophasic growth was more common but final asymptotic densities were relatively low. All species tended to grow faster and / or reached a higher asymptote at 26°C than at 18°C. *S*. *minutum*, exhibited the fastest growth with an approximately four-fold increase in estimated cell density after 60 days. We do not know whether the biphasic growth was due to diauxic growth i.e., when two nutrients are present in the medium, the easily metabolized nutrient is consumed faster than the other. This cellular growth may take place in two phases: the first is the fast growth phase and the second a slower growth phase similar to that described by Monad with the bacterium *Escherichia coli*. Alternately, the biphasic growth may be due to bi-phasic life cycles in algae discussed by Thornber [101] where two organisms produce haploid gametes, fuse to form a diploid zygote which undergoes meiosis resulting in haploid cells. Haploid cells have reduced nutrient requirement unlike the diploid cells [102].

# **DIVISION RATES (GK) OF CULTURED ATHECATE AND THECATE DINOFLAGELLATES**

## *In Situ* **Division Rates**

Division rates of dinoflagellates given in publications are assembled in Table 4. There are few reports on the *in situ* division rates based on natural bloom populations; for *Ceratium tripos* from a 45 km patch in the sub-surface chlorophyll maximum in August 1978 on the Southern California shelf, it averaged  $0.25 d^{-1}$  [103]. Potential division rates based on 'post mitotic index' of samples during a cruise in the Galician rias yielded division rates 0.09 – 0.28 for *Dinophysis acuminata*, 0.17-0.20 for *D. acuta* , 0.24 for *D. caudata* and 0.50 for *D. tripos* [104]. For *Gymnodinium stellaltum*, *G. nelsoni*, *Gonyaulax tamarensis*, *G. polyedra*, *Prorocentrum marie-lebouriae*, *Pyrocystis noctiluca*, *P. fusiformis* division rates calculated on species–specific carbon assimilation  $(C<sup>14</sup>$  method) of natural samples from Chesapeake Bay corresponded to 0.3, 0.5, 0.5, 0.3, 0.5, 0.1 and 0.2 d-1 [105]. Division rates for *Pyrocystis noctiluca*, *P. fusiformis* in the Sargasso Sea were 0.33 [106]. Along the Karachi coast, growth rates (μ<sub>max</sub> d<sup>-1</sup>) of the dominant species were: *Prorocentrum gracile*, *Prorocentrum minimum*, *Prorocentrum arcuatum* (1.0-1.10), *Protoperidinium steinii* (0.92), *Gonyaulax spinifera* (0.69), *Dinophysis acuminata* (2.3), *Dinophysis caudata* (0.92), *Ceratium lineatum*, *Prorocentrum micans* (1.95), *Gyrodinium* sp. (1.88*), Ceratium (revised as Tripos) furca* (1.70), and *Alexandrium ostenfeldii* (1.34) [107] and suggested that the prevailing higher

temperature induced higher division rates but compared to the division rated (Tables 3) these values are quite high, even higher than those for several microalgae [108]. Wilkerson et al. [109] based on mitotic index reported *in situ* growth rates of intracellular zooxanthellae higher than those in oligotrophic waters and attributed it to the assimilation of higher ambient nutrient concentrations. It is of interest to note the maximum growth rates of many phytoplankton taxa measured *in situ* are like those observed in culture [96, 110].

**Table 4. Dinoflagellate culture conditions and division rates** 

# **Table 4. (Continued)**

TO=Toxic,T-Thecate, AT-Athecate; Ps – Photosynthetic , Holo- Holozoic, Mixo- Mixotrophic.

## **Division Rates: Cultures**

Results on the division rates of cultured a) athecate, b) thecate dinoflagellates, c) nontoxic and d) toxic dinoflagellates are presented (Table 4). As calculation of division rates are based on exponential growth coefficient of cells, maximal division rates of the species are compared. Thus, the division rates ranged between 0.16 for *Alexandrium ostenfeldii* [55] and 1.50 for *Karlodinium veneficum* [111] and both are toxin producers as well. Division rates for athecate dinoflagellates ranged from 0.10 div d-1 for *Pyrocystis noctiluca* [48] to 1.5 for *Karlodinium micrum* [73]; for the thecate taxa 0.11 for *Alexandrium fundyense* [112] and 1.09 for *Ostreopsis* sp.6 [83]. The range of division rates between the non-toxic and toxic species seems to be comparable.

Repetitive measurements of division rates available for a few species(Table 4) permit comparison within the species and between the species. For example, these rates ranged as in *Alexandrium fundyense* 0.11-0.38, *Amphidinium carterae* 0.29-0.87, *Gymnodinium catenatum* 0.15-0.53, *Gymnodinium aureolum* 0.29-0.44, *Karlodinium veneficum* 0.32-1.5, *Lingulodinium polyedra* 0.24-0.33, *Ostreopsis* sp. 0.25-1.09, *Prorocentrum micans* 0.31-0.41, *Prorocentrum minimum* 0.276-0.485, and *Protoceratium reticulatum* 0.19-0.37. Band-Schmidt et al. [113] reported 0.18 – 0.31 division rates of *G. catenatum* under a variety of growth conditions ; 0.14–0.21 day<sup>-1</sup> between 15 and 29°C, the highest rate (0.18–0.21 day<sup>-1</sup>) between 21 and 29°C. Between 15-36 PSU, the highest growth rates  $(0.24 \text{ day}^{-1})$  were at salinities from 26 to 30 PSU. Growth also varied with the source of the sea water and was 0.28-0.31 in seawater from Bahía Concepcion; growth was more in medium f/2 enriched with selenium at  $10^{-8}$  M than at  $10^{-7}$ . In the Tasmanian waters influx of dissolved organic matter (humic substances) via rainfall triggered the growth of blooms of the toxic dinoflagellate *Gymnodinium catenatum* [98]. Culture studies showed the trace element selenium (as 10 M selenite) limited growth rate and biomass. Also, review of Band-Schmidt et al. [113] concluded the possible existence of different ecotypes strains from Galacia-Spain, Vigo-Spain, Derwent estuary-Tasmania, Bahía Concepción and Mexico seem to have evolved physiological and nutritional requirements.

### **Division Rates: Benthic Dinoflagellates**

Benthic dinoflagellates *Amphidinium carterae* (JHWAC), *Prorocentrum rhathymum* (JHWPMX1) and *Symbiodinium* sp. were grown in f/2 and IMK media (1/2X and 1/4X) in vertical column photobioreactors (35cm diameter x 160 cm high)  $20^{\circ}$ C 40-50 μ mol photons  $m^{-2}$  sec<sup>-1</sup> [85, 114]. Medium f/2 and IMK/2 supported higher division rates than did f/4 and IMK/4. From Bizerte Bay (Tunisia, Mediterranean) monoclonal cultures of thermophilic epiphytic, benthic toxigenic dinoflagellates (*Ostreopsis* cf. *ovata*, *Prorocentrum lima* and *Coolia monotis*) had maximum growth rates of  $0.59 \pm 0.08$  d<sup>-1</sup> for *O*. cf. *ovata*,  $0.35 \pm 0.01$  d<sup>-1</sup> for *C. monotis* and 0.33 ± 0.04 d-1 for *P. lima.* The toxic benthic dinoflagellate *Ostreopsis* sp. grew rapidly at 90–199 μmol photons m−2 s−1 but growth was inhibited at ≥263 μmol photons m<sup>-2</sup> s<sup>-1</sup> [84]. In IMK and/or f/2 media, maximum growth rates (div d<sup>-1</sup>) were 0.8334 for *O.* cf. *ovate,* 0.619in *Ostreopsis* sp*.*1and 1.04 for *Ostreopsis* sp*.*6 [83] much higher than the epiphytic *Gambierdiscus toxicus*, *Prorocentrum lima*, and *Coolia monotis* cultures. Klueter et al. [99] reported faster growth rate in *Symbodinium microadriaticum* (cp-type A194; strain 04–503), *S. microadriaticum* (cp-type A194; strain CassKB8), *S. minutum* (cptype B184; strain Mf 1.05b.01.SCI.01), *S. psygmophilum* (cp-type B224; strain Mf 11.05b.01) and *S. trenchii* (cptype D206; strain Mf 2.2b) reaching a higher asymptote at  $26^{\circ}$ C than at 18<sup>0</sup>C and attributed due to modification of growth-related nutritional physiology.

# **CULTURE CONDITIONS: DIVISION RATES**

### **Salinity and Temperature**

In their growth response to changes in salinity (PSU), temperature, light, and nutrients, dinoflagellates are similar to other microalgae. Kim et al. [34] studied growth of *Cochlodinium polykrikoides*- a harmful dinoflagellate, at 60 different combinations of temperature (10–30°C) and salinity (10–40PSU) and irradiance. The maximum growth rate of 0.41 was at 25<sup>o</sup>C and 34 Pusan their optimum temperature corresponded to 21 to 26<sup>o</sup>C and at salinities from 30 to 36 units PSU. *Akashiwo sanguinea* had a broad tolerance to salinity PSU (10 to 35), more than *Prorocentrum micans* (25-35) [115]. The optimum irradiance for growth for *Akaqshiwo sanguinea* was >90 μmol m−2 s −1and photoinhibition did not occur at 230 μmol m<sup>-2</sup> s<sup>-1</sup>.

Growth rates of *Alexandrium fundyense* [116] at five temperatures (5, 10, 15, 20, 25ºC), six irradiance levels  $(6, 25, 50, 100, 175, 42 \mu \text{mol m}^{-2} \text{ s}^{-1})$ , and five salinities  $(15, 20, 25, 30, 100, 175, 42 \mu \text{mol m}^{-2} \text{ s}^{-1})$ 35 PSU) showed that temperature exerted the greatest impact; the highest growth rate was 0.68 div  $d^{-1}$  at 15<sup>o</sup>C; at 25<sup>o</sup>C cells failed to grow. Growth rates generally increased with increasing irradiance up to  $450 \mu$ mol m<sup>-2</sup>s<sup>-1</sup>. Salinity did not impact growth significantly. In the harmful red tide dinoflagellate, *Cochlodinium polykrikoides* growth was monitored at 60 combinations of 10-30°C and salinity 10-40 PSU under 130 µmol  $m^{-2}$  s<sup>-1</sup> cool-white fluorescent illumination on a 12 h:12 h light: dark cycle. At a combination of  $25^{\circ}$ C and 34 PSU, specific growth rate was 0.41 and optimum growth rates occurred between 21 to 26°C and at salinities from 30 to 36. *C. polycrikoides* did not grow below 10°C and salinities >30 if the temperature was >15 °C. The optimum irradiance for growth was >90 µmol m<sup>-2</sup> s<sup>-1</sup>.

In *Karenia brevis* (Florida clone) growth occurred under various combinations of irradiance (19, 31, 52, 67, and 123 µmol m<sup>-2</sup> s<sup>-1</sup>), salinity (25, 30, 35, 40 and 45 PSU), and temperature (15, 20, 25, and  $30^{\circ}$ C) [117]. Maximum growth rates varied from 0.17 to 0.36 div  $day<sup>-1</sup>$  with exponential growth rates increased with increasing irradiance. Growth was limited at 19 µmol m<sup>-2</sup> s<sup>-1</sup>. Maximum growth rates at  $15^{\circ}$ C were much lower than at other temperatures. Of interest is the similarity between Florida clone and Texas clone in their temperature tolerance (15-30°C) and light saturation 65 µmol m<sup>-2</sup> s<sup>-1.</sup>

From 42 different combinations of temperature (10–31°C) and salinity (10–40 PSU) under saturated irradiance, *Prorocentrum donghaiense* had a maximum specific growth rate of 0.77  $d^{-1}$  at a combination of  $27^{\circ}$ C and salinity of 30 PSU [118]. The range for optimum growth rate  $(0.60 d<sup>-1</sup>)$  was from 20 to 27<sup>°</sup>C and salinities from 25 to 35 PSU. Cells did not grow at salinities <10 and temperatures 10-20°C.

Temperature also affected the division rates in *Peridinium* sps, *Prorocentrum micans* and *P. gracile* [18] with an optimum at about 20° -27°C. In *Dinophysis caudate*, the optimum was in the range 18-30°C and division rates increased from 0.21 to 0.67 between 15°C and 30°C and decreased at >30°C [74]. This was also the case in *Gymnodinium catenatum;* cells grew well in the temperature range  $>11^{\circ}$ C to 28<sup>°</sup>C and attained a 0.53 division rate; cells did not grow below 11°C or at > 30°C [119], *Akashiwo sanguinea* [120], *Amphidinium carterae* [49], Alexandrium ostenfeldii [55]. In *Prorocentrum minimum* strain 2 at μmol m<sup>-2</sup> s<sup>-1</sup> and20<sup>°</sup>C growth was 0.42 and at 110  $\mu$ mol m<sup>-2</sup> s<sup>-1</sup>27<sup>°</sup>C division decreased to 0-.23 -0.38 [122]. Of interest are the growth rates of *Heterocapsa circularisquama* which did not grow at 10°C but had 1.3 Gk d-1at 30°C and 30 PSU. *Chattonella verruculosa* did not grow at 25°C and 10PSU but divided 1.74 times at a combination of 15°C and 25 PSU [135]. Thus this interaction of growth to temperature and salinity may result in harmful algal blooms contributed by different taxa.

### **Light**

Dinoflagellates seem to prefer low light <170  $\mu$ mol m<sup>-2</sup> s<sup>-1</sup>. Yamaguchi et al. [84] using white light-emitting diodes, devised a new photoirradiation-culture system to study the growth of the benthic dinoflagellate *Ostreopsisovate* cultured in irradiances up to 460 μmol  $m<sup>2</sup>$  s<sup>-1</sup>. The threshold irradiance for growth was 29.8 µmol m<sup>-2</sup> s<sup>-1.</sup> At the optimum light 196 μmol m<sup>-2</sup> s<sup>-1</sup> division rate was 0.659 day<sup>-1</sup> and decreased to 95% at 130–330 μmol m<sup>-2</sup> s<sup>-1</sup>, further decreased to 80% at 90 µmol m<sup>-2</sup> s<sup>-1</sup>. Photoinhibition was at 460 µmol m<sup>-2</sup> s<sup>-1</sup> and the division rate was 80% of the maximum [84]. Results on *Akashiwo sanguinea*, *Prorocentrum micans* and *Scrippsiella trochoidea* are instructive [123]. Division of cells grown at low (LL, 87–90 μmol photons m<sup>-2</sup> s<sup>-1</sup>) and high (HL, 450–490 μmol photons m<sup>-2</sup> s<sup>-1</sup>) were similar for *A. sanguine* ( $\mu$ =0,26–0,33 d<sup>-1</sup>) and *P. micans* ( $\mu$ =0,25–0,31 d<sup>-1</sup>) while they were significantly higher in *Scripsiella trochoidea* under HL (0,29±0.02; p b 0,001) than LL (μ=0,23±0.01 d−1 ). Cells grown at higher irradiance had higher lipid that served as a protective mechanism. Using a monochromator, cell divisions of *Heterocapsa pygmaea* were similar and averaged  $0.7 d^{-1}$  [124].

### **Nutrient Phosphate and Nitrate**

In *Alexandrium fundyense* cultures grown in f/2 medium the phosphate, nitrate and ammonia levels decreased as growth progressed and were abundant by the 21st or  $29<sup>th</sup>$  day, the time at which the cells attained their peak growth; compared to the initial levels remaining phosphate levels were 38–43%, nitrates were 82–98% and 14–97% ammonium chloride [33]. Even at the stationary phase, these nutrients were not exhausted and by the  $50<sup>th</sup>$  day were reduced to 38–51% phosphate, and 10–97% nitrate. In *Alexandrium tamarense* grown in K medium, when nitrate exceeded 264  $\mu$ M, cell division decreased to 0.5 div d<sup>-1</sup> compared to 0.6 div  $d^{-1}$  with K medium [125]. High salinity, low light and high nitrate and low phosphate favored toxin production in this species. *A. fundyense* can remove dissolved free amino acids (DFAAs) during early exponential growth, at a rate 0.8 pmol-N cell  $h^{-1}$ ), equivalent to ~20% of the total N requirement but this does not enhance toxin content [126]. Production of some of these mycosporine-like amino acids (MAAs) is more when exposed to PAR+/UVA without UVB as in *Heterocapsa* sp. and may be photoprotective [127].

Observations on cultures of nearshore dinoflagellates *Prorocentrum minimum*, *Prorocentrum donghaiense*, *Karlodinium veneficum*, and an off-shore *Karenia brevis* grown in  $f/2$  medium with  $NO<sub>3</sub>$  as nitrogen source are interesting [128]. Growth rates of *Karlodinium veneficum* were  $0.32$  div  $d^{-1}$  did not differ significantly between low and high N: P ratios (12 and 145) suggesting excessive or luxury consumption of nutrients unrelated to growth. When urea was used as a nitrogen source there was a long lag phase followed by a growth phase of one week with a decrease in growth rate to  $0.24$  div  $d^{-1}$ . In phosphorus minimum with nitrate as a source, growth rate was  $0.17$ - $0.27$  d<sup>-1</sup> in low N: P and  $0.23$  to  $0.33$ in high N: P ratio. Growth rates of *K.brevis* and *Prorocentrum donghaiense* were reduced in a mixed culture with *Synechococcus* [128]. Lopez-Rosales et al. [80] in a study to optimize medium formulation for culturing *Karlodinium veneficum* and used 25 components including the macronutrients, trace elements and vitamins and compared 30:1 N:P ratio to the control L1 medium with 25:1 N:P; the former enhanced cell density by 120%, 14% greater division rate  $(0.0 - 0.33 d^{-1})$  and the ichthyotoxic (haemolytic) activity of the culture filtrate by 190% compared to  $(0.29 d<sup>-1</sup>) L1$  medium.

## **Iron**

More than phosphate and nitrate, iron appears to be important for the growth of dinoflagellates. In phytoplankton growth is limited by lack of iron [129, 130]. *Alexandrium fundyense* cells exposed to 366 mm iron (Harrison medium – Ha) reached a peak in 18 days while in the absence of iron  $(f/2 - Fe - control)$  they did not grow [33]. In Harrison's medium in a gradient of Fe (36.6, 73.2, 146.4, and366 mMFe) cell division corresponded to 0.25, 0.208, 0.172 and 0.21  $d^{-1}$ . At 732 mM Fe, however, cells divided slowly (0.159  $d^{-1}$ ). In *Scrippsiella trochoidea* that produces harmful algal blooms off Japan, Korea and China [131], results from a gradient experiment (low iron:  $0.063$  mg L<sup>-1</sup>, medium iron:  $0.63$  mg L<sup>-1</sup> and high iron: 6.3 mg  $L^{-1}$ ) showed under high Fe and high light cells divided 0.22 d<sup>-1</sup> compared to  $0.06$  d<sup>-1</sup> in low Fe and low light [81].

*Protoceratium reticulatum* was grown in nutrient-enriched seawater (1/10 GP medium) without iron or with  $0.076$  and  $0.0076$   $\mu$ M iron added; the growth rate in treatments without added iron was also significantly reduced to  $(\mu=0.16 \text{ day}^{-1})$  compared to  $\mu=0.23 \text{ day}^{-1}$  with iron [132].

## **MIXOTROPHIC CULTURES**

Mixotrophy, a combination of phototrophy and phagotrophy, appears to be common amongst dinoflagellates [144, 145] and it enhanced division rates. Stoecker lists 46 mixotrophic dinoflagellate species belonging to Prorocentrales (4), Dinophysiales (2), Gymnodiniales (13), Noctilucales (1) Gonyaulacales (15), Peridiniales (2), Blastodiniales (5), Phytodiniales (3) and Dinamoebales (1). Several are to be added to the mixotrophs listed in Table 5. Plausible advantages of being mixotrophic include a) it extends the range of nutritional substrates to meet growth requirements as in *K. brevis*, particularly in N-poor waters [146] b) it acts as a survival strategy during the time when photosynthesis cannot support growth as in *D. norvegica* [32, 88] or c) it serves as a primary source of carbon as in *D. acuminata* [147] and d) it meets inorganic nutrient limitation during summer stratification of the water column as in *Prorocentrum minimum feeding* on cryptophytes material [145]. *Pfiesteria shumwayae*, the predatory dinoflagellate axenically grown in dark on a semidefined biphasic culture medium rich in certain dissolved and particulate organic compounds, including amino acids and lipid particles, attained cell densities ranging from  $0.1 \times 10^5$  to 4.0  $\times$  10<sup>5</sup> cells/ml and 0.5 to 1.7 div/day [93]. Feeding on insoluble lipid particles suggests phagocytosis may be a requirement in this dinoflagellate.

Dinoflagellates grown heterotrophically had higher growth rates (with prey versus autotrophic, Table 5). In *Karlodinium micrum* fed on *Storeatula major* (Cryptophyceae) (0.52 to 0.75 vs 0.55) [148], *Yihiella yeosuensis* fed on *Pyramimonas* sp. *Teleaulax* sp. (1.32 *vs* 0.026) [149], *Protoperidinium hirobis*, a thecate heterotrophic dinoflagellate fed on the diatom *Leptocylindrus danicus* reached a maximum 1.7 vs 1.0 [150], *Polykrikos hartmannii*  fed on *C. polykrikoides* (0.03 vs 0.023) [151], *Alexandrium andersonii* fed on *Pyramimonas*  sp., the cryptophyte *Teleaulax* sp., and the dinoflagellate *Heterocapsa rotundata* (0.432 vs 0.243) [29], *Alexandrium pohangense* fed on *Cochlodinium polykrikoides*(0.487 vs 0.091) [30], *Karenia brevis* fed on *Synechococcus* (0.53 vs 0.25) [146], *Dinophysis acuminata* fed on *Mesodinium rubrum* (0.17-0.51 vs 0.2) [147], *Fragilidium duplocampanaeforme* fed on *D. acuminata, D. caudata, Mesodinium* (0.07-0.6 vs 0.21-0.26) [152], and *Dinophysis caudata* fed on *Myrionecta rubra, Teleaulax amphioxeia* (1.03 vs 0. 28) [30]. Phagotrophy probably serves as an alternative option to acquire nutrients.

In a mixed culture (Table 5) *Prorocentrum minimum* with 0.377-0.485 Gk out grew *Karlodinium veneficum* and *Prorocentrum donghaiense* outgrew *Karenia brevis* [128]. When fed with the microalga *Rhodomonas,* growth of *P. minimum* was inhibited [128]. In the presence of *Synechococcus* growth rates of both *K. brevis* and *P. donghaiense* were reduced.These reciprocal inhibitory effects may be due to allelochemical potency observed between the toxic *Alexandrium ostenfeldii* and other dinoflagellates *Kryptoperidinium foliaceum*, *Levanderina fissa* and *Heterocapsa triquetra* [153] or allelopathic effects between the species [120].

#### **Table 5. Cultures and growth of mixotrophic dinoflagellates**

*Gymnodinium smaydae* preyed on *Heterocapsa rotundata. H.triquerea, Heterocapsa* sp.*, Scripsiella trochoidea* but did not on *Heterosigma akashiwo*, *Teleaulax, Rhodomonas salina*  and Amphidinium carterae [154]. Their mixotrophic growth rates (d<sup>-1</sup>) were higher (1.053-2.226), compared to the autotrophic without prey (0.005 -0.0051). *Gyrodinium dominans*, *G. moestrupii*, *Oxyrrhis marina*, *Pfiesteria piscicida*, and *P. kofoidii* were able to feed on the toxic epiphytic benthic dinoflagellate *Ostreopsis cf. ovata*; but not on *Gyrodinium spirale*, *Protoperidinium bipes*, *Stoeckeria algicida*, and *Strobilidium* sp. [31]. Growth rates *G. moestrupii* and *P. kofoidii* on *O*. cf. *ovate* corresponded to 0.86 and 0.73 coinciding with high ingestion rates.

*Takayama helix* another dinoflagellate that causes fishkills feeds on diverse algal species [155]. It ingests large dinoflagellates ≥15 μm, on *Alexandrium minutum*, *A. lusitanicum*, *A. tamarense*, *A. pacificum*, *A.insuetum*, *Cochlodinium polykrikoides*, *Coolia canariensis*, *Coolia malayensis*, *Gambierdiscus caribaeus*, *Gymnodinium aureolum*, *Gymnodinium catenatum*, *Gymnodinium instriatum*, *Heterocapsa triquetra*, *Lingulodinium polyedrum*, and *Scrippsiella trochoidea* except for the dinoflagellates *Karenia mikimotoi*, *Akashiwo sanguinea*, and *Prorocentrum micans*. However, it does not feed on flagellates and dinoflagellates <13 μm in size (i.e., the prymnesiophyte *Isochrysis galbana*; the cryptophytes

*Teleaulax* sp., *Storeatula major*, and *Rhodomonas salina*; the raphidophyte *Heterosigma akashiwo*; the dinoflagellates *Heterocapsa rotundata*, *Amphidinium carterae*, *Prorocentrum minimum*; or the small diatom *Skeletonema costatum*). However, *T. helix* did not feed on small flagellates and dinoflagellates <13 μm in size (i.e., the prymnesiophyte *Isochrysis galbana*; the cryptophytes *Teleaulax* sp., *Storeatula major*, and *Rhodomonas salina*; the raphidophyte *Heterosigma akashiwo*; the dinoflagellates *Heterocapsa rotundata*, *Amphidinium carterae*, *Prorocentrum minimum*; or the small diatom *Skeletonema costatum*). Growth rates in the mixotrophic mode were  $0.268 - 0.272$  d<sup>-1</sup> compared to  $0.094 - 0.152$  d<sup>-1</sup> in the autotrophic growth.

## **CONCLUSION**

About 100 autotrophic, heterotrophic, toxigenic and symbiotic dinoflagellate species are amenable for culturing. Their growth rates are studied in enriched sea water media or enriched artificial seawater media. Dinoflagellate division rates are low compared to 14 pennate diatoms with maximum division rates of 3.2 div d<sup>-1</sup> [156], and 2.47 for *Phaeodactylum tricornutum* [157] or *Leptocylindrus danicus* with 2.7 div day<sup>-1</sup> [158], or the green flagellate *Dunaliella tertiolecta* with high growth rates 0.8- 2.64 [35]. Physiological difference between the dinoflagellates and other microalgae exist. Photosynthetic and thecate dinoflagellates which have a cellulose cell wall are significantly more carbon-dense than diatoms [159] evident from their Carbon: Nitrogen that ranged from 3.44 to 6.456. Log phase dinoflagellates although have lower photosynthetic rates per unit chlotophyll *a* than diatoms which have lower carbon: chlorophyll *a* ratio [160,161]. A review of 31 dinoflagellates species showed lower growth rates which are related to lower chlorophyll *a* to carbon ratio; these two variables explain 68% of variation in growth [161]. Because of these physiological differences, it is possible that dinoflagellates expend much energy into the production of cellulose skeleton and toxins which result in their lower division rates. In mixotrophic and heterotrophic dinoflagellates which prey on high energy biota, their division rates are higher than when grown autotrophically (controls) or compared to other autotrophic dinoflagellates. If this conclusion is correct, then it needs to be substantiated with detailed observations on the Carbon: Nitrogen dynamics in a variety of dinoflagellate cultures.

Dinoflagellates are influenced by a variety of abiotic (e.g., temperature, salinity, stratification, nutrient enrichment) and biotic (e.g., grazing) factors and no single factor accounts for their blooming, a conclusion drawn by Vargo [162]. Vargo based his conclusion on a review of 24 thoughts and hypotheses to account for the initiation, growth and maintenance, and termination of Karenia *brevis* blooms on the West Florida shelf. It is possible sheltered bays or coastal waters get seeded by large numbers of cysts by advection [163]. Based on a study of 27 estuaries between Prince Edward Island, Canada and Maine to Delaware, Price et al. [164] distinguished four main estuary types i.e., riverine, lagoon, coastal embayment, and fjord, in which tidal range, sea surface temperature (SST), and sea surface salinity (SSS) are statistically significant parameters influencing cyst assemblages. Since cysts are resistant to adverse environmental conditions, encystment enables the survival of cells. With their slow asexual reproduction (binary fission), the rapid ephemeral massive occurrences of monospecific dinoflagellate blooms in a short time are intriguing.

Studies from 23 northeast USA estuaries and 9 estuaries from Prince Edward Island, Canada [165], and in the Tunisian Gulf of Gabes, Mediterranean Sea [166] suggest the association of dinoflagellate blooms with environmental variables. Redundancy analysis of 10-year data using a generalized linear mixed-effect model (GLMM) suggested that in the Gulf of Gabes, blooms of *Karenia selliformis* are related to the different spatial gradients caused by anthropogenic activity- positively with nitrate and negatively with total phosphorus [165]. Results from the NW Atlantic estuaries [164] showed that the overall abundance of cysts of heterotrophic dinoflagellates correlates with modelled nitrogen loading. In view of this, studies on the Carbon: Nitrogen dynamics utilizing community dinoflagellate cultures vs individual species (axenic), particularly those rich in lipids, carotenoids and bioactive compounds with potential biotechnological utility, using unprocessed or partially processed sewage water and in post-bloom water would be instructive.

## **ACKNOWLEDGMENTS**

For permission to quote the biphasic model for growth rates, we are most grateful to Dr. A. Klueter, University at Buffalo, The State University of New York, USA and to an anonymous reviewer for comments and constructive criticism of an earlier version of this manuscript.

## **ABSTRACT**

Since Park et al. (2006) succeeded in cultivating the toxic dinoflagellate *Dinophysis acuminata* by feeding them the ciliate *Mesodinium rubrum* grown with a cryptophyte *Teleaulax* sp., we succeeded in establishing six *Dinophysis* species, i.e., *D. acuminata*, *D. caudata*, *D. fortii*, *D. infundibulum*, *D*. cf. *ovum* and *D. tripos* under laboratory conditions and maintaining clonal strains kept at relatively high abundance  $(>2,000$  cells mL<sup>-1</sup>) for a long period (>6 months) when fed on *M. rubrum* with the addition of *Teleaulax*  amphioxeia. The six *Dinophysis* species grew at growth rates of 0.50-1.03 day<sup>-1</sup>, reaching maximum concentrations of ca. 2,200-11,000 cells  $mL^{-1}$  at temperature ranges of 18-25oC, suggesting that these *Dinophysis* species are able to grow as rapidly as other redtide forming species. In the transmission electron microscopic observation of *D. fortii* cells, which had fully fed on the ciliate prey, well-developed chloroplasts (5–12 μm in length) were seen and three thylakoids were usually arranged in most of the chloroplasts observed, but chloroplasts having two thylakoids were sometimes confirmed. In cells starved for 4 weeks, a decrease in chloroplast numbers and disappearance of large chloroplasts were observed, and only a few small chloroplasts (0.5–2 μm in length) remained in the marginal regions. In the observation of the sequestration process of the

 $\overline{a}$

chloroplasts ingested from *M. rubrum* by *Dinophysis*, within 15 min after *Dinophyis* captured *M. rubrum*, incorporation of almost all of the chloroplasts was observed, while most of the other cell contents still remained in the *M. rubrum* cell. After that, dispersion of the ingested chloroplasts toward the marginal regions was confirmed, suggesting that chloroplasts of *M. rubrum* are ingested and dispersed in *Dinophysis* cells in advance of the ingestion of the other cell contents to prevent them from being digested in food vacuoles. The ingested chloroplasts can function as kleptoplastids. Molecular analyses of *Mesodinium rubrum* and several *Dinophysis* species plastid genes from natural samples showed a simple food web among *Teleaulax*/*Mesodinium*/*Dinophysis*. However, *Dinophysis* may still utilize other unknown prey species as the success rate in establishing *Dinophysis* cultures is still variable, and thus, a further study is needed.

#### **1.INTRODUCTION**

Diarrhetic shellfish poisoning (DSP) is a severe gastrointestinal disease caused by the consumption of shellfish contaminated with DSP toxins (Yasumoto et al. 1978, 1980). DSP toxins are produced by dinoflagellates belonging to the genera *Dinophysis* Ehrenberg and benthic *Prorocentrum* Ehrenberg (Yasumoto et al. 1980; Lee et al. 1989) and result in serious economic losses to shellfish culture industries worldwide (Della Loggia et al. 1993). At present, 10 *Dinophysis* and 2 *Phalacroma* species are known to be toxic (Lee et al. 1989; Maestrini 1998; Moestrup 2004; Reguera and Pizarro 2008; Moestrup, et al. 2019, Figure 1). In phylogenetic analyses, the *Dinophysis* species cluster into two or three main groups depending on the gene and/or region targeted (Edvardsen et al. 2003; Guillou et al. 2002; Handy et al. 2009; Jensen & Daugbjerg 2009; Nagai et al. 2008; Nishitani et al. 2008a; Papaefthimiou et al, 2010; Qiu et al, 2011; Raho et al, 2008, 2013; Stern et al, 2014, Figures 2, 3). Both the ribosomal RNA and mitochondrial genes, however, lack the sufficient resolution to differentiate between all *Dinophysis* species or strains of different geographic origin (Edvardsen et al., 2003; Hart et al., 2007; Raho et al., 2008, 2013; Rodríguez et al., 2012; Stern et al., 2014). Thus, morphology-based observations facilitate more detailed species identification compared to molecular methods.

Field investigations on the population dynamics of *Dinophysis* species have been carried out in various areas (Koike et al. 2001; Nishitani et al. 2002, 2005; Lindahl et al. 2007). Despite extensive studies on the distribution and population dynamics of *Dinophysis* species in the last two decades (e.g., Maestrini, et al. 1998; Hällfors, et al. 2011; Sjöqvist & Lindholm, 2011; Reguera, et al. 2012; Díaz, et al. 2013, 2016, 2019; Singh, et al. 2014; Hattenrath-Lehmann, et al. 2015; MacKenzie, et al. 2019), many aspects of ecophysiology and bloom mechanisms of *Dinophysis* species are still unknown, primarily due to the inability to culture them (Sampayo 1993; Jacobson & Andersen 1994; Maestrini 1998; Nishitani et al. 2003). Non-photosynthetic species of *Phalacroma* feed by myzocytosis, a process whereby a peduncle (or feeding tube) sucks up the cytoplasm from the prey, leaving behind the plasmalemma (Hansen 1991). Photosynthetic species of *Dinophysis* share this structure and,

although they had not been observed feeding (but see Park et al. 2006), food vacuoles were often found in their cytoplasm, clearly indicating mixotrophy (Jacobson and Andersen 1994; Koike et al. 2000). Many phototrophic species have an orange autofluorescence under blue or green light suggesting the presence of phycobilin (Geider and Gunter 1989; Hallegraeff and Lucas 1988; Lessard and Swift 1986; Schnepf and Elbrächter 1988; Imai and Nishitani 2000) and phycoerythrin (Geider and Gunter 1989; Hewes et al. 1998; Vesk et al. 1996). Based on ultrastructural analyses, the plastids have paired stacked thylakoids with electron-dense contents in the relatively wide lumen, similar to cryptophyte thylakoids (Schnepf and Elbrächter 1988; Lucas and Vesk 1990). These observations suggested that the *Dinophysis* plastids originated from cryptophytes (Schnepf and Elbrächter 1988; Meyer-Harms & Pollehne 1998). Molecular analyses of several *Dinophysis* species using plastid sequences such as *psbA*, 16S-rDNA, and *rbcL* (encoding the large subunit of RuBisCO) genes also proved the *Dinophysis* plastid to be of cryptomonad origin (Takishita et al. 2002; Hackett et al. 2003; Janson and Granéli 2003; Janson 2004; Takahashi et al. 2005). This led to the suggestion that the plastid of *Dinophysis* might be a kleptoplastid, a temporary but functioning plastid captured from a prey (Melkonian 1996; Janson 2004; Minnhagen & Janson 2006). However, whether the plastids of *Dinophysis* result of a permanent endosymbiosis or predation of a cryptophyte was not clarified until 2006.

Figure 2. A maximum-likelihood tree based on ITS alignment (579 bp, incl. insertions/deletions) including 31 sequences and *Heterocapsa circularisquama* serving as an outgroup. Bootstrap values > 50% are shown.

Since Park et al. (2006) succeeded in cultivating the toxic dinoflagellate *Dinophysis acuminata* by feeding them the ciliate *Mesodinium rubrum* grown with a cryptophyte *Teleaulax* sp., other seven species were also successfully cultured, namely *D. acuta* (Jaén et al. 2009), *D. caudata* (Nishitani et al. 2008b) *D. fortii* (Nagai et al. 2008), *D. infundibulum*  (Nishitani et al. 2008a), *D*. cf. *ovum* (Mafra et al. 2016), *D. sacculus* (Riobó et al. 2013) and *D. tripos* (Nagai et al. 2013). Although further supportive data are clearly required, this evidence strongly suggests that *Dinophysis* species depend on predator-prey interactions with *M. rubrum* and *Teleaulax* or *Teleaulax*-related species (Nagai et al. 2008; Nishitani et al. 2008a) for their photosynthetic capability. Cultured strains of *Dinophysis* species can be established and maintained by feeding with the ciliate prey grown with *Teleaulax* or *Teleaulax*-related species (Nagai et al. 2008; Nishitani et al. 2008a; Kamiyama & Suzuki 2009). Here we report on the feeding behavior and the growth characteristics of several *Dinophysis* species under laboratory conditions and the sequestration process of the chloroplasts ingested from *M. rubrum* by *Dinophysis* on the basis of transmission electron microscopy (TEM) and epifluorescence microscopy (EMF).

## **2. BIOGEOGRAPHY OF** *DINOPHYSIS* **AND** *PHALACROMA* **SPECIES ASSOCIATED WITH DSP EVENTS**

The *Dinophysis* and *Phalacroma* species listed as toxic in the IOC-UNESCO Taxonomic Reference List of Harmful Micro Algae (Moestrup, et al. 2019) are widely distributed, however, six species display more global distribution (*D. acuminata*, *D. acuta*, *D. caudata*, *D. norvegica*, *D. tripos*, *P. rotundatum*: Figure 4, OBIS, 2019). Majority of those *Dinophysis* and *Phalacroma* species have been detected from a wide salinity range of 0 to 35 with the highest number of reports from the salinity of 30-35 (Table 1, OBIS, 2019). At the same time, three species: *D. infundibulm*, *D. miles,* and *P. mitra*, occur in a narrower salinity range (25- 35 or 30-35), which can be explained by their appearance in the fully oceanic conditions (Figure 4, OBIS, 2019). The temperature range for the majority of the species is similarly broad, from -5 to 30 $^{\circ}$ C and with the highest number of reports from 10 to 20 $^{\circ}$ C (Table, 1, OBIS, 2019). Effect of temperature on the growth of *Dinophysis* species in laboratory conditions has been currently only investigated for *D. caudata*, *D. acuminata* and *D. tripos* (Kamiyama, et al. 2010; Rodríguez, et al. 2012; Basti et al. 2015; 2018; Gao, et al. 2017). *Dinophysis tripos* showed growth under the three tested temperatures (15, 19 and 25°C) with growth rates of 0.32, 0.37 and 0.35 day<sup>-1</sup> (d<sup>-1</sup>, Rodríguez, et al. 2012). Growth in *D. caudata* and *D. acuminata* was confirmed in the range of 15-32.5 $\degree$ C and 8-32 $\degree$ C and no growth was observed below 10 and 5°C, respectively (Basti, et al. 2015; 2018). Growth rates and maximum cell yields in *D. caudata* were 0.21 (15°C) - 0.67 (30°C) d-1 and 840 (15°C) - 7,000  $(32.5^{\circ}\text{C})$  cells mL<sup>-1</sup>, respectively (Basti, et al. 2015). The growth rate at 15<sup>o</sup>C was significantly lower than at other temperatures, suggesting that *D. caudata* prefers a relatively high temperature between 27-32.5°C. Similarly, the growth rates and the maximum cell yields in *D. acuminata* were 0.27 (8°C) - 0.93 (26°C) d<sup>-1</sup> and 400 (8°C) - 6,900 (20°C) cells mL-1 , respectively (Basti, et al. 2018). The results are consistent with their distributions as *D. caudata* is distributed in tropical and temperate waters (Okaichi 1967, Figure 4C) and *D. acuminata* is a cosmopolitan species present in the Pacific and Atlantic Oceans, and in the Mediterranean Sea (Figure 4A, OBIS, 2019).

Species	Water temperature $(^{\circ}C)$ range	Temperature $({}^{\circ}C)$ - highest number of reports	Salinity range	Salinity - highest number of reports

### **3. ISOLATION OF CLONAL STRAINS, GROWTH AND FEEDING PROCESS**

#### **3.1. Importance of the Establishment of Clonal Culture Strains**

Regarding toxin production by *Dinophysis* species, pectenotoxin-2 (PTX-2), dinophysistoxin-1 (DTX-1), and okadaic acid (OA) have been detected from several species obtained from natural samples from Japanese coastal waters (Suzuki et al. 1997, 1998, Uchida et al. 2018). OA and DTX-2 are the dominant toxins in some European *Dinophysis* species (Lee et al. 1989; Draisci et al. 1999; Pavela-Vrančič et al. 2001; Fernández-Puente et al. 2004a,b; Vale 2004; Fernández et al. 2006)., *Dinophysis acuminata*, *D. acuta*, *D. caudata*, *D. norvegica* and *D. sacculus* have caused DSP outbreaks around the world (Table 1 in Uchida et al. 2018). Further, PTX-11, which is a dominant toxin in *D. acuta* in New Zealand (MacKenzie et al. 2002, 2005; Suzuki et al. 2004, 2006), has not been detected in any *Dinophysis* species in Hokkaido, Japan (Suzuki et al. 2009). Although it is well known that various shellfish species exhibit different patterns of biotoxin uptake, biotransformation, and depuration (MacKenzie et al. 1997), another potential cause of this variability is the presence of qualitative and quantitative differences in the toxin profiles of different species of *Dinophysis* at different locations and times (MacKenzie et al. 2005). To explain the wide variation in toxin content of the same species of *Dinophysis* collected at the same site, it has been suggested that *Dinophysis*-toxin precursors actually originate from other microorganisms (Imai & Nishitani 2000; Nishitani et al. 2002). However, the production of DTX-1 and PTX-2 by a clonal culture of *D. acuminata* isolated from Japan and fed with the ciliate *M. rubrum* was conclusively proven by liquid chromatography (LC)-mass spectrometry (MS) analysis (Kamiyama & Suzuki 2009). The studies on the toxin profiles of several *Dinophysis* species obtained from samples from Hokkaido, Japan, have indicated significantly higher cellular content of DTX-1 in *D. fortii* than in other *Dinophysis* species, suggesting that *D. fortii* is the species responsible for DSP toxin contamination in shellfish in Hokkaido (Miyazono et al. 2008; Suzuki et al. 2009; Nagai et al. 2011). Thus, establishing clonal strains is very important to understand not only feeding behaviors or growth characteristics but also toxin production in *Dinophysis.*

#### **3.2. Establishment of** *Dinophysis* **Cultures**

In *D. fortii*, forty-eight cultures from 60 single cell isolates were grown with the addition of the marine ciliate *M. rubrum* and the cryptophyte *T. amphioxeia* as prey species. They were successfully established as clonal strains and the success rate for isolation was 80.0% (48/60). The cultures reached maximum cell densities of 417-2,550 cells  $mL^{-1}$  (1,048  $\pm$  99) (mean  $\pm$  SD, n = 48) at the end of one-month incubation (Figure 5A). In contrast, reduced growth of *D. fortii* (max. of 3-4 divisions) and formation of small cells was observed in the absence of the ciliate or when provided only with *T. amphioxeia*, showing that *D. fortii* can not utilize *T. amphioxeia* as prey (Nagai et al. 2008). *D. acuminata* cultures were also successfully established as clonal strains and the success rate for isolation was 78.0% (47/60). The cultures reached maximum cell densities of 700-7,500 cells mL<sup>-1</sup> (2,229  $\pm$  1,549) at the end of the one-month incubation (Figure 5B) (Nagai & Kamiyama 2016). Park et al. (2006), Nishitani et al. (2008a, b), Kamiyama et al. (2010), Nagai et al. (2008, 2011, 2013) and Mafra et al. (2016) showed that *D. acuminata*, *D. caudata*, *D. fortii*, *D. infundibulum*, *D*. cf. *ovum* and *D. tripos* required *M. rubrum* grown with *Teleaulax* as prey for their propagation. Although further examples are required, the evidence suggests *Dinophysis* species photosynthetic capacity dependence on the prey-predator interactions occurring among *Dinophysis*, *M. rubrum* and *Teleaulax/Geminigera*. In short, culture strains of *Dinophysis* species could potentially be established and maintained by feeding the dinoflagellates with ciliate prey grown with *Teleaulax/Plagioselmis/Geminigera*. Interestingly, in *D. fortii* sampled from the Okhotsk Sea (144 $\degree$  20' E, 44 $\degree$  03' N), the percentage of isolation success was 26/192 (13.5%) (Nagai et al. 2008) which was much lower than for the Hiroshima Bay population (48/60, 80.0%). Although most of the single cells isolated from the Okhotsk Sea grew once, the maintenance of the culture was unsuccessful due to poor growth after the *Dinophysis* cells were re-inoculated into *M. rubrum* culture. In addition, trials for the establishment of clonal cultures in *D. tripos* sampled from the Okhotsk Sea were unsuccessful, although a phylogenetic analysis inferred from plastid genome supported chloroplast origin from the cryptophytes *Teleaulax/Plagioselmis*/*Geminigera* clade (Koike et al. 2005; Takahashi et al. 2005). Thus, with regard to *D. fortii* or *D. tripos* in the Okhotsk Sea, the predator and prey cultures may be incompatible or the prey species may be slightly different from those found in the northern part of Japan.

#### **3.3. Growth under Laboratory Conditions**

To allow a preliminary investigation of the effect of nitrogen and phosphate levels on the growth of *D. fortii*, growth experiments were conducted under different nutrient conditions (Nagai et al. 2008). Cell numbers of *D. fortii* increased exponentially until Day 16 with a growth rate of  $0.45$  d<sup>-1</sup> over the first 6 days (Figure 6A, Table 2) under nutrient conditions of 1/3 nitrate, phosphate and metals and 1/10 vitamins of f/2 medium. The initial abundance of *M. rubrum* was around 1,000 cells mL<sup>-1</sup> and increased until reaching the peak of ca. 7,500 cells mL<sup>-1</sup> on Day 10 (0.48 d<sup>-1</sup> during Day 6-10), although *M. rubrum* did not grow smoothly during Day 2-6. After the peak, *M. rubrum* declined rapidly in cell number and disappeared completely on Day 16 with the increase in the abundance of *D. fortii* by feeding or by the death due to unknown reasons, as seen in Figure 6A. After the full consumption of *M. rubrum*, *D. fortii* slowly continued to increase in number until Day 20 and reached a maximum cell density of ca. 2,470 cells mL-1 . The cell number of *T. amphioxeia* increased exponentially until Day 6 with a growth rate of 1.78  $d^{-1}$  over the 4 days after Day 2. After the peak, the abundance of *T. amphioxeia* decreased rapidly and the decrease continued until the end of incubation. As controls, *D. fortii* was incubated with or without the addition of *T. amphioxeia* at the initial concentrations of ca. 180 (*D. fortii*) and 1,000 or 0 (*T. amphioxeia*) cells mL-1 (Nagai et al. 2008). *M. rubrum* alone was also incubated at the initial concentration of ca. 1,000 cells mL-1 . Cell numbers of *D. fortii* declined slightly in both the presence and absence of *T. amphioxeia*, showing that *D. fortii* can not utilize *T. amphioxeia* as prey (Figure 6B). Most *D. fortii* cells survived during 41 days of starvation including 21 days of the preincubation period. On the other hand, the rapid growth of *T. amphioxeia* was observed until Day 6 (2.0 d<sup>-1</sup>) and the number of cells declined gradually thereafter. In the control of *M*. *rubrum* without the predator, they grew exponentially for the first 10 days, with a growth rate of 0.45  $d^{-1}$  during Day 6-10, and a gradual reduction in the number of cells thereafter due to unknown reasons. Yet, ca. 670 cells mL-1 of *M. rubrum* still survived at the end of incubation (Figure 6C).

Similarly, growth experiments in *D. caudata* and *D. infundibulum* were carried out (Nishitani et al. 2008a, b). The number of cells of *D. caudata* increased exponentially until Day 10 with a growth rate of 1.03  $d^{-1}$  during Days 2-5 (Figure 6D, Table 2). The initial abundance of *M. rubrum* was ca. 1,500 cells well<sup>-1</sup> (810 μL) and grew until reaching a peak of ca. 8,900 cells mL-1 on Day 4 (0.74 d-1 ). After the peak, the number of cells of *M. rubrum* declined rapidly and disappeared by Day 8 due to active feeding by *D. caudata* and natural death. Even after the disappearance of *M. rubrum*, *D. caudata* continued to increase in number until Day 10 and reached a maximum cell density of ca.  $5,200 \pm 550$  cells mL<sup>-1</sup> (mean ± SD) (Nishitani et al. 2008b). In *D. infundibulum*, a clonal strain grew actively when *M. rubrum* cells were added as prey (Figure 6E). The number of *D. infundibulum* cells increased exponentially with a growth rate of 0.87 (Day 1-4, Table 2)  $d^{-1}$ . Even after the disappearance of *M. rubrum*, *D. infundibulum* continued to increase in number until Day 19-22, and the cell densities reached its maximum yields,  $2.3 \times 10^3$  cells mL<sup>-1</sup> (Figure 6E).

Figure 5. Maximum cell yields of *Dinophysis fortii* (A) and *Dinophysis acuminata* (B) isolated from single cells in Hiroshima Bay, Japan and established as clonal strains by feeding on the ciliate prey *Mesodinium rubrum* grown with the cryptophyte *Teleaulax amphioxeia*. A, Nagai et al. (2008); B, Nagai, and Kamiyama (2016).

Figure 6. Growth experiments of *Dinophysis fortii*, *D. caudata*, and *D. infundibulum* fed on the ciliate prey *Mesodinium rubrum* grown with the cryptophyte *Teleaulax amphioxeia* (modified from Nagai et al. 2008 and Nishitani et al. 2008a, b). *D. fortii* was grown in 48 wells microplates under two different nutrient conditions; A) 1/3 nitrate, phosphate and metals and 1/10 vitamins in f/2 medium. Initial concentrations of *D. fortii, M. rubrum* and *T. amphioxeia* were 10-20, 1.0 x 10<sup>3</sup> and 50 cells  $mL<sup>-1</sup>$ respectively; B) As controls, *D. fortii* was grown with/without *T. amphioxeia* in 48 wells microplates. Initial concentrations of *D. fortii* and *T. amphioxeia* were 180 and 1,000 or 0 cells mL-1 respectively; C) As a control, *M. rubrum* was grown alone without the predator *D. fortii* and the prey *T. amphioxeia*. An initial concentration of *M. rubrum* was 1,000 cells mL<sup>-1</sup>. Averages of triplicate counts and the standard deviation were plotted; D) Growth of *D. caudata* given 5,000 cells well<sup>-1</sup> (48 well microplate) of *M. rubrum* as the initial concentration, E) Growth of *D. infundibulum* given 1,500 cells mL-1 of *M. rubrum* as the initial concentration.

Growth rates of several *Dinophysis* species, estimated under *in situ* and laboratory conditions, are summarized in Table 2; rates varied from  $0.13$  to  $1.37$  d<sup>-1</sup>, due to the different methods and conditions used for growth rate estimation. For example, growth rates of *D. caudata* grown with *M. rubrum* (Nishitani et al. 2008b; Basti et al. 2015) were very high in comparison with previous reports for *D. caudata*, which were estimated from field

observations (Reguera et al. 2003) and a cultivation trial under laboratory conditions (Nishitani et al. 2003). When *D. fortii* is grown in the absence of ciliate prey, after feeding heavily on *M. rubrum*, the growth only occurs during the first 7 days at a rate of 0.73 d<sup>-1</sup> (Table 2, Figure 6F). High photosynthetic activities of several *Dinophysis* species were reported by Berland et al. (1994) and Granéli et al. (1995, 1997). Based on  $^{14}$ C uptake during light and dark periods, the growth rates of *D. acuminata*, *D. norvegica* and *D. acuta* were  $0.52$ -0.73,  $0.26$ -0.91 and  $0.50$ -0.59 d<sup>-1</sup>, respectively. These experimental data suggest that they were able to grow for the first few days utilizing either the accumulated nutrients or the stolen chloroplasts from the ciliate prey ingested during previous incubations or in the field. The growth rates of *D. fortii* obtained in this study varied markedly among conditions (Nagai et al. 2008), including differences in the nutrient levels or predator-prey interactions (Nagai et al. 2008; Nishitani et al. 2008b). The maximum yields also depended on the clonal strain, presumably due to their differences in feeding activity (Figure 5).

<sup>\*1</sup>, The values were estimated according to the model of Carpenter and Chang (1988). <sup>\*2</sup>, The values were estimated according to the model of Guillard (1973). \* , The ciliate *Mesodinium rubrum*, grown with the cryptophyte *Teleaulax*  sp./*T. amphioxeia*, was added as prey. \*\* , *Dinophysis* grown in the absence of prey, after being fed heavily with *M. rubrum*; \*\*\*, The growth rate was estimated by a <sup>14</sup>C method.

#### **3.4. The Feeding Behavior, Cell Division and Other Biological Observations in** *Dinophysis*

Similar to the case of *D. acuminata* (Park et al. 2006), *D. fortii* (Figure 7 A-D), *D. caudata* (Figure 8 A, C), *D. infundibulum* (Figure 9 A, B), *D. tripos* (data not shown) and *D*. cf. *ovum* (data not shown) were able to feed on *M. rubrum* (Nagai et al. 2008, 2013; Nishitani et al. 2008a, b; Mafra et al. 2016). *Dinophysis* cells swam around the prey (Figures 5B, 2D) and inserted a peduncle, which extends from around the flagellar pore region, into the cell of *M. rubrum* (Figures 7A, 7C, 8A, 9B), as has been previously reported for *P. rotundatum* (Hansen 1991) and *D. acuminata* (Park et al. 2006). The peduncle of these three *Dinophysis* species was narrower and shorter than those described in *P. rotundatum* (Hansen 1991) and *D. acuminata* (Park et al. 2006) and its length and width was  $15{\text -}20 \text{ }\mu\text{m}$  and  $2{\text -}3$ m, respectively (Figure 7A, 7C, 8A, 9B). No peduncles were visible externally to the cell of these *Dinophysis* species, indicating that the peduncle extended from the cell just before capturing the prey. Therefore, it was difficult to show the morphology of the peduncle and the transfer of cell content from the prey through the peduncle into the *Dinophysis* cell. Soon after *Dinophysis* inserted the peduncle into the cell of *M. rubrum* (Figure 7A, C), the ciliate became immobile and their cilia were shed from the cell within 1-5 minutes (Figure 7A-D, 9B), suggesting that *Dinophysis* injects some kind of toxin into the cell of the ciliate using the peduncle (Nagai et al. 2008). The captured prey was closely tethered around the flagellar pore region of *Dinophysis* cells (Figures 7A-D, 8A, 9B) and the cytoplasm of the prey was actively ingested through the peduncle. Transfer of small portions of cytoplasm into the food vacuole of *Dinophysis* cells was observed through the transparent peduncle (Figure 7A). *D. fortii* fed heavily on *M. rubrum* (Figure 7E) i.e., even when the cell was fully expanded by the active ingestion of prey, the active feeding behavior still continued (Figure 7A). *D. fortii* cells connecting with *M. rubrum* by the peduncle, lying on the bottom of the plates, were often observed during the ingestion of prey (Figure 7A). It took 45-90 min ( $n = 15$ ) until the whole cell content of *M. rubrum* was consumed. Propagation of these *Dinophysis* species was observed by frequent vegetative cell divisions (Figures. 7F, 8B, 9C), and sequential binary fission was sometimes observed without the cell separation from the previous cell division (Figures 7G, 8C, 9D). These four cells were united by their cingular lists and were still able to swim actively. After the separation, each cell was able to feed on prey and grow normally. The tetrad state is also regarded as the rejuvenation process from a resting cyst reproduced through karyogamy (Escalera & Reguera 2008).

When exposed to high *Dinophysis* cell densities (> 500 cells mL<sup>-1</sup>), *M. rubrum* cells tended to form clumps, became tangled with each other by their flagellae, swam helicoidally or rotated at the same position on the bottom of the microplate (Figures 7B, 8D, 8E), suggesting the release of an allelopathic chemical from *Dinophysis* cells. *Dinophysis* cells aggregated around these abnormally behaving *M. rubrum* and actively fed on them (Figures 7B, 8D). *M. rubrum* is an organism that can move rapidly; however, *Dinophysis* was able to capture the prey without any apparent difficulty. Therefore, it is reasonable to assume that *Dinophysis* species must have evolved a very effective capture mechanism. We observed that *M. rubrum* cilia were sometimes intertwined with the *Dinophysis* cell surface due to mucilaginous secretions on the dinoflagellate cell surface, suggesting that *Dinophysis* has various strategies to increase the chances of capturing the ciliate prey. Several mixotrophic

microalgae produce substances that deter grazing and/or inhibit the growth of competitors (allelochemicals) (Stoecker et al. 2006; Hansen, 2011), such that the additional role of these compounds in prey capture has been increasingly considered (e.g., Blossom et al. 2012).

Figure 7. Observations of the feeding behavior and propagation in *Dinophysis fortii*, which fed on the ciliate prey *Mesodinium rubrum* using the peduncle (Nagai et al. 2008). (A) *D. fortii* cell actively ingesting the prey, which shows a round shape and loss of cilia. Transport of cell contents of *M. rubrum*, captured by the *Dinophysis*, is visible through the transparent peduncle (arrows). (B) Clumping of *M. rubrum* cells, which may be caused by the release of an allelopathic chemical from *D. fortii* cells. *D. fortii* aggregated, and actively fed on, these abnormally behaving *M. rubrum* (arrows). (C) *D. fortii* cell, which has just inserted the peduncle into an *M. rubrum* cell. Arrows indicate the peduncle. (D) *D. fortii* cells actively ingesting the prey, which shows a round shape and loss of cilia. (E) An expanded cell that had fed heavily on the ciliate prey (ventral view). (F) Vegetative cell division by binary fission. (G) Sequential binary fission is seen without the cell separation of the previous cell division. (H) Harvested cells after growth experiments, showing the successful cultivation. (I) A dwarf cell produced as the result of depauperating division (cell shape was similar to that of *D. acuminata*, left) and a normal size cell (right). Scale  $bar = 50 \mu m$  (all at the same magnification).

Figure 8. Observations of feeding behavior and propagation in *Dinophysis caudata* seen during the growth experiment (Nishitani et al. 2008b). A) A *D. caudata* cell actively ingesting prey, showing the round shape and loss of cilia in the prey; B) Vegetative cell division of *D. caudata* by binary fission; C) A sequential binary fission of *D. caudata* seen without cell separation from the previous cell division; D) Harvested cells of *D. caudata* after growth experiments, showing successful cultivation; E) Clumped *Mesodinium rubrum* cells, which may be caused by the release of some kind of allelopathic chemical from *D. caudata* cells; F) A *D. caudata* cell feeding on clumped *M. rubrum* cells. All scale bars  $= 30 \mu m$ .

Figure 9. Observations of the feeding behavior and propagation in *Dinophysis infundibulum* (Nishitani et al. 2008a). Observations of feeding and propagation during maintenance culture or growth experiment. A) A natural cell collected from Hiroshima Bay, Japan; B) A cell actively ingesting prey, showing the round shape and loss of cilia in the prey. The arrow indicates the peduncle; C) Vegetative cell division by binary fission; D) Sequential binary fission observed without the separation of cells from the previous cell division; E) Harvested cells after growth experiments, showing their successful cultivation; F) A small cell (left) and a cell after feeding on *Mesodinium rubrum* (right); G) A couplet joined at the ventral side. All scale bars  $= 20 \mu m$ .

Toxins released by the haptophyte *Prymnesium parvum*, for instance, can immobilize their otherwise swimming microalgal prey, permitting their prompt capture (Skovgaard & Hansen, 2003; Tillmann, 2003). Free polyunsaturated fatty acids (PUFAs) produced by the dinoflagellate *Karenia mikimotoi* also exhibited allelopathic effects on the diatom *Chaetoceros gracile* (Arzul et al. 1995, 1998). In fact, the hemolytic/cytotoxic effects of several dinoflagellates and raphidophytes have been associated with high concentrations of free PUFAs (mainly eicosapentaenoic acid—EPA and docosahexaenoic acid—DHA),

especially in the presence of reactive oxygen species (ROS) (Marshall et al. 2003; Dorantes-Aranda et al. 2009; Mardones et al. 2015), suggesting that PUFA may also play a role in prey capture by mixotrophic microalgae. The release of a mucus trap, as reported for the dinoflagellate *Alexandrium pseudogonyaulax* (Blossom et al. 2012), enables the capture of fast swimming microalgal prey. In co-cultures of *Dinophysis* and its ciliate prey, cells of *D.*  cf. *ovum* always succeeded in capturing their evasive prey, the jumping ciliate *M. rubrum*, even at a relatively low initial cell density of the predator (e.g.,  $\sim$  50 *Dinophysis* cells mL<sup>-1</sup>) (Mafra et al. 2016) and despite the extremely high swimming velocity of up to 1.2 cm  $s^{-1}$  and initial acceleration of about 4 cm  $s^2$  attained during *M. rubrum* jumps (Fenchel & Hansen, 2006). Hansen et al. (2013) advocated that *Dinophysis* cells would be able to blast an adhesive capture filament from a certain distance and then pull the tied prey closer to them. In addition, Nielsen & Kiørboe (2015) suggested that a reduced deformation in the flow fields around swimming *D. acuta* cells would allow them to intercept the ciliate without provoking its escape. Prey capture by *D. acuta*, *D. acuminata,* and *D.* cf. *ovum* cells has been witnessed (and documented) after *M. rubrum* had been caught in "mucus traps", eventually forming clumps of a few ciliate cells (Mafra et al. 2016; Ojamäe et al. 2016; Papiol, et al. 2016). After being attached to such adhesive, apparently filamentous/fibrous material, *M. rubrum* cilia were firmly tangled and the ciliate was not able to escape, even when only part of its cirri initially entangled within the mucus trap. At this moment, actively feeding *Dinophysis* cells would approach their prey, exhibiting an erratic, hunting swimming pattern, with their feeding peduncles already mounted. As hypothesized by Hansen et al. (2013), the capacity of *Dinophysis* to detect *M. rubrum* cells from a distance could be either due to chemical or hydromechanical sensing. Recently, the detection of *M. rubrum* by chemoreception and usage of mechanistic swimming features aiding to target resting *M. rubrum* cells by *D. acuminata* has been documented (Jiang, et al. 2018).

A large number of cells were harvested by sieving *Dinophysis* cultures with nylon mesh (10 μm, in pore diameter), showing the successful cultivation of these *Dinphysis* species (Figures. 7H, 8F, 9E). When establishing *D. fortii* clonal strains from a single cell, small and colorless cells became dominant in some isolates (Figure 7I) and we could not establish clonal strains in such cases. During the maintenance and growth experiments of *Dinophysis*, the formation of small cells was also sometimes observed, especially when cells entered their stationary phase (senescent culture) (Figures 7I-left, 9F-left, 9G-right, 11A-left). The shape of the smaller cells was similar to that of *D. acuminata* and was clearly different from the normal vegetative cells of *D. fortii* (Figure 7I-right) and *D. infundibulum* (Figure 9F-right), and thus may be a potential cause of species misidentification in natural samples. The appearances of small cells have also been reported in *D. acuta* (Reguera et al. 2004), *D. caudata* (Nishitani et al. 2003, 2008a; Reguera et al. 2007), *D. fortii* (Uchida et al. 1999), *D. pavillardi* (Giacobbe & Gangemi 1997) and *D. sacculus* (Delgado et al. 1996). Small cells are able to grow again to a large size in *D. acuminata* (Reguera & González-Gil 2001) and *D. fortii* (Nagai et al. 2008). The steps from gamete pairs, cell fusion, nuclear fusion and the fate of planozygotes were tracked in several *Dinophysis* species by Escalera & Reguera (2008) and others, especially cell fusion in *D. fortii* (Uchida et al. 1999; Koike et al. 2006), *D. infundibulum* (Figure 9. G), *D*. *pavillardi* (Giacobbe & Gangemi 1997), *D. acuminata*, *D*. cf. *ovum* and *D. acuta* (Escalera & Reguera 2008) and nuclear fusion in *D. fortii* (Koike et al. 2006) and *D.* cf. *ovum* (Escalera & Reguera 2008).

The general morphology of the cells, including a prominent nucleus, numerous chloroplasts with pyrenoids, several food vacuoles and the rhabdosomes (Vesk & Lucas 1986; Lucas & Vesk 1990) is shown in Figure 10. Three thylakoids were usually arranged parallel to the longitudinal axis of most chloroplasts observed in this study, but chloroplasts having two thylakoids were sometimes confirmed (Figure 10B, arrows). The pyrenoid apparently appeared as a homogeneous body with a diameter larger than 1 µm and was attached to one end of the chloroplast (Figure 10A-C). In *D. fortii* cells that heavily fed on the ciliate prey, an enormously developed food vacuole, with dimensions approximately the same as those of the nucleus, was observed (Figure 10A). Although the majority of food vacuoles were homogenous, membrane-like structures and/or mitochondria-like particles were also confirmed in some food vacuoles (Figure 10A, B, D), indicating active ingestion of the ciliate prey (Figure 10A, D). Large numbers of rhabdosomes were seen in all cells of *D. fortii* examined (data not shown) and they were mainly located in the cytoplasm (Figure 10C). Starch-like grains appeared either in the food vacuoles or in the cytoplasm (Figure 10A, D). Starved cells contained no food vacuoles, but a few numbers of small starch-like grains and a few small chloroplasts  $(0.5-2 \mu m)$  remained in the marginal regions. The number of chloroplasts in these starved cells was significantly decreased and, in particular, large chloroplasts were completely disappeared (Figure 11A-right). The disappearance of large chloroplasts was also seen in the small cells that were produced as a result of the depauperating division (Figure 11A-left). Interestingly, we observed typical dinoflagellate chromosome structures inside food vacuoles in a *D. fortii* cell, clearly showing their cannibal behavior (Figure 11B).

#### **3.5. Observation of the Chloroplasts Sequestration Process by** *Dinophysis*

TEM observation of *Dinophysis* cells that fed heavily on the ciliate prey revealed the majority of food vacuoles were homogenous, membrane-like structures and⁄or mitochondrialike particles, indicating active ingestion of the ciliate prey (Figure 12, A and D). Chloroplastlike particles, however, have not been confirmed in food vacuoles (Nagai et al. 2008), thus *Dinophysis* has a system to spare the stolen chloroplasts from digestion in food vacuoles for retaining those as kleptoplastids.

The sequestration process of the chloroplasts ingested from *M. rubrum* has been investigated in *D. fortii* (Nagai, et al. 2008) and *D. infundibulum* (Nishitani, et al. 2008a). After 40 days of starvation, chloroplasts in most *Dinophysis* cells were reduced in number and size, and the cells became colorless as shown in Figure 12A, B, Figure 13A, B. The color of chloroplasts, which had been kept by *Dinophysis* when the feeding started, was more orange than those ingested from *M. rubrum*, accordingly, they were distinguishable in most cases. After one minute, no ingestion of the chloroplasts by *Dinophysis* was started yet (Figure 12A, B; Figure 13A, B). After five minutes, ingestion of the chloroplasts via the peduncle had already started. Accumulation and retention of the ingested chloroplasts were seen in the center of the cell (Figure 12C, D; Figure 13C, D). After ten minutes, more than half of the chloroplasts were ingested and retained in the center of the cell (Figure 12E, F; Figure 13E, F). After 15 minutes, almost all the chloroplasts were ingested and the beginning of the dispersion of the chloroplasts was seen, while most other cell contents still remained in the *M. rubrum* cell (Figure 12G; H, Figure 13G, H). After 40 minutes, dispersion of the

chloroplasts throughout the cell was seen, but many more of them were located in the marginal region. By then, almost all cell contents of *M. rubrum* were ingested (Figure 12I, J; Figure 13I, J) (Nagai et al. 2008; Nishitani et al. 2008a).

Figure 10. TEM observations of fully expanded *Dinophysis fortii* cells that had fed heavily on *Mesodinium rubrum* (Nagai et al. 2008). A, Lateral section of a cell showing a prominent nucleus, chloroplasts with pyrenoids (arrowheads), several food vacuoles, including homogeneous and nonhomogeneous ones and starch-like grains. Scale bar =  $10 \mu m$ ; B, Enlargement of A, a homogenous/ round-shape pyrenoid and a chloroplast elongating vertically toward the cell wall and having three thylakoids oriented along the long axis of the organelle. A small chloroplast having a pair of thylakoids was also confirmed (arrows). Scale  $bar = 1 \mu m$ ; C, a high magnification of chloroplasts clearly showing three thylakoids (arrowheads). Scale bar = 1 µm; D, another example of lateral section of a *D. fortii* cell fully expanded by feeding heavily on the ciliate prey. Numerous chloroplasts (arrowheads), food vacuoles and starch-like grains (arrows) are contained. Scale bar = 10 µm. Abbreviation; C, chloroplast; N, nucleus; P, pyrenoid; R, rhabdosome; S, starch-like grain; T, thylakoid; \*, food vacuole (HF = homogeneous; NHF, non-homogeneous).

In the study by Nagai, et al. (2008), the ultrastructural observation by TEM showed several well-developed food vacuoles in *D. fortii* cells that had fully fed on the prey (Figure 10A), and membrane-like structures and/or mitochondria-like particles were confirmed in the vacuoles (Figure 10A, B, D). Chloroplast-like particles having thylakoid bands were, however, not contained in the vacuoles, although numerous sections of more than ten cells were observed. The epifluorescent microscopic observation of the chloroplast ingestion process showed that within 15 minutes after *D. fortii* captured *M. rubrum*, *D. fortii* had ingested almost all the chloroplasts and concentrated them in the center of their cells, while most of the other ciliate cell contents remained in the *M. rubrum* cell. After ingestion, the chloroplasts moved toward the marginal regions of the dinoflagellate cell (Figure 10, 12I), suggesting that chloroplasts are ingested from *M. rubrum* and dispersed in *D. fortii* cells in advance compared to the ingestion of other cell contents in order to spare the chloroplasts from digestion so that they utilized as kleptoplastids.

Figure 11. A TEM observation of *Dinophysis fortii* (modified from Nagai et al. 2008). *D. fortii* cells were incubated for 4 weeks under starvation conditions (after the growth experiment shown in Figure 6A). A); Longitudinal sections of a starved cell (right) and a small cell, produced as a result of depauperating division (left), showing no food vacuoles and only a few small chloroplasts (0.5-2  $\mu$ m) in the marginal regions of the cell (arrows); B) A typical dinoflagellate chromosome structure observed in the food vacuoles in a *D. fortii* cell showing the cannibal behavior. Scale bar =  $10 \mu m$ .

In both *D. acuminata* (Park et al. 2006) and *D. fortii* (Figure 10) chloroplast-like particles from  $M$ . *rubrum*, smaller than 5  $\mu$ m in diameter, were ingested via peduncle. In contrast, much larger chloroplasts,  $> 10 \mu m$  in length, were observed in *D. fortii* using TEM observations (Figure 10A). These reported observations led us to question: Can *Dinophysis* control the size of stolen chloroplasts during retention? We observed the disappearance of relatively large chloroplasts ( $> 5 \mu$ m in length) from *D. fortii* after  $> 4$  weeks of incubation without the ciliate prey, and only a few small chloroplasts  $(0.5-2 \mu m)$  in length) remained in the marginal region of the cells, especially in small cells (Figure 11), although the dinoflagellates survived more than two months incubation without feeding on prey. For *D. caudata* decrease in plastid DNA cell<sup>-1</sup>  $d^{-1}$  closely followed culture growth rate (Pearson correlation,  $r = 0.91$ ), indicating that existing plastids were diluted within the growing

population and that no new plastids were synthesized by the cells (Minnhagen et al. 2011). There are interesting studies in *D. acuminata* and *D. fortii* reporting that they harbor several genes encoding plastid-related proteins, which are thought to have originated from fucoxanthin dinoflagellates, haptophytes and cryptophytes via lateral gene transfer (LGT) (Wisecaver & Hackett 2010; Hongo et al. 2019). Expression of genes related to cryptophyte plastid function and maintenance is lower in *D. acuminata* than in completely phototrophic algae with permanent plastids (Wisecaver & Hackett 2010), suggesting that *D. acuminata*  cannot retain kleptoplastids as the permanent plastids. In a recent study, however, 58 gene products involved in porphyrin, chlorophyll, isoprenoid, and carotenoid biosyntheses as well as in photosynthesis were identified in *D. fortii* (Hongo et al. 2019), showing the concrete evidence that *D. fortii* obtained these genes to utilize stolen plastids more efficiently in the evolutional process. One hypothesis is that *D. fortii* might ingest *M. rubrum* as merely a heterotrophic nutrient source and utilize the stolen chloroplasts for an ancillary function because the growth of *D. fortii* was observed only during the first 7 days after the removal of prey (Nagai et al. 2008). In our observations of *D. fortii* cells that were incubated without the prey ciliate for ca. two months still retain a few small chloroplasts, as shown in Figure 11A (by arrows). Are they permanent chloroplasts or retained kleptoplastids? Gene sequences of *Dinophysis* plastids showed striking similarities with those of the cryptophyte *Teleaulax*/*Geminigera* (Janson 2004, Minnhagen and Janson 2006), implying that more variable regions in the plastid genome may need to be analyzed to definitively answer this question. In a recent examination of *M. rubrum* based on ultrastructure by TEM and on the dynamics of photosynthesis, ingestion and growth rates in laboratory conditions, Hansen & Fenchel (2006) presented evidence that *M. rubrum* harbors a permanent cryptophyte endosymbiont that has different and larger chloroplasts than the *Teleaulax* added as prey. Three thylakoids were found in most of the chloroplasts of *D. fortii* cultured in this study, with a few exceptions (Figure 10B, C). This suggests that the chloroplasts observed in *D. fortii* originate from the permanent symbiont of *M. rubrum* because three thylakoid bands were clearly shown in TEM observation of chloroplasts in *M. rubrum* by Hibberd (1977) and Lindholm et al. (1988). In addition, *T. amphioxeia*, which we added to *M. rubrum* as prey, was observed to have pairs of thylakoid bands (Nagai et al. 2008). However, most of the TEM observations of naturally occurring photosynthetic *Dinophysis* species showed two thylakoid bands (Hallegraeff & Lucas 1988, Schnepf and Elbrächter 1988, Lucas & Vesk 1990, Jacobson & Andersen 1994, Carpenter et al. 1995, Vesk et al. 1996), except for one natural sample of *Dinophysis* sp., showing three thylakoid bands (Clement et al. 1988). In our TEM observations, we used *D. fortii* fed with *M. rubrum* that was pre-incubated for three weeks without addition of the cryptophyte prey. Thus, the difference in number of thylakoids observed in *Dinophysis* cells might be caused by the difference in abundance of the permanent cryptophyte symbiont and the cryptophyte prey inside the cells of *M. rubrum*. Otherwise, these contradictory results may show the instability of thylakoid bands formation. To trace the cryptophyte chloroplasts in cells of *Dinophysis* via *M. rubrum*, development of new technology such as chloroplast transformation with DNA encoding Green Fluorescent Protein (GFP) may be needed.

Figure 12. Observation of the sequestration process of the chloroplasts ingested from *Mesodinium rubrum* by *Dinophysis fortii* (Nagai et al. 2008). A and B, micrographs at one minute after the *D. fortii*  cell captured *M. rubrum* showing that no ingestion of the chloroplasts by *D. fortii* had started. A, observation by an inverted epifluorescence microscope (EFM); B, observation by an inverted normal light microscope (LM). C (EFM) and D (LM), micrographs at five minutes after the *D. fortii* cell captured *M. rubrum*. Ingestion of the chloroplasts through the peduncle had already started. Accumulation and concentration of the ingested chloroplasts were seen in the center of the cell. E (EFM) and F (LM), micrographs at ten minutes after the *D. fortii* cell captured *M. rubrum*. More than half of the chloroplasts were ingested and retained in the center of the cell. G (EFM) and H (LM), micrographs at fifteen minutes after the *D. fortii* cell captured *M. rubrum*. Almost all of the chloroplasts were ingested and the beginning of the dispersion of the chloroplasts was observed, while most of the other cell contents still remained in the *M. rubrum* cell. I (EFM) and J (LM), micrographs at forty minutes after the *D. fortii* cell captured *M. rubrum*. Dispersion of the chloroplasts throughout the cell was observed, but many more of them were located in the marginal region. Most of the other cell contents were ingested. White arrows show chloroplasts, which had been retained by *D. fortii*, when the feeding experiment started. This is not a sequential series of observations and the cells shown in A, C, E, G and I are not the same. Scale bar  $= 50 \mu m$  (All at the same magnification).

It has become clear that plastid sequences of the 16S rRNA gene and *psbA* (encoding the photosystem II [PSII] reaction center protein D1) in natural *Dinophysis* cells (except *Dinophysis mitra*) (Koike et al. 2005) originate from cryptophyte *Teleaulax*/ *Geminigera*/*Plagioselmis* clade (Janson 2004; Minnhagen & Johnson 2006; Takahashi et al. 2005; Takishita et al. 2002). Minnhagen & Janson (2006) also reported an exception to this finding in natural *D. acuminata* cells, isolated from the Greenland Sea, containing a plastid 16S rRNA gene sequence that was more closely related to *Geminigera cryophila*. These characteristics are probably caused by the cryptophyte prey preference of *M. rubrum* in natural environments. Under laboratory conditions, *M. rubrum* can be cultivated by providing the cryptophyte *T. amphioxeia* (Nagai et al. 2008, 2011, 2013; Nishitani et al. 2008a, b), *Teleaulax acuta* (Johnson & Stoecker 2005), or *G. cryophila* (Johnson et al. 2006). The first report of its prey preference in natural environments originated from Japanese coastal waters (Nishitani et al. 2010), motivated by unsuccessful culturing of some species, e.g., *D. norvegica* and the low percentages of the isolation success seen in *D. fortii* or *D. tripos* in the Okhotsk Sea (Nagai et al. 2008, 2013). The prey organisms of *M. rubrum* were determined by sequencing the cryptophyte nucleomorph 18S rRNA gene in natural *M. rubrum* cells; this genetic region has high substitution rates and facilitates species identification (Hoef-Emden et al. 2002). The origins of plastids in *Dinophysis* spp. were revealed by sequencing the plastid 16S rRNA gene and *psbA* in natural *Dinophysis* cells.

A total of 715 nucleomorph sequences from 114 PCR products of 134 *M. rubrum* cells were determined. Of these, 713 sequences were identical to the sequence of *T. amphioxeia*  (99.7%), while the other 2 sequences (representing 0.3%), which were detected from the Harima-Nada station *M. rubrum* cells (cell identifier [ID] HAR12 and HAR76), were closely related to those of *G. cryophila* and *T. acuta* (Table 3 and Figure 14). These two *M. rubrum*  cells contained two different cryptophyte sequences in each cell; in each of these cells, the sequences detected occurred in the proportion of seven sequences of *T. amphioxeia* to one other sequence. Knowledge of the availability of suitable prey for *M. rubrum* is very limited, but up to now, *M. rubrum* has been successfully cultured using *P. prolonga* (Hernández-Urcera, et al. 2018), *T. amphioxeia* (Nagai et al. 2008, Nishitani et al. 2008a, b), *T. acuta*  (Johnson & Stoecker 2005), and *G. cryophila* (Johnson et al. 2006) as prey. In addition, Park et al. (2007) have isolated several *T. amphioxeia* like cryptophyte species inferred from the nuclear 18S rRNA gene phylogeny and have cultured *M. rubrum* by addition of those cryptophytes as prey. Considering these facts, the genera *Teleaulax* and *Geminigera* seem to be preferred prey for *M. rubrum.* In the study, however, the nucleomorph sequences of *T. acuta* and *G. cryophila* were never detected from natural cells of *M. rubrum*, suggesting that the two species are unlikely to become the prey of *M. rubrum*, at least in Japanese coastal waters. Accordingly, this study found that *T. amphioxeia* is probably the most important species for *M. rubrum* as a prey source (but see Rial, et al. 2015).

Figure 13. *Dinophysis infundibulum* (Nishitani et al. 2008a). Observations of the sequestration process of the chloroplasts ingested from *Mesodinium rubrum*. The left- and right-hand columns show micrographs by an inverted normal light microscope and an inverted epifluorescence microscope, respectively. This is not a series of sequential observations, and the *D. infundibulum* cells shown in the left-hand micrographs are not the same cell. (A, B) A cell cultivated for 51 days without the addition of *M. rubrum* and *Teleaulax amphioxeia*. (C, D) 2 min after the cell captured *M. rubrum*. Ingestion of the chloroplasts through the peduncle had not started. (E, F) 15 min after the cell captured *M. rubrum*. Most of the chloroplasts were ingested. Accumulation and concentration of the ingested chloroplasts were observed in the center of the cell. (G, H) 30 min after the cell captured *M. rubrum*. Apparently, all the chloroplasts were ingested, and the beginning of the dispersion of the chloroplasts was observed. (I, J) The *D. infundibulum* cell 2 days after *M. rubrum* was provided; the cell has certainly ingested some ciliates and shows accumulation of the ingested chloroplasts, possibly functioning as kleptoplastids. All scale bars  $= 20 \mu m$  (all at the same magnification).

Figure 14. A maximum-likelihood tree inferred from the cryptophyte nucleomorph 18S rRNA gene (Nishitani et al. 2008a). Cryptophyte sequences detected from natural cells of *M. rubrum* are indicated by gray boxes. Bootstrap support values (left) and posterior probabilities (right) are provided. For further information on Cell ID, refer to Nishitani et al. (2010).

Plastid genes in natural *Dinophysis* cells were analyzed and 564 sequences of 16S from the successfully amplified PCR products  $(n = 68)$  were determined. Of these, 527 sequences were identical to the sequence of *T. amphioxeia* (93.4%). No variation among the sequences was confirmed (Figure 15), although Hackett et al. (2003) previously detected several variations (less than 16 bp out of ca. 1,200 bp) in the plastid 16S rRNA gene sequences in *Dinophysis* spp. isolated from the East Coast of North America. The remaining 37 sequences obtained in this study (5.6%), which were all identical and were detected only from the Funka Bay sample (*D. acuminata*, cell ID FUN03; *D. norvegica*, cell ID FUN07), showed a close phylogenetic affiliation and a divergence of 0.7% and 0.9% compared with sequences of *G. cryophila* and *T. acuta*, respectively (Table 3 and Figure 15). These *Dinophysis* cells contained two different cryptophyte sequences in a single cell. Four sequences of *T. amphioxeia* and 31 other sequences were detected from the *D. acuminata* cell (cell ID FUN03), and two sequences of *T. amphioxeia* and six other sequences were detected from the *D. norvegica* cell (cell ID FUN07). Interestingly, the other sequence was identical to that of a *D. acuminata* cell isolated from the Greenland Sea (Minnhagen & Janson 2006) although the cryptophyte species was not identified.

The result of the plastid *psbA* analysis was similar to that of the plastid 16S rRNA gene (Table 3). The partial plastid *psbA* sequences determined in this study were 890 bp, and 355 *psbA* sequences were determined from the successfully amplified PCR products. Of these, 352 sequences were identical to the sequence of *T. amphioxeia* (99.4%), and no variation was observed. As in the analysis of the plastid 16S rRNA gene, another three sequences, which were all identical and detected only from the Funka Bay sample (*D. acuminata*, cell ID FUN03; *D. infundibulum*, cell ID FUN04) (0.6%), showed a close phylogenetic affiliation and a 2.6% divergence from that of *G. cryophila* (Table 3 and Figure 16). Six sequences of *T. amphioxeia* and one other sequence were detected from the *D. acuminata* cell (cell ID FUN03), and five sequences of *T. amphioxeia* and two other sequences were detected from the *D. infundibulum* cell (cell ID FUN04). The high congruence of *M. rubrum* prey (cryptophyte *T. amphioxeia*) and *Dinophysis* plastid identities obtained in Japanese coastal waters are all identical with those collected from the Baltic Sea and the North Sea (Janson & Granéli 2003; Minnhagen & Johnson 2006), the North Atlantic Ocean (Janson & Granéli 2003), a Norwegian fjord (Minnhagen & Johnson 2006), and the North American East Coast (Hackett et al. 2003), showing the simple food web among *Teleaulax*/*Mesodinium*/*Dinophysis*  species.

Species belonging to the genus *Mesodinium* are among the most widely distributed and abundant marine ciliates in the coastal and estuarine ecosystems (Leppanen & Bruun 1986; Sanders 1995; Bell & Laybourn-Parry 1999). Phylogenetic analysis of rRNA genes (ITS region) has demonstrated that *M. rubrum* is actually a species complex, composed of at least six major clades (Herfort et al. 2011; Garcia-Cuetos et al. 2012; Johnson et al. 2016). One of these clades was described as a new species, *M. major,* based on molecular and ultrastructural characteristics, and is larger and has more plastids than *M. rubrum* (Garcia-Cuetos et al. 2012). The growth of *Dinophysis acuminata* and *D. acuta* fed on two *M. rubrum* strains isolated from different geographic origins, i.e., Spain and Denmark, was significantly different (García-Portela et al. 2018). This suggests that local *Mesodinium* populations may have different nutritional value, which may affect the metabolic functions for the growth of *Dinophysis*, causing differences in the success rate of establishing *Dinophysis* cultures. Otherwise, the difference may simply be caused by food preferences of *Dinophysis* that consume different *Mesodinium* species. Nishitani et al. (2018) developed a molecular technique to identify prey species consumed by *Dinophysis*, but it was applied only to *Phalacroma mitra* (previously named *Dinophysis mitra*). This method revealed the presence of several other prey species (several ciliate species, cryptophytes, dinoflagellate, and radiolaria) in addition to *M. rubrum*. This method may solve the mystery of *Dinophysis* food webs and allow a deeper understanding of *Dinophysis* ecology.

#### **ACKNOWLEDGMENTS**

We are grateful to two anonymous reviewers to give positive comments and suggestions to significantly improve the manuscript. This work was supported by a Grant-In-Aid for Scientific Research from the Japan Society for the Promotion of Science (No. 25.03517, 20380116, 18KK0182), Regulatory Research Projects for food safety, animal and plant protection (No. 2303), and Cross-Ministerial Strategic Innovation Promotion Program. # **CARBON ASSIMILATION: DINOFLAGELLATES**

# *D. V. Subba Rao , Ravi V. Durvasula and Adinarayana Kunamneni*

Department of Medicine, Loyola University Medical Center, Maywood, Chicago, Illinois, US

# **ABSTRACT**

Nearly 50% of the estimated 2377 dinoflagellate species are photosynthetic while a few are mixotrophic; these make an important contribution to the global biological carbon pump. We reviewed the involvement of pigments in the photosynthetic carbon assimilation and photoprotection in the athecate, thecate and symbiotic groups of dinoflagellates. We collated the much scattered and limited data on carbon assimilation in dinoflagellates. A variety of units for photosynthesis have been reported based on biomass expressed as cell numbers, chlorophyll *a*, cell carbon and cell volume which makes intercomparison of results difficult. The impacts of temperature, irradiance, nutrients in the carbon assimilation are discussed. Intra and inter specific variations in carbon assimilation are observed. Carbon assimilation was higher in heterotrophic dinoflagellates compared to autotrophic cultures. Mixotrophy provides a competitive advantage for long-term survival. Photosynthetic rates in dinoflagellate groups are low, even lower than the senescent cells of diatoms and microflagellates. Perhaps in the dinoflagellates, the channeling of energy for toxin production together with their need to support a disproportionately large DNA requires a heavy metabolic requirement and may explain their lower carbon assimilation rates.

**Keywords**: photosynthesis, carbon assimilation, autotrophs, mixotrophs, comparison

# **INTRODUCTION**

Dinoflagellates live in marine and freshwater habitats. Of the estimated 2377 dinoflagellate species, 1555 are described species of which 220 are from freshwater [1].

 $\overline{a}$ 

<sup>\*</sup> Corresponding Author's Email: Karin.Rengefors@biol.lu.se.

Nutritionally the dinoflagellates present a great diversity including photosynthesis, heterotrophy, phagotrophy, mixotrophy, parasitism and symbiosis. Nearly 50% of the dinoflagellates are photosynthetic [2] and make an important contribution to the global biological carbon pump [3]. Some species cause red tides which are ephemeral but contribute to algal biomass, for example off Kuwait  $(\sim 2$  billion cells  $1<sup>-1</sup>$  and  $\sim 4525$  Chl *a*  $1<sup>-1</sup>$  [4]. Winter blooms of *Heterocapsa triquetra* in Patagonian fjord ecosystem contribute 0.6 -1.6 gCm<sup>-2</sup> d<sup>-1</sup> to gross primary production. In the West Florida Shelf, blooms last one month and photosynthetic production during the blooms is higher than that during non-bloom conditions; on the average blooms contribute to 40% of the annual non-bloom production [5]. Recurrent seasonal occurrence as in "Florida red tide" caused by extensive blooms of *Karenia*, or *Alexandrium* along the northeastern U.S. coastline [6, 7] suggest their potential impact on the carbon footprint in the marine environment.

Nearly 75-80% of toxigenic red-tide algae are dinoflagellates [8], produce phycotoxins and impact the commercially important fisheries and human health. The saxitoxin produced by *Alexandrium* is 1000 times more potent than cyanide [9]. Red tides being ephemeral, studies are carried out in a sense of urgency, and are limited in duration. Such studies are focused more on the qualitative and quantitative abundance of the organisms, their origin, growth, distribution and production of phycotoxins rather than their ecophysiology. Difficulty in establishing dinoflagellate cultures stymied their ecophysiological studies. In contrast, more comprehensive studies have been carried out on the benign microalgae such as the diatoms and microflagellates because of their utility in aquaculture and their amenability for culturing. This explains why more "Cinderellas" or "weed species" are present amongst diatoms (*Thalassiosira, Nitzschia, Cylindrotheca, and Phaeodactylum*) and microflagellates (*Dunaliella, Monochrysis*) than the dinoflagellates.

In this essay we collated the much scattered and limited data on carbon assimilation in dinoflagellates. We reviewed the involvement of pigments in the photosynthetic carbon assimilation and photoprotection in the athecate, thecate and symbiotic groups of dinoflagellates. Photosynthetic rates in dinoflagellate groups are low compared to other planktonic microalgae. The need to emphasize systematic concerted studies on the dinoflagellate photophysiology is pointed out.

# **GENERAL METHODOLOGY**

Usually red tides are constituted by a few species; these natural assemblages are fractionated using suitable sieves [10-12] and used for biomass and carbon assimilation determinations [13]. Cultured cells of dinoflagellates are used to express their biomass as cell abundance, chlorophyll and carbon assimilation rates. Symbiotic dinoflagellates from anthozoans are studied on isolates either by stripping coral tissues using Water-Pik method [14], manual fractionation [15] or treatment with NaOH solution [16].

The process of carbon assimilation in dinoflagellates is similar to that carried out by other microalgae, and is dependent on chlorophyll *a*, carbon dioxide, and light energy. Details on quantification of natural assemblages of phytoplankton cells and pigments are sufficiently documented which could be suitably modified for dinoflagellates. Cells are enumerated under a microscope using a haemocytometer, Sedgwick Rafter slides, or sedimentation chambers with Utermohl's inverted microscope [17]. Details on the microscopic and molecular methods

for phytoplankton quantitative analysis are discussed [18]. Flow cytometry has been increasingly used to obtain data on cell abundance, volumes of microalgae and their fluorescence [19].

Chlorophyll *a* is the main photosynthetic pigment. Pigments are determined by spectrophotometry and fluorometry [20-22]. For determining the phytoplankton composition and for estimating the biomass of the different algal groups High Pressure Liquid Chromatography (HPLC) offers a rapid, very sensitive and objective method [23, 24]*.*

Photosynthesis is determined using the dark and light bottle oxygen exchange method originally described by Gaarder and Gran [25] and used for dinoflagellate [26] or by oxygen electrodes [27-29]. Using oxygen exchange method, respiration was measured in darkened cells [30-32]. Alternatively, a more sensitive method, the tracer technique using carbon-14, originally described by Steemann Nielsen [33] is utilized to determine photosynthetic activities of cultured dinoflagellates [34, 35]. Details of the oxygen exchange method and carbon-14 method and sources of error are discussed [17, 36].

Chlorophyll *a* specific photosynthesis (*P*)–irradiance (*I* µmol m<sup>-2</sup> s<sup>-1</sup>) in microalgae are shown in Figure 1 [37].

Measurements include determination of the initial slope of the light limited portion of the *P-I* relationship: the photosynthetic efficiency ( $\alpha$  μg C μg Chl  $\alpha$ <sup>-1</sup> h<sup>-1</sup>μmol m<sup>-2</sup> s<sup>-1</sup>), irradiance at which photosynthesis gets light saturated  $E_k$  ( $\mu$ mol m<sup>-2</sup> s<sup>-1</sup>), light saturated photosynthesis  $P<sup>B</sup>$ <sub>max</sub> and photoinhibitory decrease β (μmol m<sup>-2</sup> s<sup>-1</sup>) [36, 38] expressed as

$$
P_{\text{m}}^{\text{Chi}} = P_{\text{s}}^{\text{Chi}} \left( \frac{\alpha}{\alpha + \beta} \right) \left( \frac{\beta}{\alpha + \beta} \right) \left( \beta / \alpha \right)
$$

Usually log phase algal cultures are utilized and the initial slope, *Pmax* and *Ek* are used as indicators of the physiological functioning of the alga.

Figure 1. Photosynthesis-Irradiance model.

#### **Photosynthetic Rates**

A variety of units for photosynthesis have been reported based on biomass expressed as cell numbers, chlorophyll *a*, cell carbon and cell volume as given below.

Units reported include:

```
Pmax (Cell) = (10^{-6}) X µmol O<sub>2</sub> µg Cell<sup>-1</sup> h<sup>-1</sup>,
Total 14C fixed ((DPM x 10^{-3}).10^6 cells<sup>-1</sup>)
μmol O_2 per min per 10<sup>9</sup> cells
μmol O<sup>2</sup> per cell h<sup>-1</sup> (x10<sup>7</sup>)
μmol O<sub>2</sub> per μmol chl a h<sup>-1</sup> (x10)
μmol O<sub>2</sub> μg Chl a -1 h<sup>-1</sup>oxygen evolved/cm3/h<sup>-1</sup>
Pmax (Chl) = (10<sup>-1</sup>) X μmol O<sub>2</sub> μg Chl a<sup>-1</sup> h<sup>-1</sup>
Pmax (C) = (10<sup>-3</sup>) X µmol O<sub>2</sub> µg C<sup>-1</sup> h<sup>-1</sup>
Oxygen production (micromoles O_2 h<sup>-1</sup> (10<sup>6</sup> cells<sup>-1</sup>)
nmol O2 (μg Chl a)-1 min-1
mol oxygen evolved/cm3/h
Photosynthetic oxygen evolution (nmol/cell x 10^5 h<sup>-1</sup>)
pg O<sub>2</sub> zooxanthella<sup>-1</sup> h<sup>-1</sup>, \mug O<sub>2</sub> polyp<sup>-1</sup>
mg C m<sup>-3</sup> h<sup>-1</sup>
pgC. Cell-1
, DPM cell-1
μgC Cell<sup>-1</sup>h<sup>-1</sup> (x10<sup>-5</sup>)
mg C mg-1 Chl a h
-1
```
As the cell constituents vary with the physiological state of the alga, comparison of the physiological rates should be based on organisms in the same growth phase. Values normalized per cell could be a single largest source of uncertainty because cell volumes of big dinoflagellates are 1500 times larger than small dinoflagellate species [39]. This is also the case with diatoms; larger diatoms have cell volumes 20,000 times more than the smaller species [40]. For example the dinoflagellate *Pyrocystis noctiluca* with a cell volume of 22x 10<sup>6</sup> μm<sup>3</sup> has the lowest growth rate of 0.1 d-1 , compared to *Gonyaulax tamarensis* with a cell volume of 22x 10<sup>3</sup> μm<sup>3</sup> and a rate of 0.5 d-1 [41]. Even in the cultures of *Karlodionium veneficum* cell volumes varied with the growth phase; in the exponential phase cell volumes varied between 416.6 and 646.8  $\mu$ m<sup>3</sup> and in the stationary phase between 389.8 and 610.3  $\mu$ m<sup>3</sup> [42]. Finkel and Irwin [43] noted that often the allometric  $\frac{3}{4}$  rule deviates in scaling phytoplankton and does not account for the size dependence of light absorption and photosynthesis; they suggested a composite allometric and bio-optic model to provide a mechanistic explanation for microalgal photosynthesis and growth. Banse [44] summarized that in microalgae with increasing cell size growth rate decreased and proposed cell carbon as a scaling factor in comparative algal physiology but determination of cell carbon has analytical issues such as contamination due to organic matter and dead cells. Although cellular pigment varies with the growth phase, chlorophyll  $a$  –is the photosynthetic pigment and serves as a better index for normalizing photosynthesis. More comparable data utilizing dinoflagellate cultures are needed to address this issue.

The ratio of the energy stored (organic products) to the light energy (photons or formally Einsteins) absorbed is defined as photosynthetic efficiency. This is determined by whole cell fluorescence on controls (without DCMU) and those treated with DCMU  $(F_{+DCMU}/F_{-DCMU})$  in cultures of *Symbiodinium microadriaticum* [45] or  $F_v/F_m$  in the peridinin-containing dinoflagellates *Akashiwo sanguinea*, *Prorocentrum micans* and *Scrippsiella trochoidea* [46] or *Fq'*/*Fm'* the effective quantum yield of PS II under actinic irradiance [47]. Maximum Quantum Yield of Photosystem II is expressed as:

$$
Fv/_{Fm} = \left(\frac{Fm - F0}{Fm}\right)
$$

where *Fv* is the Chl *a* fluorescence*, F0* and *Fm* correspond to the minimum and maximum *in vivo* Chl *a* fluorescence yield (relative) in a dark-adapted state [48].

Overall the process of carbon assimilation in dinoflagellates is essentially the same as photosynthesis carried out by other microalgae and is dependent on chlorophyll *a*, carbon dioxide, and light energy.

#### **Photosynthetic Pigments**

Dinoflagellates contain five pigment types: chlorophylls  $a$  and  $c_2$  as well as peridinin- the carotenoid only found in dinoflagellates- and small amounts of the xanthophylls, diadinoxanthin and dinoxanthin [49, 50]. More information on the pigments is presented in Chapter 2. [51].

Figure 2. Calvin-Benson cycle of photosynthesis, adapted from https://courses.lumenlearning.com/ biology1/chapter/the-calvin-cycle/.

The dinoflagellate chloroplasts contain membranes enclosing 3 thylakoids (lipids, chlorophyll, and proteins, electron carriers). Chloroplasts are the active sites of photosynthesis which is initiated by absorption of light energy by antennae of light harvesting pigments or photochemically reactive proteins and passed on to the photosynthetic reaction centers via the flow of electrons from one molecular donor to another acceptor known as the Calvin cycle (Figure 2).

The electron carriers capture energy for reducing NADPH<sup>2</sup> and ATP, and ribulose 1, 5 bisphosphate carboxylase/oxygenase (Rubisco) enzymes to fix CO2. When light energy is too high, carotenoids quench superfluous light and prevent build up of toxic oxygen radicals.

High performance liquid chromatography (HPLC) data of 40 species using 45 strains of dinoflagellates including three habitat types- the sand-dwelling benthic forms, tidal pool inhabitants and planktonic species- showed that dinoflagellates seem to produce a part of their pigments in response to their habitats [52]. A greater diversity of pigments is found in the sand dwelling dinoflagellates than in the planktonic and tidal pool forms. Twelve pigments including Enol-13(2), 17(3)-cyclopheophorbide a enol (cPPB-aE) occurred only in benthic sand-dwelling species of red alga-derived type. An additional sixteen pigments including Chl *c* 3 (diatom-derived chloroplasts) were found only in sand-dwelling forms.

#### **Peridinin and Photoprotection**

Unique to photosynthetic dinoflagellates are the peridinin-plastids, a class of lightharvesting proteins known as peridinin-chlorophyll *a*-proteins (PCP) which consists of a central chlorophyll molecule and four peridinin molecules – the peridinin quartet. From the PCP, Schulte et al. [53] identified one specific carotenoid as a type of integrated lightning rod which operates on a nanosecond scale with the photosystems of chlorophyll where energy transformation and oxygen production take place.

These plastids contain less than 16 genes [54, 55] compared to 165-185 found in cryptomonads and diatoms. Unlike in other algae, the dinoflgellate plastids have an alphaproteo bacterial type of rubisco (type II) with much lower specificity for  $CO_2$  over  $O_2$ [56, 57]. Of interest is the presence of the oxygen-sensitive homomeric type-II form of the enzyme in the dinoflagellate *Amphidinium carterae,* usually found in heterotrophic anaerobic proteobacteria and cyanobacteria [58]. Peridinin molecules while transferring the incoming light energy in the blue-green wavelengths (470 to 550 nm) to chlorophyll molecules with extremely high efficiency [59] also prevent the organism from building toxic oxygen radicals when solar radiation is too high. In experiments of >30 min duration utilizing *Glenodinium* sp. grown in the range  $250-3000 \mu W/cm^2$  irradiance, cellular chlorophyll *a* and peridinin increased under decreasing light but the photosynthetic rates remained unchanged which is considered significant in maintaining cellular photosynthesis even when irradiance decreases [30]. However, Schulte et al. [53] using femtosecond (10<sup>-5</sup>seconds) resolution absorption spectroscopy investigated this carotenoid-chlorophyll interaction and identified a single peridinin molecule within the peridinin quartet which efficiently senses Chl *a* excitation. Studies of Kvíčalová et al. [60] showed that in *A. carterae* chlorophyll *a*–chlorophyll c2– peridinin protein complex quenches light with 100% efficiency with faster transfer times of 0.1 nS.

In two peridinin-containing red tide dinoflagellates, *Heterocapsa pygmaea* and *Prorocentrum minimum,* spectral dependency of the maximum quantum yield (φmax) for carbon fixation was reported [61]. This spectral dependency was most significant in *H.* 

*pygmaea* under nearly all growth conditions but not detectable for *P. minimum* under any growth condition attributed to differences in the structure of their photosynthetic machinery and their cellular absorption properties.

Besides peridinin, intracellular lipid may play a protective role. In *A. sanguinea*, *Prorocentrum micans* and *Scripsiella trochoidea* grown both under low light (LL, 87–90 μmol photons m<sup>-2</sup> s<sup>-1</sup>) and high (HL, 450–490 μmol photons m<sup>-2</sup> s<sup>-1</sup>) peridinin was low but varied [46]. However, *S. trochoidea* and *P. micans* showed higher photosynthetic efficiency (average:  $F_v/F_m > 0.5$ ) compared to *A. anguinea* ( $F_v/F_m \sim 0.2$ ). Intracellular lipid concentration increased at HL in these species, which may serve as a protective mechanism for the cells. The *Chatonella marina* strain isolated from Australia had 110 fg cell<sup>-1</sup> UVabsorbing mycosporine amino acids (MAAs), absent in the Japanese strain which accounts for its tolerance to high intensities of visible light. In cultures of *Akashiwo sanguinea (*=*Gymnodinium sanguineum*) and *Gymnodinium (*= *Gyrodinium)* cf. *instriatum* established from the Chesapeake Bay*,* sensitivity to UV was less efficient particularly in N-limited cells but was elevated by a decrease in cell volume (10<sup>4</sup> μm<sup>3</sup> ); in *A*. *sanguinea* it was 4.46 in nutrient replete medium vs 1.53 and 1.39 in media with 25 and 5  $\mu$ M NO<sub>3</sub> [62]. Corresponding cell volumes for *G.* cf. *instriatum* were 3.19 and 2.39. The photosynthetic inhibition ( $P^{B}$ <sub>S</sub> g C g Chl  $a$ <sup>-1</sup> h<sup>-1</sup>) in *A. sanguine* nutrient replete cultures (25  $\mu$ M NO<sub>3</sub>) ranged between 4.57 and 4.66, while in cultures grown at 5  $\mu$ M NO<sub>3</sub>, it was 3.63. For *G*. cf. *instriatum* corresponding values were 31.3 and 8.06. In nutrient limited cultures the UV-B inhibition was 1.5 times greater which would affect the sensitivity and productivity of phytoplankton and in the concentration of photoprotective mycosporine –like aminoacids [62].

# **Carbon Assimilation**

During photosynthesis carbon dioxide is fixed in light summarized as:

$$
2H_2O + 2 NADP + 3 ADP + 3 Pi >> 8hv >> O2 + 2 NADPH_2 + 3 ATP
$$

and in dark via the Calvin-Benson cycles as:

$$
CO_2 + 2 \text{ NADPH}_2 + 3 \text{ ATP} \gggtgtgtgtgt; H_2O + (CH_2O) + 3 \text{ ADP} + 3\text{Pi} + 2 \text{ NADP} +
$$

Ribulose biphosphate carboxylase/oxygenase (RuBisCO) is a 550-kDa enzyme and carries out the photosynthetic fixation of carbon dioxide in the chloroplast [63]. In vivo activities of extracellular and intracellular carbonic anhydrase (CA), photosynthetic  $O<sub>2</sub>$ evolution,  $CO<sub>2</sub>$  and  $HCO<sub>3</sub>$  uptake rates were measured in bloom-forming dinoflagellates, *Prorocentrum minimum*, *Heterocapsa triquetra* and *Ceratium lineatum,* by membrane inlet mass spectrometry (MIMS) in cells acclimated to low pH (8.0) and high pH (8.5 or 9.1) [12]. Results showed the extracellular carbonic anhydrase (eCA) activity depended on the pH; at low pH it was negligible compared to that at high pH. Half-saturation concentrations  $(K_{1/2})$ for photosynthetic  $O_2$  evolution were low compared to RUBISCO kinetics. This affinity for HCO3- and increased maximum uptake rates under higher pH suggest the operation of an efficient CO<sup>2</sup> concentration mechanism (CCM) in these dinoflagellates. Results obtained on

*Protoceratium reticulatum,* a potentially toxic dinoflagellate that has a form II RUBISCO, confirmed that cells grown in low  $CO<sub>2</sub>$  (370 pCO ppm) are more efficient in using dissolved inorganic carbon than cells grown in high  $CO<sub>2</sub>$  (5000 pCO ppm); the  $K<sub>1/2</sub>$  (CO<sub>2</sub>, DIC) corresponded to 1.66 and 11.5. Photosynthesis (pmol  $O_2$  h<sup>-1</sup> cell<sup>-1</sup>) for cells at 370 pCO ppm was 3.14 compared to 2.70 for cells at 5000 pCO ppm.

The usual storage products in dinoflagellates are starch and oil. Buck et al. [64] reported a dinoflagellate cyst with thickening of its wall from 0.2 to 0.8 μm over 2 months and an increase in storage bodies. *Crypthecodinium cohnii*, a heterotrophic dinoflagellate produces neutral lipids (NL), glycolipids (GL) and phospholipids (PL) in the form of triacylglycerol, Docosahexaenoic Acid (DHA) and oils [65] that have commercial value.

# **Uptake in Dark**

Not all dinoflagellates are totally photosynthetic [66]; but some carry on a mix of autotrophy and mixotrophy devouring diatoms or other protists, a few dinoflagellates, and even fish eggs as in the genus *Noctiluca. Noctiluca* also harbors a phototrophic prasinophycean endosymbiont, *Pedinomonas noctilucae* [67]. Because of their nutritional strategies these phagotrophs acquire plastids from their prey. In phagotrophic dinoflagellates, the acquired plastids, also known as kleptochloroplasts ('stolen chloroplasts') retain their own genome and function as permanent intracellular metabolite transporters [68]. Plastid-derived gene minicircles exist in the nucleus of the host, as for example in *Heterocapsa triquetra*, and become intimately connected with the biology of their host. Although understanding the functioning of such plastid physiology is fundamental and fascinating, it is beyond the scope of this chapter and the reader is referred to a review by Dorrell and Howe [68] on the plastids of the dinoflagellate *Karenia mikimotoi*. It is possible the plastids are integrated into their host's photosynthesis. Waller and Kořený [69] discussed the plastid complexity in dinoflagellates and pointed out that peridinin uses unusual protein trafficking routes and therefore there is a need to revise notions of the origin of the peridinin plastid.

Uptake of carbon in the dark varied in dinoflagellates from the Gullmar Fjord, and from the Koster Strait, the Swedish west coast [11]. In *Ceratium lineatum* and *C. furca* the uptake was in the light as well as in the dark. In the heterotrophic *Dinophysis rotundata*, *Protoperidinium granii* and *P. divergens* <sup>14</sup>C uptake (pg C cell<sup>-1</sup> h<sup>-1</sup>) ranged from 0.07 to 13.7, in the autotrophic *C. furca*, *C. lineatum* and *C. tripos,* 21.69 and 148.31, and in the mixotrophic *Dinophysis acuminata*, *D. acuta*, *D. norvegica,* 18.22-107.61. Of interest, the uptake in dark was significantly higher than in light in *D. norvegica,* and *D, acuta* which suggests the importance of mixotrophy i.e., direct uptake of  $^{14}$ C-labeled dissolved or particulate organic matter*.*

#### **Uptake in Light**

Photosynthetic carbon assimilation rates are presented for the athecate (Table 1), thecate dinoflagellates (Table 2) and for the symbiotic zooxanthellae that reside in corals (Table 3).

Table 1. Carbon assimilation characteristics of select athecate dinoflagellates **Table 1. Carbon assimilation characteristics of select athecate dinoflagellates**

Units: I Irradiance (I) μmol m-2  $\rm s^{-1}$  ; Ps 10° cells h  $(=$  pg C cell-1 h ); Ps  $(Z)$  μg C μg Chl a  $^{-1}$  h<sup>-1</sup>; I<sub>k</sub> µmol m<sup>-2</sup> s<sup>-1</sup> ; ɑ μg C μg Chl ɑ  $\mathbf{q}$  $^{-1}$ μmol m<sup>-2</sup> s<sup>-1</sup>.

Table 2. Carbon assimilation characteristics of select thecate dinoflagellates **Table 2. Carbon assimilation characteristics of select thecate dinoflagellates**

 $\overline{\phantom{a}}$ 

 $\mathbf{r}$ 

Values are extracted from the various publications; they are not absolute due to methodological considerations in the  $C<sup>14</sup>$  measurements: a) total carbon dioxide in the medium b) isotopic discrimination c) respiratory losses d) dark fixation and e) utilization of newly labelled products or respiration [17]. It should be noted that carbon assimilation values are often reported for a discrete light energy level but not on a photosynthesis-irradiance curve; so the P<sup>B</sup> values may be either light limited or at inhibitory irradiance. The physiological state of the cells that affects the photosynthetic rates is also unknown.

## **Athecate Dinoflagellates**

Photosynthetic measurements were made on cultured athecate dinoflagellates (Table 1) under a wide range of conditions i.e., temperature  $10\n-25^{\circ}\text{C}$  and irradiance  $35\n-500\mu$ mol m<sup>-2</sup> s<sup>-1.</sup> On a cellular basis, carbon assimilation ( $\mu$ g C 10<sup>6</sup> cells h<sup>-1</sup> = pg C cell<sup>-1</sup> h<sup>-1</sup>) varied between ~20-46.7 in *Gyrodinium galatheanum* [70], 104 in *Gymnodinium stellatum* [41], 138 in *Gymnodinium nelsoni,* 935 in *Pyrocystis fusiformis* and 2950 in *Pyrocystis noctiluca* [71].

In *Gyrodinium galatheanum,* a photosynthetic, mixotrophic dinoflagellate, carbon assimilation was 20-46.7  $\mu$ g C 10<sup>6</sup> cells h<sup>-1</sup> and growth rates were 2- to 3 times higher than under strictly phototrophic conditions at the same irradiances [70]. In the cells grown under low light and/or nutrient-limited conditions, phagotrophy also enhanced photosynthetic capacity ( $P_{max}$ <sup>cell</sup>), and/or by increased photosynthetic efficiency.

On chlorophyll basis, photosynthetic rates ( $\mu$ g C  $\mu$ g Chl  $\alpha$ <sup>-1</sup> h<sup>-1</sup>) were generally low and ranged from 1.8 to 3.2 in *Gymnodinium splendens* from natural assemblages [72] and 4.9 in cultures of *Gymnodinium nelson* [41]. In *G. galatheanum* the rates were 3.3 [70], *in Akashiow sanguinae* 3.63-4.66 [62] and 4.3 in *G. instriatum* [62]. In *Gymnodinium aureolum* cells (Table 1) from a bloom in Denmark at 20°C, photosynthesis ( $\mu$ g C  $\mu$ g Chl  $\alpha$ <sup>-1</sup> h<sup>-1)</sup> increased with irradiance 35-380 Irradiance ( $\mu$ mol m<sup>-2</sup> s<sup>-1</sup>) and ranged between 1.4 and 1.8 [26]. The irradiance at which photosynthesis is saturated  $(I_k \mu \text{mol m}^2 \text{ s}^{-1})$  varied between 59 and 361; in *Gymnodinium aureolum* the photosynthetic efficiency (a  $\mu$ g C  $\mu$ g Chl a<sup>-1</sup> h<sup>-1</sup> $\mu$ mol m<sup>-2</sup> s<sup>-1</sup>) ranged between 0.788-1.125  $x10^{-3}$  and cells grown at lower irradiance (I) <100 µmol m<sup>-2</sup> s<sup>-1</sup> had higher efficiency [26] (Table 1). The saturating irradiance (I) 274- 444 in *Akashiow sanguinea* is comparable to other athecate species *Gyrodinium galatheanum*, *Pyrocystis noctiluca* and *P. fusiformis* (Table 1).

#### **Thecate Dinoflagellates**

A wide range of carbon assimilation rates ( $\mu$ g C 10<sup>6</sup> cells h<sup>-1</sup>) were observed in the thecate dinoflagellates (Table 2). The highest range 0.9-28.6 was in *Prorocentrum mariaelebouriae* [73] but in *Dinophysis accuminata, D. acuta, Ceratium tripos, C. furca, Gonyaulax polyedra, G. tamarense* and *G. digitale* they ranged 2 to 6 times (Table 4). *Prorocentrum mariae-lebouriae* adapts rapidly to changes in irradiance. Within 72 h of a shift to low light chlorophyll *a* increased from 2.6 to 5.1 pg cell<sup>-1</sup>, chl c from 1.8 to 3.0 pg cell<sup>-1</sup>, and peridinin from 2.2 to 3.1 pg cell<sup>-1</sup> but the rate of carbon fixation remained the the same which according to Harding et al. [73] is a strategy of this dinoflagellate to reduced light.

In *Dinophysis acuta* carbon assimilation in holozoic fed cells was 23.7 and decreased to 16.8 pg cell<sup>-1</sup> when starved [78]. In *Dinophysis acuminata* photosynthetic rates (pg cell<sup>-1</sup>) decreased with the age of cells, thus 38 for 3 day cultures, 11 for 6 days, 8 for 9 days, 8 for 20 days growth [75], similar to what has been observed in batch cultures of other microalgae.

In the thecate dinoflagellates, carbon assimilation rates (Table 2) normalized to chlorophyll *a* ( $\mu$ g C  $\mu$ g Chl  $\alpha$ <sup>-1</sup> h<sup>-1</sup>) also showed a wide range. The minimum 0.1 was in *Alexandrium tamarense* [85] but Schofield et al. [86] reported higher rates 1.6 to 4.9. Higher rates (Table 5) comparable to those reported in diatoms and microflagellates were reported in *Glenodinium* sp. (8.6), *Gonyaulax polyedra* (9.0), *Prorocentrum mariae-lebouriae* (11.2).

**Table 4. Range of carbon assimilation rates (μg C 10<sup>6</sup> cells h-1 ) in thecate dinoflagellates**

## **Table 5. Range of carbon assimilation rates (μg C μg Chl ɑ -1 h -1 ) in thecate dinoflagellates**

Figure 3. Photosynthesis in phytoflagellates, diatoms and dinoflagellates grown for 5, 12 and 26 days. Where A to C – Phytoflagellates: A*-Monmochrysis lutheri*, B-*Dunaliella tertiolecta*, C- Chrysomonad A; E to I- Diatoms: E-*Skeletonema costatum*, F-*Phaeodactylum tricornutum,* G- *Nitzschia* sp , H-Centric diatom 42, and I- T*halassiosira nordenskioldii. and* K to L- Dinoflagellates: K- *Prorocentrum micans* and L- *Cachonina niei.*

The photosynthetic rates ( $\mu$ g C  $\mu$ g Chl  $\alpha$ <sup>-1</sup> h<sup>-1</sup>) in most of the athecate and thecate dinoflagellates (Table 5) are low  $\langle$  <6.2) compared to the photosynthetic rates of 5 day old log phase cultures (Figure 3) of diatoms *Skeletonema costatum* (9.0), *Thalassiosira rotula* (9.1- 13.9), for centric diatom 42 (9.4), flagellates *Monochrysis lutheri* (5.7), *Dunaliella tertiolecta* (5.6) and *chrysomonad* (5.7) [13]. The highest photosynthetic rates, 22.8 and 18.1, were in the green flagellate Chlamydomonas *plethora* and the diatom *Nitzschia frustule,* respectively [88], and in *Nitzschia*, *Thalassiosira*, *Amphiprora* and *Prorocentrum* [89]. These are lower even compared to 26 day senescent cells (Figure 3) that yielded photosynthetic rates for centric diatom 42 (5.0), flagellates *Monochrysis lutheri* (3.7), *Dunaliella tertiolecta* (1.7) and a chrysomonad (2.3).

The few data on the irradiance at which photosynthesis is saturated  $(I_k \mu \text{mol m}^2 \text{ s}^{-1})$  in the thecate dinoflagellates varied between 60-300 (Table 2), comparable to the results on athecate species (Table 1). In *Alexandrium fundyense* the range was 128-190 [86], 40-251 in *Prorocentrum mariae-lebouriae* [75], 72-190 for *D. acuminata* [78], 60-160 *Peridimium cinctum* fa *westii* [31] and 300 in *D. acuminata* [77].

The thecate marine dinoflagellates *Gonyaulax polyedra, Glenodinium* sp. and *Ceratium furca* exhibit circadian rhythms in photosynthesis, usually with a maximum by about midday and show a 3 to 5 fold change in the photosynthetic magnitude over the day [81]. Observations of Prézelin et al. [81] on the dinoflagellates are similar to the rhythms in metabolic pathways in another dinoflagellate, *Lingulodinium polyedrum,* or in photosynthesis reported for the diatoms, *Phaeodactylum tricornutum*, *Acetabularia crenulata*, *Chlorella pyrenoidosa* and *Scenedesmus obliqus*.

#### **Zooxanthellae**

Some corals host symbiotic photosynthetic dinoflagellates – zooxanthellae belonging to the genus *Symbiodinium-* which awaits formal taxonomic description [90, 91]. Corals cover 6  $\times$  10<sup>5</sup> km<sup>2</sup> of the world's oceans, from 10-50% of the reef surface, and zooxanthellae are about  $10^6$  cells per cm<sup>-2</sup> and contribute to carbon fixation in the reef [92]. Loss of photosynthetic activity of zooxanthellae due to global warming, acidification, anthropogenic activities, and pollution results in coral "bleaching" that has been reported world-wide [93]. Expulsion of zooxanthellae, likely under sub aerial exposure and high water temperature, causes disorganization of thylakoid membranes of the zooxanthellae resulting in bleaching of corals [94, 95].

Because of their close-knit symbiotic relationship and integration with the life of their host, studies on the photosynthesis (*P*) *vs.* irradiation (*I*) (*P-I*) studies of cultured or isolated zooxanthellae, determined either by oxygen exchange using an electrode or by  $C<sup>14</sup>$  tracer uptake, or by photosynthetic efficiency measured on whole cell fluorescence  $(F_{+DCMU}/F_{-DCMU})$ would be instructive.

Photosynthesis determined by oxygen electrode ranged between 0.5 and 1.5 μgC per 10<sup>9</sup> cells per  $h^{-1}$  and was extremely low compared to the athecate dinoflagellates given in Table 1. On chlorophyll *a* basis, photosynthesis ( $\mu$ g C  $\mu$ g Chl  $\alpha$ <sup>-1</sup> h<sup>-1</sup>) and photosynthetic efficiency ( $\alpha$ μg C μg Chl α<sup>-1</sup> h<sup>-1</sup>μmol m<sup>-2</sup> s<sup>-1</sup>) were also low. The irradiance for saturated photosynthesis (I<sub>k</sub> μmol m<sup>-2</sup> s<sup>-1</sup>) varied between 42 and 181, low compared to the athecate dinoflagellates (Table 1). Photosynthetic efficiency measured on whole cell fluorescence  $(F_{+DCMU}/F_{-DCMU})$  of *Symbodinium microadriaticum* cultures was maximum  $(\sim 2.2)$  at  $24^{\circ}$ C and decreased steadily as a "stress" response at temperatures higher than  $30^{\circ}$ C and ceased at  $34$ - $36^{\circ}$ C [45].

In the scleratinian corals, *Favia* sp. and *Acropora* sp., the *P-I* curves demonstrated an adaptation of zooxanthellae to low light; the initial slope was low at 0.05,  $P_{\text{max}}$  13.65 nmol  $O_2$ cm<sup>-2</sup>s<sup>-1</sup>, and the  $I_K$  273  $\mu$ E m<sup>-2</sup>s<sup>-1</sup> [96]. *Symbiodinium*, living in the tropical hydroid, *Myrionema amboinense,* acclimates to low photon flux by increasing the amount of photosynthetic pigments per algal cell [28], which protects algae from photobleaching of pigments and or photoinhibition of photosynthesis at high light intensities present in shallow water habitats.

Zooxanthellae associated with the hydroid host tissue are " shade" adapted and have low maximum photosynthesis  $(P_{\text{max}})$  compared to symbionts removed from the host, suggesting that the availability of carbon dioxide for photosynthesis may be limited in the intact hydroid [87]. Photosynthetic rates (pg C per  $\mu$ g chl a h<sup>-1</sup>) of intact zooxanthellae adapted to low light usually available in the tissue were low (3.64) compared to 6.6 in cells isolated from the tissue [28]. In *Symbiodinium,* sustained photosynthetic alternative electron flows (AEF) were reported under high light intensities [98] which act as a photoprotective mechanism and leads to an increase of the ATP/NADPH ratio.

#### **Host Factor**

Gates et al. [15] investigated the impact of a homogenate of *Aiptasia pulchella,* a tropical sea anemone, designated it as a "host factor" or "synthetic host factor" (HRF or SHF), on the photosynthetic physiology of a symbiotic dinoflagellate. Compared to dinoflagellates

incubated in sea water in vitro, the host factor resulted in release of fixed carbon, higher photosynthetic carbon fixation, heterotrophic carbon fixation, photosynthetic oxygen production, respiration rates, and cell specific concentrations of chlorophyll *a*. Gates et al. [15] suggested that in nature, symbiotic dinoflagellates released from anthozoan hosts may survive in amino acid rich environments such as fish guts and "intermediate hosts." Interestingly, zooxanthellae that were excreted through feces of the host had similar photosynthetic rates similar to regular zooxanthellae that did not pass through a digestive tract [99]. There is a constant nutrient shuffling between the host and the zooxanthellae, for example ammonium retained by the anemone is utilized by the zooxanthellae in the light [100]. Together they can synthesize 20 aminoacids [101]. Photosynthetic activity enhanced the calcification rate of the coral *Plesiastrea urvillei* from 0.35 to 1.80  $g.m^{-2} d^{-1}$ [102]. *Symbiodinium* produced higher amounts of carbohydrates when living inside a host rather than when free living [103].

Extracts (HRF) from fed and starved sea anemone *Aiptasia pallida* released different proportions of photosynthetic products [104]. In filtered seawater alone it was about 5% of photosynthate, 14% with addition of 10-kDa ultrafiltrate of *A. pallida* and increased to over 25% from anemones starved for 29 days or more. Carbon fixation by zooxanthellae from *A.pallida* was dependent on temperature; it increased exponentially in the range 12-32<sup>o</sup>C and decreased at  $34.5^{\circ}C$  [105]. Translocation of the photosynthate was 82% at 12<sup>o</sup>C compared to 63% at 27<sup>O</sup>C. The marine coelenterates, *Zoanthus flos marinus (*Zoantharia*), Stoichactis helianthus* (Actinaria) and *Scolymia lacera* (Madreporaria), incorporated C<sup>14</sup> after 3h photosynthesis; between 24 and 40 per cent of the total photosynthate was in the tissues of the anemones [106].

Investigations on the mechanisms of dissolved inorganic carbon (DIC) uptake by the scleractinian coral, *Galaxea fascicularis*, and its delivery to the photosynthetic endosymbionts showed that zooxanthellae inside the host had lower photosynthetic rates than isolated cells [27]. Further, intact cells had higher light saturation (I*k*) and were able to utilize DIC. The maximum rate of photosynthetic production  $\mu$ g C  $\mu$ g Chl  $\alpha$ <sup>1</sup> h<sup>-1</sup> (Table 3) was 0.3 in the coral, 0.30 in freshly isolated zooxanthellae (FIZ) and 2.0 in cultured zooxanthellae (CZ) , and the half-maximal rate of photosynthetic rate is achieved at 408, 71 and 178 μM HCO, for coral, FIZ , and (CZ), respectively [27]. Between FIZ and CZ marked differences existed in the photosynthetic characteristics; in the FIZ,  $I_K$  was 42 and  $\alpha$  was 0.031; for CZ they were higher and corresponded to 80 and 0.095 [27].

Additional studies [107] showed bicarbonate uptake depended on the 4, 4' diisothiocyanato-stilbene-2, 2'-disulfonic acid – DIDS sensitive carriers. Carbonic anhydrase located in the zooxanthellae participates in the carbon supply while in cultured cells bicarbonate uptake appears to be strictly Na+ dependent.

The Photosynthesis: respiration ratio (P:R) in *Symbiodinium microadriaticum* is about 2 [45]. The zooxanthellae provide enough oxygen for their host as evident from the P:R ratios, in *Favia* it was 77.7% [96], in *A. pulchella* 95% [15], it ranged from 1.26 to 1.66 in *P. urvillei* [102], *Anthopleura elegantissima* exhibited net photosynthesis twice that of zoochlorellae [108]. The P:R ratios in *Anthopleura elegantissima* ranged between 2 and 3 for starved anemones but not over 1 for fed anemones [109]. Of interest is the P:R ratios of the dinoflagellate with a phototrophic endosymbiont, *Pedimonas noctilucae* [67]. Gross photosynthesis: respiration was 1.6 in the non-feeding *Noctiluca* without a food vacuole, compared to 0.8 in those with a food vacuole [67]. The concentration of humic, fulvic and

hydrophilic acids affect P:R; in *Prorocentrum minimum* cells treated with >25 μg ml<sup>-1</sup>, fulvic acid only produced more oxygen in excess of the respired [32] unlike the humic, and hydrophilic acids fractions. There appears to be a difference in the response of the symbiotic *Symbiodinium* and free-living dinoflagellate *Prorocentrum minimum* in their response to ammonium limited conditions; in the former there was no enhancement of photosynthetic efficiency  $(F_v/F_m)$  whereas it recovered within 2 days in the latter [110].

Although data on photosynthesis of dinoflagellates are insufficient and not systematic (Tables 1, 2 and 3), we summarize briefly the general processes such as irradiance, temperature, nutrients and their carbon assimilation.

## **Irradiance**

Generally, photosynthesis ( $\mu$ gC  $\mu$ g Chl  $\alpha$ <sup>-1</sup> h<sup>-1</sup>) is usually low at low light and attains a maximum at higher light. In *Gymnodinium aureolum* (Table 1), it increased from 1.4 at 35 μmol photons m<sup>-2</sup> s<sup>-1</sup> to 1.8 at 120 photons and decreased to 1.6 at 380 photons [26]. In the thecate *Gonyaulax polyedra* (Table 2) at 37 photons it was 1.9 and steadily increased to a maximum of 3.2 at 233 µmol m<sup>-2</sup> s<sup>-1</sup>and at 373 µmol m<sup>-2</sup> s<sup>-1</sup>(Table 2) [111]. It should be noted that inhibition of photosynthesis was not observed in *Glenodinium* sp. cultures at 560 μmol m<sup>-2</sup> s<sup>-1</sup>[30], in *G. polyedra* at 746 μmol m<sup>-2</sup> s<sup>-1</sup> [111], in natural concentrates of *Dinophysis norwegica* at 1600 μmol m<sup>-2</sup> s<sup>-1</sup> [10], and in *Prorocentrum mariae-lebouriae* at 400 μmol m<sup>-2</sup>  $s<sup>-1</sup>$  [75]. However, freshly isolated zooxanthellae and cultured zooxanthellae showd  $\sim$ 20% inhibition of the maximum [27]. In zooxanthelle living in shade  $(300 \mu \text{mol m}^2 \text{ s}^{-1})$  it was 9.7pg  $O_2$  h<sup>-1</sup> chl<sup>-1</sup> compared to 17.6 pg  $O_2$  h<sup>-1</sup> chl<sup>-1</sup> at 1500-1900 μmol m<sup>-2</sup> s<sup>-1</sup> [28]. This is mainly because cells grown at high light (HL) have less chlorophyll, smaller antenna and use high light more effectively than those grown at low light. Photosynthetic efficiency (a), Initial Slope of P vs I, is lower for HL grown cells. Fitt and Cook suggested that the host cell environment reduced the available light to zooxanthellae by  $>50\%$  which prevents photobleaching of the algae. The photosynthetic efficiencies ngC [ng Chl  $a$ ]  $^{-1}$  h<sup>-1</sup> [ $\mu$  mol m<sup>-2</sup> s<sup>-</sup>  $1$ ]  $-1$  in dinoflagellates (Tables 1, 2, 3) are low compared to 39.6 and 79.5 reported for microalgae *C. plethora* and *N. frustula* [88].

In *Peridinium cinctum* fa.*westii* cultures established form Lake Kinneret, Israel Ik varied between  $~60$  and  $~>160$  (µmol m<sup>-2</sup> s<sup>-1)</sup> with the quality of light [31], so did the compensation point and saturation light. The reduction in antenna size is regarded as a strategy to increase productivity; under continuous yellow light production of *Chlamydomonas reinhardtii* was 54 g m<sup>-2</sup> d<sup>-1</sup>, twice that obtained in blue and red light [112]. *Pmax* in three out of four temperate dinoflagellates i.e., *Gonyaulax hyalina, Gymnodinium splendens, Dinophysis caudata*, and *Glenodinium* sp. daylength did not influence photosynthesis unlike in polar diatoms; the *Pmax: Pmin was similar for polar diatoms and temperate dinoflagellates [113]. Observations* on the maximum quantum yield for photosystem II (determined by differences in oxygen production rates and other biochemical parameters), showed minimal alterations ( $FV/F_M$  = variable fluorescence/maximum fluorescence) in *Gymnodinium breve* (*Karenia brevis*) cultures possess an inherent resistance to UV and a robust photosynthetic activity [114]. Response to light seems to be species specific. For example, in a high light-adapted species *Alexandrium fundyense* results with Chl *a* inversely proportional to growth irradiance, FV/*F*<sup>M</sup>

data suggested a trade-off between photoprotection and carbon fixation [139]. In contrast, *Heterocapsa rotundata*, a low light‐adapted species with high photosynthetic efficiencies, the trade‐offs were in the form of substantial photoinhibition and a lack of plasticity in Chl *a* content [139]. Previous light history of cultured *Gymnodinium chlorophorum* cells affected the photochemical quantum yield [115]; yield was more in cultures raised at 100  $\mu$ mol m<sup>-2</sup> s<sup>-1</sup> than at 250 µmol m<sup>-2</sup> s<sup>-1</sup> between 15-20 <sup>o</sup>C but at 25<sup>o</sup>C it was the opposite. In the toxigenic *Gambierdiscus carolinianus* and *G. silvae* exposure to increasing photon flux density up to 1464 µmol photons  $m^{-2} s^{-1}$ , cell size and chlorophyll content increased but photosynthetic efficiency was reduced [116]. Net photosynthesis (pgC cell<sup>-1</sup> h<sup>-1</sup>) in cultures of *Gonyaulax polyedra* increased, from 54 to 130 during phase 1 (light limiting) and from 58 to 134 after light adaptation phase, as the irradiance increased from 60 to 210  $\mu$ E m<sup>-2</sup> s<sup>-1</sup>.

Rates of carbon incorporation per cell<sup>-1</sup>  $h^{-1}$  (Table 6) ranged widely from 12 in *Prorocentrum mariae-lebouriae* to 2950 in *Pyrocystis noctiluca.* The data show that the lowest rates were in cells with smaller cell - volume *Prorocentrum mariae-lebouriae and Heterocapsa triquetra;* they increased with the cell volume.

Taxa	$\mu$ g C 10 <sup>6</sup> cells h <sup>-1</sup>
Gymnodinium stellatum	$104 \pm 4$ n = 84
G. nelson	$42-189 \pm 13 \text{ n} = 32$
	$189 \pm 14$ n = 29
Gonyaulax polyedra	$144 \pm 8$ n = 40
G. tamarensis	$136 \pm 11$ n = 44
Prorocentrum mariae-lebouriae	$17 \pm 1$ n = 77
	$12 \pm 1$ n = 66
Heterocapsa triquetra	$16 \pm 2 n = 22$
Pyrocystis noctiluca	$2950 \pm 85$ n = 49
P.fusiformis	$935 \pm 27$ n = 53

**Table 6. Range of carbon assimilation (μg C 10<sup>6</sup>cells h-1) in dinoflagellates (Rivkin and Seliger 1981)**

## **Temperature**

With an increase in temperature, photosynthesis increased ( $\mu$ g C  $\mu$ g Chl  $\alpha^{-1}$  h<sup>-1</sup>); in *Alexandrium fundyense* (Table 2) it was 1.58 at  $6^{\circ}$ C, 2.04 at 15<sup> $\circ$ </sup>C and 4.96 at 24<sup> $\circ$ </sup>C; their I<sub>k</sub> values corresponded to 133,128 and 190 and a photosynthetic efficiency ( $\alpha \mu g$  C  $\mu g$  Chl  $\alpha$ <sup>-1</sup> h<sup>-</sup> <sup>1</sup>µmol m<sup>-2</sup> s<sup>-1</sup>) of 0.012, 0.016 and 0.026 [86]. In the zooxanthellae *Symbiodinium microadriaticum* (Table 3) between 20ºC and 30ºC, photosynthesis increased with temperature but was impaired at 34-36°C; thus Ps ( $\mu$ mol O<sub>2</sub> 10° cells) 3 at 20°C, 4 at 25°C, 5.5 at 30ºC and 0 at 35ºC [45]. Results on *Prorocentrum mariae-lebouriae* at photon flux densities (PFD) from 1.7 to 170 µmol of quanta s<sup>-1</sup> m<sup>-2</sup> showed a 50% increase in photosynthesis from 10 $^{\circ}$ C to 30 $^{\circ}$ C at saturating photon flux density [138]. Such an increase in magnitude with increased PFD is transient and known as  $CO_2$ -'burst' and  $CO_2$ -'gulp' [138]. From Lake Kinneret, Israel the bloom forming dinoflagellate *Peridinium cinctum* fa. *westii*, cultures established at irradiances 9 to 105 ( $\mu$ E.m<sup>-2</sup>.s<sup>-1</sup>), the photosynthetic Q<sub>10</sub> increased with irradiance but decreased as the temperature increased [31]. The photosynthetic  $Q_{10}$  ranged from 1.6 to 2.3 in the temperature range 10-20°C, thus 1.2-1.7 for 15-25°C, and

1.0-1.2 for 20-30ºC [31]. Photosynthetic performance of *Prorocentrum donghaiense* and *Karenia mikimotoi* was temperature dependent [117]; in the former the *Fq'*/*Fm'* was 0.517 at 16ºC and decreased to 0.490 at 28ºC. In these dinoflagellates the ɑ also decreased and corresponded 0.248 and 0.239 and their I<sup>k</sup> 775 and 970*.* In *K. mikimotoi Fq'*/*Fm' was* 0.260 at 16<sup>o</sup>C and 0.353 at 28<sup>o</sup>C, their a corresponded to 0.154 and 0.193 and the  $I_k$  699 and 900.

#### **Nutrients**

Dinoflagellate cultures are raised in media based on enrichments and are utilized to study their division rates to elucidate consequences of eutrophication [6, 118-121]. However, only a few studies exist on the impact of nutrients on photosynthetic functioning of the dinoflagellates.

Studies by Summons et al. [122] with <sup>15</sup>NH<sup>+</sup>4 on the symbiotic *Gymnodinium microadriaticum,* from tridacnid clams and corals, demonstrated light stimulated ammonium uptake but not photosynthesis; they concluded that the glutamine synthase-glutamate synthetase pathway of ammonium incorporation is light-driven.

Encouraged by observations of others on neretic and oceanic phytoplankton, Doucette and Harrison [123] tested iron limitation on the vivo fluorescence (F) and DCMU-enhanced F (FD) in the dinoflagellate *Gymnodinium sanguineum.* In nitrogen depleted medium, chlorophyll *a* quota (Qchl) decreased while chlorophyll fluorescence (F/chl *a*) and fluorescence DCMU (FD/chl *a*) increased. But severe iron stress modified F/chl *a* and adversely affected the utilization of harvested light energy. Phosphate deprivation significantly affected fluorescence in *Karenia mikimotoi* [124].

The toxigenic *Alexandrium tamarense* was able to take up substantial amounts of nitrate, ammonium and urea in the dark and changes in the C: N ratios were dependent on the N supply mode rather than the nutrient status of the cell [125]. This implies that in the absence of continuous supply of nutrients, growth will be uninterrupted to the advantage of the alga [125]. Burkholder et al. [126] discussed the linkage of growth of 31 species of dinoflagellates to nutrient enrichment in eutrophic or marine coastal waters. In mixotrophic mode, growth was significantly higher in harmful algal species (HAS) than in phototrophic mode; detailed investigations are suggested on phototrophy, osmotrophy and phagotrophy in the nutritional ecology of HAS utilizing assemblages from various phases of the bloom from eutrophic waters.

A few studies were carried out on the same species by different investigators (Table 2) which facilitates comparison of intra and inter species specific carbon assimilation. These are summarized in Table 5. Data presented in Table 7 permit comparison of photosynthetic rates (μg C 10<sup>6</sup> cells h<sup>-1</sup> and μg C μg Chl  $\alpha$ <sup>-1</sup> h<sup>-1</sup>) within and between the species. The lowest rates (μg C  $10<sup>6</sup>$  cells h<sup>-1</sup>) were in *Alexandrium tamarense* (0.1–4.9) and the highest (1700-2950) in *Pyrocystis noctiluca*. Within the species the range (max:min) was <1.7x in *Pyrocystis noctiluca*, 3.5-3.8x *Dinophysis acuta*, *Gonyaulax polyedra*, 36.4x in *Prorocentrum mariaelebouriae*, 44x in *Dinophysis acuminata*, 49x in *Alexandrium tamarense* and 120x in *Dinophysis norwegica*.

The range of photosynthetic rates ( $\mu$ g C  $\mu$ g Chl  $\alpha^{-1}$  h<sup>-1</sup>) within the species was however was low 1.2–3.8 times. Between the species their rates ranged between 0.5 and 11.3, the highest was in *Gonyaulax polyedra* (Prézelin, and Matlick 1983). While this wide latitude of

values could be due to differences in experimental variables, light, temperature, growth phase of cells, production of toxin, presence of plastids acquired through phagotrophy, differences between strains and genomic differences all point out the need for the usage of standard methodology.

In 7 strains of *Dinophysis acuminata* isolated from different locations in Denmark the photosynthetic rate increased from about 7 to 38 pg C cell<sup>-1</sup>  $h$ <sup>-1</sup> in the presence of the prey (>1000 cells of *Mesodinium rubrum*) within the first 2 days, but subsequent starvation decreased rapidly to a pre-feeding level [76]. Intraspecific variability in pectenotoxin -2 (PTX-2) in the range 12.7 to 35.6 pg cell-1 existed in 7 strains of *Dinophysis acuminata* and are related more likely to the growth phase and genetic differences [128]. In these strains when the prey was in abundance, photosynthetic rate at 130 µmol photons  $m<sup>2</sup> s<sup>-1</sup>$  was 51.7 but the role of kleptoplasty in this is not known [128]. Intraspecific variability in the growth rates, mixotrophy and lipid composition of *Karlodinium veneficum* existed in isolates from Aklfacs Bay, in the NW Mediterranean coastal waters [42]. Growth and feeding responses also varied in two strains. More investigations utilizing cells of the same growth phase (continuous cultures) are needed to establish intra and interspecific differences in their carbon assimilation rates.

#### **Response to Chemical Perturbation**

Copper sulfate treatment inhibited photosynthesis in *Prorocentrum minimum* and is attributed to 515 genes of which 8.6 % are related to chloroplast and mitochondria. This suggests the possibility of  $CuSO<sub>4</sub>$  caused cellular oxidative stress to photo system [129]. Photosynthetic activity of toxigenic *Alexandrium catenella* and the benthic *Ostreopsis* cf. *ovata* exposed to increasing concentrations of  $Cu^{2+}$  (10<sup>-4</sup> to 31 nM) or Butylin (0.084 to 84 nM) for seven days decreased [130]. In *Prorocentrum minimum* 609 genes were identified of which 10.2% responded to PCB treatment [131]. While these were related with cell cycle, apoptosis, signal transduction, and transport pathway, photosynthesis was not inhibited.

# **Survival Strategies**

The dinoflagellates are characterized by low division rates, low carbon assimilation rates (μg C10<sup>6</sup> cells h<sup>-1</sup>, μg C μg Chl  $\alpha^{-1}$  h<sup>-1</sup>) and low  $\alpha$  μg C μg Chl  $\alpha^{-1}$  h<sup>-1</sup>μmol m<sup>-2</sup> s<sup>-1</sup> which suggest they are photosynthetically inefficient. To overcome this disadvantage, the dinoflagellates have to develop a survival strategy to supplement their energy requirements. Although the supporting data are dire, we comment on how the dinoflagellates use a diverse range of strategies for long-term survival. Of the strategies, the most important one is mixotrophy as it provides a competitive advantage. Mixotrophy (phototrophy and phagotrophy) appears to be common amongst dinoflagellates. As stated earlier, Stoecker lists 46 mixotrophic dinoflagellate species belonging to Prorocentrales (4), Dinophysiales (2), Gymnodiniales (13), Noctilucales (1) Gonyaulacales (15), Peridiniales (2), Blastodiniales (5), Phytodiniales (3) and Dinamoebales (1). Jeong et al. [132] reported *Takayama helix* (family Kareniaceae) injested large dinoflagellates *Alexandrium minutum, A. lusitanicum, A. tamarense, A. pacificum, A. insuetum, Cochlodinium polykrikoides, Coolia canariensis, Coolia malayensis, Gambierdiscus caribaeus, Gymnodinium aureolum, Gymnodinium catenatum, Gymnodinium instriatum, Heterocapsa triquetra, Lingulodinium polyedrum,* and *Scrippsiella trochoidea* but not small flagellates and dinoflagellates ≥13 μm in size. The newly described *Yihiella yeosuensis* grows mixotrophically only and feeds on 2 bacillariophytes, 3 Prymnesiophytes, 2 Prasinophytes, 4 cryptophytes, 1 taphidophyte, and 6 dinoflagellates [131]. The usual storage products of dinoflagellates are starch and oil and supply the necessary energy. *Crypthecodinium cohnii*, a heterotrophic dinoflagellate produces neutral lipids (NL), glycolipids (GL) and phospholipids (PL) in the form of triacylglycerol, Docosahexaenoic Acids (DHA) and oils [65].

Other survival strategies include: a) rapid adaptation to changing conditions and with the phase of cell division, with photosynthetic rates of 54-130 μg C 10<sup>6</sup> cells h<sup>-1</sup>) in light limiting phase 1 (60  $\mu$ E m<sup>-2</sup> s<sup>-1</sup>) and 134 after adaptation to 210  $\mu$ E m<sup>-2</sup> s<sup>-1</sup> in *Gonyaulax polyedra* [71], b) a 3-5 fold increase in their photosynthetic magnitude over the day through circadian rhythms in photosynthesis as in the thecate marine dinoflagellates, *Gonyaulax polyedra, Glenodinium* sp. and *Ceratium furca,* which allows them to survive even in the dark [81], c) reduction of metabolic rates by encystment and d) adjustments in carbon concentrating mechanisms, as in the dinoflagellates *Scripsiella trochoidea* and *Alexandrium tamarense* [85]. In *Gyrodinium galatheanum,* a photosynthetic, mixotrophic dinoflagellate, growth rates were 2 to 3 times higher than under strictly phototrophic conditions at the same irradiances [70]. In the cells grown under low light and/or nutrient-limited conditions, phagotrophy also enhanced photosynthetic capacity ( $P_{max}^{cell}$ ), and/or by increased photosynthetic efficiency. Photosynthesis and respiration remained unaltered in *S. trochoidea* whereas respiration increased in *A. tamarense.* In *S. trochoidea* it was facilitated by exceptionally high and CO2 independent carbonic anhydrase activity. This strategy enables both species to maintain growth over a wide range of ecologically relevant pCO2.

# **CONCLUSION**

Dinoflagellates are the main constituents of toxigenic red tides and consequently impact human health and cause economic losses. Difficulties in culturing dinoflgellates hindered studies aimed at understanding their physiological ecology. Majority of dinoflagellates assimilate carbon via photosynthesis while a few heterotrophs and mixotrophs assimilate carbon in dark as well. Analyses of photosynthetic carbon assimilation patterns in the athecate, thecate and symbiotic dinoflagellates (zooxanthellae) showed that in general their photosynthesis – irradiance relationships conform to the patterns established for diatoms and microflagellates. Peridinin, an exclusive pigment to dinoflagellates, prevents photoinhibition.

Intraspecific variability in photosynthesis existed amongst strains. In general, carbon assimilation rates (µg C10<sup>6</sup> cells h<sup>-1</sup>, µg C µg Chl  $\alpha$ <sup>-1</sup> h<sup>-1</sup> and ngC [ng Chl *a*] <sup>-1</sup> h<sup>-1</sup> [µ mol m<sup>-2</sup> s<sup>-</sup> <sup>1</sup>]<sup>-1</sup>) in dinoflagellates were low, even lower than the scenescent cells of diatoms and microflagellates. This is perhaps due to channeling of energy for toxin production and synthesis of cellulose skeleton, suggested by the differences in the carbon: volume ( $pgC$  cell<sup>-1</sup> 0.288 x volume 0.811) relationships in phylogenetic groups [134]. In photosynthetic and thecate dinoflagellates carbon density was higher than in heterotrophic and athecate dinoflagellates; chlorophytes, chrysophytes, prasinophytes and prymnesiophytes have similar carbon to volume relationships. Dinoflagellates use a diverse range of strategies for long-term survival of which the most common and important one is mixotrophy which occurs in nearly 50 species and it provides a competitive advantage.

Also, dinoflagelaltes have large amount of DNA (3000–215000 Mb), which is orders of magnitude larger than other eukaryotic cells, or compared to 3180 Mb for the haploid human genome [135]. Supporting this disproportionately large DNA results in heavy metabolic requirements which may explain the lower carbon assimilation rates in dinoflagellates compared to other unicellular algae.

#### **ACKNOWLEDGMENTS**

We are grateful to Emeritus Professor Gabriel A. Vargo, University of South Florida, College of Marine Science, St. Petersburg, FL, United States for constructive comments on the manuscript. We are thankful to Prof. Satoru Taguchi, Hokkaido for several suggestions.

### **ABSTRACT**

This chapter reviews the current knowledge on "mixotrophy" among freshwater and marine dinoflagellates. The term "mixotrophy" is here used for the combination of phototrophy and phagotrophy in the same organism. Among the dinoflagellates it includes species with their own permanent chloroplasts (called constitutive mixotrophs, CMs) and species which lack their own chloroplasts and instead sequester chloroplasts from their prey (called non-constitutive mixotrophs, NCMs). We document here that mixotrophy is widespread among dinoflagellates with species representatives of both groups. Feeding may not always be expressed among the CM dinoflagellates, especially as light and nutrients impact feeding for the majority of dinoflagellates. Mixotrophic dinoflagellates primarily eat other protists, but some species can exploit large prey and metazoans as part of their diet. Some mixotrophic dinoflagellates are highly selective in which prey types they ingest, while others are quite omnivorous. Especially the NCM dinoflagellates seem to be quite restricted in which types of prey they can utilize as donors of chloroplasts and other cell organelles. Few data are available on *in situ* grazing rates of mixotrophic dinoflagellates, and there is a strong need to develop new techniques to measure *in situ* grazing rates. Development of reliable *in situ* techniques to measure feeding is not only important to assess the significance of phagotrophy as a way for dinoflagellates to harvest nutrients in inorganic nutrient limited waters, but also to assess the impact dinoflagellate mixotrophy on the food web.

**Keywords:** mixotrophy, phototrophy, phagotrophy, chloroplasts, grazing rates, symbionts

#### **INTRODUCTION**

Recently, mixotrophy has been recognized as a traditionally unappreciated, but important and widespread trait of photosynthetic protists (Flynn et al., 2013; Mitra et al., 2014; Mitra et al., 2016; Stoecker et al., 2017). The term "mixotrophy" is largely self-explanatory as a mix or combination of autotrophy and heterotrophy in a single organism. Despite its seemingly straightforward meaning, a few more definitions are needed. Mixotophy is sometimes (e.g., Pringsheim, 1958; Gaines and Elbrächter, 1987; Schnepf and Elbrächter, 1992), but not here, used in a strict sense only when an organism cannot thrive by a single trophic mode, whereas the term amphitrophy refers to organisms that facultatively combine, but do not rely on, different trophic modes. Moreover, mixotrophy may include any combination of trophic modes. Heterotrophy may refer to phagotrophy and/or uptake of dissolved organic substrates (often termed osmotrophy, although osmotic pressure processes are not involved). In the protistan realm, however, the uptake of organic molecules (e.g., amino acids) is ubiquitous so using osmotrophy as a discriminating feature of mixotrophy in protists appears weak, as de facto all protist would be mixotrophs by such a definition (Flynn et al., 2013; Mitra et al., 2014; Mitra et al., 2016; Stoecker et al., 2017). We thus use here the definition of Mitra et al. (2016) with mixotrophy as the dual capability of engaging phototrophy and phagotrophy by a single cell, regardless of being obligate (i.e., mixotrophy sensu stricto) or facultative (i.e., amphitrophy).

Dinoflagellates as a group are well known for their high diversity of lifestyles and trophic modes, and have been traditionally divided into autotrophic and heterotrophic species. However, we are now aware that such a classification is not appropriate (Jeong et al., 2010b; Hansen, 2011), as many species belonging to either group may actually combine phototrophy and prey uptake, and thus be mixotrophic. Studies of geographic distribution of mixotrophic protists on the global scale have shown that mixotrophic dinoflagellates are ubiquitous. They are common in polar, temperate, subtropical and tropical freshwater and seawater (Leles et al., 2017; 2019). Very few studies have dealt with *in situ* grazing rates of mixotrophic dinoflagellates, simply because rates are difficult to measure due to prey selectivity and low feeding frequency.

Dinoflagellate mixotrophy has been the subject of a number of reviews in the past. Most of the earlier reported cases of mixotrophy in dinoflagellates were limited to observations of what was interpreted as "food vacuoles" (reviewed by Hansen, 1998; Hansen and Calado, 1999; Stoecker, 1999). At that time, very little was known about feeding mechanisms, prey preferences, or the role of food uptake. Since then, many more protists have been studied, especially the dinoflagellates, and some of this knowledge has been presented briefly in recent broad review papers (Burkholder et al., 2008; Stoecker et al., 2009) or in reviews specifically on dinoflagellates (Jeong et al., 2010b; Hansen, 2011). The review by Jeong et al. (2010) treated current knowledge of prey preferences and scaling of ingestion and growth rates among heterotrophic and mixotrophic dinoflagellates (Jeong et al., 2010b), while the review by Hansen (2011) treated the importance of photosynthesis and food uptake for growth of marine planktonic dinoflagellates, dealing with different functional groups within the dinoflagellates. Since then knowledge on dinoflagellate mixotrophy has increased considerably, especially for species that sequester chloroplasts and other cell organelles from their prey.

This review will give a short historical survey of dinoflagellate mixotrophy research and discuss how common mixotrophy is among the dinoflagellates. To do this, we have compiled literature we could find on dinoflagellates in which mixotrophy has been indicated and provide comprehensive tables summarizing all the published information. We then provide some details concerning feeding mechanisms, prey size and prey specificity, and discuss the role of environmental controls on the physiology of mixotrophic dinoflagellates. We specifically focus on how light and inorganic nutrients affect feeding and growth among the different types of mixotrophic dinoflagellates. Finally, we discuss the influence of mixotrophic dinoflagellates as grazers in natural waters.

## **A SHORT HISTORICAL SURVEY OF DINOFLAGELLATE MIXOTROPHY RESEARCH**

Since the dawn of dinoflagellate research, the phylogenetic placement and the trophic nature of these peculiar unicellular organisms have been a matter of debate and controversy. The plant/animal dichotomy of macroscopic life in the  $18<sup>th</sup>$  century understandably was translated to all the newly discovered microorganisms. In analogy to the macro-world, many researchers considered motility of microscopic organisms as a clear sign for their animal nature, and consequently the search for evidence of food uptake was in focus early on. So, records and observations of ingested food (or particles) in dinoflagellates can be found in the very early literature.

The earliest observation probably comes from Christian Gotthilf Ehrenberg (1795-1876), who reported his use of carmine and/or indigo suspensions to systematically study particle uptake by protistan species (Ehrenberg, 1830). For the dinoflagellates, which he at the time considered as "Kranzthierchen," Ehrenberg reported uptake of indigo particles by two freshwater species, *Peridinium pulvisculus* and *P. cinctum*. While Ehrenberg was wrong with some of his ideas about unicellular organisation (e.g., he considered chloroplasts to be the female ovaries), he was right that particle uptake may be regarded as an "animal character" in dinoflagellates. *Peridinium cinctum* doubtlessly has chloroplasts (see Figure 1 A), and original drawings of Ehrenberg for *P. pulvisculus* imply chloroplasts for that species as well (Ehrenberg, 1838). Thus, this seems to be the first documented cases of dinoflagellate mixotrophy, although not recognized as such by Ehrenberg. Subsequent observations of ingested food inside of dinoflagellates by e.g., Schmarda (1854), Stein (1878), Bergh (1881), and Schilling (1891) mainly refer to heterotrophic species. However, Friedrich Ritter von Stein (1818-1885), who -like Ehrenberg- considered all dinoflagellates as animals, described food particles ("große grüne gefressene Körner" [large, green ingested grains]) inside the freshwater species *Hemidinium nasutum* (Stein, 1878), which is a phototrophic species with its own chloroplasts. Stein explicitly mentioned the yellowish colour of that species. Another early hint for dinoflagellate mixotrophy comes from Gourret (1883), who described the presence of an algal fragment inside of the phototrophic species *Ceratium tripos* (=*Tripos muelleri*). Likewise, Kaarlo Levander (1867-1943) in 1894 observed inclusions inside of the phototrophic species *Gymnodinium fissum* (now regarded conspecific with *Levanderian fissa*, see Moestrup et al., 2014), which he described and depicted as a diatom and a long spiny particle of unknown origin (Levander, 1894).

Figure 1. Some historic drawings of mixotrophic dinoflagellates. A: *Peridinium cinctum*, (redrawn from Ehrenberg 1838, Tafel XXII, Figure XIII). This species was described by Ehrenberg (1830) to take up indigo particles. B–F: Various drawings of dinoflagellate species with inclusions, redrawn from Schütt (1895). B: *Tripos muelleri* (as *Ceratium tripos*, Tafel 10, 40.27). Schütt´s abbreviations: δ = δ-oil, C = chromatophore, N = nucleus. C–D: *Cochlodinium pirum* (as *Gymnodinium pirum*, Tafel 23, 76.1 (D) and 76.1 (C)) Note the many chloroplast in C, and the presence of two different inclusions  $K^1$ and K<sup>2</sup> in D. E–F: *Podolampas bipes* (Tafel 19, 56.1 (E) and 56.20 (F). Schütt´s abbreviations:  $C =$  chromatophore,  $Cs =$  chromatosphere (clumps of chromatophores), Am = amoeboid plasma. G, H: Drawings of two dinoflagellate species with inclusions, redrawn from Kofoid & Swezy (1921). G: *Gymnodinium flavum* (Plate 9, Figure 100), original legend: "…Note the presence of food body and yellow chromatophores….".H: *Gyrodinium melo* (Plate 5, Figure 50), original legend: "…Note the presence of both food bodies and green chromatophores…".I: *Levanderia fissa* (as *Gyrodinium pavilardii*), redrawn from Biecheler (1952), Figure LXIX. Two different stages *of G. pavilardii* ingesting a *Strombidium* cell.

In contrast to Ehrenberg and Stein (among others), Franz Schütt (1859-1921) considered dinoflagellates strictly as plants. Consequently, in all his descriptions and illustrations (e.g., Schütt, 1895), he interpreted any unusual inclusion inside dinoflagellate cells as either conglomerates of plastids ("chromosperes") or as "Klumpen" [clumps], which he thought were endogenous storage products (either oil or starch) (see Figure 1 B–F). Schütt not only described such clumps inside naked heterotrophic species known at his time as phagotrophs (e.g., *Gyrodinium spirale*), but also in a number of species with chloroplasts, and even for some thecate species (e.g., *Dinophysis*, *Podolampas*). Other researchers (Dogiel, 1906; Entz, 1907) were thus prompted to consider Schütt´s observation as evidence that phagotrophy was in fact quite widespread in dinoflagellates. The presence of foreign bodies inside phototrophic species was also noted by Entz (1907) for *Ceratium hirudinella*, *Gonyaulax spinifera*, and *G. polygramma* based on LM observations using thin sections.

Charles Atwood Kofoid (1865-1947) and Olive Swezy (1878-??) compiled and illustrated all available information on naked dinoflagellates (Kofoid and Sweezy, 1921). They put much emphasis on including all information on the presence of chloroplasts and ingested food particles visible inside the cells, and explicitly identified nine species with chloroplasts as also being phagotrophs (i.e., mixotrophic) (Table 1, see also Figure 1 G, H). Other researchers more specifically worked on the nutrition of individual species. For example, Hofeneder

(1930) extensively worked on the animal nutrition of *Ceratium hirudinella,* a freshwater phototrophic dinoflagellate. While some of his observations (e.g., on extruding plasma networks) may be artefacts, his descriptions of inclusion bodies of different sizes identifiable as "Cyclotellen" (i.e., diatoms) and *Vorticella* (a ciliate) is convincing evidence that *Ceratium hirudinella* indeed is mixotrophic. So, all these observations led Schiller (1933) in his encyclopedic compilation on dinoflagellates to shortly summarize dinoflagellate nutrition as: "Trophic mode variable, at times even within the same species; either holophytic (autotroph), holozoic or mixotroph, often also saprophytic..." He was thus probably the first to use the term "mixotroph,"which originally was coined by Pfeffer (1897) for higher plants, in a dinoflagellate context.

The actual ingestion process of mixotrophic dinoflagellates probably was observed first and described in detail in the fascinating work of Berte Biecheler (Biecheler, 1936b, a), which was also published posthumously with detailed drawings 20 years later (Biecheler, 1952). She described *Gyrodinium pavillardii* (now considered to be identical to *Levanderina fissa*, see Moestrup et al., 2014) ingesting other small dinoflagellates and ciliates (see Figure 1 I). Likewise, for her newly described phototrophic species *Gyrodinum vorax* (note the name vorax means voracious), Biecheler observed ingestion of a large dinoflagellate (and, ironically, here *Gyrodinium pavillardii* was the prey) using a peduncle (a tube, see the section on feeding mechanisms). Among the early workers on freshwater dinoflagellates, the pioneering early work of Harris (1940) has to be highlighted. He systematically included observations on nutritional mode in his compilation of freshwater dinoflagellates of the British Isles, listing six species with chloroplasts and ingested food (Table 1).

During the last decades of the 20<sup>th</sup> century, ultrastructural studies of a number of dinoflagellate species (largely motivated by theories of an endosymbiotic origin of chloroplasts) documented for the first time that what was originally described as chloroplasts were in fact symbionts, or suggested them to be "endosymbiont-like phagocytotic vacuoles" (Wilcox and Wedemayer, 1984, 1985; Larsen, 1988; Schnepf et al., 1989). Schnepf et al. (1989) suggested for the first time the term "cleptochloroplasts," in analogy to the "cleptocnides" of some molluscs. At roughly the same time, new conceptual and methodological developments in the area of microbial ecology in the  $1980<sup>th</sup>$  (e.g., the "microbial loop": Azam et al., 1983) led to an increased interest among marine ecologists in prostistan phagotrophy, including mixotrophic phytoflagellates (Baird and Kalff, 1986; Boraas et al., 1988; Porter, 1988; Sanders and Porter, 1988). For dinoflagellates, this interest in mixotrophic species coincided with a general interest in dinoflagellate food uptake mechanisms (Schnepf and Deichgräber, 1983; Gaines and Taylor, 1984; Jacobson and Anderson, 1986), which led to a rapid progress in revealing the great trophic diversity of dinoflagellates (Gaines and Elbrächter, 1987; Schnepf and Elbrächter, 1992; Jacobson and Andersen, 1994; Jacobson and Anderson, 1996; Jacobson, 1999). In the last few decades, with advanced cell isolation-and culture techniques, more and more detailed studies and observations of mixotrophy of many dinophyte species emerged (e.g., Jeong et al., 2010b). Dinoflagellate research on mixotrophy thus ultimately developed from a descriptive to an experimental and quantitative stage, now providing many data on e.g. growth, ingestion, and food spectrum for a variety of species (Tables 1, 2).

### **MIXOTROPHY IS A WIDESPREAD PHENOMENON AMONG DINOFLAGELLATES**

Mixotrophy can be displayed in different ways among the dinoflagellates. The dinoflagellates that have permanently built-in chloroplasts do not acquire chloroplasts or any other cell organelles from their prey. Instead, these utilize the ingested material for improved growth. Such organisms have recently been referred to as constitutive mixotrophs, CMs (Mitra et al., 2016) (Figures 2, 3).

Figure 2. Light microscopy images of some important (mostly bloom-forming) constitutivemixotrophic dinoflagellate species. A: *Akashiwo sanguinea*. B: *Karlodinium veneficum*. C: *Prorocentrum micans*. D: *Karenia mikimotoi*. E. *Tripos fusus*. F: *Prorcentrum cordatum*. G. *Heterocapsa steinii*. H. *Gymnodinium catenatum*. I. *Tripos furca*. J: *Protoceratium reticulatum*. K: *Heterocapsa rotundata*. L: *Scrippsiella acuminata*. M: *Dissodinium pseudolunula*. (a mixotrophic parasite of copepod eggs). N: *Alexandrium catenella*. O: *Levanderina fissa* (picture courtesy: Niels Daugbjerg). Scale bars = 5  $\mu$ m (B, F–G, J–L) or 10  $\mu$ m (A, C–E, H–I, M–O).

Figure 3. (Continued).

Figure 3. Collection of dinoflagellate field sample specimens with (food?) inclusions (arrows) (**A–Q**), or from algal cultures (**S–W**). **A**: Two focal planes of an unidentified gymnodiniod species. **B**: Unidentified thecate species (likely to be *Fragilidium* sp?). **C**: Unidentified species of *Gonyaulax*. **D**: *Oxytoxum* cf. *caudatum*. **E**: Unidentified gymnodinioid species. **F**: Two focal planes of an unidentified gymnodinioid species. **G**: Unidentified gymnodinioid species. **H**: Unidentified species of a planktic *Prorocentrum.* **I:** Two focal planes of an unidentified gymnodinioid species (likely to be a *Margalefidinium*?). **J**: *Alexandrium pseudogonyaulax*. **K**: *Alexandrium* sp. **L**: *Alexandrium ostenfeldii.*  **M**: Unidentified gymnodinioid species. **N**: Unidentified cell of *Margalefidinium*. **O**: an unidentified species of *Nematodinium* in bright field (left) and epifluorescence (right) to indicate presence of chloroplasts. **P**: Two views of the same cell of *Tripos muelleri*. **Q**: Mature cell of *Spatulodinium pseudonoctiluca*. The upper left insert shows a total view of this large tentacle-bearing species. The lower left insert shows a fluorescent view of the cell to indicate the presence of chloroplast. **R:** An immature stage of *Spatulodinium pseudonoctiluca* in bright field (left) and epifluorescence (right) to indicate presence of chloroplasts. **S–U**: *Fragilidium subglobsoum* ingesting *Tripos muelleri*. **S**: Late stage of ingestion, note that the two short horns of *T. muelleri* are not yet ingested. **T**: Epifluorescence view of calcofluor stained cells of five *Fragilidium* during ingestion. Note how thecal plates of *Fragilidium* separate to allow for increase in size. **U**: Two different stages of three cells of *F. subglobosum* attacking and ingesting a *T. muelleri* cell. **V**: *Alexandrium pseudogonyaulax* attached to a mucus trap with many immobilizes cells of *Heterocapsa rotundata*. **W**: *Karlodinium armiger*, whole cell (left) and low magnification view (right) of *K. armiger* cells feeding on an immobilized polychaete larva. Scale bars =  $5 \mu$ m (A, D, F, G, M, W (left)), 10  $\mu$ m (B, C, H, E, I, K, L, N, O, J), 20 µm (P, R, S–U, V), or 50 µm (Q).

Other dinoflagellates lack chloroplasts of their own, but instead acquire/sequester chloroplasts from their prey. Such mixotrophic organisms are now referred to as Non-Constitutive Mixotrophs (NCMs; Mitra et al., 2016) (Figure 4). This NCM group has been subdivided into prey specialist (SNCM) and prey generalist (GNCM). Some of the SNCM dinoflagellates harbor intact symbionts, either as endosymbionts (i.e., the green *Noctiluca* and *Amphisolenia* spp.) or as ectosymbionts (i.e., *Histioneis*, *Ornithocercus*, *Amphisolenia*) (Hansen et al., 2004; Tarangkoon et al., 2010), and are labelled eSNCMs. Other species take up algal prey and digest parts of the ingested cells, whereafter they keep these "reduced" endosymbionts for some time (days to a month) (i.e., *Gymnodinium gracilentum* and *Nusuttodinium* spp.) (Skovgaard, 1998; Drumm et al., 2017), or just sequester the chloroplasts, while remaining parts of the ingested cells are digested (i.e., *Dinophysis* spp.) (Hansen et al., 2013). These two groups have previously been referred to as pSNCMs (Mitra et al., 2016), but here we use the term reSNCMS to separate out the species that have reduced endosymbionts.

A thorough literature search indicates mixotrophic capabilities for  $\sim$  249 chloroplastbearing species belonging to 91 genera (Tables 1–3), of which approx. 202 species are marine, while the rest are freshwater species. Thus, mixotrophy among dinoflagellates is quite widespread. Of these species, 116 can be considered CMs (Table 1), while 109 are NCMs (Table 2), and 24 are parasites (Table 3). Of the NCMs, 75 species have entire endo/ectosymbionts (eSNCMs), 26 species have reduced endosymbionts (reSNCMS) and 8 only harbour the chloroplasts from their prey (pSNCMs) (Table 2.)

Figure 4. Light microscopy images of some selected non-constitutive mixotrophic dinoflagellate species. A: *Dinophysis tripos*. B: *Dinophysis acuta*. C: *Amylax triacantha*. D: *Gymnodinium myriopyrenoides* (picture courtesy: Myung Gil Park). E: *Amphidinium poecilochroum* (picture courtesy: Myung Gil Park). F: *Nusuttodinium aeruginosum* (picture courtesy: Niels Daugbjerg. G: *Ornitocercus steinii* (picture courtesy: Gert Hansen). H: green *Noctiluca scintillans*. I: *Amphisolenia thrinax* (picture courtesy: Gert Hansen). Scale bars =  $10 \mu m$  (A–G) or 50  $\mu m$  (H, I).

Howewever, it is important to note that prey uptake has not yet been documented for some NCMs listed in Table 2, which host endosymbionts (e.g., *Amphisolenia*/*Triposolenia*). Some of the CMs, e.g., the dinotoms (dinoflagellates harboring reduced diatom endosymbionts), can be grown in monocultures without the supply of algal prey. To which extent these can still ingest prey is unknown. Recently, it has been shown that at least one of the dinotom species cannot maintain the endosymbiont, but relies on continual ingestion of a diatom (Yamada et al., 2019), making this species belonging to the NCMs.

In quantitative terms, the list of course is heavily biased for example by a large number of parasitic CM species (and thereby are easily classified as mixotrophs), or by the large number of warm-water species with ecto-and endosymbionts (eNCMs), which are over-represented because species determination with light microscopy is possible in this case. Likewise, restrictions in the list of mixotrophic species are likely due to lack of cultures for many species and difficulties in species determination for field collected phototrophic dinoflagellates with food inclusions (e.g., Figure 3 A–N). It is important to note that the evidence in the literature for phagotropic capabilities for the different species is of course quite varied. For a large number of species, LM studies of field samples report the presence of "food vacuoles," "ingested food," or vague descriptions of other unusual structure such as "inclusion bodies" or "accumulation bodies" inside of cells. However, the presence of "particles" inside a dinoflagellate cell does not necessary prove phagotrophy, as other explanations such as internal storage products or endosymbiotic bacteria have to be taken into account. Some inclusions of dinoflagellates may involve endoparasitic infections (Jacobson, 1999) such as early or late trophocyte stages of *Parvilucifera* (Alacid et al., 2016) or *Amoebophrya*. Moreover, autolytic accumulation bodies may also be present in nonphagotrophic dinoflagellates (Lee, 1977; Schnepf and Elbrächter, 1992), and orangefluorescent PAS bodies (named because these are stained by the periodic acid-Schiff reaction) e.g., in *Alexandrium* spp., which resemble e.g., ingested cryptophytes because of their orange autofluorescence, have been linked to autophagy or to a digestive use of stored metabolites (Schmitter and Jurkiewicz, 1981).

Thus, many cases of limited evidence listed in Table 1 are in need of confirmation by more detailed direct observations and/or methods that are more specific. For example, clear LM identification of intracellular inclusions as ingested prey is possible using protargolstaining (Bockstahler and Coats, 1993a), or thin sections and transmission electron microscopy (TEM) can give information of the presence of food vacuoles and even the type of ingested prey cells (Jacobson and Anderson, 1996). Other methods that can be applied to field samples include the use of adding labelled prey (i.e. using either fluorescent or radioactive labelled prey) that subsequently can be detected in target cells (Nygaard and Tobiesen, 1993).

For a number of species included in Table 1, phagotrophy based on ingestion of food has not yet been observed directly, or indirectly. In those cases, phagotrophy was suggested based on ultrastructural evidence for the presence of a microtubular basket (e.g., Schnepf and Winter, 1990), which dinoflagellates that use a feeding tube always have. Here it has to be kept in mind that we currently do not know if such a structure may serve also for other cellular functions, e.g., sexuality. With a few exceptions (Biecheler, 1952), older studies indicating mixotrophy in dinoflagellates provide little information on the actual ingestion process. In the last couple of years, however, increased interest in mixotrophy and improved algal culture techniques have led to a significant number of culture-based studies providing detailed new observations and experimental data for many dinoflagellate species, including identification and documentation (sometimes with videos, see Table 1) of the actual feeding process. The majority of these are on marine species and comparable studies for freshwater

species (e.g., *Bernardinium*: Fawcett and Parrow, 2014; and *Nussotodinium*: Drumm et al., 2017) seem to be exceptions.

The compilation of data on dinoflagellates revealed that evidence for mixotrophy is available for most of the higher taxonomic groups (orders, see Table 1–3), with a lack of records only for a few poorly known orders having a limited number of genera/species (e.g., Ptychodiscales, Desmomastigales, Gloeodiniales, Lophodiniales, Haplozoodiniales). Almost all of the basal dinoflagellates are heterotrophic, but mixotrophy can be found here as well: within Noctilucales, the green form of *Noctiluca scintillans* harbours endosymbiotic phototrophs (Sweeney, 1976). Moreover, life stages of *Spatulodinium pseudonoctiluca*, including the gymnodinoid stage also described as a separate species (*Gymnodinium lebourae*) and the large round *Noctiluca*-like stage that feeds with a large tentacle, contain plastids (see Figure 3 O, P), and thus are probably the deepest branching CM-dinoflagellates (Gómez et al., 2010). Although most of the parasitic dinoflagellates are heterotrophic, 24 species from 10 genera are known to contain plastids (Table 3). While heterotrophy in these mixotrophic parasites is obvious, the role of photosynthesis is less well known, but may be important for survival during their dispersal stage. There are of course dinoflagellate genera without known mixotrophs, such as most of the parasitic forms that lack chloroplasts. Pure heterotrophy in pallium feeding genera (see section 3.2) such as *Protoperidinium*, *Oblea*, *Diplopsalis* etc. may indicate that this feeding mechanism is not compatible with mixotrophy. However, the minute drawings and descriptions of Schütt for *Podolampas bipes* (Schütt, 1895, see Figure 1 E, F) present substantial evidence that this species is photosynthetic and performs pallium feeding. Phototrophic abilities of *P. bipes* (and of *P. reticulata* as well) were later shown to be based on the presence of eukaryotic dictyochophycean endocytobionts (Schweikert and Elbrächter, 2004). Of course, there are also genera of phototrophic species where mixotrophy is yet undescribed and unknown (e.g., *Azadinium*, *Amphidoma*), but this is likely because detailed studies for these genera have not yet been performed.

## **PREY TYPE, FEEDING MECHANISMS, PREY SIZE AND PREY SELECTIVITY**

#### **Prey Types**

The most common prey for mixotrophic dinoflagellates are other protists, but some reports also show uptake of small prokaryotic prey (single cells of bacteria and cyanobacteria; 0.5-2 µm) and very large prey, including metazoans like copepods and larvae of benthic invertebrates (see reviews by Jeong et al., 2010 and Hansen, 2011). In the large majority of studied cases, however, other protists are the ecologically relevant prey types. The role of heterotrophic bacterial uptake in dinoflagellates is still controversial, and data demonstrating increased growth at natural heterotrophic bacterial concentrations and sizes of bacteria are lacking. However, significant uptake rates of small cyanobacteria (*Synechoccoccus* sp.) and elevated growth rates have been reported for *Karenia brevis* (CM) cultures that have been starved of major nutrients (Glibert et al., 2009).

#### **Feeding Mechanisms, Prey Capture and Prey Size**

Three types of feeding mechanisms occur among dinoflagellates: direct engulfment, tube feeding, and pallium feeding. The pallium-feeders have almost exclusively been found among heterotrophic dinoflagellates (see the discussion in the previous paragraph), but the two other feeding mechanisms are common among mixotrophic dinoflagellates (see Tables 1, 2). Prey size matters for dinoflagellates (Hansen et al., 1994; Jeong et al., 2010b). However, entire prey size spectra have so far only been investigated for heterotrophic dinoflagellates (Hansen, 1992; Naustvoll, 2000a, b). Dinoflagellates typically detect their prey before ingestion. When encountering a prey item, dinoflagellates will typically change swimming behavior (Jacobson and Anderson, 1986; Hansen and Calado, 1999). In some cases, it has been shown that dinoflagellates will respond to chemical cues (e.g., Hansen and Calado, 1999; Martel, 2006; Berge et al., 2012), but to what extent they are dependent on a chemical cue is presently unknown. Following the detection of a given prey, many dinoflagellates use a capture or tow filament (similar to a harpoon) to attach to the prey cells. In most cases, we do not know the nature of these capture filaments; however, they have been demonstrated to be related to nematocysts/trichocysts in some cases (Gavelis et al., 2017). The use of a capture filament allows dinoflagellates to catch motile and in some case fast swimming prey, like ciliates for instance. Some dinoflagellates that eat large prey cells do not seem to require a capture filament or any other attachment techniques at all (i.e., *Fragilidium* spp., Skovgaard, 1996b; Jeong et al., 1997).

Dinoflagellates generally ingest single particles and thus localization/detection of prey items is essential. Consequently, lower prey size limit exist (Hansen, 1992; Hansen et al., 1994; Jeong et al., 2010b). This is why uptake of bacteria in mixotrophic dinoflagellates is generally of minor importance, at least in terms of carbon supply. Uptake of bacteria might play a role in acquisition of nutrients (N, P), vitamins or trace metals, but this needs to be explored further in the future. An upper prey size limit is found among species that take up prey by direct engulfment. The upper prey size limit for mixotrophic species seems to be somewhat lower than for purely heterotrophic species (see review by Jeong et al., 2010), which have been reported to be able to ingest particles five times their initial cell volume (Hansen, 1992). Nevertheless, mixotrophic *Fragilidium* can ingest prey items that are double their own initial cell volume (Hansen and Nielsen, 1997; Park and Kim, 2010). An upper size limit does not seem to exist for at least some species that use a feeding tube to suck out the contents of the prey. Examples of this have been found in the case of *Karlodinium* species, like *Karlodinium armiger*, which have been shown to kill and ingest copepods and invertebrate larvae that are >100 times larger in linear dimensions (Berge et al., 2012) (see Figure 3 W).

Some species of mixotrophic dinoflagellates are very selective, and will only ingest certain prey items, even if other available prey is within the right size range. Examples of this include *Fragilidium* species (all CMs). It has even been shown that the prey items fed upon differ among *Fragilidium* species (Hansen and Nielsen, 1997; Jeong et al., 1997; Jeong et al., 1999; Park and Kim, 2010). Among the NCMs, *Dinophysis* spp. have been shown to feed only on ciliates of the genus *Mesodinium* (Hansen et al., 2013). However, many species have proven to be much more versatile and to ingest a wide range of different prey items within a certain size range (Jeong et al., 2010, Berge et al., 2012). Examples of omnivorous species include common bloom-forming species like *Akashiwo sanguinea, Lingulodinium polyedra*

and *Prorocentrum micans* (Jeong et al., 2010). The most extreme species is *Karlodinium armiger*, which utilizes a huge prey size spectrum, from small 4  $\mu$ m flagellates to mm-cm large metazoans, like copepods and nematodes (Berge et al., 2010, 2012).

#### **Toxin or Mucus Assisted Prey Capture**

Some dinoflagellates appear to use toxins to immobilize their prey cells. An example of this is *Karlodinium armiger*, which produce a toxin, karmitoxin (Rasmussen et al., 2017). The chemical structure of this toxin resembles the karlotoxins (from *K. veneficum*) and amphidinols (from *Amphidinium carterae*). *Karlodinium armiger* is an excellent prey for planktonic grazers like copepods (Berge et al., 2012) when it occurs in low cell concentrations. Adult female copepods produce viable eggs when fed this alga, and the copepod nauplii are able to exploit it as prey as well. However, if the *K. armiger* exceeds a certain cell concentration, the food chain is reversed, and the dinoflagellate becomes the predator of copepods. The dinoflagellate not only immobilizes and feeds on adult copepods (using a feeding tube), it also feeds on the eggs, nauplii and even the fecal pellets of the copepods (Berge et al., 2012). Karmitoxin leaks to the surrounding water. However, relatively high concentrations of karmitoxin are required to observe lysis of target cells and organisms (EC50: 100-400 nM; Andersen et al., 2017). Videos indicate potential transfer/application of the toxin to the prey either by the close contact of the *K. armiger* cells or through the feeding tube (Berge et al., 2012). *Karlodinium armiger* has recently also been shown to kill adult mussels (*Mytilus edulis*) as well as mussel embryos and larvae (Binzer et al., 2018). Lytic extracellular compounds of yet unknown chemical configuration that immobilize and kill other protists are also known for a number of gonyaulacoid species, *Alexandrium* spp. (Tillmann and Hansen, 2009), *Protoceratium reticulatum* (Sala-Peréz et al., 2016), *Fragilidium* spp. (Tillmann et al., 2008; Park and Kim, 2010), and thus are probably linked to phagotrophy of these species. This has in fact been shown experimentally for the photosynthetic *Alexandrium pohangense*, which chemically immobilizes the fast swimming *Margalefidinium polykrikoides* prey prior to ingestion (Lim et al., 2015).

Other dinoflagellates utilize mucus to catch their prey, which then may include relatively small cells that otherwise the dinoflagellates are unable to catch efficiently. This phenomenon is expressed in different ways. In *Noctiluca scintillans* mucus is secreted on the tip of its tentacle, to which prey cells get caught prior to ingestion (Kiorboe and Titelman, 1998). Other species, i.e., *Dinophysis* spp., secrete clumps of mucus that float freely around in the surrounding water. Prey cells, in this case the fast jumping ciliate *Mesodinium rubrum*, are caught and immobilized in the mucus (Mafra et al., 2016; Ojamäe et al., 2016; Papiol et al., 2016). This allows *Dinophysis* spp. to localize prey cells and to start feeding directly on the ciliates using a feeding tube and thus not requiring a capture filament.

Another way of utilizing mucus to capture preys is to form a "mucus trap" to which the dinoflagellate is attached. In *Alexandrium pseudogonyaulax*, mucus is secreted at the tip of the longitudinal flagellum and the mucus trap enlarges as prey cells are caught in the trap (Blossom et al., 2012; Blossom et al., 2017) (see Figure 3 V). The dinoflagellate can then ingest trapped single cells individually, while still carrying the other prey cells caught in the mucus trap. When the trap has reached a certain size it is abandoned, and the dinoflagellate starts to make another one. Since the prey cells are immobilized, it has been speculated that the dinoflagellate may have excreted toxins in the mucus.

## **ENVIRONMENTAL CONTROLS OF FEEDING, GROWTH AND PHOTOSYNTHESIS**

The utilization of food uptake may serve many different roles in CM and NCM dinoflagellates. While some dinoflagellates will always ingest prey, others will only take up prey if limited by environmental factors (e.g., nutrient limitation). In the following sections, the roles of irradiance, prey concentration, inorganic nutrients, and strain differences for CM and NCM dinoflagellates are discussed.

#### **Constitutive Mixotrophs (CMs)**

The CM dinoflagellates almost all have the standard dinoflagellate "peridinin-type" chloroplasts. Exceptions are a few dinoflagellates that have permanent aberrant chloroplasts and photo-pigments originating from green algae (*Lepidodinium* spp.) and diatoms (the "dinotoms", i.e., species of *Kryptoperidinium, Durinskia, Unruhdinium, Dinotrix, Galaedinium* and *Blixea*) (Hansen, 2011; Gottschling, 2017). While the green chloroplasts of *Lepidodinium* spp. are the only prey-derived organelles retained, the dinoflagellates that harbour diatom chloroplasts also have cytoplasm and cell organelles like mitochondria and nuclei derived from diatoms. These species can generally be grown as monocultures using standard algal growth medium (like the f/2 or L medium) without the supply of algal prey. To which extent these species can ingest prey is unknown. Recently, however, it has been shown that one of the dinotom, *Durinskia capensis*, sequester the symbionts from the ingestion of a diatom making this dinotom species a member of the NCMs (Yamada et al., 2019). Generally, the CM dinoflagellates tend to split into two "types" with regard to their feeding responses and growth as a function of irradiance and food concentration (Hansen, 2011): *Type 1 and Type 2.* 

*The type 1 CM group* is comprised of primarily phototrophic species that only marginally increase their growth rates even at low irradiances and food in excess (Hansen, 2011; Lim et al., 2018), when nutrients are plentiful (Figure 5). This means that carbon uptake via food uptake cannot replace carbon uptake from photosynthesis, and food uptake plays only a little role for these dinoflagellates for their carbon budget. However, the small growth increases observed are achieved at relatively low prey abundances (often  $\sim$ 100–200 µg C l<sup>-1</sup>). This group includes common "red tide" species, such as *Heterocapsa*, *Prorocentrum*, *Takayma*  and *Tripos* (=*Ceratium*) (Hansen, 2011; Lim et al., 2018). If such species (shown for *Tripos furca* and *Prorocentrum cordatum*) are subjected to nutrient limitation (N and P), food uptake will increase dramatically (Smalley et al., 2003, 2012; Johnson, 2014). At present, very limited data are available on this topic, besides the documentation of increased feeding rates. Thus, we know very little about what extent growth rates will change under different levels of inorganic nutrient limitation.

Figure 5. The effects of prey concentration on the growth rates of type 1 and type 2 constitutive mixotrophic dinoflagellates when grown at low irradiance (20  $\mu$ mol photons photons m<sup>-2</sup> s<sup>-1</sup>) and in nutrient rich culture media.

*The type 2 CM group* is comprised of species that are able to increase their growth rates to a high degree at low irradiances even when inorganic nutrients are plentiful (Figure 5). Prey concentrations required for maximum growth rates of these dinoflagellates are quite high (240–400 µg C l-1 ). Representatives of this group include *Fragilidium* spp., *Karlodinium armiger*, *Alexandrium pohangense*, and *Paragymnodinium shiwhaense* (Hansen and Nielsen, 1997; Jeong et al., 1999; Berge et al., 2008a; Yoo et al., 2010; Lim et al., 2015; Jeong et al., 2018). Most of these species can grow in standard phytoplankton growth media based on nitrate as the nitrogen source. However, as is known for *K. armiger*, some species may not grow in such media unless low concentrations of ammonium  $(50 \mu M)$  are added, suggesting lack of the main enzyme, nitrate reductase, necessary for the conversion of nitrate to ammonium (Binzer et al., 2018). The dependence on ammonium among phototrophic dinoflagellates may be more widespread than previously thought. Species like *Gymnodinium resplendens* (Skovgaard, 2000), and *Yihiella yeosuensis* (Jang et al., 2017) have been shown to depend upon food for growth, as they will not grow in standard nitrate based growth media, and their growth potential after ammonium addition need to be explored. Responses to light differ slightly among species within the group. The majority of the species studied cannot grow in complete darkness. An exception is *Fragilidium subglobosum*, which can grow in complete darkness, if fed (Skovgaard, 1996a). Among the many species within this group that require light for growth, *Paragymnodinium shiwhaense* exhibits high growth rates at low irradiance, with growth rates only slightly influenced at irradiances  $> 10$  µmol photons m<sup>-2</sup>s<sup>-1</sup> (Jeong et al., 2018). While growth rates increased slightly with increasing irradiance, ingestion rates (in carbon units) were not significantly affected. In other species, ingestion rates and growth rates depend much more on irradiance. For example, *Karlodinium veneficum*, does not ingest prey at all (Li et al., 1999) or at reduced rates (Calbet et al., 2011) in darkness, but ingestion rates increase dramatically with irradiance (Li et al., 1999). The strain of *K. veneficum* studied by Li et al., increased its growth rate from a maximum of 0.25  $d^{-1}$  in monoculture to 0.7  $d^{-1}$  when grown mixotrophically at irradiances > 100 µmol photons  $m^{-2}s^{-1}$ .

#### **Non Constitutive Mixotrophs (NCMs)**

The NCM dinoflagellates are a very diverse group of organisms, which handle ingested prey very differently. At one extreme, we have organisms that retain entire algal cells either intracellular or extracellular. At the other extreme organisms are found that only sequester chloroplasts. In between exist organisms that retain only parts of the ingested prey, typically prey cytoplasm, prey mitochondria and prey nuclei. These different groups of NCMs are treated separately here because they have very different physiologies.

#### **Species That Harbour Intact Symbionts**

This group (eNCMs) includes species that harbour intact prey cells as endosymbionts*,* like the green *Noctiluca scintillans* (see Figure 4 H) and several species of *Amphisolenia* (see Figure 4 I) and *Triposolenia*, as well as species that harbour intact ectosymbionts*,* which can be found among the genera *Cistharistes*, *Histioneis* and *Ornithocercus* (see Figure 4 G) (Table 2)*.* All these species are found in the euphotic zone of tropical waters. However, while the green *Noctiluca scintillans* is found in eutrophic tropical waters (Harrison et al., 2011), the other species are exclusively found in oligotrophic waters (Tarangkoon et al., 2010). The green *Noctiluca scintillans* is unfortunately the only one where data on physiology are available (Hansen et al., 2004; Gomes et al., 2018). For material collected from Manila Bay, it was shown that the growth rate of *N. scintillans* was dependent upon both light and prey concentration. A comparison of the contribution of photosynthesis and phagotrophy to carbon metabolism revealed that phagotrophy only contributed significantly (30%) to direct growth of green *N. scintillans* at very high prey concentrations. At natural prey concentrations (<500  $\mu$ g C l<sup>-1</sup>) contribution of prey ingestion to the carbon metabolism was < 10% at high light, 150 μmol photons m<sup>-2</sup> s<sup>-1</sup> (Hansen et al., 2004).

#### **Species That Harbour "Reduced Endosymbionts"**

Some species of NCM dinoflagellates ingest whole cells but retain only parts of prey cells, including chloroplasts, mitochondria, prey nuclei and prey cytoplasm. Such species thus retain "reduced endosymbionts" (reNCMS). The taxonomy of this group of dinoflagellates is still unresolved, but it is clear that they are not all closely related. The group includes freshwater as well as marine species (Table 2). Information on the physiology of species within this group is sparse. The dependency of feeding and growth on irradiance has so far only been studied in three marine species *Gymnodinium gracilentum, Nusuttodinium poecilochroum* and *Amylax triacantha* (Skovgaard, 1998; Jakobsen et al., 2000; Park et al., 2013; Kim et al., 2014), and in one freshwater species (*Nusuttodinium aeruginosum*) (Drumm et al., 2017).

*Gymnodinium gracilentum* and *N. poecilochroum* are the only species that can grow in complete darkness if supplied with fresh prey. However, their growth rates depend on irradiance, and rates increase by a factor of 2–3 at irradiances > 50 µmol photons  $m^2 s^{-1}$ compared to in darkness. Ingestion rates are also light dependent, and the rates increase by the same factor. *Amylax triacantha* is much more dependent upon light. In complete darkness,

this species does not feed at all, and although short-term growth rates have been reported (Park et al., 2013), these rates are most likely due to residual cell divisions. Feeding in this species is quite dependent upon irradiance, and ingestion rates are quite high at high irradiances ( $\sim$ 4 ciliates d<sup>-1</sup>). Growth rates as high as 0.8 d<sup>-1</sup> have been reported at high food concentrations and irradiances. In many ways, *N. aeruginosum* functions similar to *A. triacantha*. Experiments have not been carried out with this species in complete darkness, but the light compensation point, where the dinoflagellate are able to sustain itself, was achieved at an irradiance of ~10 µmol photons  $m^2 s^{-1}$ . Maximum growth rates of 0.3 (d) were obtained at irradiances of ~40 µmol photons  $m^2 s^{-1}$  (Drumm et al., 2017).

To what extent can measured rates of photosynthesis explain increased growth rates in these dinoflagellates? This question has so far only been addressed for *N. aeruginosum*. In this species, highest rates of photosynthesis only corresponded to  $\sim$ 26% of cell carbon content, with estimated biomass production and measured rates of photosynthesis of fed cells unable to explain observed increased growth rates at high irradiances (Drumm et al., 2017). A hypothesis to explain this phenomenon could be that high irradiance induces and aids digestion of phytoplankton. Some studies have shown that prey, especially phototrophic prey, are digested faster in the light (Klein Breteler et al., 1986; Strom, 2001). This is supported by a recent study demonstrating that the oxidation of carbohydrates by enzymes increased substantially in light (Cannella et al., 2016). Another pathway to utilize solar energy could be through the protein, rhodopsin, which was recently shown in the heterotrophic dinoflagellate *Oxyrrhis marina* (Guo et al., 2014). Thus, three explanations for the observed positive effect of light have been put forward (Drumm et al., 2017): (1) Algal pigments are highly labile in the presence of light and oxygen, making ingested material more readily utilizable for growth (Porra et al., 1997); (2) Enzymes or other proteins are expressed to a greater extent in light; (3) ATP produced by photosynthetic activity aids ingestion and digestion of prey, rather than glucose production. In the latter, photosynthesis increases with increasing irradiance resulting in higher productions of ATP, allowing faster digestion and hence greater ingestion rates. More research is definitely required to explore this further.

Prey starvation responses within this group have also been studied in some detail in a few species. In *G. gracilentum*, photosynthetic activity decreases rapidly when starved for prey. Hardly any photosynthesis was measured in prey-starved cultures after 48h. Populations of *G. gracilentum* that were subjected to sudden prey starvation divided only once at maximum, and cells did not survive more than seven days. Similar population starvation response has been shown for *A. poecilochroum*. Thus, these species rely heavily on the continuous ingestion of prey. In general, these species did not survive much better in the light compared to in the dark when starved for prey (Skovgaard, 1998; Jakobsen et al., 2000). Other species, *A. triacantha* and *N. aeruginosum*, maintained their functionally active kleptochloroplasts for a much longer time (Park et al., 2013; Drumm et al., 2017). In *A. triacantha* the acquired plastids were retained for up to one month, and they have been shown to be functionally active for ~ 18 d, when measured by a pulse-amplitude modulation fluorometer. Likewise, *N. aeruginosum* can be starved for up to a month. The kleptochloroplasts were photosynthetically active for at least 27 days in prey-starved cultures  $(^{14}C$  measurements), and *N. aeruginosum* maintained a high photosynthetic rate for the first nine days, despite going through three cell divisions. These observations indicate that *N. aeruginosum*, unlike the other species in this group, is able to divide their sequestered chloroplasts, but details need to be investigated further.

In conclusion, the species within this group that are able to grow at a fairly high rates in darkness (*G. gracilentum* and *A. poecilochroum*) are not able to maintain high rates of photosynthesis when prey-starved. The two other species, *A. triacantha* and *N. aeruginosum*  cannot grow in the dark even if supplied with food in excess. However, they can maintain their acquired chloroplasts for a much longer time than *G. gracilentum* and *A. poechilochroum*. This indicates that the ability to maintain functional chloroplasts for a long time comes at the expense of not being able to grow in complete darkness. It will be interesting to explore gene expression in these dinoflagellates to discover the mechanisms underlying host control of retained reduced endosymbionts.

#### **Species That Only Sequester the Chloroplasts**

The only dinoflagellates that exclusively sequester chloroplasts from their prey (pNCMs) are found in the genera *Dinophysis and Phalacroma*. While many *Dinophysis* species have been shown to harbour cryptophyte chloroplasts, only one species of *Phalacroma*, *P. mitra*, has been reported to retain chloroplasts, and their origin seem to be of mainly haptophyte origin (Koike et al., 2005; Nishitani et al., 2012; 2018). While *Dinophysis* species have been cultured since 2006 (Park et al., 2006), *P. mitra* has not yet been brought into culture and nothing is known of its physiology. Six species out of the existing ~100 described *Dinophysis*  species have been successfully cultured (Hansen et al., 2013); all cultured on *Mesodinium rubrum* as prey. To what extent *Dinophysi*s relies on sequestered chloroplasts and/or whether *Dinophysis* species permanently maintain chloroplasts was debated for some time (see Hansen et al., 2013 for a discussion). The final proof that the chloroplasts are continuously sequestered from its prey was provided by Kim et al. (2012). They were able to show the movement of sequestered chloroplasts to the different chloroplast centers inside the *Dinophysis* cell using video recordings. They were also able to show morphological changes of the chloroplasts following their incorporation in the *Dinophysis* cell.

*Dinophysis* species cannot grow in complete darkness, even if they are fed prey in excess (Kim et al., 2008). Both food uptake and growth are highly dependent upon irradiance (Kim et al., 2008) and of course prey concentration (Kim et al., 2008; Riisgaard and Hansen, 2009). In addition, prey quality (growth rate of the prey ciliate) affects apparent prey ingestion (Riisgaard and Hansen, 2009). However, grazing rates published by Kim et al. (2008) and Riisgaard and Hansen (2009) should be interpreted with caution. Estimations of grazing rates of *Dinophysis* on its prey have been based on the reduction of prey in grazing bottles (with *Dinophysis* and *M. rubrum*) as compared to control bottles (with *M. rubrum* alone) using standard grazing equations. Thus, the grazing rates are calculated assuming that the differences in *M. rubrum* cell concentration in the grazing and control bottles are due to cells that have been ingested by *Dinophysis*. Recent papers, however, have shown that *Dinophysis*  species exudate/excrete mucus in which the prey, *M. rubrum,* is caught (Mafra et al., 2016; Ojamäe et al., 2016; Papiol et al., 2016). Some of the ciliates that are caught in the mucus lyse and disintegrate and thus are no longer available to *Dinophysis* for ingestion. Since the ability of the mucus clumps to catch prey is dependent on prey and predator concentrations (Ojamäe et al., 2016), the "lysis problem" will mostly be a problem at high *Dinophysis* cell concentrations, and therefore this phenomenon will especially impact calculated grazing rates at high prey concentrations (where you need high *Dinophysis* concentrations to detect the

grazing response). The implication of this is that grazing rates of *Dinophysis* on its prey most probably have been overestimated. Thus, it is most likely that *Dinophysis* species get most of their carbon from photosynthesis (Ojamäe et al., 2016).

*Dinophysis* species can starve for months without food, and the cells may divide up to  $\sim$ four times before cell divisions stops (Park et al., 2008; Riisgaard and Hansen, 2009). It has been shown that *D. acuminata* and *D. acuta* can maintain functionally active chloroplasts for many weeks, up to months without access to prey (Park et al., 2008; Hansen et al., 2016). Prey-starved *D. acuta* cells cannot only maintain photosynthetic activity for an extended period, they also are able to produce photosynthetic and photoprotective pigments (Hansen et al., 2016). Also, both *D. acuminata* and *D. acuta* have been shown to be able to divide their ingested chloroplasts, at least once, sometimes twice (Rusterholz et al., 2017). Thus, *Dinophysis* species seem to have considerable control of their ingested cryptophyte chloroplasts compared to species that also sequester prey nuclei (i.e., red *Mesodinium* spp. and *A. triacantha*). The photosynthetic performances of kleptochloroplasts in these latter species are coupled to the sequestration of prey nuclei and nucleomorph material. This is not the case in *Dinophysis* spp. Thus, it seems that the function of chloroplasts in *Dinophysis* may depend upon genes that in the past have been transferred from prey nuclei and nucleomorphs to the dinoflagellate genome.

Very little is known about such a transfer of genes from the cryptophyte genome to the genome of *Dinophysis* spp. Five proteins, complete with plastid-targeting peptides that may function in photosystem stabilization and metabolite transport, have been found encoded in the nuclear genome of *D. acuminata* (Wisecaver and Hackett, 2010). However, four of the five proteins appear to have been derived from haptophytes and/or fucoxanthin dinoflagellates, while only the fifth protein appear to derive from cryptophytes via lateral gene transfer. Recently, Hongo et al., (2019) investigated the origin of plastid proteins in *Dinophysis fortii* via RNA sequencing, and identified 58 gene products involved in porphyrin, chlorophyll, isoprenoid and carotenoid biosyntheses as well as in photosynthesis. Their phylogenetic analysis revealed that the genes associated with chlorophyll and carotenoid biosyntheses and photosynthesis originated from fucoxanthin dinoflagellates, haptophytes, chlorarachniophytes, cyanobacteria and cryptophytes. Thus, it appears that *Dinophysis* spp. have maintained genes from an earlier event and only later incorporated cryptophyte chloroplasts. All together the experimental and molecular findings suggest that *Dinophysis* spp. have some functional control of their plastids, but that these species rely on feeding to sustain growth.

## **IMPORTANCE OF MIXOTROPHIC DINOFLAGELLATES AS GRAZERS IN NATURAL WATERS**

Mixotrophic dinoflagellates are common in freshwater, brackish and marine environments (Tables 1–3) and are found in aquatic systems at all latitudes (Leles et al., 2017; Leles et al., 2019). Also, mixotrophic dinoflagellates are found in eutrophic as well as in oligotrophic waters. Thus, they are indeed ubiquitous. Despite the growing awareness of mixotrophic dinoflagellates as grazers in pelagic waters, estimations of their grazing impacts are quite limited. There are many reasons related to prey preference and physiology for why

this is the case. First, some dinoflagellates ingest only specific prey items, while others are quite omnivorous within a certain prey size range. The prey items are often of the same size as the dinoflagellates themselves, and prey items may include heterotrophic protists and metazoans. Second, a number of physical and chemical factors like irradiance, temperature and nutrients influence feeding rates. Lastly, different types of dinoflagellates feed for various reasons like acquiring carbon and/or nutrients and vitamins for enhanced growth (the CMs). Others, the NCMs, also ingest prey to sequester functional chloroplasts.

The prevalence of CMs with food vacuoles has been measured in field samples in a number of cases, and those studies provide valuable information on spatial and temporal variations in the importance of food uptake in CMs in red tide species such as *Akashiwa sanguinea*, *Tripos furca* and *Levandering fissa* (Bockstahler and Coats, 1993a; Bockstahler and Coats, 1993b; Li et al., 1996), *Karlodinium veneficum* (Li et al., 1996; Adolf et al., 2008) and *Prorocentrum cordatum* (Li et al., 1996; Stoecker et al., 1997; Johnson et al., 2018). The published data indicate that 0–20% of the CM dinoflagellates have easily identifiable food vacuoles. However, values as high as 50% have been reported in *P. cordatum* (Stoecker et al., 1997). The percentage of dinoflagellate cells with food vacuoles depend on irradiance, time of day, food availability, and nutrient (N, P) concentration (Stoecker et al., 1997; Li et al., 2001).

The transformation of data on the prevalence of cells with food vacuoles to ingestion rates is not trivial as digestion rates are affected by a number of factors like light, nutritional quality and quantity of prey cells and water temperature (Bockstahler and Coats, 1993b; Li et al., 1996; Stoecker et al., 1997; Li et al., 2001). Nevertheless, Bockstahler and Coats (1993b) using the "gut clearance/gut fullness" approach, reported estimates of *in situ* ingestion and clearance rates of *Akashiwo sanguinea* that ranged from 0–0.06 prey dinoflagellate<sup>-1</sup> h<sup>-1</sup> and  $0$ –5.8 µl dinoflagellate<sup>-1</sup> h<sup>-1</sup>, respectively, with daily removal of ciliate biomass representing 6 to  $67\%$  of the  $\lt 20 \mu m$  oligotrich ciliate standing stock. Daily consumption of ciliate biomass by *A. sanguinea* averaged 2.5% of body carbon and 4.0% of body nitrogen, with maximal values of 11.6 and 18.5 %, respectively (Bockstahler and Coats, 1993b). Likewise, for *K. veneficum* feeding on cryptophytes, Li et al., (2001) reported that ingestion rates ranged from 0–0.26 prey dinoflagellate<sup>-1</sup> d<sup>-1</sup>, corresponding to an estimated daily ingestion of 0–12% body carbon, 0-13 % of body nitrogen and 0-21% of body phosphorous  $d^{-1}$  and leading to a daily removal of 0–4 % of the cryptophyte standing stock in that specific study.

An approach that has been used to document the uptake of specific prey cells in CM dinoflagellates involves studying the changes in prevalence of ingested prey cells over time following the addition of live, untreated, prey organisms (e.g., cryptophytes) to field samples. This approach has been used to indicate the willingness of natural *K. veneficum* populations to feed, but has not been able to provide *in situ* grazing rates (Stoecker et al., 1997; Adolf et al., 2008). Nevertheless, it was shown that feeding rates depend on time of the day, with highest prey uptake during night (Stoecker et al., 1997). Addition of live stained-prey to natural plankton communities has been attempted in the past, with some success in tracking prey uptake in heterotrophic (Martinez et al., 2014) and CM dinoflagellates (Stoecker et al., 1997; Johnson et al., 2018). Some of the more successful dyes (e.g., CellTracker, LysoSensor) do not seem to affect prey or the predator in the concentrations used and as such seems promising. However, the tested stains generally stain only certain algal species, not others. Thus, further research is needed to obtain more universal dyes.

Addition of live prey to natural populations is problematic, since nutrients may be added along with the algal prey. Thus, the use of fluorescent beads or fluorescently labelled heatkilled prey have been attempted instead to measure grazing in protists (Sherr et al., 1987; Rublee and Gallegos, 1989; Beisner et al., 2019). Such methods have provided valuable data for filter feeding heterotrophic ciliates and flagellates. However, these methods may lead to reduced feeding rates for raptorial predators (Stoecker, 1988; Nygaard and Hessen, 1990; Putt, 1991; Verity, 1991; Landry, 1994; Li et al., 1996; Beisner et al., 2019), and the approach does not seem to work very well for CM dinoflagellates.

Finally, since *in situ* grazing rates are so difficult to obtain, laboratory-generated grazing rates have been used to infer potential impacts of specific CM dinoflagellates on specific prey items. Using the prey density depended grazing responses (functional responses) of the dinoflagellates on specific preys and applying them to *in situ* cell concentrations of dinoflagellates and their prey, the potential grazing impacts have been estimated. Such approaches have been used for evaluating grazing impacts of red tide species, like *Heterocapsa steinii*, *Gonyaulax polygramma*, *Lingulodinium polyedra*, *Prorocentrum donghaiense*, *P. micans* and *Scrippsiella acuminata* (Jeong et al., 2005a; 2005b). Measured grazing rates were temperature corrected using a standard  $Q_{10}$  value (of 2.8). Reported grazing rates lie in the range 0–98% of prey populations removed per h. The highest estimated removal rates of prey were during blooms of the specific dinoflagellates, while the lowest rates were observed when the dinoflagellates were less abundant and/or the prey items were very abundant.

#### **CONCLUSION**

Mixotrophy among dinoflagellates is quite common among freshwater and marine dinoflagellates, including species with their own permanent chloroplasts (CM dinoflagellates) and species that sequester chloroplasts from their prey (NCM dinoflagellates). In fact, mixotrophy among dinoflagellates may now be considered more the rule than the exception. Feeding may not always be expressed among the CM dinoflagellates, especially as light and nutrients impact feeding for the majority of species. Mixotrophic dinoflagellates primarily eat other protists, but some species can exploit much larger metazoans as part of their diet. Some mixotrophic dinoflagellates are highly selective in which prey types they ingest, while others are quite omnivorous. Especially the NCM dinoflagellates seem to be quite restricted in which types of prey they can utilize as donors of chloroplasts and other cell organelles. Few data are available on *in situ* grazing rates of mixotrophic dinoflagellates, and there is a strong need to develop new techniques to measure *in situ* grazing rates. Development of reliable *in situ* techniques to measure feeding is not only important to assess the significance of phagotrophy as a way for dinoflagellates to harvest nutrients in inorganic nutrient limited waters, but also to assess the impact dinoflagellate mixotrophy on the food web.

#### **ABSTRACT**

A *harmful algal bloom* or HAB can refer to any number of different "harmful" attributes related to the proliferation of a particular species or consortium of species of microscopic algae. The vast majority of HABs are caused by dinoflagellates. The family Kareniaceae is a primarily photosynthetic, unarmored lineage of dinoflagellates that includes the marine genus, *Karenia.* The majority of the ten validly described *Karenia*  species can be taxonomically differentiated by morphology and molecular phylogeny. Phycotoxins have been characterized in six species. Brevetoxins, produced largely by *K. brevis*, can cause extensive wildlife mortalities during and after a bloom as well as human health impacts when aerosolized via sea spray or consumed via contaminated shellfish. Due to the substantial impacts related to *K. brevis* and *K. mikimotoi* blooms in particular, progress towards understanding the drivers of sequential phases of blooms – initiation, growth, maintenance, and termination – has necessitated an interdisciplinary approach to best consider linkages between offshore and nearshore processes. Laboratory and field studies demonstrate the versatility of *K. brevis* and *K. mikimotoi* necessary to exist across ecological niches. Although measured growth rates are moderate, strategies such as diel vertical migration, allelopathy, and mixotrophy further broaden the potential niche of these species. Yet, in spite of these similarities, there are intriguing differences between *K. brevis* and *K. mikimotoi* and among the other *Karenia* species in terms of the toxins they produce, the frequency and magnitude of impacts related to blooms, and their biogeographic distribution. High frequency ocean observing technology is needed to complement routine monitoring in the development and validation of more

comprehensive forecasting and hindcasting systems. Future approaches need to be flexible in assimilating new discoveries into bloom dynamics gleaned from contemplating the variable and shared characteristics of *Karenia* species and other ecologically similar – or different – HABs.

**Keywords:** Kareniaceae, *Karenia brevis*, *Karenia mikimotoi*, bloom, brevetoxin, Gulf of Mexico, Florida

#### **1.INTRODUCTION**

#### **1.1.** *Karenia* **and Algal Blooms**

"Harmful Algal Blooms" (HABs) occur world-wide in freshwater, brackish, coastal and open marine waters, and in both the pelagic and benthic realms. Over 60% of toxic marine microalgae are dinoflagellates (Moestrup et al., 2009). The marine dinoflagellate genus *Karenia* is currently represented by ten species, six of which are confirmed to produce toxins, three suspected of producing toxins because of associated effects, and one undocumented to produce toxins (Tables 1–2). In 2000, when Danish scientists Daugbjerg, Hansen, Larsen and Moestrup described the genus *Karenia*, there were only three species; now there are ten with several morphs still awaiting morphologic and genetic characterization. *Karenia* is now recognized to be a genus with representation world-wide, even though the most documented species, *K. brevis* (C.C. Davis) Gert Hansen & Moestrup, is only verified from the Gulf of Mexico, adjacent Caribbean, and US Atlantic waters influenced by the Gulf Stream (Figure 1). A bloom of *K. brevis*, for example, is often defined by its effects, which may vary, that is, cell concentrations that can cause respiratory irritation and shellfish toxicity, cell concentrations that reach high enough numbers to kill fish or concentrations that may discolor the water and even be detected by satellite (Table 3).

All HABs, regardless of final biomass, go through sequential development phases: initiation, growth, maintenance, and dispersal/termination of blooms (Steidinger et al., 1998). However, the entire development cycle may not be in the same area or habitat, and life cycle history varies across species. Depending on species and/or the event, initiation can originate from a planktonic population or a benthic population (cyst or resting stage) and, in the marine environment, can occur in oceanic or coastal waters, or in the estuarine environment, in areas that tend to have longer residence times such as bays. After initiation comes growth (or bloom development), when the influence of environmental parameters such as temperature, light, salinity, nitrogen, phosphorus, silicates, humic substances, grazing, etc. determine if growth will exceed loss and result in increases in biomass. Bloom maintenance requires that population growth be sustained for some period of time, and that may also include retention in a gyre, a current, thin layer, or some other physical dimension. Termination of a bloom may be physical (transported out of an area), chemical (change in nutrients, salinity, temperature, etc.), or biological (grazing by predators, viral infection, parasites, life cycle transitions).

Figure 1. World distribution of *Karenia* spp. Numbers correspond to species in chronological order in which they were described: 1 – *mikimotoi*, 2 – *brevis*, 3 – *brevisulcata*, 4 – *longicanalis*, 5 – *bicuneiformis*, 6 – *cristata*, 7 – *asterichroma*, 8 – *concordia*, 9 – *papilionacea*, and 10 – *selliformis*. Plain text is used for morphological information only and bold for genetic information only; circles are used when both types of information are available. Genetic information is based on *Karenia* sequences available in NCBI's Genbank database as of April 2019 that provide location of origin (see Table 1), except for the following species: 1 in India (Godhe et al., 2001); 10 in Chile (Guillou et al. 2002, GenBank AF318247 as *Gymnodinium* sp., J. Mardones pers. comm.); 1, 2, 4, 7, and 9 in the Gulf of Mexico (FWC, unpublished), 2 and 4 on the Florida East Coast (FWC, unpublished); and 1 in New Hampshire, USA (FWC, unpublished). Source of morphological information is as follows: 9 in Pacific South America (Gómez, 2006); 1, 3, 5, 7, 9, 10 in Pacific Mexico (del Castillo et al., 2013); 1 in Alaska (NCCOS, 2014); 1 in Argentina (Negri et al., 1992); 2 in Trinidad (Lackley, 1956); 2 and 9 in Jamaica (Ranston, 2008); Gulf of Mexico (Steidinger, 2018); Florida East Coast (FWC, 2019); 1 in Delaware, USA (www.dnrec.delaware.gov/Pages/RedTideINformation.aspx, accessed on May 2019); 2, 9, and 10 in Delaware, USA (ARC, Algal Resources Collection http://www.algalresourcescollection.com, accessed on May 2019); 1 in eastern Canada (Blasco et al., 1996); 5 an 6 in South Africa (Botes et al., 2003); 1 in northwestern Europe (Hansen et al., 2000); 9 in northwestern Europe (Fraga & Sanchez, 1985; Nézan, 1998); 5, 6, 9, and 10 in eastern Italy (Zingone et al., 2006); 1 in the Aegian Sea (Bizsel & Bizsel, 2002); 10 in the Arabian Sea (Heil et al., 2001); 1 in India (Robin et al., 2013); 9 in Madagascar (Sournia, 1972); 1 in Japan (Oda, 1935); 4 in China (Chang, 1999); 1, 4, 5, 7, 9, 10 in Australia (Hallegraeff et al., 2010); and 1, 3, 4, 5, 8, 9, 10 in New Zealand (Haywood et al., 2004; Chang & Ryan, 2004).

In this chapter, we discuss the ecophysiology and bloom dynamics of *K. brevis*. To this end, we have set the stage by summarizing our current understanding of *Karenia* taxonomy, their worldwide distribution, and the effects of toxin production. This is followed by some basic information on life cycle, behavioral, and physiological aspects that are key to better understand bloom dynamics. As much as possible, we have traced contrasts and parallels with what is known for *K. mikimotoi* (Miyake & Kominami ex Oda) Gert Hansen & Moestrup, another extensively studied species in the genus. Although there is not a large body of work directly comparing *K*. *brevis* with *K. mikimotoi*, there are a number of viable comparisons of interest that can be made from independent research efforts.

#### **1.2. Taxonomy and Distribution**

The family Kareniaceae Bergholts, Daugbjerg, Moestrup & Fernández-Tejedor was established to accommodate *Karenia* G. Hansen & Moestrup, *Karlodinium* J. Larsen, and *Takayama* M.F. Salas, Bolch, Botes & Hallegraeff (Bergholtz et al., 2005). This is a wellsupported evolutionary lineage, as inferred from partial LSU rDNA sequences of unarmored, primarily photosynthetic dinoflagellates with straight or "s" shaped apical grooves. Pigment composition is also typical for this family, that is, lack of peridinin and the presence of gyroxanthin-diester and a host of fucoxanthin-type accessory pigments (Steidinger et al., 2008 and references therein). Refinement of our understanding of phylogenetic relationships indicates a close association between Kareniaceae and *Brachidinium capitatum* F.J.R. Taylor (e.g., Henrichs et al. (2011); Kretschmann et al. (2015)). If this branch is recognized as a valid grouping at the family level, then Brachinidiaceae (Sournia, 1972) would take priority over Kareniaceae, in agreement with the International Code of Nomenclature for algae, fungi and plants. In addition, phylogeny based on nucleus-encoded rDNAs suggests that the recently described *Gertia stigmatica* K. Takahashi & Iwataki may be also positioned within Kareniaceae (Takahashi et al., 2019); the presence of peridinin in this new taxon, however, is not recognized as a taxonomic character for this family.

Understanding past and current morphological diagnostic characters used to discriminate the taxa in question is important to help navigate recent and future updates in the taxonomy and nomenclature of *Karenia* species. Until recently, morphological differentiation of *Karlodinium* from *Karenia*, both with straight apical grooves, was mostly based on the presence of a ventral pore to the left of the groove on the former. However, as the presence of a ventral pore has proved to be a variable character (e.g., de Salas et al. (2008)), a better way to distinguish these two genera morphologically has been suggested based on pyrenoid shape: an internal lenticular pyrenoid in *Karlodinium* vs. a triangular, multi-stalked pyrenoid in *Karenia* (Lou et al., 2018 and references therein).

All ten validly published *Karenia* species are marine and most were originally described from bloom events, except for *K. papilionacea* A.J. Haywood & K.A. Steidinger that was isolated from a water sample of  $\langle 500 \text{ cells } L^{-1}$ . All taxa have been studied using morphological and molecular data combined, except for *K. concordia*, for which only morphological information is available (Table 1). The taxa listed in the literature as *Karenia umbella* Salas, Bolch & Hallegraeff and *Karenia digitata* [Yang, Takayama, Matsuoka &](http://www.algaebase.org/search/species/detail/?species_id=44332)  [Hodgkiss](http://www.algaebase.org/search/species/detail/?species_id=44332) have undergone recent taxonomic revision. *Karenia umbella* is now established as a junior synonym of *K. longicanalis* (Wang et al., 2018). In the second case, *K. digitata* has been transferred to *Karlodinium digitatum* [\(Yang, Takayama, Matsuoka & Hodgkiss\) Gu,](http://www.algaebase.org/search/species/detail/?species_id=169636)  [Chan & Lu,](http://www.algaebase.org/search/species/detail/?species_id=169636) based on its genetic make-up, lack of ventral pore, and the presence of lenticular pyrenoids (Lou et al., 2018).

Diagnostic characters helpful in discriminating between *Karenia* species using light microscopy (LM) are cell outline and nucleus shape and position, especially when stained with Lugol's solution (see illustrations in Table 2). Apical groove and sulcal design are key taxonomic features discernable under LM optimal settings and with electron microscopy (EM). Except for *K. mikimotoi*, named after Mikimoto Koukichi who was involved with red tides while establishing the famous Akoya pearl oyster hatchery in Japan in the early 1900s, all other *Karenia* species have very descriptive names (see etymology in Table 2). That said,
unarmored dinoflagellates are pleomorphic because of their flexible amphiesma or theca, and *Karenia* species can also be polymorphic due to sexual stages (see section 2.1; see Figure 2).

Eight of the ten *Karenia* species have been implicated in wildlife and/or human health impacts, and only six of them have had toxin(s) characterized: *K. brevis*, *K. brevisulcata*, *K. concordia*, *K. mikimotoi*, *K. papilionacea*, and *K. selliformis* (Table 2)*.* Only *K. asterichroma* and *K. bicuneiformis* are not known (or confirmed) to produce toxins. Due to the difficulties in the identification of unarmored dinoflagellates from field preserved samples, one may expect that as of yet unnamed taxa could fit in the genus *Karenia* once their genetics and description of other characters are properly assessed. Some *Karenia* morphotypes have actually already been established, based on field material from the Gulf of Mexico (Steidinger et al., 2008). Ideally, species descriptions would be based on a combination of morphological and genetic characters, in association with biochemical (pigment composition, toxin profiles) and behavioral features such as swimming pattern and modes/stages in sexual reproduction. Biogeographic distribution patterns vary among species – and potentially intraspecific variants – and can be another important factor to consider as part of taxonomic evaluation.

Karenia species	Synonym	$(1)$ Genbank representation
<sup>(1)</sup> K. <i>mikimotoi</i> (Miyake & Kominami ex Oda) Gert Hansen & Moestrup	Gymnodinium mikimotoi Miyake & Kominami ex Oda Gyrodinium nagasakiense Takayama & Adachi Gymnodinium nagasakiense H. <sup>(2)</sup> Based on Lassus et al. (2016 and references therein), except otherwise noted.

(3) Fish kill observed in Tasmania (de Salas et al., 2004a) but toxin not confirmed (Yang et al. 2001; de Salas et al., 2004a).

(4) Brevetoxins from preliminary ELISA in culture (as *K. bidigitata* in Haywood et al., 2004) have not been confirmed.

<sup>(5)</sup> Toxin results presented in conference abstract (Chang et al., 2006) without further details or corroboration.

 $(6)$  Fowler et al. (2015).

The perception that *Karenia* are typically neritic species, though not incorrect, is likely biased by the many reports of bloom manifestations in coastal waters. As will be discussed in sections 2 and 3, multiple sources of evidence suggest that at least *K. brevis* and *K. mikimotoi* can also thrive in more oligotrophic, offshore waters. Likewise, *K. papilionacea* and *K. asterichroma* reports indicate their distributions may extend offshore the Florida west coast (respectively, Steidinger et al., 2008 and FWC, 2019). Geographic locations where the highest numbers  $(\geq 4)$  of *Karenia* species have been reported are, not unexpectedly, where more intensive and targeted research (and bloom-related impacts) have taken place (Figure 1): the Gulf of Mexico, North America Atlantic coast (Florida, Delaware, and Newfoundland), the Pacific coast of Mexico, the northeast coast of Europe, the west coast of Italy, New Zealand, Tasmania, and China (Hong Kong region). Admittedly, there may be species checklists that cite a *Karenia* species not included in our assessment that only considered morphological records with illustrations and/or a minimal description of identifiable taxonomic characters and/or a corresponding sequence in NCBI's Genbank database. Gaps in our understanding of *Karenia* diversity worldwide are more critical in the southeast Pacific, the south Atlantic, and the Indian Ocean.

The range of *Karenia brevis* is restricted to the region encompassing the Gulf of Mexico and the Caribbean (Jamaica, and possibly Trinidad), the eastern Atlantic coast of the US from the Florida Keys up to Delaware, as well as the Gulf Stream (Figure 1). The Gulf Stream has been a transport mechanism of surface waters from the Gulf of Mexico and Caribbean to northern latitudes (Tester et al., 1989). *Karenia mikimotoi*, *K. papilionacea*, and *K. seliformis* records, on the other hand, are the most widespread of all *Karenia* species (Figure 1). One should be aware that, prior to its description in 2004, some *K. papilionacea* records were published as an unidentified dinoflagellate (Sournia, 1972) and as *Gymnodinium* breve-like cells (Fraga & Sanchez, 1985; Nézan, 1998). Illustrations in those cases, however, are unequivocal: cell wider than long; hypotheca deeply excavated posteriorly forming an inverted V indentation; the left hypothecal lobe rounded and the right hypothecal lobe truncate; and round nucleus in left hypothecal lobe (see line drawing in Table 2).

Reconciling past and current information on *K. mikimotoi* (the first *Karenia* ever to be described in Oda (1935)) requires following the trail of not only its synonyms (Table 1) but also three decades of its misidentification as *Gymnodinium aureolum* (Hulburt) G. Hansen (=*Gyrodinium aureolum* Hulburt) in European waters (Hansen et al. 2000). The identity and distribution of this taxon is actually still unfolding. At least two distinct populations have been suggested based on sequences from ribosomal RNA (28S and ITS) and the *rbc*L genes. Isolates from Europe and New Zealand are more closely related to each other than to isolates from Japan (Al-Kandari et al., 2011). Similarly, our knowledge of the degree of intraspecific genotypic diversity within *K. brevis* is limited. To date, 18S rRNA sequencing analyses by Loret et al. (2002) identified little intra-specific diversity within this gene, whereas finer scale microsatellite population markers developed by Renshaw et al. (2006) and Henrichs et al. (2013) identified a larger degree of genotypic diversity among *K. brevis*.

Not surprisingly, *K. brevis* and *K. mikimotoi* have the highest number of sequences submitted to Genbank, approximately seven times as many sequences as the next highest species, *K. papilionacea* (Table 1). Three *Karenia* species, *K. asterichroma*, *K. breviculcata*, and *K. cristata* have less than 10 Genbank submissions and *K. concordia* has no sequences submitted to Genbank. The seven most represented regions among *Karenia* species are: 5.8S, 18S, and 28S and ITS1/ITS2 (ribosomal RNA genes and associated intergenic spacers,

respectively), *cox1* (cytochrome c oxidase subunit I), and *rbcL* (ribulose-1,5-bisphosphate carboxylase/oxygenase large subunit). *K. brevis*, *K. mikimotoi*, *K. bicuneformis*, and *K. selliformis* have sequences submitted for all seven of these genes and *K. papilionacea* is only missing one (*rbcL*) of the seven genes. Overall, 28S is the best represented gene as all *Karenia* species that have submitted Genbank sequences have at least one 28S sequence.

Figure 2. *Karenia brevis* life cycle. (a) Vegetative 1N cell that is capable of mitotic division or producing gametes. (b) First stage in gamete formation with movement of nucleus to center. (c) Second stage of gamete formation with division of nucleus. (d) Third stage with production of isogametes. In heterothallic strains, there are + and – mating types that fuse. In homothallic strains, gametes are the same mating type. (e) (f) Cytoplasmic fusion precedes nuclear fusion. (g) Planozygote with 2N nucleus and 2 longitudinal flagella. (h) Motile planozygote. (i) Unconfirmed presumed hypnozygote. (j) Unconfirmed meiocyte. (k) Resultant 4 1N cells from meiosis II. In Steidinger et al. (1998), copyright permission from K. Steidinger.

Large scale sequencing efforts for *Karenia* began with sequencing of EST (expressed sequence tag) libraries of *K. brevis* in 2005, which was subsequently used to evaluate the transcriptome by microarray (Liddie et al., 2005; Morey et al., 2011; Johnson et al., 2012; Morey & Van Dolah, 2013). This data has led to valuable insight into the molecular underpinnings of *K. brevis* and of its chimeric proteome, which has been acquired over the course of multiple plastid replacements (Nosenko et al., 2006). Since then, numerous high throughput sequencing efforts have been conducted targeting transcriptomes of *K. brevis* (Keeling et al., 2014; Ryan et al., 2014) and *K. mikimotoi* (Kimura et al., 2015; Dorrell et al., 2016; Luo et al., 2017), which promise even finer phylogenetic analyses of the Kareniaceae (e.g., Janouškovec et al. (2017)). Nuclear genome size is approximately four times larger in *K. brevis* as compared with *K. mikimotoi* (Cuadrado et al., 2019); this large genome has numerous implications, including having different genetic stocks available for evolutionary adaptation, altering the nutritional requirements due to greater/lesser nucleic acid biosynthesis, and possibly thereafter affecting the time required for DNA synthesis and gating thresholds for S-phase initiation (see Section 2.2).

To date, there are no draft genomes for any *Karenia* species, although these and other new approaches will continue to yield further important genomic insights into these and other toxic dinoflagellates in spite of challenges associated with the large genome sizes of dinoflagellates.

## **1.3. Toxins and Their Effects**

*Karenia* species may produce a host of bioactive compounds (Caruana & Amzil, 2018 and references therein), some cytotoxic whose effects have been tested solely in bioassaymodel cells (e.g., Tanaka et al. (2013)). Phycotoxins that have been demonstrated to negatively affect wildlife and/or human health are brevetoxins, gymnodimine, brevisulcenals (KBTs), and brevisulcatic acids (BSXs) (Table 2). There are also reports on the production by some *Karenia* species of allelochemical compounds that suppress the growth of other microalgae (e.g., Freeburg et al. (1979); Kubanek et al. (2005); Prince et al. (2008); Chang (2011)), although stimulation of diatom growth has also been observed under certain experimental conditions (e.g., Poulson et al. (2010)). Here we focus on the effects of brevetoxins, and the reader is referred to Miles et al. (2000) for information on gymnodimine and Holland et al. (2012) for KBTs and BSXs. Interestingly, *K. brevis* from laboratory cultures and natural samples also produces brevenal, which is a natural inhibitor of brevetoxin action in sodium channel receptor binding assays thus antagonistic to brevetoxin toxicity (Bourdelais et al., 2004; Errera et al., 2010).

Brevetoxins are neurotoxins produced by at least three *Karenia* species (Table 2). These toxins are a suite of at least nine structurally related congener compounds from which numerous derivatives and metabolites of varying toxicity may be produced (Baden et al., 2005; Abraham et al., 2006; Caruana & Amzil, 2018). Brevetoxins may cause indiscriminate wildlife mortalities, affecting hundreds of fish species, as well as birds, turtles, and marine mammals. Examples of the diversity of toxin molecule structures, the toxicokinetics at the cellular level, and the species affected and their symptoms are detailed in Landsberg (2002). Although the most common perception of harmful effects to wildlife is that of massive mortality during intense blooms (e.g., Gunter et al. (1947); Forrester et al. (1977); Bossart et al. (1998); Flewelling et al. (2010); Fauquier et al. (2013); Fire et al. (2015); Foley et al. (2019)), there is mounting evidence for effects on wildlife resulting from lower level, chronic exposures to brevetoxins (e.g., Walsh et al. (2015); Perrault et al. (2016)). The complexity of assessing chronic exposure rests in a combination of factors, such as the *K. brevis* strain/population in question, the brevetoxin type and its extracellular stability, the exposure routes, and the susceptibility of the affected species (Landsberg, 2002; Landsberg et al., 2014). Toxins transferred through the food web is an additional layer of complexity given that brevetoxins may be present in different forms and compartments, such as inside the cell, dissolved in the water (once cells lyse or die), aerosolized in sea spray, adsorbed to particles in the water or in the sediments, and stored in biota tissue (Landsberg et al., 2009; Landsberg et al., 2014). For instance, the space-time decoupling between *K. brevis* blooms and marine mammals found sick or dead on the Gulf coast of Florida has been traced to fish and seagrass acting as toxin vectors for, respectively, bottlenose dolphins (*Tursioples truncatus*) and manatees (*Trichecus manatus latirostris*) (Flewelling et al., 2005). Likewise, evidence suggests that brevetoxins may cause negative effects to nesting loggerhead sea turtles (*Caretta caretta*) long after a bloom has dissipated, with signs of impairment to their immune and reproductive systems, including hatching success (Perrault et al., 2016). Brevetoxincontaminated fish that wash on beaches may also represent a risk factor for terrestrial mammals (Castle et al., 2013) and scavenging shorebirds (van Deventer et al., 2012), with potential consequences to resident or migratory populations not fully understood.

## **Table 3.** *Karenia brevis* **concentrations and corresponding expected effects, based on criteria established by the Florida Fish and Wildlife Conservation Commission for the statewide status report on red tide monitoring and prediction**

(https://myfwc.com/research/redtide/statewide/, accessed on April 2019). This discussion considers "medium" and "high" concentrations as bloom level, even though effects may be observed and management procedures start at "very low" concentrations due to brevetoxins' high toxicity.

Brevetoxins can threaten human health in two primary ways:

- *Aerosolized brevetoxins.* The toxins from ruptured *K. brevis* cells can be aerosolized in sea spray so that beachgoers and nearby communities can experience respiratory irritation such as coughing, sneezing, tearing, and itchy throat. Because the toxins are aerosolized as waves break, the severity of respiratory symptoms depends on both *K. brevis* cell concentration in the water (e.g., Table 3), on wind speed and direction, as well as vulnerability of the person exposed.
- *Brevetoxin contaminated shellfish.* Bivalve and gastropod molluscan shellfish accumulate the toxins in their tissues and can cause neurotoxic shellfish poisoning (NSP) in human and animal consumers. NSP symptoms can include few to several of the following: headache, nausea, diarrhea, abdominal pain, tingling of the mouth, reversal of hot-cold temperature sensation, vertigo, loss of coordination, slurred speech, slow heart rate, dilated pupils, muscle pain, and respiratory distress (Landsberg, 2002; Watkins et al., 2008). No human fatalities have been attributed to NSP, and no outbreaks have occurred in Florida from legally harvested bivalve molluscs since regulatory guidelines were put in place in the 1970s based on cell abundance as a proxy for brevetoxins. In a continued effort to prevent NSP, systematic monitoring of *K. brevis* concentrations in Florida waters has informed timely closures of commercial shellfish beds (Table 3) in association with toxin testing in the tissues of the harvestable molluscs (NSSP, 2017). Communication loopholes still need to be addressed to guarantee the same level of public safety when it comes to recreational harvest of bivalve shellfish and gastropods (Reich et al., 2015).

# **2. LIFE CYCLE, BEHAVIOR AND PHYSIOLOGY OF** *K. BREVIS*  **(WITH CONTRASTS AND PARALLELS FOR** *K. MIKIMOTOI***)**

Understanding the life cycle and ecophysiology of the target organism(s) sets the stage to investigate and interpret the biological and oceanographic connections involved in bloom dynamics. *Karenia brevis* is by far the most intensively studied species within the genus, seconded by *K. mikimotoi*. Among many other publications, information on the basic biology of the former has been discussed as it pertains to bloom dynamics in Steidinger et al. (1998) and in special issues edited by Walsh & Kirkpatrick (2008) and O'Neil & Heil (2014); the latter has been the focus of reviews by Partensky et al. (1991) and Gentien (1998) for European waters, and by Honjo (2004) for Japanese waters. The review by Brand et al. (2012) also provides extensive material on many aspects relating to *Karenia* species.

#### **2.1. Life History, Diel Cycle and Vertical Migration**

Vegetative cells of *K. brevis* reproduce asexually by oblique binary division, and its sexual cycle has been described only through the planozygote stage (Walker, 1982; Steidinger et al., 1998) (Figure 2). Gamete production has been observed in both homothallic and heterothallic strains. Gametes are identifiable by their smaller size, which is typically 1/3 to 1/2 the size of the vegetative cell, which also differs morphologically and cytologically (Figure 2d, e). Gamete conjugation is the same for homothallic and heterothallic strains, that is, cytoplasmic fusion precedes nuclear fusion (Figure 2f) and a planozygote with two longitudinal flagella is generated (Figure 2g, h). Production of hypnozygotes (resting cysts, diploid) have not been observed in culture, although thick-walled round cells that form within the cell membrane have been seen in nature (not to be mistaken for the single layered, rounded stressed or dying cells also observed in nature, often during blooms). The thickwalled palmelloid (non-motile) stage has not been confirmed as a resting cyst or a stressed cell (see alternative interpretation for such forms in Persson et al. (2013)), and this remains to be an important and challenging question to address. A life cycle with a benthic resting phase would have important implications for bloom dynamics (Steidinger, 1975) as has been shown with other dinoflagellates. According to Walker (1982), gametes and planozygotes have been detected only in the fall to late winter in both cultures and field samples from Florida waters, which suggests that transitions in *K. brevis* life cycle phases may be endogenously controlled or possibly seasonally mediated through exogenous cues. This information must be taken with caution, however, since field data in those days were skewed towards event response only, thus not providing the best representation of year around *in situ* dynamics.

Further characterizing *K. brevis* cell behavior, that is, diel phased cell division and diel vertical migration (DVM), brings additional insights into bloom dynamics. Efforts to understand these processes at the molecular level are reviewed in Van Dolah et al. (2009). *Karenia brevis* cell cycle has been demonstrated to be under circadian clock control (Brunelle et al., 2007). One five-year study of cell growth in batch cultures, followed by a mesocosm column experiment and measurements of *in situ* populations yielded the following findings (Van Dolah et al., 2008): (1) *K. brevis* displays diel phased cell division with S-phase beginning a minimum of 6 h after the onset of light and continuing for 12–14 h; (2) mitosis

takes place during the dark period and is generally completed by the beginning of the following day; and (3) the timing of cell cycle phases within the circadian cycle does not differ substantially with temperature, day length, or in bloom populations displaying distinct growth rates ( $\mu_{min}$  0.17–0.55). Likewise, both experimental and *in situ* observations of the migratory behavior of *K. brevis* have described a pattern of cell aggregation in a narrow band (~ 1-5cm) at the surface during daylight hours and dispersion through the water column at night. These behaviors are interpreted, in part, as phototactic and geotactic responses that realize their full potential in nature in the absence of a thermocline (Heil, 1986; Kamykowski et al., 1998a; Heil et al., 2014b; Garrett, 2015).

The rhythm of cell cycle progression in *K. brevis* was found to be independent from the rhythm controlling DVM (Van Dolah et al., 2008); nevertheless, biochemical changes occurring over the cell cycle seem to also play a role in cell displacement in the water column. For instance, a pattern of cell segregation between surface and mid-water populations has been identified during the daylight period, in which a larger percentage of the surface population is composed of cells that have entered the cell cycle (S-phase) whereas the midwater population is composed of cells with higher carbohydrate, lipid, protein, and chlorophyll *a* concentrations (Heil, 1986; Kamykowski et al., 1998b; Van Dolah et al., 2008). There is evidence that daughter cells resulting from asexual division receive unequal shares of the parental resources so that nutrient reduced cells were more strongly influenced by phototaxis for carbon production through photosynthesis, thus resulting in behavior inequality within population during DVM (Schaeffer et al., 2009). Once photosynthate accumulation/utilization reaches a certain threshold, it is challenging to tease apart how much of the cell orientation is triggered by a sensory response to environmental cues or from a displacement mechanism due to the ballast effect of mass distribution in the cells.

*Karenia brevis* nutritional requirements (discussed in section 2.2), as well as nutrient sources in the predominantly oligotrophic waters of the Gulf of Mexico (discussed in section 3), are quite complex (Figure 3). DVM is a strategy that greatly expands *K. brevis* niches for nutrient exploitation. On one hand, it has been postulated that migration toward and aggregation in the surface microlayer may provide access to additional nutrient sources since this was shown to be an area of rapid nutrient cycling (Heil et al., 2014b). On the other end of the spectrum, it has also been suggested that *K. brevis* populations may be adapted to a coupled planktonic-benthic habitat. Accumulations of *K. brevis*, observed during DVM in the bottom half of a 22 m-deep water column, have been assumed to be able to either access nutrient flux at the sediment/water interface or to migrate into the sediment pores where higher nutrient concentrations exist (Sinclair et al., 2006). Indeed, there is laboratory evidence that migration does occur from the overlying water through thin layers of sediment, and that this behavior increases in response to elevated nutrient concentrations (Sinclair & Kamykovski, 2008).

The potential relationship between DVM and a purported immotile benthic life stage in *K. brevis* is, of course, hypothetical. That said, if cysts and/or newly excysted cells were demonstrated to be present at a particular time and location, the possibility of asynchronous division occurring under pre-bloom conditions would have to be taken into account when interpreting bloom initiation (i.e., implying more rapid growth rates than synchronous population division allows). Meanwhile, studies of *K. brevis* bloom dynamics from seeding through maintenance, currently rely on our understanding of the synchronous division of vegetative cells within the nighttime.

Figure 3. Schematic of nitrogen and phosphorus sources supporting *Karenia brevis* blooms over the four bloom environments and bloom stages on the west Florida coast and shelf. Length and width of bars indicate relative importance of specific nutrient source in each environment and bloom stage. Reproduced from Heil et al. (2014a), with copyright permission.

DVM in *K. mikimotoi* follows the same pattern described for *K. brevis*, with patches forming at the surface during daytime and downward movement in the dark hours when synchronous mitotic division is observed (Honjo et al., 1990; Koizumi et al., 1996; Partensky et al., 1991). In nature, swimming speeds of *K. mikimotoi* are estimated to vary between 0.3– 1.3 (2.2) m/h in Japanese waters (Honjo, 2004 and references therein) while the range for *K. brevis* is 0.5–1 m/h (Hu et al., 2016). Field observations for *K. mikimotoi* vertical distribution in NW European waters, a region marked by oceanographic frontal zones, expose an interesting pattern reliant on the degree of water column stratification: migration takes place within a range of up to 15m in mixed or slightly stratified waters whereas a non-migrating, population maximum is observed in the pycnocline when stratification is greater (Gentien, 1998 and references therein).

Swimming speeds estimated in laboratory experiments are between 0.01–0.8 m/h in *K. mikimotoi* (Throndsen, 1973, Bauerfeind et al., 1986) and 0.4–1.4 m/h in *K. brevis* (respectively, at 13°C and 21°C, McKay et al., 2006). These laboratory assays indicate that swimming pattern in *K. brevis* can be quite complex, suggesting a dependence on environmental conditions such as temperature, nutrient availability, and light regime (faster swimming at higher light, though variable according to light:dark cycles). Indeed, the interactive effects of high light and nutrient availability have also been shown to be important determinants of migration and cell death in *K. mikimotoi* (Yuasa et al., 2018). A layer of complexity is added when one compares swimming capabilities of *Karenia* cells at different stages of the cell cycle, that is, swimming speeds in fully grown cells of *K. brevis* are significantly higher than recently divided, doublet cells (Heil, 1986).

Details of *K. mikimotoi* life cycle are also scarce. Pairing gametes transitioning into a nonmotile globular zygote and then into a zygote with the same shape as the vegetative cells were observed in non-clonal cultures from Japanese waters (Ouchi et al., 1994). Similarly to *K. brevis*, an idealized model for the life cycle of *K. mikimotoi* with possible transitions between life stages has been proposed by Liu et al. (2019) after observing delicate diploid resting cells in cultures, and detecting morphologically similar cells (confirmed to be *K. mikimotoi* by molecular methods) in aged sediment samples from known bloom areas in the East China Sea.

#### **2.2. Cell Growth and Its Requisites**

Specific growth rates for *K. brevis* have been shown to be between  $0-1$  divisions  $d^{-1}$ , based primarily on circadian cell cycle gating which is expected to limit the maximum rate. The maximum growth rates in laboratory cultures generally approach  $0.5-0.6$  divisions  $d^{-1}$ (e.g., Hardison et al. (2012); Sunda et al. (2013); Hardison et al. (2013); Hardison et al. (2014)), though there is also substantial intra-specific variability (Errera et al., 2010). Particularly, cultures such as the 'Wilson' clone, which is nearing 70 years, may no longer yield reliable growth rates or other physiological information as *in vitro* selection has proceeded (Berge et al., 2012). And, although cell growth information is of interest, the relatively low rates of growth of *K. brevis* have led to hypotheses that physical accumulations may be key to bloom dynamics in certain areas in the Gulf of Mexico (see section 3.3). It is not clear, however, what the relative importance of cell growth vs. cell accumulation is in bloom formation/persistence. Few growth rates have been measured *in situ*, in part due to the technical nature of making these measurements without disturbing the cells. *In situ* measures by flow cytometry line up well with average laboratory culture growth rates (Van Dolah et al. 2008; Redalje et al. 2008). Another approach applied *in situ*, that of using C<sup>14</sup> radiolabeling of gyroxanthin-diesters, confirmed rates between  $0.1-0.4$  divisions  $d^{-1}$ , with a maximal rate of  $0.7 d<sup>-1</sup>$  (Richardson et al., 2006). Imaging flow cytometry has shown promise as a technique for measuring *Karenia* growth rates *in situ* (Campbell et al., 2013), and has already been used to estimate growth rates of a bloom of *B. capitatum*, a sister genus to *Karenia* (Henrichs et al., 2011).

Specific growth rates for *K. mikimotoi* also range between  $0-1$  divisions  $d^{-1}$  (Gentien, 1998 and references therein). Efforts to estimate *K. mikimotoi* growth rates *in situ* also suffer from the same difficulties as those for *K. brevis* and phytoplankton more generally (e.g., undersampling, Barnes et al. (2015)). There appear to be fewer estimates of field growth rates published for *K. mikimotoi*, however Davidson et al. (2009) estimated a realistic value of 0.44 divisions d-1 , similar in magnitude to rates estimated for *K. brevis in situ*. Fortunately, nonmicroscopic techniques have been developed to measure cell abundance of both *K. brevis* and *K. mikimotoi* (e.g., gyroxanthin diester quantification (Örnólfsdóttir et al., 2003; Staehr & Cullen, 2003) and nucleic acid sequence based amplification - NASBA (Casper et al., 2004; Ulrich et al., 2010)), which may help in the generation of new/improved estimates of growth rates *in situ* due to the higher sample throughput potential.

In terms of phosphorus nutrient uptake, both *K. brevis* and *K. mikimotoi* show similar usage/preferences for organic and inorganic phosphate compounds tested (Richardson & Corcoran, 2015). Moreover, half saturation constants for growth with phosphate are similar: 0.14 µM for *K. mikimotoi* (Yamaguchi, 1994) and 0.18 µM for *K. brevis* (Sinclair et al., 2009). In terms of nitrogen, *K. mikimotoi* exhibits an 80% reduction in growth rate when grown on urea compared to nitrate (Yamaguchi, 1994), whereas *K. brevis* exhibits a 20% faster growth rate on urea compared to nitrate under a subsaturating light regime (Sinclair et al., 2009). Both species seem to be capable of dark nitrate uptake, which in concert with DVM, may afford these species a competitive advantage over non-migrators.

The two species seem to share similar photophysiological attributes including, for example, capabilities to exploit low light levels with compensation irradiances between 10 to 30 µmol photons m<sup>-2</sup> s<sup>-1</sup> (Richardson & Kullenberg 1987; Shanley & Vargo 1993; Gentien, 1998; Magaña & Villareal 2006), saturation of photosynthesis at relatively high irradiances, and little inhibition upon exposure to high light (Gentien, 1998; Dixon & Holligan, 1989; McKay et al., 2006; Schaefer et al., 2007). Their last common ancestor, which exchanged a peridinin containing plastid for a fucoxanthin containing plastid, likely imparted some degree of photosynthetic similarities (Yoon et al., 2005).

Temperature range for *K. brevis* grown in laboratory cultures varies from about 9°C to  $33^{\circ}$ C with optimum growth between  $22-28^{\circ}$ C (Kusek et al., 1999; Vargo, 2009 and references therein). However, the uppermost *in situ* temperature range ( $>$ 3 $^{\circ}$ C) has not been achieved with certain cultures (Magaña & Villareal, 2006, Eng-Wilmot et al., 1977). The salinity range for *K. brevis* grown *in vitro* indicates optimum growth between 27–37 with decreased yields below 24 (Steidinger et al., 1998 and references therein). Japanese strains of *K. mikimotoi* have optimum growth at  $25^{\circ}$ C, with a lower threshold at  $15^{\circ}$ C, and are able to grow at salinities between 15–35 (Honjo, 2004 and references therein). *In situ* temperature and salinity tolerances for both *K. brevis* and *K. mikimotoi* can be illustrated by 30 years of data acquired from estuarine to offshore waters around Florida (Figure 4). It confirms that both species follow a very similar pattern of having fairly broad temperature and salinity tolerances (98% of the data points between, respectively, 14–33°C and 20–37), though geared towards warmer waters and a salinity more typical of coastal to offshore areas.

Figure 4. Abundance of *K. brevis* and *K. mikimotoi* in Florida coastal and offshore waters, according to temperature and salinity, from January 1995 to January 2019 (FWC, 2019). Cut-off values for salinity was 37, even though we acknowledge that higher values may be detected in some areas such as beach surf-zones and shallow embayments in the Florida Keys; however, those few data points could not be easily teased apart from likely spurious high values. The low cutoff value on the Y-axis (333 cells  $L<sup>-1</sup>$ ) corresponds to the detection limit established for routine cell counts.

Both *K. brevis* and *K. mikimotoi* exhibit allelopathic interactions in culture with other phytoplankton (e.g., Uchida et al. (1999); Kubanek et al. (2005); Gentien et al. (2007); Legrand et al. (2003)), and both can exhibit anti-grazer properties (e.g., Waggett et al. (2012); Dang et al. (2015)). Their potential to inhibit grazers does not preclude the importance of grazers at certain bloom stages (e.g., during initiation when chemical defenses may not be effective due to low cell concentrations). Few studies have assessed grazing rates on *K. brevis* in the field (but see Walsh & O'Neil (2014)). Local adaptation to *K. brevis* allelopathy has been proposed as a mechanism that might facilitate different phytoplankton dynamics over time (Kubanek et al., 2007). Notably, the allelopathic effects of *K. brevis* are unrelated to the NSP-causing brevetoxins (Kubanek et al., 2005), though brevetoxins themselves have been shown to affect bacterioplankton communities (Sipler et al., 2014). Allelopathy by *K. brevis* is clearly complex and, though new investigative approaches have improved our understanding of this phenomenon (Granéli & Hansen, 2006; Poulin et al., 2018), its role during blooms remains in its infancy.

Like most dinoflagellates, both *K. brevis* and *K. mikimotoi* exploit mixotrophic strategies (Glibert et al., 2009; Zhang et al., 2011), with some evidence for phagocytosis of cyanobacteria in *K. brevis* and phagocytosis of eukaryotic nanoplankton in *K. mikimotoi*. Collectively, these accounts highlight the multitude of strategies and mechanisms that can potentially play a role in the formation and duration of high biomass blooms as well as in cell upkeeping during non-bloom periods.

## **3. BLOOM DYNAMICS OF** *K. BREVIS*

An operational definition of what constitutes a bloom is necessary for the function and advancement of HAB monitoring and management programs, yet this definition can vary for a given taxon and/or region. Long-term monitoring and observation efforts, coupled with modeling, have helped tighten the bounds of bloom classification for *K. brevis* in Florida waters (Tester et al., 2008; Heil & Steidinger, 2009; Weisberg et al., 2009; see section 1.1). Keeping in mind that a bloom can be characterized by different indicators such as cell abundance, water discoloration, associated impacts, etc. (Smayda, 1997), here we will use *K. brevis* cell concentrations as our main criteria in the discussion that follows. Our threshold for bloom level will be  $\geq 100,000$  cells L<sup>-1</sup>, even though effects may be observed and management procedures start at lower cell concentrations due to brevetoxins' high toxicity (Table 3). Concentrations  $< 1,000$  cells  $L^{-1}$  will be referred to as background levels. We will conclude this section by outlining a few parallels and contrasts between *K. brevis* and *K. mikimotoi* blooms that have caused serious harm to fisheries and wildlife in other regions of the world. For the latter, however, it was not possible to standardize an operational definition of bloom that was most often considered as such in the literature when cells exceeded *ca.* 10<sup>6</sup> cells  $L<sup>-1</sup>$ , in which case it was frequently accompanied by water discoloration and fish kills.

#### **3.1. The** *Karenia* **Assemblage**

*Karenia* species are commonly found in coastal and offshore Florida waters, detected in about 31% of samples collected in the period between January 1995 and February 2019 (total n = 150,443 samples; FWC, (2019)). *K. brevis* is the dominant *Karenia* species in the region in terms of relative abundance and was present 69% of the time, followed in terms of frequency of occurrence by *K. mikimotoi*, *K. longicanalis*, *K. papilionacea*, *K. selliformis*, *K. asterichroma*, and *K. bicuneiformis* (Figure 5). This multi-species pattern is well illustrated by the severe, 17-month long bloom of 2004–2006 (Heil et al., 2006). While *K. brevis* was dominant and widespread over the entire bloom season, other species (namely, *K. mikimotoi*, *K. papilionacea*, *K. selliformis*) were also present, though temporally limited to particular times of the event or spatially restricted to specific areas within the region. Mixed *Karenia* assemblages have been detected in other regions (e.g., de Salas et al. (2004b)) and it would not be unexpected for a similar scenario to be found in areas where several *Karenia* species have been reported to occur (Figure 1). An extra challenge comes into play when other morphologically similar gymnodinioid dinoflagellates such as *Karlodinium* and *Takayama* co-occur with the *Karenia* assemblage (Steidinger et al., 2008).

Figure 5. Percent occurrence of *Karenia* species from coastal and offshore Florida between January 1995 and February 2019 (FWC, 2019). *Karenia* sp. 1, a as of yet unidentified species, often co-occurs with *K. brevis*, and is thus here combined with the latter for sake of simplicity. See Steidinger et al. (2008) for further details on *Karenia* sp. 1 morphotype, aka "Mexican hat".

As expected, phytoplankton species richness is relatively low during bloom events. The possibility of *K. brevis* exerting allelopathy to drive phytoplankton exclusion, as suggested by laboratory experiments (see section 2.2), is very challenging to demonstrate in nature (e.g., West et al. (1996)). Moreover, the ability to detect less abundant taxa in bloom samples is a limitation intrinsic to some enumeration methods, although coupling routine microscopic examination with molecular and/or imaging flow cytometric analysis has helped improve detection limits. For example, a continuous automated imaging-in-flow time series of a 2011 bloom on the Texas coast revealed that *Karenia* cells comprised at most 60–75% of the total microplankton (Campbell et al., 2013).

#### **3.2. Bloom Frequency, Duration, and Large-Scale Area Coverage**

*K. brevis* blooms in Florida waters have a well-documented seasonality, typically occurring annually in late summer/early fall (Figure 6) and subsiding in the following winter, when observed concentrations decrease to background levels.

About 34% of the time, blooms initiate during the months of September-November and most often occur on the order of months (i.e., about 70% of the time <5 months), with highly variable intensities within (i.e., spatial extent and cell concentrations). However, as bloom initiation, development and termination all depend on a series of complex and synergistic factors not fully resolved (see section 3.3), bloom duration varies greatly from event to event, may span over the expected bloom season, and even persist into the next calendar year (e.g., 2002–2004, 2004–2006, 2017–2019) (Figure 7).

The longest ever recorded bloom event occurred from 1994 to 1997 and lasted 30 months (FWC, 2019). In such cases when blooms exceed one year, the following years' bloom may augment bloom patches lingering from the prior season (and perhaps seasons) during the typical initiation period (Weisberg et al. 2019). As the environment changes over the course of a single event (see section 3.3), bloom intensity may wax and wane. Observations have shown advection of cells (both at surface and at depth) to different parts of the Gulf of Mexico and the Atlantic shores, where the bloom may proliferate and even intensify (see section 3.3). This may give the appearance of separate bloom phenomena when these are likely separate episodes of the same event. Not only regional expanse, but also timing of initiation, maintenance, and termination of a bloom event are all thought to be intertwined and tied to physical environmental forcings such as the degree of vertical stratification, the prevailing currents and advection mechanisms, as well as the dynamics of large-scale ocean features, i.e., the Gulf of Mexico Loop Current and shelf-break upwelling off of the west Florida shelf, the Texas-Louisiana coast, and the Yucatán Peninsula (Tester & Steidinger, 1997) (Figure 8a).

Looking at the recorded observations beginning in the 1950s, manifestations of *K. brevis* blooms most frequently affect the SW Florida shoreline from Pinellas to Lee counties, respectively, 28°08'N and 26°19'N (e.g., reviewed in Steidinger et al. (1998), in Walsh et al. (2006), and in Weisberg et al. (2019); FWC (2019)). While rarer, blooms can occur along the Panhandle region and the East Coast of Florida (Figure 9), and even less frequently along the coastlines of the remaining gulf U.S.A. states from Alabama to Texas (e.g., Henrichs et al. (2015); Soto et al. (2018)). Bloom events on Texas shores, however, seem to be part of a Western Gulf current transport mechanism associated with those blooms detected in northern Mexico waters (e.g., Henrichs et al. (2015)).

Figure 6. Seasonality of *K. brevis* blooms based on cell abundances in coastal and offshore Florida waters between August 1953 and February 2019 (total n = 799 months, *ca.* 38% of samples correspond to bloom condition) (FWC, 2019). See text and Table 3 for information on operational definition of bloom. Histogram bars show the number of months with at least one sample with *K. brevis*  $\geq 100,000$ cells  $\mathrm{L}^{\text{-}1}$ .

In Florida, *K. brevis* blooms have reached the Atlantic coast in the following years: 1957, 1972, 1980, 1983, 1997, 1999, 2002, 2007, 2008, 2011, and 2018 (FWC, 2019). Since the mid-1990s, with expanded and more systematic research and monitoring efforts set in place, the highest cell concentrations have been confirmed in the Southwest region, followed by the

Panhandle and the East Coast (maximum values recorded, respectively:  $2 \times 10^8$  cells L<sup>-1</sup>,  $2 \times$  $10^7$  cells L<sup>-1</sup>, and 1.2 x 10<sup>7</sup> cells L<sup>-1</sup>). There is an on-going debate centering on whether *K*. *brevis* blooms are becoming more frequent and intense or if this may be interpreted as an apparent increase instead, related to historic gaps in bloom records as the result of lower observational and monitoring efforts prior to 1995 (Steidinger et al., 2008).

Figure 7. Time series of *K. brevis* concentrations in coastal and offshore Florida waters between 2000 and February 2019 (FWC, 2019). Note that blooms can span over the typical season (mostly fall) and persist for more than 12 months.

#### **3.3. Bloom Initiation, Growth, Maintenance, and Termination**

It may come as no surprise that blooms of *K. brevis* may occur across many oceanographic zones and environments, given their somewhat unique life history strategies and physiology (section 2.2); nevertheless, the success of this species in estuarine to offshore systems is still somewhat at odds with observed growth rates, which are relatively slow and suggest that *K. brevis* would likely be out-competed by other phytoplankton. Physical forcing is considered to be one of the primary drivers of bloom initiation, development, severity and termination; however, biological and chemical processes play key roles as well (discussed below).

The initiation zone for *K. brevis* blooms that occur in Southwest Florida (including those advected to the Panhandle region and East Coast) was first hypothesized to be located between 18 and 74 km offshore by Steidinger (1975). Augmented sampling coverage and tracking of cell concentrations suggested that potential initiation zones were positioned offshore and west of the most frequent manifestation area along the southwest Florida coast, and blooms and cells in southwest Florida were the source of less frequent *K. brevis* events on the Atlantic coast (Tester & Steidinger, 1997; Walsh et al., 2006) (Figure 8b). More recently, the use of remote sensing imagery, *in situ* data streams (collected by sensors on moorings and autonomous vehicles such as gliders), and hindcasted modeling have given further credence to this theory and indicate the presence of a re-current initiation zone northwest from the coastal

Figure 8. (a) Gulf of Mexico and its generalized surface circulation with emphasis on the Loop Current (thicker arrows): (1) sometimes, it barely enters the gulf before heading to the Atlantic; (2) sometimes, it penetrates deeper into the gulf before swinging back towards the Florida Strait. **\*** asterisk indicates location of Dry Tortugas. (b) Detail of the southwest Florida coast depicting hypothesized bloom initiation areas according to (1) Tester & Steidinger (1997) and Walsh et al. (2006) and to (2) Weisberg et al. (2019).

Figure 9. Time series of *K. brevis* concentrations in coastal and offshore Florida waters between 2014 and February 2019 (FWC, 2019). Note (1) there was no bloom in 2014 and a less intense one in 2015, though it extended towards Northwest Florida; (2) that seasonality was as expected in 2016 and 2017 with high concentrations in the panhandle in the former; and that (3) a long-lasting event started in the fall of 2017 and persisted through early 2019, which expanded to both the panhandle and the Atlantic in the fall of 2018.

manifestation areas on Florida's southwest and northwest coasts (Weisberg et al., 2019) (Figure 8b). The impingement of the major current in the Gulf of Mexico, the Loop Current, on the West Florida Shelf (WFS), often observed adjacent to the Dry Tortugas, FL, can cause a regime shift across the WFS whereby colder, nutrient richer water is upwelled on the shelf (Liu et al., 2016) (Figure 8a). The timing, intensity, and duration of this interaction can alter the physical and thereby chemical environment on the shelf. Intense and persistent summer and fall upwelling events on the WFS are associated with increased nutrient loading, which appear to favor faster growing phytoplankton (i.e., diatoms) and subsequently act to suppress *K. brevis* blooms (e.g., Weisberg et al. (2014); Weisberg et al. (2016)). The same studies found that, in the majority of years, more moderate upwelling conditions prevail and thus favor bloom development in Southwest Florida. Prior to blooms and during bloom initiation, cells may reside offshore in low concentrations throughout the water column, thus out of reach from the detection capability of remote sensing satellite imagery (see Table 3) and rendering the use of autonomous detection vehicles such as gliders ever more valuable (Robbins et al., 2006; Hu et al., 2016).

A similar overall strategy for studying bloom initiation applies for blooms that occur along the Texas and northern Mexico coastlines. With the limited data available, it has been hypothesized that the initiation zone in this case is the region west of the Yucatan Peninsula (Henrichs et al., 2015). The WFS and Campeche Bank (west of Yucatán) are similar environments in that both occur in a semi-enclosed back-arc basin (Gulf of Mexico), are broad and relatively shallow shelfs, and both interact with the dominating oceanographic feature in the Gulf, the Loop Current (Figure 8a).

Most years, in the summer/fall, cells that reside at depth are thought to be transported coastward via the bottom Ekman layer (Liu & Weisberg, 2012) (Figure 10). Blooms typically manifest in coastal waters where advection, accumulation, and/or cell growth are further impacted by physicochemical conditions occurring there and in associated estuaries (e.g., Walsh et al. (2003); Stumpf et al. (2008); Weisberg et al. (2009)). The offshore and nearshore environment of the WFS where blooms initiate and occur is also prone to vertical stratification, which can develop and persist during typical bloom periods, though varying in intensity throughout the event. This becomes increasingly important with respect to *K. brevis* DVM to access nutrients, trophic impacts, as well as bloom advection and the development, duration, and extent of hypoxic and anoxic zones that can cause wildlife mortality and damage benthic and reef habitats (e.g., Colella et al. (2008); Dupont et al. (2010)).

Research has suggested certain characteristics that may lend this species to outcompeting other taxa across the same range of oceanographic zones, such as the aforementioned DVM behavior (Sinclair & Kamykowski, 2008; Hu et al., 2016; Garrett 2015); the broad distribution of seed populations and capacity to exploit nutrient sources at the surface, throughout the water column, and seafloor (Kamykowski et al., 1998ab; Walsh et al., 2006; Dixon et al., 2014; Heil et al., 2014b); and the ability to utilize a multitude of nutrients with respect to both form and source (Heil et al., 2014c) (Figure 3). There is continued debate around the purpose for ichthyotoxin production in *K. brevis*. The nutrients released from the decay of fish, primarily in the form of dissolved ammonia, can be quickly and readily used by *K. brevis* blooms, suggesting that fish kills could provide a continued source of nutrients as the bloom continues and/or intensifies (Killberg-Thoreson et al., 2014). In offshore oligotrophic waters, where dissolved inorganic nutrients are relatively limited and cells are typically less abundant, *K. brevis* nitrogen requirements can be met from exudates from the often co-occurring cyanobacteria *Trichodesmium* [Ehrenberg ex Gomont](http://www.algaebase.org/search/species/detail/?species_id=24714) (Mulholland et al., 2006), which similarly can change position in the water column throughout the day. Heil et al. (2014c) estimated that nutrient fixation and regeneration by *Trichodesimium* alone was capable of sustaining coastal and offshore *K. brevis* blooms based on estimated cellular nitrogen and phosphorus requirements. As mentioned earlier, blooms of *K. brevis* have allelopathic properties, and perhaps a combination of these properties, as well as species ability to thrive in multiple niches, is why persistent blooms occur and may become mono-specific as they intensify. Overall, *K. brevis* exhibits a "ecologically flexible" strategy which allows the species to exist across niches, and exploit a multitude of nutrient sources. However, the exclusion of certain conditions (as in the examples provided earlier) could temper and inhibit intense bloom events.

The DVM behavior in *K. brevis* has the potential to influence cell distribution offshore, along the coast, and in nearshore zones and contribute to localized bloom persistence and/or advection. For example, daytime cells entrained in surface water masses that are driven offshore during upwelling-favorable and/or offshore winds may be advected back to shore via sub-surface currents during night hours, providing a mechanism for entrainment in the nearshore environment (Ruiz-de la Torre, 2013) (Figure 10). Studies have shown that changes in migratory behavior related to stratification intensity not only modulates access to nutrient pools and therefore growth, but can also alter distribution and advection of the population (as described above); thus, degree of vertical stratification plays a critical role in determining the occurrence and rate of DVM (Garrett, 2015). Further studies have found that growth of *K. brevis* under moderate to high light intensities is comparable to or greater than growth under low light (Tilney et al., 2019), so that DVM might be one way to achieve optimal growth. Less is known about if and how growth and termination are modulated by life cycle dynamics vs. environmental factors, in addition to physical concentration or dissipation.

Figure 10. Offshore-inshore transport of *K. brevis* cells on the West Florida Shelf and mechanism for entrainment in the nearshore environment. Cells that reside at depth are thought to be transported coastward via the bottom Ekman layer. Once close to shore, cells accumulated closer to the surface (enhanced by upward migration during day time) may be driven offshore during periods of upwellingfavorable and/or offshore winds, only to be advected back to shore during night hours (downward vertical migration).

Although several blooms have lasted for more than one year, blooms may also dissipate within months. Background or even higher cell concentrations are not uncommon and appear occasionally in the absence of a larger-scale bloom. As alluded to, multiple interacting and complex factors contribute to bloom initiation and severity, although varied aspects of these dynamics as well as bloom termination (beyond physical dissipation) remain enigmatic. Nevertheless, as new tools and studies emerge, our understanding of the overall importance of drivers, and their importance in timing, underlying these key bloom dynamics will continue to evolve.

#### **3.4. Comparison with** *K. mikimotoi* **Blooms**

*K. mikimotoi* is a regular component of the phytoplankton assemblages of Florida waters, and it is often a co-dominant taxa during *K. brevis* blooms (see Figure 4) with whom it also shares some ecophysiological attributes (see section 2.2). By exploring some of the similarities and contrasts between these two phylogenetically related taxa, we expect to broaden our understanding of likely trends observed under controlled experimental conditions and in nature or, at the least, set the stage for mindsets that may spark future, novel research questions.

Re-current *K. mikimotoi* blooms have been reported in temperate waters, most notably in the Setouchi region but more recently in Hokkaido in Japan (e.g., Oda (1935); Honjo (2004) and references therein; Shimada et al. (2016)), as well as in northwest Europe from Galicia to the Baltic Sea (e.g., Braarud & Heimdal (1970); Pingree et al. (1975); Gentien (1998) and references therein; Raine et al. (2001); Davidson et al. (2009)). Blooms have also been recorded in Atlantic Canada (Blasco et al., 1996), Alaska (NCCOS, 2014), Argentina (Negri et. al, 1992), the Aegean Sea on the Turkish coast (Bizsel & Bizsel, 2002), the Arabian Sea on the Indian coast (Robin et al., 2013), as well as in Hong Kong, South Korea, and New Zealand (Lassus et al. 2016 and some references therein). It was not possible to verify reports of *K. mikimotoi* blooms, then identified as *Gyrodinium aureolum*, in Maquoit Bay (Maine) and in Long Island Sound (New York) (respectively, Heinig & Campbell (1992) and Chang & Carpenter (1985)).

According to Gentien (1998)'s review, shoreline manifestations of *K. mikimotoi* blooms have been observed in semi-confined water bodies, buoyant plumes and estuaries, and tidal fronts. An apparently consistent feature of the blooms in European and Japanese waters is that these are summer events that may extend into the fall. Except for cases in which a population develops in shallow and weakly stratified embayments, bloom initiation, growth, and maintenance have been associated with offshore frontal zones, especially in connection with the establishment of the seasonal pycnocline; this may be followed or not by advection to the shoreline since the bloom tends to disappear rapidly as the thermocline is somehow disrupted (Holligan, 1987). In an earlier description as a "magic carpet" (Bjoersen & Nielsen, 1991), it was proposed that this *K. mikimotoi* thin layer may be transported as a result of wind-regimes that promote relaxation of upwelling and subsequent incursion of offshore waters shorewards. Recent modeling of large-scale blooms in the northwest European continental shelf corroborates this mechanism may be in place; it also pointed out to the need to take into account multiple spatially distinct seed populations at the shelf break to properly describe patterns of bloom transport (Gillibrand et al., 2016). Multiple seed population areas offshore may also need to be investigated to account for variability in bloom manifestation on the SW Florida shores (Figure 8).

As shown for *K. brevis*, the eco-physiological versatility of *K. mikimotoi* observed in culture also translates into successful strategies in nature. For example, its ability to sustain low growth rates and take advantage of subdued light levels (see section 2.2) may explain bloom reports in southern Norway (59°–60° N) as late as mid-November at much reduced water temperatures and surface irradiation (Tangen, 1977). Likewise, DVM capability has shown to be an asset not only in shallow waters by providing potential access to nutrient uptake from the sediment (Koizumi et al., 1996), but also offshore where populations may either be "free" for vertical displacement in weakly stratified water columns or exhibit a nonmigrating maximum at the pycnocline/nutricline under stratified water column scenarios (Birrien et al., 1991).

Unravelling niche partitioning between *K. brevis* and *K. mikimotoi* may bring new light into understanding their bloom dynamics in Florida waters, where the latter often codominates (Figure 4), and elsewhere. If it were not for *K. brevis*, would *K. mikimotoi* blooms be the main culprit of fish kills and wildlife mortalities in the Gulf of Mexico, as it is in several other regions? Indeed, high level of hemolytic activity among *K. mikimotoi* strains isolated from the Gulf of Mexico has been demonstrated, with one Texas strain inducing significantly higher hemolysis compared to Florida *K. brevis* isolates (Neely & Campbell, 2006).

### **3.5.** *K. brevis* **Bloom Dynamics and the Life-Form Selection Approach**

The life-form selection approach provides a conceptual framework when seeking to identify similar and contrasting characteristics among phytoplankton taxa, dinoflagellate HAB species included (Smayda & Reynolds, 2001). In other words, how do *Karenia* species "fit in the dinoflagellate world"? This method stands on the following foundations: (1) literature support to the axiom that species assemblage-types characterize water masses and current systems; (2) the considerable influence of species size and shape on phytoplankton processes supports the axiom that form follows function, that is, habitat selection of a given morphotype is also favoring the selection of a given process, such as growth rate, suspension mode, etc. (Margalef, 1978; Sournia, 1982; Reynolds, 1988).

Dinoflagellate HAB species were thus classified by Smayda & Reynolds (2001) according to their size and shape, in association with some ecological attributes observed in nature, into nine categories ranging from coastal small, fast-growing, high surface-to-volume colonist (C) species, to offshore large, slow-growing but biomass conserving, nutrient stresstolerant (S) species. A third category, of special interest to this discussion, was that of attuning, light-harvesting, disturbance-tolerant ruderal (R) species, represented by HAB dinoflagellates adapted to: increased velocities of shear/stress forces in physically-disturbed water masses such as frontal zones (Type IV); areas of reduced but still elevated vertical mixing during relaxations in coastal upwelling (Type V); perform while being entrained in and dispersed by coastal currents (Type VI). Examples given for Types IV–VI were, respectively, *K. mikimotoi*, *Gymnodinium catenatum* H.W. Graham, and *K. brevis*. Of course, there is overlapping and intergrading traits among Type IV–VI species and, according to the authors, these may reveal to encompass a single category as our understanding of bloom dynamics progresses. Indeed, we contend that, at least for *K. brevis*, Types IV–VI may actually represent our current understanding of sequential stages (or strategies) in bloom dynamics for this species: relaxation in coastal upwelling for initiation (Type V), frontal zone during transport and delivery shoreward (Type IV), and current entrained during further coastal transport, including alongshore and via the Gulf Stream (Type VI).

This analysis questioned the long-standing paradigm that dinoflagellates are best adapted to less turbulent, stratified environments (Margalef, 1978) and proposed that HAB dinoflagellate R-Type species and their habitats are intermediate between the diatom dominated domains and the other dinoflagellate life-form Types favored by more pronounced stratification (e.g., *Dinophysis*, *Ornithocercus*, *Pyrocystis*). Is *K. brevis* somehow better adapted to tolerating shear/stress forces? According to Smayda (2002, citing paleo-circulation hypothesis from Emslie & Morgan, 1994), this could be a trait inherited from a time when upwelling may have been more common in the Gulf of Mexico. Could behavior such as DVM help minimize exposure to unfavorable conditions while also contributing to maintenance of cells in conditions associated with reduced loss and/or enhanced growth? The authors also advocate that Types IV–VI survival strategies rely heavily on light-harvesting mechanisms which is, actually, an important on-going line of investigation for *K. brevis* (Tilney et al., 2019). Furthermore, life-form selection acknowledges a stochastic aspect regarding growth opportunities for the best fit species "on site", that is, taxa with the most appropriate preadaptations and largest inoculum are likely to gain the greatest advantage. It is a matter of being the best candidate at the right place at the right time. This underscores the importance of high frequency, small-scale ocean observing technology as well as forecasting and hindcasting modeling as part of routine monitoring.

## **ACKNOWLEDGMENTS**

We first acknowledge the FWC-FWRI HAB Monitoring Database. Decades worth of data would not have been available without the direct and indirect involvement of individuals (volunteers) and partner agencies, too many to be properly named here, in tireless field work hours. We are equally indebted to many phytoplankton analysts, from FWRI and Mote Marine Laboratory, for their microscopy expertise. L. Markley was instrumental in performing database support. L. Flewelling (FWRI-FWC) and an anonymous reviewer shared valuable comments. We are grateful to Subba Rao Durvasula, the editor of this volume, for the invitation. We also acknowledge funding from a GOMA Gulf Star Award (#121634), and a grant through NOAA's Prevention, Control, and Mitigation of Harmful Algal Blooms (PCMHAB) program (grant #NA15NOS4780194).

Fish and Wildlife Research Institute Florida Fish and Wildlife Conservation Commission 100 Eighth Avenue SE St. Petersburg, FL 33701, USA

*Celia Villac* is a Research Scientist with the Harmful Algal Bloom Group, Fish and Wildlife Research Institute, Florida Fish and Wildlife Conservation Commission. She received her Ph.D. degree in Oceanography from Texas A&M University, USA. Her background is in the taxonomy and ecology of marine phytoplankton from a community structure perspective and emphasis on HABs. She is currently focusing on *Karenia* and *Pseudo-nitzschia* from Florida waters.

Email: [Celia.Villac@MyFWC.com.](mailto:Celia.Villac@MyFWC.com)

*Alicia Hoeglund* is a Research Assistant with the Harmful Algal Bloom Group, Fish and Wildlife Research Institute, Florida Fish and Wildlife Conservation Commission. She received her B.S. degree in Biology from Truman State University, USA. She has recently been focusing on the genetic variation of, and population dynamics among, different species within the *Kareniacea* family that are found in Florida waters and the *in situ* detection of *Karenia brevis* via genetics and microscopy.

Email: [Alicia.Hoeglund@MyFWC.com.](mailto:Alicia.Hoeglund@MyFWC.com)

*Charles Tilney* is an Associate Research Scientist with the Harmful Algal Bloom Group, Fish and Wildlife Research Institute, Florida Fish and Wildlife Conservation Commission. He received his Ph.D. degree in Marine Biosciences from the University of Delaware, USA. He is currently interested in dinoflagellate ecophysiology, especially dinoflagellate-microbial interactions, photo-physiology, and the molecular functioning of the chloroplast.

Email: [Charles.Tilney@MyFWC.com.](mailto:Charles.Tilney@MyFWC.com)

*Matt Garrett* is an Assistant Research Scientist with the Harmful Algal Bloom Group, Fish and Wildlife Research Institute, Florida Fish and Wildlife Conservation Commission. He received his M.S. degree in Biological Oceanography from the University of South Florida, USA. His research interests include the biological, chemical and physical oceanography of the West Florida Shelf, as it pertains to the initiation and persistence of HABs. He is also interested in the migratory behavior of *Karenia brevis* and how environmental conditions can modify this behavior and how that can relate to bloom formation.

Email: [Matt.Garrett@MyFWC.com.](mailto:Matt.Garrett@MyFWC.com)

*Cary Lopez* is an Assistant Research Scientist with the Harmful Algal Bloom Group, Fish and Wildlife Research Institute, Florida Fish and Wildlife Conservation Commission. She received her M.S. degree in Marine Sciences from the University of South Alabama, USA, where she first became interested in phytoplankton ecology and harmful algae. A current focus of her research is the role of dinoflagellate life cycles and life cycle transitions in bloom ecology.

Email: [Cary.Lopez@MyFWC.com.](mailto:Cary.Lopez@MyFWC.com)

*Kate Hubbard* is a Research Scientist with the Harmful Algal Bloom Group, Fish and Wildlife Research Institute, Florida Fish and Wildlife Conservation Commission. She received her Ph. D. degree in Biological Oceanography from the University of Washington, USA. Her background and interests focus on uniting interdisciplinary laboratory, field, and modeling studies to better understand and predict HAB dynamics across relevant taxonomic/spatiotemporal scales.

Email: [Katherine.Hubbard@MyFWC.com.](mailto:Katherine.Hubbard@MyFWC.com)

*Karen Steidinger* is a part-time Research Scientist with the Harmful Algal Bloom Group, Fish and Wildlife Research Institute, Florida Fish and Wildlife Conservation Commission. She received her Ph.D. degree in Biology from the University of South Florida, USA. Her interests continue to be the biology and ecology of marine dinoflagellates.

# **ABSTRACT**

In the 1990's the estuarine dinoflagellate *Pfiesteria piscicida* came under intense scientific scrutiny and garnered widespread media and public attention, as it was blamed for causing dramatic finfish kills and human health effects in coastal North Carolina and Chesapeake Bay. Universities, marine science institutions and state agencies in the region focused on environmental and human health, quickly turned their attention to research on, and monitoring of, this organism and its' perceived adverse health impacts. Federal and state funding quickly became available to support these efforts and resulted in rapid scientific advances, but also troubling controversies regarding interpretation of data. Researchers soon realized that morphologically similar dinoflagellates, now known as *Pfiesteria*-like dinoflagellates (PLDs), were initially counted as *Pfiesteria* cells, often cooccurred at fish kill events, and that this resulted in early *Pfiesteria* cell counts at fish kills likely being significantly inflated. Further, although *P. piscicida* might be observed in a water sample collected from a fish kill event, it was often found at low abundance or was absent. Other PLDs, most notably *Karlodinium veneficum*, were subsequently found at high abundance in samples from several mortality events in Maryland waters of Chesapeake Bay. Additionally, the complex multi-stage life cycle of *P. piscicida,* initially reported to involve several amoebae and chrysophyte-like cyst stages, came under intense

 $\overline{a}$ 

<sup>\*</sup> Corresponding Author's Email: kreece@vims.edu.

scrutiny. The life cycle was ultimately shown to be simpler; lacking amoebae and chysophyte-like cyst stages and typical of other dinoflagellate species. However, the longest-standing and most troubling controversy surrounded the possible production of a toxin by *P. piscicida* and *Pseudopfiesteria shumwayae*, and the role that toxin played in adverse human health effects and as a cause of finfish mortalities and ulcerous lesions often observed on fish during kill events. The causes of the fish kill events in North Carolina estuaries during the late 1990's have never been identified, however, the deeply penetrating ulcers in menhaden, *Brevoortia tyrannus*, at the time attributed to *Pfiesteria*  toxin, are now known to be caused by a highly pathogenic water mold called *Aphanomyces invadans*. *Pfiesteria* has been clearly shown capable of killing fish in a captive environment from which the fish cannot escape, however, the mechanism of pathogenicity has been shown not to be due to toxin but to the micropredatory feeding activity (myzocytosis), which at abnormally high cell concentrations results in disruption and loss of the fish epidermis and ultimately, loss of osmoregulatory ability and death. To date, the full structure of a *Pfiesteria* toxin remains unresolved and no adverse human health impacts from contact with coastal waters where *Pfiesteria* occurs have been confirmed, despite an extensive multistate study conducted by the Centers for Disease Control and Prevention. It also has been demonstrated that *Pfiesteria* has a simple dinoflagellate life cycle lacking amoeboid or chrysophyte stages and does not cause fish lesions or kill fish by means of a toxin. The history of the events, controversies, research and current status surrounding the *Pfiesteria* story will be reviewed in this chapter.

**Keywords:** *Pfiesteria piscicida*, *Pseudopfiesteria shumwayae*, *Pfiesteria*-like dinoflagellates, fish kills, fish lesions, life cycle, amoebae, dinospore, *Karlodinium veneficum*, *Aphanomyces invadans*

# **INTRODUCTION**

*Pfiesteria piscicida,* a dinoflagellate whose name means "fish killer", was first identified in 1991 from fish tanks maintained by Dr. Edward Noga at North Carolina State University (Litaker et al. 2002). These tanks had been inoculated with water from the Pamlico River, North Carolina, USA. Subsequently, fish began to die as a bloom of a small heterotrophic dinoflagellate developed. By transferring these dinoflagellates to other tanks containing fish and observing similar mortality rates, a cause-effect relationship was made, with the dinoflagellates believed to produce potent ichthyotoxins that killed the fish. In 1991, shortly after this discovery, high densities of morphologically similar dinoflagellates, presumed to be *Pfiesteria piscicida*, were identified in water samples collected after massive fish kills in North Carolina estuaries, including samples from the Pamlico River (Burkholder et al. 1992). The assumption was made that the fish kills observed in the field were caused by the same organism that was killing fish in Dr. Noga's tanks, since the water used in the tanks was from the same general area where fish kills were occurring. However, no detailed morphological or molecular information was provided to confirm that the dinoflagellate species in the tanks was identical to those associated with the estuarine fish kill events. Many of the dead fish, primarily menhaden, at these sites had deep ulcerative lesions, which at the time were assumed to be caused by exposure to a *Pfiesteria* toxin (Burkholder and Glasgow 1995, 1997a; Burkholder et al. 1992).

Despite being first observed in 1991, *Pfiesteria piscicida* was not formally described as a new genus and species until 1996 (Steidinger et al. 1996). By that time there was growing controversy within the scientific community regarding the role, if any, of *P. piscicida* in the fish kills and in causing the deep ulcerative lesions that were frequently observed on menhaden, the fish species most often involved in those kill events. Over the next decade additional dinoflagellate species would be found in association with these fish kills in the mid-Atlantic, including several species that are morphologically similar to *P. piscicida* known as *Pfiesteria*-like dinoflagellates (PLDs). These include *Pseudopfiesteria shumwayae, Luciella* species, *Cryptoperidiniopsis* species and *Karlodinium veneficum*. The next decade also would find the intensification and expansion of scientific debates surrounding the roles of *P. piscicida* and *P. shumwayae* in fish kills, their life cycles and toxigenicity of *P. piscicida*  and the PLDs and, perhaps most importantly, the hypothesized human health effects of these organisms. This chapter will attempt to present the data from the years of scientific research,

as well as different views on the several controversial topics surrounding *P. piscicida* and the PLDs.

## **TAXONOMY**

*Pfiesteria piscicida* and PLDs are small (~10-15 μm), heterotrophic dinoflagellates and, although often referred to as microalgae, they are not true algae. Although many dinoflagellates are photosynthetic, *Pfiesteria* and most of the PLDs lack chloroplasts (note: *K. veneficum* does contain chloroplasts and is mixotrophic) and obtain their energy through consumption of cells and tissues of other organisms (see below for more discussion on this topic). As noted above, by the time the genus *Pfiesteria* was formally described (Steidinger et al. 1996; Figure 1), a controversy had arisen regarding how to distinguish *P. piscicida* from morphologically similar co-occurring heterotrophic dinoflagellates (Steidinger et al. 2001). The controversy arose after other research groups funded to study *Pfiesteria* began isolating small heterotrophic dinoflagellates from "*Pfiesteria* fish kill" sites. They found convincing morphological and molecular evidence indicating that not all of the microorganisms at these sites were *P. piscicida* or *Pfiesteria shumwayae*, a second closely related species that was described in 2001 (Glasgow et al. 2001b; Figure 2) and now called *Pseudopfiesteria shumwayae* (Litaker et al. 2005) (see below). Prior to these findings, the prevailing practice was to count all morphologically similar heterotrophic dinoflagellates from the "fish kill" sites as *Pfiesteria* (Burkholder, Mallin and Glasgow 1992; Burkholder 1999; Burkholder and Marshall 2012). Groups finding these morphologically distinct isolates asserted that they should be described as new species where appropriate and their abundance relative to the *Pfiesteria* species determined. In response, the groups which had been counting all small heterotrophic cells as *Pfiesteria* argued that this practice should be continued.

While the controversy continued, several groups worked to characterize their environmental isolates in greater detail morphologically and molecularly. The morphological characters investigated included both the size and shape of the cell and the number and shape of the thecal plates covering the cells. These thecal cellulose plates are a key diagnostic feature used in identifying many dinoflagellate species and are organized into series according to a classification system first developed by Kofoid (1911; Figure 3). In this system, a single difference in the number of plates in one of the major plate series is typically sufficient to place species in separate genera (Table 1). Using these criteria, it was possible to identify three new genera co-occurring with *Pfiesteria* – *Pseudopfiesteria* (Litaker et al. 2005), *Cryptoperidiniopsis* (Steidinger et al. 2006) and *Luciella* (Mason et al. 2007; Table 1), each containing one or more species. Additionally, rDNA region sequence data were obtained from the same isolates and analyzed phylogenetically. The results of these molecular studies were congruent with the morphologically described species and genera (Litaker et al. 2005; Mason et al. 2007; Steidinger et al. 2006). The resulting rDNA sequence data were also used to develop molecular assays capable of quantifying *Pfiesteria* abundance (i.e., quantitative polymerase chain reaction-qPCR assays) in the field. Results obtained using those assays indicated *Pfiesteria* densities in nature were low and comprised only a small portion of the heterotrophic dinoflagellates observed in the field. This argued against the generic classification of small heterotrophic dinoflagellates as *Pfiesteria*.

*Pfiesteria* 3727

Currently, the only remaining taxonomic controversy with regard to the genus and species described above is that regarding *Pseudopfiesteria shumwayae*. Originally this species was published as *Pfiesteria shumwayae* (Glasgow et al. 2001b). This new species was included in the genus *Pfiesteria* despite having a Kofoidian plate tabulation with 6 precingular (′′) plates compared to *P*. *piscicida* with 5 precingular (′′) plates. All the other closely related dinoflagellate genera described before and after *P. shumwayae*, including *Aduncodinium*, (Kang et al. 2015), *Speroidium* (Moestrup and Calado 2018), *Stoeckeria* (Jeong et al. 2005) and *Tyrannodinium* (Calado et al. 2009) were distinguished by at least one or more differences in the number of plates in the major Kofoidian plate series relative to the other described genera (Table 1). There are no instances where a genus in either the family Pfiesteriaceae or the closely related family, Thoracosphaeraceae, has been described as containing a variable number of plates in one of the major Kofoidian plate series. Accordingly, Litaker et al. (2005) formally transferred *P*. *shumwayae* to the genus *Pseudopfiesteria shumwayae* maintaining the convention that plate difference is sufficient to define a new genus.

Figure 3. Line drawings from Litaker et al. (2005; fig. 3) showing the plate tabulations of (A) *Pseudopfiesteria shumwayae* and (B) *Pfiesteria piscicida* and providing illustration of the plate series referred to in Table 1. Reprinted with permission from the *Journal of Phycology,* from Litaker, R. Wayne, Karen A. Steidinger, Patrice L. Mason, Jan H. Landsberg, Jeffrey D. Shields, Kimberly S. Reece, Leonard W. Haas, Wolfgang K. Vogelbein, Mark W. Vandersea, Steven R. Kibler, and Patricia A. Tester. 2005. "The Reclassification of *Pfiesteria shumwayae* (Dinophyceae): Pseudopfiesteria, Gen. Nov.1." *Journal of Phycology* 41(3):643–51. https://doi.org/10.1111/j.1529-8817.2005.00075.x.; Figure 2.

Despite established convention, Marshall, Seaborn and Wolny (2006) proposed that *Pseudopfiesteria shumwayae* be reassigned back to *Pfiesteria*. The primary argument supporting this proposal was an rDNA phylogeny employing the 159 bp 5.8S gene that showed *Pfiesteria* and *Pseudopfiesteria* having the same DNA sequence in this region. This gene, however, is not typically used for phylogenetic analyses because it is often conserved among species. Other analyses conducted since that time have used more phylogenetically informative rDNA region sequences and have shown that *Pfiesteria* and *Pseudopfiesteria* are

not any more closely related to each other than *Pseudopfiesteria* is to other distinct genera such as *Cryptoperidiniopsis* or *Luciella* (Grzebyk et al. 2017; Kang et al. 2015). These phylogentic analyses along with the differences in a major plate tabulation series support the original establishment of *Pseudopfiesteria* as a distinct genus.

**Table 1. Comparison of the plate formulae among the genera in the dinoflagellate genera Pfiesteriaceae and representative members of the closely related family Thoracosphaeraceae. Delineation of species is based on the following enhanced Kofoidian nomenclature: apical series (′), anterior intercalaries (a), precingular series (′′), cingulars (c), peduncle cover (PC), sulcals (s), postcingular series (′′′), posterior intercalaries (p), and antapical series (′′′′). Additional plates supplement the Kofoidian series, i.e., Po (pore plate), cp (closing plate), X (canal plate), and PC (peduncle cover plate)**

<sup>1</sup> The questionable presence of a PC plate in *Speroidium* may, upon further evaluation, be confirmed.

# *PFIESTERIA* **LIFE CYCLE**

The original description of the *Pfiesteria piscicida* life cycle was very different from that published previously for any other dinoflagellate (Burkholder and Glasgow 1995; 1997a; 1997b). It contained over 35 separate stages including numerous amoeboid forms never before observed in dinoflagellate life cycles. It was reported that these amoebae, upon sensing fish or fish excreta, could readily transform into free-swimming dinospores that could track and kill fish. Later publications showed an even more complex version of the life cycle that included dinospore-, amoeboid-, and chrysophyte-like cyst forms with varying toxicity that were theorized to provide *Pfiesteria piscicida* access to diverse food resources (Burkholder and Glasgow 2002; Burkholder, Glasgow, and Deamer-Melia 2001; Burkholder et al. 2001a; Burkholder, Glasgow and Steidinger 1997; Parrow and Burkholder 2003; Parrow et al. 2002). Given the uniqueness of this life cycle, and the proposed role of this organism in causing massive fish kills (Burkholder et al. 1992), these findings generated considerable interest. Close examination of the original data, however, raised concerns. The photomicrographs of the amoebae showed morphologies and surface structures usually considered diagnostic of Gymnamoebia of the class Lobosea and not dinoflagellates (Page and Siemensma 1991). Both photosynthetic and non-photosynthetic life cycle stages were reported without any

explanation as to how photosynthesis could be lost and gained in the same life cycle (Burkholder and Glasgow 1997b). Later, the presence of chloroplasts was attributed to a process called kleptochloroplasty. Some heterotrophic dinoflagellates such as *P. piscicida* and all the PLDs feed on other plankton using a peduncle (Figure 4), a tube-like structure that attaches to a prey cell and withdraws contents for food through a process called myzocytosis (Steidinger et al. 2001; Figure 5). When feeding myzocytotically on photosynthetic microalgae, *P. piscicida* can capture chloroplasts from microalgal prey and then sequester them in food vacuoles (Burkholder and Glasgow 1995; 1997a; Burkholder and Marshall 2012; Steidinger et al. 1996). There was some evidence that these chloroplasts had limited function for a few days (Lewitus, Glasgow and Burkholder 1999). When exposed to prey cells, 25-54% of the *P. piscicida* cells contained intact chloroplasts on days 1-2. Retention dropped to  $< 15\%$  after 3-4 days and  $\sim 1\text{-}2\%$  thereafter. At the peak of chloroplast retention on day 2, carbon (C) fixation normalized to the total population was at most  $8.16 \pm 0.48$  pg  $C$ •cell<sup>-1</sup> day<sup>-1</sup> (Lewitus, Glasgow and Burkholder 1999). Given the reported estimate of 180 pg total C•Pfiesteria cell<sup>-1</sup>, kleptochloroplasty would have supplied no more than 9% of the total C demand needed for cell division over days 1-2 (i.e. 4.5% per day for the first two days). That contribution declined to 2.5% on days 3-4 and was negligible thereafter. These data indicate that the growth demand for C contributed by kleptochloroplasty was minimal compare to the C acquired through direct consumption of prey cells.

Figure 4. Scanning electron micrograph of a single *Pseudopfiesteria shumwayae* dinospore (Z) attached to the skin of a larval finfish via the peduncle (P) and actively feeding. Note the extensive damage to epidermal cells (\*). Scale bar: 2.0 µm.

Further, Burkholder and Glasgow (1995; 1997a; 1997b) did not use single cell isolates to determine the life cycle and were unwilling to share cultures with other researchers so that their observations could be verified. Instead, their proposed life cycle was inferred by observing aliquots of water removed from laboratory tanks where abnormally dense cultures of *Pfiesteria* had been killing fish for months. Another striking feature of the original papers are the narratives describing how *Pfiesteria* could transform into the various forms (e.g., ameboid, dinospore or chrysophyte cyst) with no accompanying methods of how the observations were made (Burkholder and Glasgow, 1995, Burkholder et al. 1997a, Burkholder and Glasgow 1997b). This made it impossible for other investigators to set up controlled experiments that would allow confirmation of how the descriptive determinations of stage transformation or highly unusual behaviors being presented were determined.

Figure 5. Scanning and transmission electron micrographs of the direct physical attachment of P*seudopfiesteria shumwayae* to the epidermis of a larval finfish. A. Dinoflagellate/fish skin interface and attachment site. Dinoflagellate (D) attaches to the fish epidermis (EC) by peduncle (P), seen here withdrawing the contents of several dead cells. Extensive cell damage (arrows) due to active feeding. B. An as yet unattached *P. shumwayae* peduncle exhibiting numerous electron-dense granules and rodlets (G), not evident once dinoflagellate is attached and feeding (See panel A). C. *Pseudopfiesteria shumwayae* dinospore (Z) attached to the fish skin via a peduncle (P) and actively feeding. Note damage to epidermal cells. Scale bars: A, C,  $10 \mu m$ ; B,  $5 \mu m$ . Figure reprinted with permission from Nature from: Vogelbein, Wolfgang K., Vincent J. Lovko, Jeffrey D. Shields, Kimberly S. Reece, Patrice L. Mason, Leonard W. Haas, and Calvin C. Walker. 2002. "*Pseudofiesteria shumwayae* Kills Fish by Myzocytosis Not Exotoxin Secretion." *Nature* 418:967-970. https://doi.org/10.1038/nature01008.

Given these concerns and the lack of sufficient information to repeat the previous studies, Litaker et al. (2002) began systematically investigating the *P. piscicida* life cycle by first establishing single cell isolates. Initially, cells matching the morphology of *P. piscicida* were isolated from the estuarine system from which they had first been reported. Once cultures containing *P. piscicida* were identified, single cell isolates were used to establish secondary cultures (Litaker et al. 2002). This process was repeated multiple times with the initial subcultures often containing both *Pfiesteria* dinospores and amoebae. By the third or fourth isolation, however, subclones yielded only typical amoebae or dinospore (*P. piscicida*) life

*Pfiesteria* 3731

cycle stages. After cell cultures were established, genomic DNA was extracted and the SSU, ITS and 5.8S ribosomal RNA (rDNA) genes were PCR amplified using dinoflagellatespecific primers, cloned and sequenced to determine their composition (Bowers et al. 2000; Litaker et al. 1999; Saito et al. 2002). These latter clonal cultures were maintained and observed for several years. Cultures containing typical dinoflagellate life cycle stages never produced amoebae and the amoebae cultures never produced dinospore life cycle stages. To verify the identity of the amoebae and dinoflagellate cultures, genomic DNA was sequenced as described above and compared with sequences in GenBank. The results confirmed the amoebae cultures were indeed true free-living amoebae and the sequences of the dinospore cultures completely matched *P. piscicida*.

Figure 6. Life cycle of *Pfiesteria piscicida* typical for a heterotrophic dinoflagellate. During the asexual phase of the life cycle, mitosis occurs in resting cysts and not by binary fission of motile cells. Cells shed their flagellae, form thin walled cysts, their sulcus becomes indistinct, and over a period of minutes to hours they undergo mitosis. Once complete, a cyst germinates releasing a protoplast that almost instantly separates and transforms to produce two free-swimming dinospores (Litaker et al. 2002). The sexual phase consists of a fusion of gametes, formation of hypnozygote cysts, meiosis, and release of 4 daughter cells. The hypnozygotes remain viable for a period of months and perhaps longer. Redrawn from information provided in Litaker et al. (2002).

Another group of researchers obtained similar results with cultures established from water and sediment samples collected in Chesapeake Bay and from Noga's tanks at North Carolina State University where fish mortality had been attributed to *Pfiesteria* (Peglar et al. 2004). They followed eleven clonal PLD cultures from Chesapeake Bay over a three-year period and also observed typical dinoflagellate life cycles with no evidence of amoeboid forms. From those same Chesapeake Bay samples and from the Noga tank samples they also isolated several amoebae that had morphological characteristics consistent with various forms that had been described as *Pfiesteria* amoebae. They stated "Most lobosean amoebae have the ability to produce a rayed floating form and light microscopic observations cannot differentiate these amoebae from the "filose star amoeba" described in the life cycles of *Pfiesteria*-like dinoflagellates". These data were again consistent with the original amoeboid stages in the life cycle being simple contaminants introduced into the original fish tank system. Such amoebae are commonly found on fish epithelium (English et al. 2019).

To further test the hypothesis that amoebae were not part of the life cycle, two fluorescently labeled i*n situ* hybridization probes were developed. One targeted amoebae species and the other was specific for *P. piscicida* (Litaker et al. 2002). The process of selecting the fluorophore for the probes proved challenging as amoebae naturally fluoresce at commonly used fluorescent wavelengths. To avoid this problem, Cy5 fluorophores with farred excitation wavelengths were coupled to the hybridization probes. *In situ* hybridization controls included universal eukaryotic and prokaryotic rDNA probes. The former control confirmed that all cells, including amoebae, contained intact RNA and the latter control helped identify non-specific probe hybridization. Samples from tanks where *Pfiesteria* were feeding on fish were preserved using standard methods and probed (Litaker et al. 2002). Only life cycle stages typical of dinoflagellates were positive with the *P. piscicida* probe. The amoebae probe only hybridized to amoebae and not to typical dinoflagellate life cycle stages.

Finally, the constant "stage transformations" where dinospores rapidly convert to amoebae, and back again is not possible. All alveolates, which include dinoflagellates, are characterized by the presence of cortical alveoli (sacs). flattened vesicles underlying the plasma membrane and supported by a single-layered sheet of microtubules forming a corset surrounding the entire algal cell. In dinoflagellates the alveoli can also form the characteristic "thecal plates". In contrast, no amoebae, whether they belong to the Amoebozoa, Rhizaria, Excavata, or Opisthokonta, have a cytoskeletal cell cortex under their plasma membrane. The amoebae described in the original *Pfiesteria* life cycle met the morphological criteria for true free-living amoebae in every respect. That the complex dinoflagellate cell cortex/alveolar system could somehow dissolve immediately upon transformation into an amoeba, and then instantly reform upon transformation from amoeba to dinospore is untenable based on everything known about the cellular structure of these organisms.

Litaker et al. (2002) used detailed light microcopy, including time-lapse photographic studies, in conjunction with *in situ* hybridization probes to document the life cycle of *P. piscicida*. This work was done using the single cell isolates established as described above. The results showed a typical marine dinoflagellate life cycle with relatively few asexual and sexual stages (Figure 6). A similar life cycle lacking amoeboid stages was reported for *P. piscidida, Pseudopfiesteria shumwayae* and the Cryptoperidiniopsis species from the Burkholder laboratory (Parrow and Burkholder 2003; Parrow and Burkholder 2004). It also should be noted that another set of *in situ* hybridization probes was developed prior to the Litaker et al. (2002) study and used to screen field samples, but results obtained are

questionable (Burkholder, Glasgow, and Deamer-Melia 2001; Rublee et al. 1999; Rublee et al. 2005). The reason is that those probes were labeled with fluorophores that fluoresced at the wavelengths at which amoebae naturally autofluoresce. Consequently, the observed signals likely represented false positives. Furthermore, those studies lacked the necessary "no probe" controls that would have demonstrated the amoebae's native fluorescence characteristics that would allow false positives to be identified. PCR positive "*Pfiesteria*" amoebae were similarly reported (Burkholder et al. 2001a), but these data are also suspect for the following reasons: 1) Negative controls to detect cross contamination with *Pfiesteria* DNA were not performed, (2) No amoebae-specific primer sets were used to confirm that positives did not contain true amoebae DNA and that amplification in those samples was not due to contamination with co-occurring *Pfiesteria* cells or DNA and (3) Most of the identified "*Pfiesteria*" amoebae that were screened showed no amplification with the *Pfiesteria* speciesspecific primers.

The finding that *Pfiesteria* lacked "amoeboid" life cycle stages is significant. These amoebae were a key component of the "Ambush Predator Hypothesis" put forward to account for how *Pfiesteria* kills fish in nature (Burkholder 1999; Burkholder and Glasgow 1997b; Burkholder, Glasgow and Steidinger 1995). At temperatures between 12 and 15°C these amoebae were claimed to be the only stage capable of killing fish (Burkholder 1999). These amoebae were also described as abundant in sediments and capable of exploiting a variety of food sources thereby significantly increasing *Pfiesteria*'s effective population size. Upon sensing fish excreta these amoebae were reported to transform into free swimming dinospores, some of which released toxins that killed fish. When food became more limiting, the dinospores were said to be capable of transforming back to amoebae. The absence of any amoebae in the life cycle obviously calls into question much of the Ambush Predator Hypothesis, particularly at 12 to 15°C where the amoebae were the only life cycle stage reported as capable of killing fish.

## **GEOGRAPHIC DISTRIBUTION OF THE PLDS**

For many years the reports of *P. piscicida* and other PLDs were restricted to the US mid-Atlantic coast from Delaware Bay to North Carolina where the initial reports of associations with fish kills originated (Burkholder and Glasgow 2001; Burkholder, Glasgow and Steidinger 1995; Burkholder et al. 1992; Coyne et al. 2001; Lin, Zhang and Dubois 2006; Zhang and Lin 2005 Tables  $2 \& 3$ ). Development of PCR assays to detect these organisms provided the ability to screen for the DNA of cells in water samples from all over the world. *Pseudopfiesteria shumwayae* DNA was detected in Europe, Asia, South America, Australia and New Zealand (Jakobsen et al. 2002; Rublee et al. 2004; Rublee et al. 2005; Zhang and Lin 2005). Likewise, *Pfiesteria piscicida* was reported in Norway, China, Hawaii, New Zealand, in ballast water from Indonesia, along the Chilean coast and in a saline lake in Antarctica using molecular techniques (Jakobsen et al. 2002; Lin, Zhang and Dubois 2006; Park et al. 2007; Rublee et al. 2004; Rublee et al. 2005). *Luciella masanensis*, one of the PLDs, was primarily reported in the mid-Atlantic, but was also found in Korea (Mason et al. 2007). In addition to PCR detection, cells of *P. shumwayae* were observed and analyzed by SEM in New Zealand (Rhodes et al. 2002), and in Norway cultures of *P. shumwayae* were established (Jakobsen et al. 2002). *Luciella masanensis* from Korea was cultured to allow a complete characterization of this species in two geographic locations (Mason et al. 2007). *Cryptoperidiniopsis brodyi* was found recently outside of the US in Portugal (Moestrup et al. 2014).

In several locations where *P. piscicida* or *P. shumwayae* first had been detected using PCR, including South America, most locations in Asia and Europe, and in Antarctica, there were no live cells observed nor cultures established for further morphological or genetic characterization. Park et al. (2007) attempted to observe *P. piscicida* cysts and live cells microscopically in water samples from the saline Antarctic lake, Ace Lake, and added several potential prey species to PCR positive samples in an attempt to confirm the presence of viable cells or prompt excystment but were unsuccessful. Therefore, it is not clear whether *P. piscicida* was viable under the current conditions in Ace Lake or the DNA that was detected by the PCR assay was from an exogenous source.

Most studies using quantitative methods determined that, although *Pfiesteria* and PLDs could be detected in many locations, environmental cell concentrations were very low, generally < 10 cells  $L^{-1}$  and seldom exceeding 100 cells  $L^{-1}$  (Coyne et al. 2001; Lewitus et al. 2002; Lin, Zhang and Dubois 2006). Although there were some fish kills where elevated levels of *Pfiesteria* were reported (Burkholder, Glasgow and Deamer-Melia 2001), there were kill events in the mid-Atlantic region associated with other HAB organisms (see Fish Kill section below and Tables  $2 \& 3$ ). Furthermore, no fish kills had been reported in association with the presence of *Pfiesteria* or PLDs other than in the mid-Atlantic US estuaries until 2012 when *P. piscicida* was reported to be present during large fish kills in a saline lake in Greece (Oikonomou et al. 2012). Although the authors suggested that *P. piscicida* likely played a role in the two fish kills, there were many other toxic organisms present in water samples that were collected including several cyanobacterial species such as *Planktothrix* and *Anabaena* species, the haptophyte, *Prymnesium parvum*, and fish pathogens, including *Dermocystidium* species. They were unable to provide definitive data on cell concentrations from their molecular analyses and their microscopic cell counts indicated that PLDs were only 0.4% of the plankton biomass by visual counts in the water samples (Oikonomou et al. 2012). Further, a BLAST search of the reported SSU rDNA sequence from the species revealed it to be a PLD more closely related to the genera *Luciella* and *Cryptoperidiniopsis*.

## **ECOLOGY AND NUTRITION**

*Pfiesteria piscicida* and the PLDs have largely been reported from shallow estuaries, although as mentioned above, there have been rare instances where PLD DNA has been detected in saline lakes in Greece and Antarctica (Oikonomou et al. 2012; Park et al. 2007). *Pfiesteria* and PLDs are typically found in nutrient-rich estuarine waters with salinities ranging between 5-20 ppt and at temperatures ranging between 15-30°C, although from laboratory experiments it is known that they can tolerate an even wider range of temperatures (i.e., 6–31°C) (Burkholder, Glasgow and Steidinger 1995; Lin, Zhang and Dubois 2006; Rublee et al. 2004). As this group of dinoflagellates is heterotrophic, it is not surprising that a light intensity optimum for growth has not been reported for these organisms (Burkholder, Glasgow and Steidinger 1995; Eriksen, Hayes and Lewitus 2002).

# concentrations were determined **concentrations were determined**

The available data indicate that *Pfiesteria*, as well as PLDs, feed on prey items ranging from bacteria to multi-cellular eukaryotic cells (Burkholder and Glasgow 1995; Burkholder, Glasgow, and Deamer-Melia 2001; Jeong et al. 2006; Parrow et al. 2005). They grow well on certain microalgae, particularly cryptophyte species, their preferred prey (Burkholder and Glasgow 1995, 1997a; Jeong et al. 2006, 2007, 2008; Kim et al. 2019; Lim et al. 2014). In the field, these dinoflagellates have a much higher probability of encountering microalgal prey than invertebrates or fish and, therefore, microalgae probably constitute their primary food source. This dependency on microalagae is indirectly supported by laboratory studies where the growth of *P. piscicida* was stimulated by nutrient addition, including the addition of diluted swine waste (Burkholder and Glasgow 2001; Burkholder et al. 1992). Those nutrient additions stimulated the growth of co-occurring microalgal prey, secondarily fostering *Pfiesteria* growth (Burkholder et al. 2001a; Burkholder, Glasgow, and Lewitus 1998). When presented with cryptophyte prey (*Rhodomonas sp.*) in the laboratory, *P. piscicida* increases its speed, radius and angular velocity but slightly reduces the pitch of its right-handed helix trajectory, suggesting the preferred predation tactics of an "active hunter" (Sheng et al. 2007) and not an ambush predator. The slower *K. veneficum,* in contrast, exhibits "ambush predator behavior", by reducing its velocity, radius and pitch to near zero. It increases its angular velocity, a change that reduces its hydrodynamic signature, while still scanning its environment as "a spinning antenna" (Sheng et al. 2007). Furthermore, field measurements showed a direct correlation between phytoplankton biomass (as measured by chlorophyll *a* concentration), primary production and the density of *Pfiesteria*-like dinospores in the Neuse River estuary, NC, one of the areas identified as the primary *Pfiesteria* fish kill sites (Burkholder, Glasgow, and Lewitus 1998; Pinckney et al. 2000).

The preference of *Pfiesteria* and *Pseudopfiesteria* for protists other than microalgae and their ability to grow on them is little studied. Existing information suggests that their ability to do this may be poor given *Pfiesteria piscicida*'s inability to grow on rotifers (Burkholder and Glasgow 1995) or *Mesodinium rubrum* (Lee et al. 2014). Parrow et al. (2005) also examined the nutritional value of a salmon cell line to axenic (bacteria free) *P. piscicida* and *P. shumwayae* cultures. That study found that although *P. shumwayae* could grow well on fish tissue culture cells, *P. piscicida* (fish killer) could not. This suggested *P. piscicida* required certain phytonutrients or critical microbial associates and could not grow on fish tissue alone.

*Pfiesteria* itself is readily consumed by numerous predators. These include the heterotrophic dinoflagellates *Oxyrrhis marina* and *Gyrodinium* spp. (Jeong et al. 2017), the ciliate *Strombidinopsis* sp. (Jeong et al. 2017), large tintinnids and oligotrichous ciliates (Stoecker, Shaw and Gustafson 2000), and rotifers and copepods such as *Acartia tonsa* (Mallin et al. 1995). Field measurements have suggested that grazing pressure from these predators is generally high enough to keep PLD densities at relatively low levels (Stoecker and Gustafson 2002; Stoecker, Shaw and Gustafson 2000).

# **IMPACTS**

During the 1990**'**s, the massive fish kills in North Carolina estuaries and Chesapeake Bay, usually of Atlantic menhaden with ulcerative lesions (Figure 7), were attributed to toxic *Pfiesteria* 3739

*Pfiesteria* (Burkholder 1999; Burkholder and Glasgow 1997a, 1997b; Burkholder, Glasgow and Deamer-Melia 2001; Magnien 2001). The identification of small heterotrophic dinoflagellates, i.e., PLDs, in water samples collected from fish kill events in which many of the fish exhibited deep ulcerative lesions (Figure 8) led to the inference that *Pfiesteria* and its toxin caused both the mortality and the lesions (Burkholder, Glasgow and Deamer-Melia 2001; Glasgow et al. 2001b; Burkholder, Glasgow and Steidinger 1995). However, other researchers disputed the assertion that the fish kills or the lesions were caused by *Pfiesteria* or the action of a *Pfiesteria* toxin. The following sections specially address these various controversies in greater detail.

Figure 7. Acute fish kill event (menhaden, *Brevoortia tyrannus*) in Narragansett Bay (RI) attributed to an anoxia/upwelling event. Photo courtesy of Thomas Ardito, Narragansett Bay Estuary Program, [www.nbep.org.](http://www.nbep.org/)

Figure 8. a) Gross appearance of ulcerative mycosis in juvenile Atlantic menhaden, *Brevoortia tyrannus*. These ulcers were commonly attributed to *Pfiesteria* spp. during the 1990s but are now known to be caused by the oomycete, *Aphanomyces invadans*. Ulcers are commonly located peri-anally (arrow) and penetrate deeply into underlying muscle and viscera.

#### **Fish Kills**

The causal link between *Pfiesteria* and the fish kills was based on the following logic: High densities of *Pfiesteria*-like cells were present in estuaries, and *Pfiesteria* in tanks have complex life-cycle stages that kill fish. Ergo *Pfiesteria* was responsible for killing fish in estuaries. This conclusion was reached even though the conditions in the tank bioassays and field were vastly different and without confirmation that the complex life cycle of *Pfiesteria* existed in the field. In addition, all *Pfiesteria*-like organisms at fish kill sites were counted using light microscopy and classified as *Pfiesteria*, which inflated estimates of *Pfiesteria* abundance. In actuality, many other small heterotrophic dinoflagellates not easily distinguished from *Pfiesteria* using light microcopy were present (see Taxonomy section).

One of these species was *Karlodinium veneficum*. This mixotrophic species often cooccurs with *Pfiesteria*, forms dense blooms, and produces a well-defined toxin that kills fish in the environments where the original *Pfiesteria* studies were conducted (Adolf et al. 2015; Bachvaroff et al. 2008; Hall et al. 2008). *Karlodinium veneficum* uses its toxin to immobilize cryptophyte prey prior to ingestion (Sheng et al. 2010) and fish kills are collateral damage from a bloom (Place et al. 2012). It should be noted that unlike *Pfiesteria*, whose growth is dependent on consuming prey, *K. veneficum* can acquire C equally well by heterotrophy and photosynthesis. This ability to grow photosynthetically thereby supplying its own C makes achieving higher cell densities much easier for *K. veneficum* relative to *P. piscicida* which rapidly depletes its food supply. *Pfiesteria piscicida* can consume 6 ± 2 prey cells on average in a 10-minute period (Burkholder and Glasgow 1997b), with other experiments showing it removes on average between 2% and 15% of a microalgal prey population in just 1 h (Jeong et al. 2006). It is quite possible that in many instances the high densities of *Pfiesteria* originally reported in the 1990's (e.g., Burkholder et al. 1992; Burkholder and Glasgow 1995) were actually *K*. *veneficum* (Coyne et al. 2001; Fensin 2004; Handy et al. 2008; Marshall 1999; Marshall, Seaborn and Wolny 1999). The original samples were never checked for chlorophyll fluorescence which would have helped to distinguish the photosynthetic *Karlodinium* from heterotrophic *Pfiesteria*. Support for this potential confusion comes from subsequent surveys that have shown that *Pfiesteria* cells are typically present in natural system at  $\sim$ 10 cells L<sup>-1</sup> and are not observed to form dense blooms (Coyne et al. 2001; Handy et al. 2008; Lewitus et al. 2002; Lin, Zhang and Dubois 2006; Marshall 1999; Marshall, Seaborn and Wolny 1999; Zhang and Lin 2005).

In addition, Paerl et al. (1998) reported that 80-85% of the fish kills in Pamlico Sound could be attributed to hypoxia/anoxia (oxygen depletion) of the bottom waters caused by eutrophication, which led to dense algal blooms of other species and subsequent die-offs and bacterial degradation that depleted the oxygen*.* Burkholder, Mallin and Glasgow (1999) challenged the Paerl et al. (1998) reasoning of oxygen depletion as an alternative explanation to *Pfiesteria* toxin as a cause of the fish kills. However, Paerl et al. (1999) provided a plausible mechanism whereby surface-dwelling menhaden might succumb to oxygendepleted bottom waters in their response. A common problem with ascribing causality to fish kills is that they are frequently observed and reported many hours or even days after the fish have died. The conditions where the dead fish are found may no longer reflect conditions that preceded the mortality event or fish may have been transported long distances away from the initial location of the event. Dissolved oxygen levels measured in the presence of floating dead fish are often not relevant to the conditions that were present when the fish died.

Concentrations of several HAB species in water samples collected at sites during and following reported fish kill events in both Virginia and Maryland waters of Chesapeake Bay have been monitored for the past two decades. As mentioned above, often oxygen depletion may have contributed to a kill event and ascribing cause to a particular HAB species may be erroneous in many instances. Nonetheless, several kill events in Chesapeake Bay have been associated with HAB species, but these are species other than *P. piscicida* and *P. shumwayae*, both of which have been notably absent during most of these fish kills (see Tables  $2 \& 3$ ). In Maryland, many fish kills have been associated with *K. veneficum* blooms with high cell numbers and karlotoxins being detected in water samples collected from sites where dead fish are reported and at nearby stations (Table 2). Frequently the gill pathology in moribund fish is consistent with that described for laboratory exposure to karlotoxins (Deeds, Reimschuessel, and Place 2006). Likewise, in Virginia, there have also been fish kills associated with *K. veneficum* blooms with karlotoxins detected in a Potomac River sample from 2015 (Table 3). Mortality events of fish, rapa whelks, oysters, rays, eels and crabs have also been observed in Virginia in association with high cell numbers (i.e.,  $> 1,000$  cells/ml) of other HAB organisms including *Margalefidinium* (formerly *Cochlodinium*) *polykrikoides*, *Alexandrium monilatum*, *Chattonella subsalsa* and *Prorocentrum minimum* (Table 3). It is interesting to note that, in association with some of the water and fish samples collected from the *C. subsalsa* bloom and kill events, low levels of brevetoxin were detected (Table 3).

#### **Lesions**

In the late 1990's, the claim was made that *Pfiesteria* caused the deeply penetrating skin ulcers observed on finfish, predominantly menhaden (*Brevoortia tyrannus*), from massive fish kill events in North Carolina estuaries (Burkholder and Glasgow 1997a; Burkholder, Glasgow, and Deamer-Melia 2001; Burkholder et al. 2001b; Glasgow et al. 2001b). This contention fueled tremendous negative publicity and resulted in significant economic losses by the restaurant, charter boat and seafood industries in North Carolina and Chesapeake Bay (Lipton 1998; Meyer 1997). Whenever people observed or heard of reported lesions, they assumed recreational waters and seafood products were unsafe and avoided them accordingly. This negative perception predominated despite a clear understanding at the time that many factors can cause the appearance of skin lesions on fish. Those factors include a variety of infectious agents, immunological responses, nutritional or metabolic stress and physical damage, as well as toxic compounds such as polycyclic aromatic hydrocarbons (PAHs) or those produced by HABs (Kane, Oldach and Reimschuessel 1998; Law 2001; Noga 2000; Sindermann 1988). This basic knowledge led scientists to question the tacit assumption that all fish kills in North Carolina and Chesapeake Bay estuaries where finfish ulcers were observed were caused by *Pfiesteria* (Blazer et al. 1999; Vogelbein et al. 2001).

There were sound reasons for this skepticism. Historically, studies had shown that the deeply penetrating, and largely single, ulcerous lesions observed on menhaden along the US East coast including Chesapeake Bay and North Carolina were most often associated with oomycete (water molds) infections (Dykstra et al. 1986; Dykstra et al. 1989; Noga 1993; Levine et al. 1990a, 1990b; Noga and Dykstra 1986; Noga et al. 1988). This disease was termed ulcerative mycosis (UM) and characterized by the presence of severe dermatitis, underlying granulomatous myositis and tissue destruction associated with fungus-like hyphae

(Dykstra et al. 1986; Noga and Dykstra 1986). Additionally, lesions typically exhibited a diverse mixture of microbial contaminants colonizing the outermost necrotic tissues (Dykstra et al. 1986, 1989; Noga et al. 1988, 1993; Levine et al. 1990a; Blazer et al. 1999). Initial attempts to fulfill Koch's postulates by re-infecting the fish with oomycetes such as *Saprolegnia* sp. and *Aphanomyces* sp. ATCC 62427 isolated from affected menhaden failed to reproduce the typical lesions seen in wild fish. This left unresolved whether the mixture of microbial agents, including the deeply invasive oomycete found in the ulcers, were (a) opportunists colonizing a superficial lesion caused by unknown environmental stressors or biological insults, or (b) whether one of the microbes was a primary pathogen capable of causing UM directly without other stressors playing a role (Noga et al. 1996; Kane, et al. 1998; Noga 2000). Noga et al. (1996) and Sindermann (1999) proposed that ulcerative lesions in finfishes were multi-factorial in their etiology.

At the time the hypothesis that *Pfiesteria* was the underlying cause of UM in US East Coast menhaden was gaining global attention, a similar ulcerative disease was reported in over 100 species of wild and cultured freshwater and estuarine fishes from the Indo-Pacific region (Callinan 1994a, 1994b). This disease was also characterized by the occurrence of deep tissue necrosis and granulomatous inflammation associated with fungus-like hyphae. The occurrence of water mold infections around the world was variously termed epizootic ulcerative syndrome (EUS) in Asia, red spot disease (RSD) in Australia and mycotic granulomatosis (MG) in Japan (Callinan et al. 1995; Egusa and Masuda 1971; Fraser, Callinan and Calder 1992; Hatai 1980; Hatai et al. 1977; Lilley et al. 1998; Willoughby, Roberts and Chinabut 1995). However, unlike the North American experience with *Aphanomyces* strain ATCC-62427, numerous laboratories independently established that one highly pathogenic oomycete species could by itself produce the typical ulcerative lesions observed in Indo-Pacific fishes through multiple laboratory exposure routes (Catap and Munday 1998; Cruz-Lacierda and Shariff 1995; Hatai et al. 1977; Khan et al. 1998; Lilley and Roberts 1997; Roberts, Willoughby and Chinabut 1993; Wada et al. 1996). This included aqueous challenges of healthy fish to secondary zoospores, the infective stage of this oomycete. These studies clearly established the agent in the Indo-Pacific region, *Aphanomyces invadans*, as a primary pathogen (Callinan, Sammut and Fraser 1996), which is now believed to be the cause of major fish kills affecting both wild and farmed fisheries on a global scale. This water mold is recognized as a single species of cosmopolitan distribution and is listed in the Index of Fungi as *Aphanomyces invadans* (David and Kirk 1997). The disease has since that time been collectively referred to as EUS (Kar 2016; Lilley and Roberts 1997).

Given the experience in the Indo-Pacific region, Blazer et al. (1999) re-investigated menhaden mortality and lesion events attributed to *Pfiesteria* in the Chesapeake Bay. They reconfirmed that the "*Pfiesteria*" lesions in fish were identical to those reported as menhaden UM from eastern US estuaries during the 1980s (e.g., Noga and Dykstra 1986). Additionally, new oomycete isolates obtained from Chesapeake Bay menhaden were definitively identified as *A. invadans* based on growth characteristics, PCR and fluorescent *in situ* hybridization (FISH) assays (Blazer et al. 2002; Lilley et al. 2003). Subsequently, molecular analyses also identified *A. invadans* in all ulcerative lesions found on menhaden collected from North Carolina estuaries where *Pfiesteria* was first reported to have caused fish kills and fish lesion events (Vandersea et al. 2006). Additional controlled laboratory challenges of menhaden with Chesapeake Bay and North Carolina *A. invadans* isolates definitively confirmed this water

mold as a primary pathogen and the causative agent of menhaden EUS (Figure 9) (Kiryu et al. 2002; 2003; Vandersea et al. 2006).

Other observations increasingly led to questions regarding the purported role of *Pfiesteria* in fish kill and lesion events (Dykstra and Kane 2000; Vogelbein et al. 2001). *Pfiesteria* pathology occurring in laboratory fish bioassays and attributed to toxin production was described as widespread surficial erosion of epidermis that formed rapidly in as little as several hours (Noga et al. 1996). In contrast, the *A. invadans* lesions found on wild menhaden exhibited a typical granulomatous inflammatory response and the consistent presence of oomycete hyphae (Figure 9). This inflammatory response takes days to weeks to develop and could not have formed rapidly in response to acute toxin exposure. These data further argued against *Pfiesteria* causing the deep ulcerative lesions observed in wild menhaden. Despite these findings, claims that EUS in Mid-Atlantic USA estuaries was caused by *Pfiesteria* toxin have persisted (Burkholder and Marshall 2012; Burkholder and Marshall 2018).

[https://doi.org/10.1289/ehp.01109s5687.](https://doi.org/10.1289/ehp.01109s5687)

Because menhaden are mobile, the presence of a chronic lesion days to weeks old may have no bearing on current local conditions where fish are collected. Vogelbein et al. (2001) distinguished menhaden UM from laboratory-induced pfiesteriosis in tilapia based on histopathology (Figure 10). Tilapia (*Oreochromis* sp.) experimentally exposed to *P. shumwayae* using the standard fish bioassay approach (Burkholder, Glasgow, and Deamer-Melia 2001; Burkholder et al. 2001a; Burkholder, Glasgow and Steidinger 1995), exhibited direct attachment of *Pseudopfiesteria* dinospores to surficial tissues and widespread loss of the epidermis, mucus and scales (Vogelbein et al. 2001; see section on *Fish Bioassays and Micropredation* below). This physical attachment of *Pfiesteria* dinospores was a new finding and the associated diffuse, widespread superficial pathology was clearly distinct from the deeply penetrating, single chronic ulcers in wild-caught menhaden with EUS. The diffuse epidermal damage reported in laboratory-exposed fish has never been observed in wild menhaden from fish kill or lesion events (Law 2001) and was essentially identical to that previously reported by Noga et al. (1996) as an effect of *P. piscicida* toxin. These data further argue against *Pfiesteria* as causing fish lesions in the wild.

Over the intervening years it has become well established that *A. invadans* is the causative agent of EUS and represents a global threat to wild and cultured finfishes in both fresh and saltwater globally. Since its first report from Japan, the disease was more recently observed in several southern African countries (Iberahim, Trusch and van West 2018). Although pathogenic viruses, bacteria, fungi and protozoan and metazoan parasites are routinely co-isolated from EUS-affected fishes, there is no evidence that these other pathogens causally contribute to the disease (John and George 2012; Kamilya, Dibyendu and Baruah 2014). Nor are we aware of any more recent evidence that *Pfiesteria piscicida* or *Pseudopfiesteria shumwayae* play any role in the pathogenesis of this infectious disease, as claimed in the past. Additionally, an *A. invadans* strain (NJM9701) was recently sequenced (Makkonen et al. 2016; Russ Diéguez-Uribeondo, and van West 2019), and genomic analysis has identified virulence factors called effector proteins that function to circumvent finfish host defenses (Iberahim, Trusch and van West 2018). These studies provide additional strong support to the idea that some strains of *A. invadans* are primary pathogens. However, under optimal environmental conditions, the skin defenses are usually sufficient to prevent infection. Immune suppression associated with poor environmental quality may, however, augment the potential for this pathogen to infect fishes and cause disease (Iberahim, Trusch and van West 2018; Kamilya, Dibyendu and Baruah 2014; Kiryu et al. 2005). Although superficial skin damage may enhance infectivity of *A. invadans* (Kiryu et al. 2002), it is not a necessary criterion for infection. Given the low *Pfiesteria* cell densities found in nature, and the accompanying low probability of encountering fish, it is highly unlikely they ever inflict sufficient epidermal damage to facilitate an *A. invadans* infection. In conclusion, all available evidence indicates that *Pfiesteria* can be definitively ruled out as a cause of ulcerative lesions in wild fish.

#### **Fish Bioassays and Micropredation**

In the early days the reported biological and chemical behavior of *Pfiesteria* was based on observations from a "Gold Standard" fish bioassay developed specifically to test *Pfiesteria* toxicity (Burkholder and Glasgow 2002; Burkholder, Glasgow, and Deamer-Melia 2001; Burkholder, Glasgow and Steidinger 1995; Burkholder et al. 2001b; Glasgow et al. 2001b). In this system, juvenile tilapia were exposed in aquaria (9 - 38 liters) to *Pfiesteria* from sediment samples, water samples or laboratory cultures. Aquaria were maintained for weeks to months until fish mortalities occurred. As fish died, they were removed and replaced with live fish without changing the water. During the incubation, *Pfiesteria* and bacterial populations increased to densities that greatly exceeded those observed in the field. Because of the complex community of microorganisms and degradation of water quality that developed over time, concern was raised regarding "Gold Standard Assay" validity. Because there was no standard timeframe for assays, results were not reproducible and clearly assigning causality to fish mortality was not possible (Drgon et al. 2005; Lovko et al. 2003; Vogelbein et al. 2002). Microbial contaminants in these systems included amoebae, bacteria, chrysophytes, ciliates, diatoms, rotifers and other protists (Burkholder and Glasgow 1997a, 1997b; Burkholder, Glasgow, and Deamer-Melia 2001; Burkholder, Glasgow and Steidinger 1995; Burkholder et al. 2001b; Drgon et al. 2005; Peglar et al. 2004; Vogelbein et al. 2001). Replicating the standard aquarium-format bioassay Drgon et al. (2005) found bacteria, including pathogenic *Vibrio* spp., and *Aeromonas* spp., among the vast assemblage of microorganisms that developed. The ability of bacteria commonly associated with harmful algal species to produce toxins, or contribute to their production, had already been documented (Doucette 1995).

In response, alternative, small-scale temporally standardized bioassays (96 hr) were developed to address concerns associated with the standard bioassay of Burkholder et al. (2001b). These studies exposed larval or juvenile fishes to *Pfiesteria* in tissue culture plates or small culture flasks (Figure 11). This new format with a shorter assay duration, eliminated many of the variables that were present in the Burkholder Gold Standard Bioassay. The new assay format allowed viewing the tissue culture plates under the microscope and led to better elucidation of the mechanisms and biological factors playing a role in fish-killing by

*Pfiesteria*. Concurrent studies exhibited widespread epidermal erosion in *P. shumwayae*exposed tilapia and reported a direct physical association between *Pfiesteria* dinospores and the eroded surface epithelia of exposed fish (Vogelbein et al. 2001). Histologically, dinospores were found to be attached to damaged skin, oral mucosa, gills, and deep within the lateral line canal and olfactory organs (Figure 11). An alternative mechanism of fish pathogenicity was hypothesized whereby the dinospores attach to and feed on fish surficial epithelial tissues (Vogelbein et al. 2001). In contrast, earlier studies had held that *Pfiesteria*  toxins were responsible for adverse effects in fish and invertebrates, rather than that there was direct physical association with, or ingestion of, *Pfiesteria* (Burkholder, Glasgow, and Deamer-Melia 2001; Burkholder et al. 2001a; Burkholder, Mallin and Glasgow 1999; Burkholder, Glasgow and Steidinger 1997; Kane, Oldach and Reimschuessel 1998; Noga 2000; Noga et al. 1996; Samet et al. 2001; Silbergeld et al. 2000). In fact, the original paper describing the effects of *P. piscicida* specifically stated: "the alga has not been observed to attack fish directly" (Burkholder et al. 1992). However, intense chemoattraction to fish and heterotrophic feeding on single-celled algae, protozoans and isolated vertebrate cells such as human red blood cells had been described previously (Burkholder and Glasgow 1997a; Burkholder, Glasgow and Steidinger 1995).

Definitive studies were conducted to assess the relative importance of toxin production versus direct feeding by *P. piscicida* and *P. shumwayae* in fish mortality. Using the 96 hour larval fish bioassay of Lovko et al. (2003), Vogelbein et al. (2002) demonstrated that physical attachment and myzocytotic feeding on fish skin by *P. shumwayae* (Figure 5) resulted in epidermal damage and fish mortality identical to what had previously been reported as a toxin effect (Burkholder, Glasgow, and Deamer-Melia 2001; Noga et al. 1996). Fish mortality (100%) occurred only in treatments where fish and *P. shumwayae* dinospores were in physical contact (Figure 12). No mortalities occurred in treatments where a semi-permeable membrane prevented physical contact. Mortalities (60-100%) occurred only in fractions that contained live *Pfiesteria* dinospores, while no mortalities occurred in cell-free (soluble) or bacteria-enriched fractions or controls. These findings were further supported by exposure studies using cell-free supernatants of fish killing cultures, lysates of whole *Pfiesteria* cells and organic extracts of lyophilized *Pfiesteria* cells, all of which failed to kill larval fish (Berry et al. 2002). The most parsimonious conclusion of the studies was that finfish pathology and mortality were due to direct epidermal damage derived from a feeding process described as "micropredation" in the absence of toxin production (Vogelbein et al. 2001, 2002). This novel mechanism of pathogenicity without toxin was rapidly confirmed in studies with larval and juvenile finfish (*Cyprinodon variegatus, Oreochromis* sp.) (Burkholder, Glasgow, and Deamer-Melia 2001; Burkholder et al. 2001a, 2001b; Gordon et al. 2002), bay scallops (*Argopecten irradians*) and eastern oysters (*Crassostrea virginica*) (Springer et al. 2002). However, these investigators continued to attribute mortalities to an unidentified *Pfiesteria* toxin, insisting that micropredation was a trivial contributor to mortality.

Fish death continued to be used to identify a culture as "toxic" (TOX), whereas strains failing to cause fish distress, disease, or death were consistently referred to as non-toxic, or NON-IND, in many instances without consideration of cell densities in the assays (Burkholder, Glasgow, and Deamer-Melia 2001; Burkholder et al. 2001a; Glasgow et al. 2001a, 2001b). Variations in mortality rate were viewed mainly as differences in toxin production among strains, while the critically important role of *Pfiesteria* cell density and its effect on mortality was ignored. This interpretation became problematic because cell numbers in assay systems were known to change over time. With an adequate food source (such as fish), dinoflagellate populations in culture can increase over a relatively short time period (24- 48 hours) (Gordon and Dyer 2005; Shumway, Burkholder and Springer 2006). Higher cell densities in these assays resulted in increased feeding, greater tissue damage and shorter times to fish death. Lovko et al. (2003) demonstrated a clear dose-response in larval fish exposed to a range of *P. shumwayae* dinospore concentrations (Figure 12). The relationship between fish mortality and cell density was subsequently confirmed for *P. piscicida* using a fish tank bioassay system (Drgon et al. 2005). Ichthyocidal activity of *P. piscicida* was ascribed mostly to micropredation, rather than to a soluble toxin.

"A New Larval Fish Bioassay for Testing the Pathogenicity of *Pfiesteria* Spp. (Dinophyceae)." *Journal of Phycology* 39(3):600–609[. https://doi.org/10.1046/j.1529-8817.2003.02106.x.](https://doi.org/10.1046/j.1529-8817.2003.02106.x)

Cages with varying mesh sizes also were used to demonstrate that fish mortality was directly proportional to how well the mesh allowed the passage of intact *Pfiesteria* cells into the cage. Only 3%-10% total mortality was observed in tanks with mesh sizes that excluded *Pfiesteria* cells, suggesting the presence of a soluble factor making a minor contribution to overall fish mortality. However, the investigators could not attribute these mortalities to *Pfiesteria* directly, as the tanks contained a rich microbial flora, including bacteria, fungi, and protists, some of which are known fish pathogens and may also produce soluble toxic factors (Drgon et al. 2005). Subsequent studies applying the methods of Lovko et al. (2003) and Vogelbein et al. (2002), have confirmed micropredation as the primary mechanism of killing by *P. shumwayae* in both finfish and shellfish (Gordon and Dyer 2005; Shumway, Burkholder and Springer 2006). We are aware of no more recent investigations that have revisited this aspect of *Pfiesteria* biology, and most of the HAB community stands at consensus that the mechanism of finfish "pathogenicity" in these two organisms is through myzocytotic feeding on the surficial epithelial tissues. To date, a *Pfiesteria* toxin has not been fully characterized and a completed structure is not available. It is well-established that these dinoflagellates are heterotrophs (animal cells) that feed on autotrophic unicellular algae using a specialized feeding structure called a peduncle, rather than obtaining their energy via photosynthesis.

*Pfiesteria* 3749

We consider the mortalities that have been described in laboratory exposures to be an artifact of holding the finfish in a captive environment in which dinoflagellate cell densities can rapidly rise to concentrations that are lethal, and from which fish cannot escape. This suggests that these organisms have the ability to become a problem in closed recirculating finfish culture operations. The best documented case comes from two fish farms in Denmark, which use closed recirculating systems, and where both *P. shumwayae* and *L. masanensis* were recently documented to kill fish (Moestrup et al. 2014). Previously *Luciella* spp. had not been linked to any fish kills. In both situations, the fish could not escape and therefore, provided a nutrient rich, high density food source upon which the PLDs could graze via micropredation (see Fish Kills section). *Cryptoperidiniopsis brodyi*, has also been implicated in causing fish kills in closed recirculating systems (Noga, personal communication). Thus, in these limited circumstances, PLDs can represent a threat to certain aquaculture operations. It is unlikely however, that the proper conditions would ever occur in natural systems where finfish can simply swim away and at the low PLD densities typically observed in nature.

#### **Human Health**

Filter-feeding shellfish and finfish can accumulate algal toxins in their tissues and thereby are often vectors for transfer of these toxins to humans through consumption (Van Dolah 2000; Friedman and Levin 2005). Human exposure can also occur through direct contact or aerosol inhalation, as in the case in human brevetoxicosis at beaches, or through drinking water, which can become contaminated with cyanotoxins, for example. Many of the algal toxins are neurotoxins that cause a range of primarily gastrointestinal and neurological symptoms including nausea, vomiting, diarrhea, memory and learning deficits, abnormal sensations in the extremities (paresthesia), headaches, dizziness, fatigue, mood disorders, seizures and hallucinations (Baden, Fleming and Bean 1995; Van Dolah 2000). Although *Pfiesteria* has been reported to produce a toxin, the described properties are very different from those of other algal toxins in that it does not bioaccumulate and degrades very rapidly (Jaykus and Green 1998; McClellan-Green, Schmechel and Koltai 2001). The primary route of human exposure is thought to be through aerosols and direct contact with contaminated water.

Human health effects from *Pfiesteria* were reported during the 1990's by laboratory workers and by watermen in North Carolina and Chesapeake Bay. The concept of a human clinical syndrome associated with *Pfiesteria* was first developed based on acute exposure of three laboratory workers to *Pfiesteria* cultures and the bioassay tanks where fish were dying in a single lab that was studying the organism (Glasgow et al. 1995). One of these individuals received additional exposure through the ventilation system that was incorrectly routed from the *Pfiesteria* laboratory into an adjacent office (Schmechel and Koltai 2001). Gastrointestinal difficulties, fatigue, cognitive impairment, as well as mucosal and skin irritation and sores were among the symptoms described by these workers. The individual who had been exposed both in the laboratory and office settings was most severely affected and underwent extensive medical testing two weeks after the onset of symptoms and termination of exposure. Routine blood and urinalysis tests, as well as the neurological tests for gross motor skills were essentially normal. However, a neurophysiological exam revealed memory deficits, and impaired arithmetic, verbal learning and reading skills. Six weeks later, a follow-up screening

revealed that the patient's deficits had been largely resolved (Schmechel and Koltai 2001). One of the other two individuals affected in this laboratory was tested and results were normal; the other individual did not seek medical treatment. To our knowledge, no symptoms have been reported by workers in other laboratories where *Pfiesteria* spp. or other PLDs have been studied.

In addition to the laboratory exposures in the mid-late 1990's, as the press reports surrounding *Pfiesteria* and public awareness of this dinoflagellate increased, there was a surge of reports of symptoms such as confusion, headaches and skin irritations from citizens who had been in or near waters where a fish kill had occurred (CDC 1997; CDC 1999; Moe et al. 2001). Following the Pocomoke River, MD fish kills in 1997 a single-blind clinical study was done on a group of 24 persons who reported direct contact with lesioned fish or waters during an ongoing fish kill (Griffith 1999; Lowitt and Kauffman, 1998; Turf et al. 1999). Nineteen subjects exhibited unexplained significantly decreased performance compared to normal on neuropsychological tests, and five had skin lesions that could not be attributed to a specific cause. The researchers believed that the evidence supported the involvement of *Pfiesteria* in the observed symptoms, although a definitive cause and effect relationship with a *Pfiesteria* toxin specifically could not be found (Grattan et al. 1998). Several years later, Friedman and Levin (2005) criticized the Grattan et al. (1998) study for being limited by small sample sizes and a lack of clear evidence that *Pfiesteria* spp. cells were present in waters to which the subjects were exposed. In addition, Friedman and Levin suggested that the "impairment" observed in the neuropsychological exams could have been due to chance. Moe et al. (2001) pointed out other shortcomings of the Gratten study, including the small number of subjects, the fact that subjects were self-selected, the lack of pre-exposure cognitive testing, and that the medical team was not blinded to the exposure status of the subjects during the evaluation process. As discussed below, several other studies were unable to find an association between human health and occupational exposures to estuaries in which fish kills and lesion events attributed to *Pfiesteria* spp. had occurred (Griffith 1999; Griffith et al. 1998; Smith and Music 1998; Turf et al. 1999; Morris 2001).

In an effort to better understand the association, if any, between *Pfiesteria* and human health, in 1998, the US Congress directed CDC to fund a multi-state surveillance study in coastal North Carolina, Virginia and Maryland to investigate "possible estuary associated syndrome (PEAS)". Citizens frequenting the waterways where fish kills occurred and lesioned fish had been found had been reporting a variety of gastrointestinal, and primarily dermal, respiratory and neurological symptoms, and they thought that their symptoms were due to *Pfiesteria* exposure. It was not clear, however, whether the sensationalized media coverage was leading to the reporting of symptoms from citizens or there really were human health effects associated with exposure to impacted waterways. The reports primarily came from those with occupational exposure to the Chesapeake Bay or North Carolina coastal waters. The symptom and exposure criteria for PEAS were: 1) exposure to estuarine water with a fish kill or fish with lesions consistent with *Pfiesteria* spp., 2) symptoms of memory loss and confusion or three or more of the following symptoms: skin rash/sensation of burning skin at the site of water contact, headache, eye irritation, upper respiratory irritation, muscle cramps and gastrointestinal symptoms, any of which persist for more than 2 weeks, 3) symptoms developing within two weeks of exposure to estuarine water and persisting for two weeks or longer, and 4) inability of a health care provider to identify another cause for the symptoms (CDC 1997; CDC 1999). The results from the Virginia cohort study found no

indication of PEAS (Turf et al. 1999). Similarly, the investigators conducting a four-year CDC-funded study in Maryland found no evidence of a correlation between exposure to waters containing *Pfiesteria* spp. and PEAS symptoms (Morris et al. 2006).

There were other human health studies conducted, but results were equivocal and failed to provide clear evidence of a link between human health effects and exposure to *Pfiesteria*. Visual contrast sensitivity (VCS) testing was done on a group of 82 people reporting symptoms similar to PEAS symptoms after occupational (N=5), recreational or residential (N=77 for both) exposure to waters where fish kill and lesion events attributed to *Pfiesteria* had occurred in Maryland (Shoemaker 2001; Shoemaker and Hudnell 2001). VCS is a measure of visual pattern detection ability and is used as a proxy for neuropsychological testing. The investigators reported significantly reduced VCS in the exposed group compared to a control group of 87 individuals; 34 with exposure to marine or estuarine waters and 53 with no exposure to these waters. Another group of investigators studied 22 individuals exhibiting PEAS symptoms after exposure to waters where *Pfiesteria* had presumably caused fish kills and lesions (Hudnell 2005; Hudnell et al. 2001). Their study included 20 control individuals who had not been exposed to marine or estuarine waters. As with Shoemaker and Hudnell (2001), using the VCS test they also found significant deficits in the exposed group. The results of these VCS tests for *Pfiesteria* exposure, however, came under considerable criticism (Friedman and Levin 2005; Morris 2001; Swinker 2003a, 2003b; Swinker et al. 2001a, 2001b, 2002). The VCS test was viewed as inferior to a comprehensive neuropsychological evaluation and diagnostically non-specific for any particular disease or toxicant exposure. Abnormal VCS test results might be obtained due to chronic sunlight exposure, use of anti-convulsant medications or alcohol and occupational exposure to solvents, petrochemical fuels, heavy metals or combustion products. Critics of the studies noted that those who worked as fishers may have been exposed to these and other toxicants and would have had chronic exposure to sunlight.

Swinker et al. (2001a, 2001b) conducted two studies on individuals who had been exposed to waters where fish kills had presumably been caused by *Pfiesteria* had occurred or where lesioned fish or *Pfiesteria* cells were present. One study included only those with occupational exposure (22 cases and 21 controls) and the other was composed of cases with individuals who called a *Pfiesteria* hotline following occupational and recreational exposure (11 cases and 11 controls). They did not find an increased likelihood of PEAS symptoms in cases in either study, nor did they find evidence of persistent physical health or neuropsychological effects in exposed individuals.

Some patients exposed to *Pfiesteria* also reported development of a variety of skin lesions (Lowitt and Kauffman 1998; Shoemaker 1998). These reports and the conclusions that they were caused by *Pfiesteria* exposure, however, were based on a correlation between people having exposure to the waters where *Pfiesteria* was reportedly present, and the people reporting skin lesions of various types. The studies lacked any means of clearly demonstrating exposure and, therefore, were only correlative. Subsequent studies using *Pfiesteria* extracts from a high concentration of *Pfiesteria* cells induced mild, localized irritation in mice, but not dermal sensitization, and had no effect on humans (Burke and Tester 2002; Patterson, Noga and Germolec 2007). The original human skin irritations attributable to *Pfiesteria* were consequently thought to be due to "chronic irritation and trauma associated with fishing and crabbing work, estuarine microbes, allergens such as ragweed or pollen, intense sun and water exposures, and preexisting medical and neuropsychologic conditions" (Patterson, Noga and Germolec 2007).

# **IDENTIFICATION AND CHARACTERIZATION OF**  *PFIESTERIA* **SPP. TOXINS**

Perhaps the most troubling aspect of the *Pfiesteria* controversy has been the longstanding inability to obtain the structure of a purported toxin. Given the description of an alternate mechanism of pathogenicity (myzocytosis) in the absence of toxin and the obligate requirement of direct physical contact to cause mortality (Vogelbein et al. 2002), the existence of a *Pfiesteria* toxin has been questioned. It was initially claimed that *Pfiesteria*  must feed on fish to produce the toxin (Burkholder and Glasgow 1997a); however, later studies suggested bioactivity in algae-grown strains (Moeller et al. 2007). Secondly, the toxic activity was originally described as hydrophobic (lipophilic) and of high molecular weight (>10,000 daltons) (McClellan-Green, Jaykus and Green 1998). As noted by Drgon et al. (2005), the fish bioassay tanks contain numerous organisms, some of which are identified pathogens, which makes attribution of a toxic compound from this complex matrix impossible. A putative phthalate ester was isolated from these cells (Moeller et al. 2001) but turned out to be a plasticizer contaminant originating from the Instant Ocean salts used to make up the culture media used to grow *Pfiesteria*. The *Pfiesteria* toxin was summarized in an article in *Science* to be "…a glycoside, a molecule that's half sugar, half some other chemical group that has not been identified" (Kaiser 2002), and a partial structure for the molecule was announced at the 10th Annual Harmful Algal Bloom Symposium. The final structure of this toxin has never been reported.

Around the same time other groups began investigating the toxicity of *Pfiesteria* using alternative approaches. One group examined organic extracts of lyophilized *P. shumwayae*  cells, all of which failed to kill larval fish (Berry et al. 2002). Since most known algal toxins have a polyketide structure, these researchers used molecular primers to demonstrate that *P. shumwayae* most likely lacked the polyketide synthases needed to synthesize this class of toxins (Berry et al. 2002).

In 2007, a very different structural framework for a putative *Pfiesteria* toxin was described to be a ligated copper compound with numerous congeners (Moeller et al. 2007) (Figure 13). It was hypothesized that the "rapid, free-radical-mediated toxicity of *Pfiesteria* toxins may occur via production of a redox-cycling metal center and free radical(s) that can lead to specific reactions with "pro-toxins" which, in turn, can produce more active toxic species." Under this scenario, sunlight and metal exposure are the two primary environmental factors that would combine to initiate *P. piscicida* toxicity during blooms. "Light exposure could initiate redox cycling of the metal ion(s) resulting in radical formation and release of the toxin species." Unfortunately, direct evidence that free radical formation actually takes place in estuarine waters was not provided and given the high organic load in these waters it seems unlikely that the reaction distance would be very great. More importantly, no doseresponse data were presented to confirm the concentration required to kill fish. Without these data it is not possible to rigorously establish the environmental relevance of the described activity. Toxicity was inferred primarily from the work presented by Burkholder et al. (2005),

however, there are several inconsistencies in the authors' interpretation of their data. The first issue is the toxin cell quota. *Pfiesteria* spp. have  $\sim 100$  pg total C per cell (Menden-Deuer and Lessard 2000; Miller and Belas 2004). Yet the reported toxin concentrations for several of the TOX *P. shumwayae* cultures was on the order of 43-251 pg cell<sup>-1</sup> or 0.5-2.5 X the total C of a *Pfiesteria* cell. These toxin cell quotas are not possible because they equate to more than 100% of all C in the cells. This would provide nearly 200 mg of toxin from a 90-liter culture of 10,000 cells per ml. Next, the toxicity of the extracts was reported as time to death for a fish exposed to 50 μL of *Pfiesteria* toxin (Burkholder et al. 2005). It is not at all clear, however, why they reported a volume of toxin added rather than the actual concentration of toxin, which is what is normally reported for a dose response assay when they had quantified the toxin. Also, the activity of the *Pfiesteria* toxin as measured by cytotoxicity to cultured cells was nonexistent in cells grown on algae, but high in cells grown on fish (Figure 3 of Burkholder et al. (2005), yet the chromatogram shown in Figure 4 of the original online version of Burkholder et al. (2005) showed that the NON IND strain CCMP 1832 grown on algae had the same peak as that of the toxic 2089 strain grown on fish. Other researchers, however, were not able to reproduce results reported from the TOX cultures. As mentioned above these purportedly TOX cultures were neither deposited in a public repository nor were other research groups able to obtain subsamples of these cultures (from the NC State Research group) for conducting experiments. Many of the other research groups, nonetheless, used cultures that had been established from Neuse River samples, the same location from which the purported "TOX' culture samples had been collected. In 2007, Moeller et al. reported that they had purified the toxin from cultures grown on algae.

Standard fish bioassays were used to assess the killing ability of *Pfiesteria* which allowed direct contact between fish and *Pfiesteria* making it impossible to determine what portion of the observed fish mortalities were due to micropredation versus the action of the toxin. As discussed above, over 90% of the observed mortality was likely due to micropredation based on observation of other studies such as Vogelbein et al. (2002). Another aspect of the Burkholder et al. (2005) study was the use of plating and DGGE gel techniques to assess the bacterial similarity or differences between the control and experimental treatments where fish mortality was occurring. The goal was to demonstrate that there were no pathogenic bacteria in the cultures of *P. piscicida* or *P. shumwayae* that were killing fish. Unfortunately, the plating techniques used were only capable of supporting the growth of less than 2% of estuarine bacteria. Since 98% or more of the bacteria would not show up using this assay; any similarities or differences noted between treatments were therefore meaningless. The premise behind the DGGE experiment is that the absence of a unique randomly amplified 16S band in the killing cultures would indicate bacteria are not involved in the production of the toxin. Unfortunately, DGGE tends to pick up only the most abundant bacteria. The lack of a uniform band cannot therefore be used to exclude bacteria as a potential source of the toxin as implied in the paper. This leaves the potential bacterial source of the toxin in limbo. Although, *Pfiesteria* species can be grown axenically on fish cells, it is critical to demonstrate that the toxin can be isolated from these cultures. The study also showed cytotoxicity data from two cultures of *P. shumwayae*. One culture showed no activity at all and the other marginal activity likely within the noise level of the assay (Figure 3 of Burkholder et al. 2005). No 16S ribosomal DGGE data are presented to confirm these cultures are actually axenic despite the fact that the techniques were used to assay bacterial abundance in other samples. It is on the basis of these data that it was concluded that bacteria-free *Pfiesteria* cultures produced toxin, thereby eliminating bacteria as the source of the toxin.

Another inference in the paper included data showing that *Pfiesteria* cell densities at a fish kill can be high  $(>1000 \text{ cell } mL^{-1})$ . The samples analyzed in Burkholder et al. 2005 were collected in 1998 and 2000 and analyzed years later. These samples stored in Lugols will have gradually deteriorated over time implying that the cell concentrations were even higher than reported. Interestingly these are the only qPCR data published from fish kill sites and are several orders of magnitude higher than previously reported by other investigators. Moreover, the 2000 sample obtained from a fish kill recorded in Arnell Creek, Delaware, had already been shown to contain large numbers of *K. veneficum* by qPCR (Humphries 2002).

Figure 13. Putative *Pfiesteria* toxin molecular framework. The approximate mass of this framework is 311 amu with a range up to greater than 700 amu. The L stands for ligands of diverse nature.

These data indicate that much research remains to be done in order to confirm the structure and source of "*Pfiesteria*" toxin, despite the fact that identical <sup>13</sup>C NMR spectra were shown from standard fish bioassay tanks and in the toxin description paper (Burkholder et al. 2005; Moeller et al. 2007). In 2007, Moeller et al. reported that they had purified the toxin from cultures grown on algae. Clearly a bioactive compound can be extracted from these cultures given that some unknown concentration was able to cause epithelial ulcerations (Figure 5 of Burkholder et al. 2005). The most important remaining question, however, is whether this bioactive compound is environmentally relevant and unique to *Pfiesteria*. The answer is likely to be no for the following reasons: 1) cell densities in nature are generally low (<10 cells mL<sup>-1</sup>) (Lin, Zhang and Dubois 2006) meaning that there are too few cells generally present to cause a problem even if the toxin proved highly potent, 2) the histology of lesioned fish from fish kill sites does not mimic that seen in the laboratory and is inconsistent with exposure to significant amounts of *Pfiesteria* toxin in the environment, 3) the toxin is very unstable which severely limits the period of effective exposure and 4) extensive epidemiological studies have found no evidence of adverse human health effects associated with this organism. Not until quantitative dose vs. mortality curves are established for the *Pfiesteria* toxin and the toxin is found to be present in the environment at quantities indicated by the dose mortality curve to be of concern, can a *Pfiesteria* toxin be considered of consequence ecologically or toxicologically. *Karlodinium veneficum* fish kills, occurring in the same locations as the "*Pfiesteria* kill sites", incidentally, have met all of the above criteria. Until a fish kill meeting the criteria can be found in which *K. veneficum* is not observed and only *P. piscicida* or *P. shumwayae* are found, can the "cell from hell" be implicated.

#### **CONCLUSION**

The emergence of the *Pfiesteria* issue in the late 1990's was highly controversial and had a major impact on research funding for harmful algal bloom issues. It spurred the rapid development and adoption of molecular techniques for detection, quantitation and monitoring of HAB species. *Pfiesteria* spp., PLDs and many other HABs are now readily identified and quantified in natural waters and sediment samples. This review of the available *Pfiesteria* literature to date forms the basis of the following conclusions regarding this controversial scientific issue.

- 1. *Pfiesteria piscicida, Pseudopfiesteria shumwayae* and related PLD's are not photosynthetic, but rather heterotrophic dinoflagellates (animal cells) that obtain C by the process of myzocytotic feeding on prey using a unique feeding structure called a peduncle.
- 2. Field investigations to date are at consensus and reaffirm the typically low abundance (<10 cells mL-1 ) of *Pfiesteria spp.* and other PLD's in natural estuarine systems.
- 3. The proximal causes of the mass finfish mortalities in Mid-Atlantic US estuaries during the late 1990's are unknown; however, their attribution to *Pfiesteria* spp. is not supported by the body of literature. More parsimonious hypotheses have been put forward including (a) hypoxia/anoxia events and/or (b) concurrent blooms of *K. veneficum,* a known producer of potent ichthyotoxins having been misidentified as *Pfiesteria*.
- 4. Attribution of ulcerous lesions in menhaden from Mid-Atlantic US estuaries to *Pfiesteria* toxin(s) is now contradicted by a large body of literature. Ulcers in menhaden are chronic (weeks old) lesions now understood to be caused by a highly pathogenic oomycete called *Aphanomyces invadans*. This pathogen is known to impact over 100 species of finfish and impacts wild and cultured fisheries worldwide.
- 5. The complex 35-stage life history initially ascribed to *Pfiesteria* is incorrect. More recent studies have shown these organisms to have simple life histories typical of other dinoflagellates. Amoebae and chrysophyte-like cysts identified as stages in the *Pfiesteria* life cycle are now known to be free-living microbial contaminants of the culture systems or the fish used in the original assay protocols.
- 6. The primary mechanism of *Pfiesteria* pathogenicity in finfishes is not secretion of potent exotoxins, but rather, the micropredatory feeding strategy employed by these organisms. If bioactive molecules are ultimately found to be produced by *Pfiesteria*  (as suggested in some studies), the body of literature indicates that it will likely be a minor component of finfish pathogenicity. In a captive environment like a bioassay vessel where the fish cannot escape, these dinoflagellates quickly attach to the epidermis and begin to feed, with resultant mortality being highly dose-dependent. It is unlikely that this occurs in the natural estuarine environment; however, we predict that impacts of these heterotrophic dinoflagellates will become more common under intensive recirculating finfish culture operations in the future.
- 7. The evidence for existence of a "*Pfiesteria*" toxin is weak. To date, the complete chemical structure of a *Pfiesteria* toxin has not been solved. Even if a toxin is present, it has not been isolated in pure form or demonstrated to produce the reported toxic effects. In addition, the low cell levels observed in nature suggest any negative impact on aquatic animals or humans from bioactive compounds produced by *Pfiesteria* would be negligible.
- 8. Human health impacts, although reported in the early literature, to date, have not been verified.
- 9. Given the well-established pathogenicity of micropredatory feeding, it is unlikely that a *Pfiesteria* toxin, should one be characterized, will be of significant consequence in causing fish mortality.

#### **ACKNOWLEDGMENTS**

This is VIMS contribution # 3867**.** This is contribution #5733 from the University of Maryland Center for Environmental Science, #20-001 from the Institute of Marine and Environmental Technology. The research results presented here were funded in part by grants from the ECOHAB STAR Program (R826791-01-0 to KSR and R828225-01-0 to WKV and KSR), as well as numerous contracts from the Virginia Department of Health (VDH) to KSR and WKV and from the US Center for Disease Control through VDH to KSR and WKV, OHH NIH R01ES021949-01/NSFOCE1313888 and NOAA-NOS-NCCOS-2012-2002987 to ARP, National Oceanic and Atmospheric Administration, National Ocean Service, Centers for Coastal Ocean Science, Centers for Coastal Ocean Science program funds to RWL. This chapter would not have been possible without the diligent help from Clara Robison who read many drafts and organized the references. Gail Scott and Patrice Hobbs also put in many hours helping with data for tables, finding the figures and tracking down the older references. We are grateful to them for all of their assistance. We also thank Dr. Thomas Harris, Dr. Mark Vandersea and an anonymous reviewer for their very valuable critical reviews.

## **ABSTRACT**

For decades, high densities of the dinoflagellate *Karlodinium veneficum* have been associated with aquatic faunal mortalities worldwide. This small  $(<8-12 \mu m)$  athecate phytoplankton, common in coastal aquatic ecosystems, has a mixed nutritional mode, relying on both photosynthesis and phagotrophy for growth (mixotrophy). It is frequently present in relatively low cell abundance  $(10^2 - 10^3 \text{ cells } \text{mL}^{-1})$ , but is capable of forming intense blooms of  $10^4 - 10^5$  cells mL<sup>-1</sup> that are often associated with fish kills. A suite of toxic compounds (karlotoxins) have been characterized, both in the laboratory and in the field, with hemolytic, ichthyotoxic, and cytotoxic properties. These toxins have been shown to generate pores in membranes with desmethyl sterols and increase the ionic permeability resulting in membrane depolarization, disruption of motor functions, osmotic cell swelling and lysis. The biological *raison d'etre* for karlotoxin production appears to be grazing deterrence and prey capture, both of which stem from the impairing effects of karlotoxin on susceptible organisms. Strain variation in types of karlotoxins and toxin cell quotas is extensive. Since the initial description of *K. veneficum* (FKA *Gymnodinium veneficum)* in 1956 by Dorothy Ballentine, toxic and nontoxic strains have been observed. Despite numerous name changes it is now clearly recognized as a cosmopolitan species with extensive ecosystem impacts. Current knowledge on the physiology, ecology, and life history of *K. veneficum* is summarized.

## **INTRODUCTION**

In the classic "Nature Adrift - The Story of Marine Plankton" by James Fraser [1] it is written,

*"A poisonous dinoflagellate lives in British waters: It is Gymnodinium veneficum, which has been grown in culture at the Marine Biological Station at Plymouth"* (Figure 1).

Figure 1. *Gymnodinium veneficium*, a dinoflagellate that produces a poison.

This statement is based on the work of B. C. Abbott and Dorothy Ballantine [2] who characterized the toxin activity of *G. veneficum,* to paraphrase their findings,

*"…The toxin molecule must be large, as it cannot penetrate a dialysis membrane; it is soluble in water and the lower alcohols, but insoluble in ether and chloroform. It is unstable in acids, … though in neutral solution is more or less thermostable. …With regard to mode of action it depolarizes nerve and muscle membranes. …This depolarization probably occurs by interference with the sodium exchange mechanism, allowing rapid entry of sodium into the cells."*

The discovery of this remarkable toxin began with the isolation of a small dinoflagellate from the region near Plymouth Sound, a bay on the English Channel at Plymouth in England (lat. N.  $50^{\circ}$  19'30," long. W  $04^{\circ}10'$ ), on June 8th, 1949 by Dr. Mary Parke (Figure 2, Left) of the Plymouth Laboratory of the Marine Biological Association. The following year on June 28<sup>th</sup> she isolated a second very similar dinoflagellate from the Hamoaze, over Rubble Bank, off King William Point, South Yard, Devonport (lat. N. 50° 21'50," long. W 04°10'55"). Both were deposited in the Type Culture Collection (Plymouth collection #102 and #103, respectively). Subsequently, Dorothy Ballantine (Figure 2, Right) described and named the two species, *Gymnodinium veneficum* and *Gymnodinium vitiligo.* Ballantine stated that neither species was shown to eat. The greatest difference between the two species was

physiological, as *G. vitiligo* was harmless and a good food for oysters, whereas *G. veneficum* produced a very powerful toxin which was lethal to fish and nearly every other organism tested including mice and a 3ft shark [2]. In 1957, B.C. Abbot and D. Ballantine described the partial purification and characterization of the toxin from *G. veneficum* [2].

Figure 2. Dr. Mary Parke (Left) and Dorothy Ballantine (Right).

## **Characterization of** *Gymnodinium (Karlodinium***)** *veneficum* **PLY103**

*G. veneficum* remained in culture at the Plymouth Laboratory until 2015 (See Figure 3 for photomicrograph taken in 2006). Fortunately, an opportunity to characterize the strain, examine its mixotrophic capabilities, and purify the toxin from PLY103 arose before it was lost. PLY103 was found to possess the ventral pore and apical groove diagnostic for *K. veneficum* (e.g., Figure 4C for CSC1). The internal transcribed spacer region (ITS) sequence of PLY103 was identical to that of CCMP 415 & 416 (Figure 4B) but differed by a 2-base insertion from all North American isolates (Figure 4A).

Figure 3. PLY103 taken in 2006 by J. Adolf. Scale bar =  $10 \mu m$ .

(B) A parsimony tree based on ITS sequences from 14 *K. veneficum* strains examined. Note that there are no sequence differences between the 11 strains from the U.S. Atlantic coast. (C) Photomicrography of CSC1 showing the ventral pore and apical groove found in all strains.

## **Pigmentation**

 $\overline{a}$ 

Ballantine [3] wrote:

*"The absorption spectra of total pigments, obtained from methanol extracts in a Unicam spectrophotometer are identical. Both show peaks at 444 and 673 mµ, with suggested peaks of pigments other than chlorophyll a at 425-430, 460-470 and 620-639 mµ."*<sup>1</sup>

As seen in Figure 5 and Table 1, the pigments from PLY103 and two additional European strains CCMP 415 & 416 are identical with the previous 14 strains of *K. veneficum* [4]. Each strain exhibited a complete absence of peridinin with the presence of fucoxanthin, 19' hexanoyloxyfucoxanthin, 19'' butanoyloxyfucoxanthin, and gyroxanthin diester pigments [5], similar to its sister genera *Karenia* and *Takayama*. Different from *Karenia* were the nearly equivalent quantities of the two gyroxanthin diesters in all North American strains of *K. veneficum* but not seen in PLY103. The UV spectra were identical for both gyroxanthin diesters peaks, and the LC–MS analysis using APCI ionization found an identical mass

<sup>1</sup> Note. The correct unit used today for *mµ* is *nm*.

(m ⁄ z 866) for both peaks. These two peaks were therefore attributed to the 9-*cis* and all *trans*  gyroxanthin diesters isolated from *K. veneficum* (*Gymnodinium galatheanum*) and characterized by Bjørnland et al. [6].

When we performed a factor analysis of the pigment profiles, a clear separation between the North American strains and European strains was evident (Figure 5 A&B). Factor 1 accounted for 30% of the variance in the pigment ratios data and was loaded with 19- hexanoyloxyfucoxanthin, 19- butanoyloxyfucoxanthin, gyroxanthin diester, chlorophyll c2, and fucoxanthin (Figure 5A). Factor 2 accounted for an additional 30% of the variance in the pigment ratios data set and was loaded with: chlorophyll c3, carotene, and *cis*-gyroxanthin diester (Figure 4A).

The biplot of factor 1 versus factor 2 scores (Figure 5B) shows a tight cluster along the factor 1 axes and contains all *K. veneficum* strains except 415 and CSC1, indicating that *K. veneficum* strains from the eastern seaboard of the U.S.show similarities among their fucoxanthin:chl a ratios and their *cis*-gyroxanthin diester:chl a values.

Figure 5. HPLC pigment analysis of PLY103, CCMP 415 and CCMP 426. Pigment designations are: Chl c3 (chlorophyll c3), Chl c2 (chlorophyll c2), Chl c1 (chlorophyll c1), Per (peridinin), But (19'-butanoyloxyfucoxanthin), Fuco (fucoxanthin), Hex (19'-hexanoyloxyfucoxanthin), Diadino (diadinoxanthin), Zea (zeaxanthin), Chl a (chlorophyll a), β-Car (β-carotene). Factor analysis of accessory pigment: Chl a ratios for strains of *K. veneficum* and an outgroup, *K. mikimotoi*. (A) Factor loadings, indicating two axes of variability within the pigment ratios data set. Points grouped along either the x- or y-axis are positively correlated to each other, while points opposite each other along either axis are negatively correlated. (B) Factor scores biplot. Clustered points are similar with regard to the attributes represented by factors 1 and 2, while separated points differ.

chlorophyll *a*

### **The Toxin from** *Gymnodinium veneficum***: It's a Karlotoxin**

Karlotoxins are released by filtration of cells on glass fiber filters, and can be removed from the filtrate by adsorption to C18 resins, and are eluted by 60 to 80% methanol/water solutions [7]. On a C8 reverse phase HPLC separation using a methanol to water gradient, karlotoxins in the methanol fractions are detected through their UV absorption at 225 nm (KmTx 1) and/or 235 nm (KmTx 2) with little UV absorption at 280 nm. Biologically active fractions are detected through hemolysis of red blood cells. In these HPLC runs an additional later-eluting peak is frequently observed when growing cultures in natural seawater. This peak produces multiple MS ions differing by 44 daltons (DA) and is likely to be a plasticizer polymer contaminant which shows hemolytic activity.

Figure 6. Reverse phase HPLC chromatogram of PLY103 80% methanol fraction assessed by absorbance at 225 nm. The individual fractions collected simultaneously were assayed using a hemolytic assay (bars). The blue arrow to the left indicates the fractions used to solve the structure of the resulting karlotoxins which are shown on the right.

Like Abbot and Ballantine [2], 85 to 90% of toxic activity was found to be released from PLY103 upon filtration and can be purified exactly as previously described for karlotoxins [7]. Hemolytic activity can be used in guided bioassay fractionation and purification (Figure 6). Two structures were elucidated using similar techniques as those previously described [8]. *Karlodinium veneficum* PLY103 produces KmTx 4 and chloro-KmTx 4 karlotoxins which are hemolytic to rainbow trout erythrocytes and found in nearly equivalent cell quotas (0.93 pg/cell vs 1.25 pg/cell). This is a relatively high cellular toxin quota among known *K veneficum* strains [4]. These structures are the smallest congeners elucidated to date and differ significantly from KmTx 2 in the C1-C18 region. KmTx 4 and chloro-KmTx 4 differ from each other only by the absence of a chlorine on the terminal diene of KmTx 4. The structure is five carbons shorter than KmTx 2, all in the polyol region.

### **Karlotoxin Identification for the Norway Strains**

We find the two strains from Norway produce different hemolytic toxins with CCMP 415 toxin having a 225 nm absorption maximum (KmTx 4) and a molecular weight of 1231.7 amu (M+Na) and CCMP 416 toxin having a 235 nm absorption maximum (KmTx 2) and a molecular weight of 1367.8 DA (M+Na) which is identical to the previously described KmTx 2. The toxin from CCMP 415 elutes (Figure 7A) earlier from the C8 column than the karlotoxins detected in the North American strains (i.e., KmTx 2). As with the North American KmTx 2, the toxins from CCMP 416 co-elute as hydroxylated congeners containing mass ions that are 16 DA larger, as well as other less abundant ions (Figure 7B).

Figure 7. (Left) Reverse Phase HPLC Chromatogram of the hemolytic (bars) fractions from CCMP 415 (A), CCMP 416 (B), and CSC1 (C). CSC1 is nontoxic. (Right) MS spectra of hemolytic fractions from CCMP 415 (A) and CCMP 416 (B). Based on the mass spectra CCMP 415 makes Kmtx 4 while CCMP 416 makes KmTx 2.

#### **Karlotoxin Potency**

Using a hemolytic assay of fish red bloods cells the potency of purified toxins from the Norwegian strains were examined using a dose response curve with purified karlotoxins (Figure 8). In all cases the purity of each karlotoxin exceeded 90% based on UV chromatographs. It should be noted that each karlotoxin examined possessed a suite of hydroxylated congeners. Fitting the data from the hemolytic assays to a Hill Equation provides estimates for the karlotoxin concentration giving 50% hemolysis (HD50%). There was nearly a 500-fold difference in hemolytic potency (HD50%) between the most active (KmTx 1) and least active (CCMP 415) karlotoxin. The overall ranking was KmTx 1  $>$ KmTx 3 > KmTx 2, CCMP 416 > CCMP 415, KmTx4 > Saponin (on a per weight basis).

Figure 8. Comparative hemolytic activity for the karlotoxins isolated from the Norwegian strains using rainbow trout erythrocytes compared to saponin (Top). Comparative hemolytic activity for karlotoxins isolated from North American strains compared to saponin and amphidinol (Bottom). Note the logarithmic scale for toxin amount. The fitted line is based on the Hill equation, and the HD50% estimates for the fitted curves are presented in the legend.

#### **Determination of Goby Kill Units**

In order to compare different batches of toxin extracts, Abbott and Ballantine [2] defined a toxin unit "*approximate lethal concentration"* necessary to cause death in 10-20 minutes for gobies *(Gobius niger* and *Gobius virescens).* Since these species of goby were not available to us, we used *Gobiosoma bosc* to determine the unit equivalency for KmTx 2. From exposures to *G. bosc* we determined that a kill unit is equivalent to 700 ng and a time to loss of balance is 355 ng for KmTx 2 (Figure 9). Using this conversion, we estimate that Abbott and Ballantine's most toxic extract contained  $4.2 \mu g/ml$  of KmTx 4 and chloro-KmTx 4.

Figure 9. The original Figure 1 from Abbott and Ballantine*.* [2] Assay curve for toxin strength using gobies. Curve a, time to complete loss of balance in fish. Curve b, time to death. Extremes shown by vertical lines. Concentration in arbitrary units defined in text [2].

#### **Sterol Dependency of Toxicity**

In amazing forsight, Abbott and Ballantine [2] found adding an ethanol suspension of cholesterol (0.2 mg/ml) to the goby bioassay completely inhibited death for a 4 unit exposure to gobies. Consistent with this finding we find that cholesterol also inhibits hemolysis karlotoxins in a concentration dependent manner but the endogenous sterol in *K. veneficum* including PLY103, gymnodinosterol (Figure 10), poorly inhibits hemolysis [9]. Hence, toxic *K. veneficum* strains have a protective mechanism against self-intoxication and sterol dependent lysis through their unique 4α-methyl sterol profiles. In contrast, all known prey for *K. veneficum* possess des-methyl sterols [10].

(24S)-4 $\alpha$ -methyl-5 $\alpha$ -ergosta-8(14), 22-diene-3 $\beta$ -ol

Figure 10. Gymnodinosterol, the dominant sterol of *K. veneficum*.

### **Can PLY103 Eat?**

Although Ballantine [3] reported that in her strains of *Gymnodinium veneficum 'Ingestion has not been observed, though both species have been given a large variety of food, both natural and artificial'*, *K. veneficum* is now recognized as what Mitra et al. [11] refers to as a constitutive mixotroph – a phagotroph that has inherent phototrophic capabilities. In the case of *K. veneficum* this is expressed as the capacity to grow phototrophically in inorganic nutrient media, coupled with the ability to grow as much as 2-3 fold faster when also feeding on particulate prey (often cryptophytes in experimental work), [12–14]. During mixotrophic growth, the relative contribution of phototrophy declines and heterotrophic C acquisition dominates growth [15], with some strains capable of prolonged survival under pure heterotrophic conditions [14]. We found that *Karlodinium veneficum* PLY103 did not feed on any of ten cryptophyte strains tested, which ranged in size from 3.9 μm to 9.3 μm equivalent spherical diameter, although 13 other *K. veneficum* strains, including CCMP 415 & 416, did feed on these cryptophytes under similar conditions [16]. Changing culture medium (from Erdschreibers to ESAW) and salinity did not change these results. This result confirms the original observation of Ballantine [3] that PLY103 is not phagotrophic, and is evidence against prolonged maintenance in culture as a reason for 'losing' the ability to feed.

Prior work had confirmed the production of karlotoxin by PLY103 [17], but the effects of different culture conditions on growth and toxicity had not been previously characterized. PLY103 had been maintained in Erdschreiber's growth medium long term at the PCC, a general purpose seawater medium that contained a soil extract. Transfer of *K. veneficum*  PLY103 to a controlled, artificial seawater medium was attempted in order to produce a more stable culture for shipping, which was unsuccessful, and to characterize nutritional effects on growth and toxicity. Modified Enriched Seawater Artificial Water (ESAW) medium [18] with 880 μM NO3, 34 μM PO4, 1 mM HEPES buffer, pH 8.0 was prepared (ESAW 'Complete'). Alternative ESAW medium was also prepared containing  $1/10$ th N (-N),  $1/10$ th P (-P), no Se (-Se), or alternative sole nitrogen sources, 54  $\mu$ M NH<sub>4</sub>, or 27  $\mu$ M urea (NH<sub>2</sub>)<sub>2</sub>CO, or sole P source of 2.1 μM glycerophosphate (GP). PLY103 was transferred in ESAW complete medium by pipeting 6 ml of the PLY stock culture (maintained in Erdschreiber's medium) into 30 ml of ESAW complete that had been pre-cooled to 15°C. These cultures were

monitored for four days and then diluted again with the appropriate ESAW medium 9:1, resulting in a final 98.4% dilution of the initial medium. PLY cryptophytes in wells of a 24 well plate (in Erdschreiber's medium) were diluted 50% (1 ml) with ESAW complete and then this was used to inoculate 15 ml of ESAW complete the next day. After the first dilution of PLY103 from Erdschreiber to ESAW, all cultures grew well, likely due to carry over effects from the inoculation. Effects of the ESAW varieties of medium on growth of PLY103 were recorded after a second 10x dilution that occurred four days following inoculation. Growth rate was highest in ESAW complete and lower in other ESAW varieties (Figure 11). Cell yield was highest in ESAW complete, -N and -P, and lower in NH<sub>4</sub>, -Se, Urea, and GP medium. Examination of cellular toxin quotas  $(KmTx4 + chloro-KmTx 4, pg KmTx cell<sup>-1</sup>)$  as a function of growth rate (Figure 11) in the different varieties of ESAW medium produced a negative trend. The ratio of KmTx4 /chloro-KmTx 4, ranged between 0.15 and 0.28 and was not correlated with growth rate. Growth in ESAW medium with  $NH<sub>4</sub>$  as the sole N source produced the most toxic cells at both the day four and final timepoints (14 days). These results are consistent with the idea that slower growth rates equate to more toxic cells. Another way to look at this is that toxin synthesis proceeds out of balance with cell division under culture conditions that slow or halt cell division. Further evidence of this is the observation that the total KmTx yield in the different ESAW cultures was relatively constant  $(301 \pm 96.0)$  ng KmTx ml-1. The data also suggest that NH4 may be an elicitor of KmTx as values were higher than for other nutrient treatments that grew at similar growth rates.

Figure 11. Growth rate and cellular KmTx quotas for PLY103 upon transfer from Erdschreiber's to different varieties of ESAW growth medium. Red triangle symbols are values measured after the first dilution (4d). Some symbols overlap and are not visible. Black circle symbols are final measurements made after an additional dilution in respective ESAW media and an additional 10d of growth.

## **Toxin Production during Batch Culturing for the Norwegian Strains**

We observed a generally stable or increasing toxin cell quota as cells moved from exponential to stationary or senescent growth phase in most strains of *K. veneficum* [4]. For the two Norwegian strains, CCMP 415 and 416, toxin cell quotas remained reasonably constant throughout the growth curve (Figure 12). Both the division rate ( $\mu$ , 0.35  $\pm$  0.072 vs  $0.27 \pm 0.029$ ) and maximum densities (321  $\pm$  53.92 vs 78.0  $\pm$  16.9 X 10<sup>3</sup> cell mL<sup>-1</sup>) were greater with CCMP 415 than CCMP 416. The Spanish isolate CSC1 produced no toxin and had significantly lower division rates ( $\mu$ , 0.11  $\pm$  0.053) and maximum densities (68.3  $\pm$  14.8  $X$  10<sup>3</sup> cell mL<sup>-1</sup>). Both CCMP 415 and CCMP 416 have been shown to eat cryptophytes [16]. In this study no attempt was made to determine the optimal growth conditions for each strain but rather to compare them under uniform laboratory conditions so these data do not necessarily define the maximum toxin production for each strain.

Figure 12. Growth rate (filled circles) and cellular KmTx quotas (filled squares) for *K. veneficum*  CCMP 415 and 416.

### **Genome Size Variation in** *K. veneficum* **Strains**

Consistent with extensive strain variation in growth rates, pigments, phagotrophic ability, types of karlotoxins and toxin cell quotas in *K. veneficum* [4]*,* we find genome size varies among strains (Figure 13). Dinoflagellates generally have large, unusually-structured genomes compared to most other eukaryotes [19, 20]. But as with most protists, genome size in dinoflagellates seems to correlate well with cell size [21, 22]. Therefore, a relatively small dinoflagellate like *K. veneficum* would be expected to have a relatively small genome, and that is more or less the case. Genome sizes among *Karlodinium* spp. strains were determined by Parrow et al*.* [23], using flow cytometric measurement of cellular DNA content as compared to a trout erythrocyte nuclei DNA standard (Figure 13). The measured basal (1C, functionally haploid) genome size measured in picograms of *K. veneficum* strains varied significantly from  $7.8 \pm 0.7$  pg DNA cell<sup>-1</sup> in a strain from Norway (CCMP 415) to  $14.7 \pm 1.5$ pg DNA cell<sup>-1</sup> in a strain from Spain (CSIC-1). The five tested strains from the U.S. eastern coast (Maryland to South Carolina) also differed significantly from these European strains, but not from one another, with an average 1C genome size of  $11.2 \pm 0.6$  pg DNA cell<sup>-1</sup>. The estimated 1C genome size of *Karlodinium armiger* (GC-3) was  $32.9 \pm 2.4$  pg DNA cell<sup>-1</sup>, significantly higher than any *K. veneficum* strain. It was notable that CCMP 415 from Norway, which may be the type specimen for *K. veneficum* (given the loss of PLY103) [24, 25], had a significantly smaller genome size than the other strains, making it a good potential candidate for genome sequencing. This strain has also been in culture the longest (since 1976), but does make low levels of toxin (see Figure 7). An apparent trend towards genome size reduction with extended time in continuous culture has been observed among strains of some dinoflagellates [26, 27], but not in others [21, 28]. Although no cause or mechanism for genome size changes are known to be attributed to clonal cultivation, natural selection likely influences genome size over time [29], and selective forces over long periods of time in serial culture are likely not the same as those acting on wild populations out in nature.

Figure 13. 1C DNA mass/genome size estimates for *Karlodinium spp.* strains. All are currently considered to be *K. veneficum*, with the exception of GC-3, which is *K. armiger* [33]. Locations of strain origins are given. Bars are **±**1 SD. Parrow et al. [23]

Lajeunesse et al*.* [21] also measured genome size by flow cytometry of two of the same *K. veneficum* strains from the eastern US coast (CCMP 1974 and 2282) by flow cytometry and reported higher values of  $16.9$  and  $16.3$  pg DNA cell<sup>-1</sup>, respectively. However, Lajeunesse et al*.* [21] used a different, smaller DNA mass standard in their studies than Parrow et al. [23] (chicken red blood cells versus trout erythrocyte nuclei), and furthermore, chose a high estimate of DNA mass for chicken red blood cells of 3.0 pg DNA based on [30]. Their values would have been lower and in close agreement with Parrow et al*.* [23] had they assumed a lower chicken red blood cell DNA standard mass of 2.33 pg (as in [22, 27, 31, 32]). The significantly higher genome size of *Karlodinium armiger* [33] from coastal Spain reported by [23] was confirmed by flow cytometry with a very similar estimate of 34.8 pg DNA cell-1 [34]. This same study found two strains of *K. veneficum* from coastal Spain to have genome sizes of 19.9 – 22.4 pg cell<sup>-1</sup>, higher than any U.S. strain. Figueroa et al. [34] used a previously published genome size for the dinoflagellate *Scrippsiella hangoei* as their DNA mass standard, which would be tied back to an estimate based on DNA fluorescence relative to triploid trout erythrocyte nuclei [35]. The three different studies on genome size in *Karlodinium* spp. dinoflagellates to date each used different DNA mass standards and different DNA fluorophores: SYBR green [23], DAPI [21], and propidium iodide [34]. Such differences in standards, and DNA flurophores (i.e., 'intercalating' dyes with little or no sequence preference such as SYBR green and propidium iodide versus 'non-intercalating' dyes such as DAPI (binds preferentially to AT-rich sequence)), and even factors such as dye concentration and incubation duration can affect relative estimations of target cell DNA fluorescence [22, 27, 30, 35].

These differences in technique may account for some of the variability in reported genome sizes for *K. veneficum*. However, the half-peak coefficients of variation (CV's) and/or standard deviations reported for the target cell DNA measurements in each of these studies were quite acceptable as compared to previous studies on protists (reviewed in [26] and even DNA measurements for clinical pathology [36], a strong indicator of high quality/certainty in the genome size estimates. Intraspecific variability in genome size has been measured for other protists, especially when isolates from different geographic regions were included in the analysis [27, 32, 37–39]. Hayhome et al*.* [38] suggested that this variation may due to clonal isolation and high degree of genetic redundancy in dinoflagellate genomes, allowing them to tolerate a less than precise division of nuclear DNA during cell division. Alternatively, since genome size is generally thought to be a well-conserved biological parameter in a given species, these data may indicate that not all of the strains presently regarded as *K. veneficum* are the same species. The high degree of variability in physiological parameters found among *K. veneficum* strains certainly suggests that numerous 'ecotype species' may occur [4, 14].

Overall, the *K. veneficum* genome size range  $(7.8 - 22.4$  pg cell<sup>-1</sup>) as determined so far falls near the range of genome sizes reported for other dinoflagellates of similar size. For example, similarly sized and geographically-overlapping dinoflagellates *Pfiesteria piscicida* and *P. shumwayae* ( $\sim$ 7-17 µm in diameter) [27, 35] have 1C genome sizes of 6.7  $\pm$  1.1 and  $16.2 \pm 1.7$  pg DNA cell<sup>-1</sup>, respectively [27]. Similarly-sized *Prorocentrum* species range from 6.9 – 8.3 pg DNA cell-1 , along with *Polarella glacialis* (7.0 pg DNA cell-1 ), and *Gymnodinium simplex* (11.6 pg DNA cell-1 ) (reviewed in LaJeunesse et al. [21]. *K. armiger* is larger in size than *K. veneficum*, and has a larger genome size (32.9 – 34.8), closer to the similarly-sized *Alexandrium minutum* (29.9 pg DNA cell<sup>-1</sup>) [23, 34]. Very small (6-9 µm

diameter) Symbiodinium spp. dinoflagellates can have genomes as small as 1.9 pg cell<sup>-1</sup> [21]. Much larger dinoflagellates can have genomes as large as 250 pg cell<sup>-1</sup> [21, 22, 40], although such massive genomes may reflect increased redundancy rather than gene coding capacity [41].

### **DNA Base Composition Variation in** *K. veneficum* **Strains**

When Peter Rae set out to described the ribosomal gene arrangement in the dinoflagellate *Crypthecondium cohnii* he noticed a large discrepancy between the GC content as determined by buoyant density *versus* the T<sup>m</sup> of the melting curve for the isolated DNA [42]. He was able to explain this discrepancy when he found the thymidines (T) were extensively replaced by the modified based 5-hydroxylmethyluracil (hmdU; Figure 14). This base has the effect of raising the density and lowering the thermal stability of the DNA. Rae went on to show this replacement was a natural feature of all dinoflagellates he examined and is now considered a diagnostic character for the phylum. Consistent with other dinoflagellates, *K. veneficum* exhibits extensive replacement (51.6 - 66.9%; Table 2) of thymidine by 5-hydroxylmethyluracil in its genomic DNA [43, 44].

Figure 14. 5-Hydroxylmethyluracil (hmdU).

**Table 2. Percent GC and 5-Hydroxylmethyluracil content in genomic DNA**

<b>Strain</b>	<b>Percent GC</b>	Percent hmdU of hmdU plus dT
<i>Karlodinium veneficum</i> (Plymouth 706)	51.6	34.9
Karlodinium veneficum (CCMP 2778) ( $N=4$ )	52.7	43.2
Karlodinium veneficum (CCMP 1609)	66.9	35.5
Karlodinium veneficum (CCMP 2936) ( $N=4$ )	53.5	25.6

#### **Cell Cycle**

*In situ studies of K. veneficum* cells progressing through the cell cycle are rare. Garcés et al*.* [46] studied a field bloom in the Mediterranean sea of what was then called *Gyrodinium corsicum* [47] via microspectrophotometry, and reported that the cell division cycle was wellphased with the ambient light: dark cycle. In the blooming population, cells in S-phase reached a maximum abundance near the middle of the dark period, and the G2+M maximum

fraction occurred at the end of the dark period. Both fractions had a maximum of 15-39% of the total population over the sampling period. The duration of S-phase was computed to be 2.1-8.7 h, and G2+M phase lasted 2.6-7.7 h. These data were later understood to likely be averaged values from a mixed population of *K. veneficum* and *K. armiger* [33], taxa with broadly differing genome sizes and growth characteristics, but nevertheless showed a distinct *Karlodinium* spp. population level cell cycle progression that was strongly linked to the photocycle.

Cell cycle progression was also studied in multiple geographic strains of *K. veneficum* in culture via flow cytometric analysis of cells stained with the DNA fluorophore SYBR Green [23, 45]. Each strain exhibited distinct 1C, intermediate, and 2C DNA subpopulations indicative of respective eukaryotic cell cycle phases G1, S, and G2M that were tightly synchronized to the light:dark cycle (Figures 15 and 16) with very good G1 DNA peak CV's of  $6.8 - 9.2\%$ .

In logarithmically growing *K. veneficum* cultures, a cohort of cells in G1 phase enter S-phase every 24 h near the end of the light cycle (Figure 17). S-phase required approximately 4-5 hours for completion, and then the cells entered  $G2+M$  phase.  $G2+M$ phase required approximately 5 hours for completion, and the cells completed cell division during the end of the dark period. By the beginning of the next light period, >95% of cells were in G1. The proportion of cells entering S-phase each cycle in exponential phase cultures was approximately 15-45% of the total, and those cells that did not enter S-phase were apparently entrained in G1 until the next photocycle (Figure 15). Stationary phase *K. veneficum* cells arrested in G1, as is typical for eukaryotes. Therefore S and G2+M phases in *K.veneficum* occur during the dark period and have distinct durations, whereas the cellular growth (G1) phase occurs primarily during light but has a variable duration depending on growth (or non-growth) conditions.

DNA Fluorescence (AU)

Figure 15. Cell cycle phases and progression of *K. veneficum* (CCMP2282) over time, showing relative proportions of cells in G1, S, and G2M phases. AU = arbitrary units [23].

Figure 16. *K. veneficum* (CCMP 415) cell cycle phase fractions G1, S, and G2M over 48 h showing diurnal entrainment with light-dark cycles. Curves are 5<sup>th</sup> degree polynomials fitted to the phase fraction data. G1 maxima occur in light, G2+M maxima occur in darkness, and S-phase maxima occur at the light-to-dark transition [23].

**Relative DNA (AU)** 

Figure 17. Representative flow cytometric histograms of forward light scatter versus relative DNA fluorescence measured every 3 h over 45 h for a strain of *K. veneficum* (CCMP 415). The pattern of phased cell cycle progression is demonstrated, with S-phase being constrained to a specific portion of the diel cycle. TN = trout nuclei, an internal DNA standard;  $AU =$  arbitrary units [23].

Therefore, both a field study [46] and culture studies [23, 45] are in general agreement on both the photoperiodicity and cell cycle phase proportions and durations in growing populations of *K. veneficum*. Other cell cycle studies on *K. veneficum* either did not measure cell cycle progression but rather infer ploidy [34], or examined whether an algicide would disrupt the cell cycle [48]. In regards to natural growth of *K. veneficum*, a major question yet to be addressed is the potential influence of mixotrophic nutrition on cell cycle progression. During mixotrophic growth cryptophytes provide significant contributions to the carbon, nitrogen, and phosphorous needs of *K. veneficum* [49], and significant differences in net growth of *K. veneficum* have been reported when comparing strains growing autotrophically  $\sim$  0.3 divisions day<sup>-1</sup>) versus when feeding on cryptophyte prey  $(\sim 0.9$  divisions day<sup>-1</sup>) [12]. The higher growth rates observed under mixotrophic conditions suggests that either a compression of the duration of certain cell cycle phases or a decoupling of the cell cycle and photocycle occurs during mixotrophic growth. If so, this could greatly impact our understanding the role of mixotrophy in K. veneficum bloom development.

## **Cell Cycle and Toxicity**

The biosynthetic pathway for karlotoxin production is currently unknown, but previous research has shown that cell quotas of karlotoxin can vary widely among different bloom and cultured populations, and within populations over time [4, 50]. Deeds et al*.* [51] observed 10-fold higher cell karlotoxin quotas in natural samples compared to clonal cultures. Significantly, research has demonstrated that *K. veneficum* karlotoxin cell quotas increase in stationary and declining phase cultures (Figure 18), particularly under growth-limiting conditions as caused by low N, P, or the micronutrient selenium [50]. In particular, it was determined that *K. veneficum* cellular quotas of karlotoxin increased 6-fold or more in stationary or declining phase cultures, and that in general, cellular karlotoxin accumulation was inversely related to growth rate. If extrapolated out into the field, these results suggest that environmental conditions that favor slowed or halted growth (e.g., stationary phase bloom populations) also favor cellular accumulation of karlotoxins, and are likely a significant factor underlying *K. veneficum*-related fish kills that require both high cell densities and higher cellular karlotoxin quotas than those generally observed in nutrient replete cultures [50]. Furthermore, it has been found that karlotoxin production is lightdependent (Figure 19), and excess reduced carbon chains produced by photosynthesis are quickly incorporated into karlotoxin molecules (Place, unpub. data). It is important to note that the molecular structure of karlotoxin does not contain N, P, or other nutrient known to typically limit phytoplankton growth but does start with glycolate, a photorespiration product. So enzymatic biosynthesis of karlotoxin could conceivably continue using only photosynthetically-reduced  $CO<sub>2</sub>$  and water even under conditions where low N or P limits production of nucleic acids and proteins needed for cell proliferation.

Although the influence of cell cycle events on toxin production in harmful algae has been studied in relatively few species, in each case it was found that toxin synthesis was phased to specific portions of the cell cycle. In *Alexandrium fundyense*, saxitoxin synthesis was restricted to 8-10 h in the G1 phase of the cell cycle [52]. In *Prorocentrum lima*, DTX4 production began in G1 and persisted into S phase, whereas DTX1 production occurred later during S and G2 phases [53]. In *Chrysochromulina polylepis*, toxicity was highest in G1 phase [54]. In most species, the photocycle had a clear role in synchronizing the cell cycle and thus toxin synthesis. These and other results suggest a simple but strongly predictive inverse relationship between the rate of cell proliferation and cellular toxin accumulation in toxin-capable *K. veneficum* cells and populations, wherein rapidly proliferating *K. veneficum* cells exhibit relatively low karlotoxin quotas while growth-limited (slowly or nonproliferating) *K. veneficum* cells arrest in G1 for multiple light/dark cycles, undergo several cycles of light-induced karlotoxin synthesis, and become significantly more toxic. This model has yet to be tested for *K. veneficum*, or for any other HAB species: we know of no previous studies that have quantifiably correlated HAB toxin production with *in situ* growth rates in natural bloom populations. Doing so for *K. veneficum* could be a big step forward in explaining why some bloom populations are highly toxic while others seem less so: the most toxic cells might be the ones that are not growing, but just persisting.

Figure 18. Example of KmTx cell quotas in different stages of *K. veneficum* culture growth. Adolf et al. [50].

# **Life Cycle**

#### *Asexual Reproduction*

Life cycle observations for *K. veneficum* began with the first paper describing the species in 1956 [3]. In this seminal paper, under the section "*Notes on Cell Division,*" Ballantine described and drew the gross morphology of cell division, and also (unwittingly) drew a stage of gamete fusion (Figure 20). As depicted, cell division in *K. veneficum* begins with a cleavage indentation at the antapex of the hyposome that proceeds through the cell towards the cell apex. Cells in the process of division thus appear to have a broad, split hyposome. In culture, dividing cells typically swim less vigorously than non-dividing cells [3]. Once the division plane reaches a point above the cingulum, division proceeds from both ends of the cell and the two offspring cells are left connected by a cytoplasmic channel at their episomes. The cells swim connected this way for a short duration (minutes), often orienting themselves at right angles to one another, until the connection breaks and the offspring cells are freed. The entire cell division process takes only 2-3 h to complete [3], or as little as 1.5h (Parrow pers. obs.). Since it also typically occurs late at night in cultures grown on a light: dark cycle (and in field blooms) [45, 46] cell division in *K. veneficum* can be easily missed, although early-morning observation of cultures often allows some stragglers or failures in the process to be viewed.

Figure 20*. K. veneficum* cell division stages as reported by Ballantine [3], then as *Gymnodinium veneficum.* This sequence is correct except illustration 14, which depicts gamete fusion, not cell division as interpreted.

Figure 21. Flagellar, nuclear, and cell division in *Karlodinium veneficum* as depicted by Leadbeater and Dodge [55], then as *Woloszynskia micra*. Nuclear and cell division occur simultaneously, and offspring pairs remain briefly attached at their episomes.

Ten years after Ballantine described *K. veneficum*, Leadbeater and Dodge [55] used this dinoflagellate (provided to them by Dr. M. Parke at the Plymouth Laboratory) to study mitosis by transmission electron microscopy in one of the first studies of its kind. Aside from providing details on how the nuclear envelope remains intact during mitosis and is penetrated by microtubule-containing cytoplasmic channels, they also confirmed the observations of Ballantine [3] on the morphology of cell division, and added that nuclear and cell division occur simultaneously in *K. veneficum*. (Figure 21). Ribosomes and mitochondria were observed inside the trans-nuclear mitotic channels (!), [55] and this was at a time when it was still openly wondered if dinoflagellates might occupy an intermediate position between prokaryotes and eukaryotes [56].

### *Sexual Reproduction*

The first depiction of a sexual stage in *K. veneficum* was drawn by Ballantine [3], who interpreted it as cell division (Figure 20, inset 13). It is clear from her writing that Ballantine was uneasy with her placement of this observation, as it does not fit with the rest of her described sequence of cell division. By her description, indentation of the cell apex does not occur until cleavage from the antapex has proceeded "*to a point above the girdle.*" The cell(s) depicted in her Figure 14 does not fit that description, and, furthermore, is the only proposed "ventral" view in the sequence. In fact, what she depicted was not cell division but rather the typical morphology of gamete fusion in *K. veneficum*. It is also not a ventral view as described, but a lateral view, from the side of the two fusing gametes, with a clear illustration of the 'copulation globule" between them, predating von Stosch's description [57]. In Ballantine's [3] defense, sexuality in dinoflagellates was essentially unknown when she made her observations [57, 58], so it may be understood why she considered all paired cells as a stage of cell division.

Figure 22. *K. veneficum* cells, from field samples of the Neuse River Estuary, NC. Scanning electron micrographs of (A) a biflagellate dinospore and (B) a quadriflagellate planozygote showing two transverse and two longitudinal flagella. Scale  $bar = 1 \mu m$  [Photos by M. Parrow].

Sex and meiosis in *K. veneficum* was reported by Parrow et al*.* [45], who first became aware of sex in this dinoflagellate (and, of its very existence) due to a graded project in a hands-on electron microscopy course in graduate school in the late 1990's. The specimens of choice for his project were mixed dinoflagellates from a field sample in a North Carolina estuary, and the best pictures he developed (on film, in the darkroom) were of dinoflagellates he later realized were most likely *K. veneficum* (then as *Gyrodinium galatheanum*) (Figure 22). The most significant of the specimens photographed was a relatively large cell with two transverse and two longitudinal flagella (Figure 22B), which was, of course, a planozygote. Beginning with von Stosch [57], a feature consistently known to be displayed by motile dinoflagellate zygotes is retention of the both longitudinal flagella from the two component gametes that formed them, allowing planozygotes to be presumptively identified and equated with sexuality in both cultures and field populations (reviewed in Parrow and Burkholder [59]. What is less common, or at least less commonly observed, is retention of both transverse flagella as well, making the planozygote quadriflagellate. *K. veneficum* is special in this regard, but not unique [60].

Since then, all known sexual stages in the life cycle of *K. veneficum* have been documented [45] (Figure 23). Gamete fusion can be found in most, but not all, *K. veneficum* cultures, particularly in dense, healthy populations. The gametes are pigmented, in the smaller end of the size range for *K. veneficum* cells, and essentially isogamous. Fusion takes place by mid-ventral union of gametes, a morphology that is quite different from cell division and thus easy to distinguish (Figure 23). This mid-ventral fusion of gametes is very similar to that of *Gymondinium pseudopalustre* (= *Biecheleria pseudopalustris*) [57, 61], *Gyrodinium uncatenum* (= *Levanderina fissa*) [60, 62], and *Polykrikos kofoidii* [63]. Like them, *K. veneficum* gamete fusion begins with formation of an attachment structure in the ventral/sulcal area that may be homologous to the "copulation globule" described by von Stosch [57] (Figure 23 B and F). This structure was also clearly illustrated by Ballantine [3] (Figure 20, inset 13). *Karlodinium veneficum* gametes orient ventrally for fusion, but the two gametes do not need be oriented in the same direction to fuse. Fusions often occur with gametes oriented ventrally but pointed in opposite directions (Figure 23 B and F), or at right angles to one another. Fusion is completed in about 1 h, with karyogamy immediately following plasmogamy, resulting in a quadriflagellate planozygote. Altogether, the morphology of life cycle events in *K. veneficum* match very closely with Coats et al*.*'*s* [60] descriptions for *Gyrodinium uncatenum* (= *Levanderina fissa*) (Figure 24). Similarities between *K. veneficum* and *Levanderina fissa* include morphology of cell division and fusion, retention of four flagella by the planozygote, a similar feeding process involving sulcal phagotrophy, and even the appearance of delicate surface striations on some cells (e.g., upper gamete hypocone in Figure 24B). These features should be investigated for homology.

Figure 23. Scanning electron (A-C) and light (D-G) micrographs of *K. veneficum* life cycle stages. (A) Early asexual cell division. (B) Gametes in early fusion. Note mid-ventral union and formation of a "copulation globule" sensu von Stosch (1973) between the gametes (arrow). (C) Planozygote with two transverse and two longitudinal flagella. (D-G) Living cells. (D) Early to mid asexual cell division. (E) Late cell division, offspring cells almost separated. (F) Early gamete attachment/fusion, with early formation of the "copulation globule." (F) Planozygote with two longitudinal flagella apparent [23]. Photos A-C by E. Allen (NCSU) and M. Parrow, D-G by M. Parrow.

Figure 24. Depiction of cell division (Left, a-f) versus gamete fusion (Right, a-f) in *Levanderina fissa* by Coats et al. [60]. Both processes are essentially the same in morphology as cell division and gamete fusion in *Karlodinium veneficum*. Note the two transverse and two longitudinal flagella in the planozygote (Right, e-f), as also occurs in *K. veneficum*.

Another feature common to dinoflagellate zygotes is nuclear cyclosis [57, 58], a dramatic swirling of the chromosomes that occurs within the nuclear envelope prior to zygote nuclear division. This process is associated with the pairing of homologous chromosomes in early-tomid-meiotic prophase, has been observed to occur specifically in dinoflagellate zygotes in a number of species (reviewed in [59, 63]). It is therefore considered to be a clear marker for meiosis in dinoflagellates. In *K. veneficum*, nuclear cyclosis can be observed in mature planozygotes with large nuclei. These cells appear to often become sluggish during nuclear cyclosis, and even settle to the bottom of the culture vessel (Parrow, pers. obs.). High resolution microcopy is required to see nuclear cyclosis in a small dinoflagellate like *K. veneficum*, but in many cases both the dual longitudinal flagella and nuclear cyclosis can be observed simultaneously in sluggish specimens. In *K. veneficum*, nuclear cyclosis occurs as a smooth unidirectional swirling of the chromosomes, and lasts for at least 2h [https://www.youtube.com/watch?v=xyWy3muIu1g].

All dinoflagellates for which sufficient information exists appear to exhibit a haplontic life cycle with zygotic meiosis, with one notable exception: the coenocytic/pseudocolonial dinoflagellate *Polykrikos kofoidii* [63], which is diplohaplontic due to a single apparent mitotic nuclear division in the diploid state. This "exception that proves the rule" may be related to the coenocytic condition of *P. kofoidii*, which is relatively unusual among dinoflagellates. In unicellular dinoflagellates exhibiting a haplontic life cycle, mitosis (asexual division) occurs only in functionally haploid 1C DNA cells. Haploid cells produced by mitosis can also act as gametes and fuse to produce a diploid zygote. The zygote divides by meiosis, restoring the haploid, 1C DNA state. All the evidence collected so far supports *K. veneficum* as having a haplontic life cycle, with zygotic meiosis, like the vast majority of dinoflagellates studied thus far appear to have. In particular, the regular, phased occurrence of 4C DNA planozygotes has been documented in *K. veneficum* cultures, and a pattern of conventional meiotic division demonstrated by DNA cell cycle analysis and flow cytometric sorting of phases for imaging of nuclear states [45] (Figure 25). In principle, it is not possible to distinguish early planozygotes with 2C relative DNA from G2 cell cycle phase asexual cells, unless they occur distinctly out of phase with the rest of the uniformly cycling population. This is difficult to prove, and requires the assumption that measured 2C DNA cells are proof of diploidy rather than potentially being G2 phase mitotic cells but has been presented as proof of sex in *K. veneficum* [34]. However, demonstration of populations of 4C DNA cells, each with single nucleus or a pair of 2C nuclei in division, is clear evidence of

diploidy and canonical meiosis. In any eukaryotic life cycle (haplontic, diplontic, or diplohaplontic), the 4C DNA nucleus exists in only 1 position: as a diploid nucleus, immediately after pre-meiotic S-phase, and before meiosis I nuclear division.

Figure 25. (A-C) Time series of DNA measurements on *Karlodinium veneficum* (CCMP2283). Meiotic DNA synthesis began at 6 pm, and produced a 4C DNA subpopulation (zygotes in meiotic prophase) by 12 am. By 4 am, zygotes had divided and offspring apparently re-entered the 2C DNA subpopulation. (D-F) Individual flow-sorted cells of *K. veneficum* from sample (B) with fluorescently stained DNA (green nuclei). 1C, 2C, and 4C DNA cells, only cells with 2C or 4C DNA were found in the processes of nuclear division (asterisks), scale bar =  $10 \mu m$  [45].

In *K. veneficum*, planozygotes appear to attain a 4C DNA content following premeiotic DNA replication prior to division, as the conventional pattern of meiosis would predict. This 4C DNA nucleus would be where nuclear cyclosis occurs (i.e., meiotic prophase I). Early planozygotes, before meiotic S-phase, would be 2C in DNA and indistinguishable from mitotic (asexual) cells in G2 of the cell cycle following the typical eukaryotic pattern of asexual cell division. However, in *K. veneficum*, cells advancing through pre-meiotic S-phase (Figure 25A), and the resulting mature planozygotes with 4C DNA content (Figure 25B) have been detected in several (but not all) strains examined by flow cytometry [45]. In general, *K. veneficum* planozygotes also appear to undergo meiosis in phase with the light-dark cycle (Figure 25, A-C), just as mitosis is phased with photocycle (above). Pre-meiotic S-phase (replication of homologous chromosomes into sister chromatids) occurs late in the light cycle, and zygotes with resulting 4C DNA divide (meiosis I) during the dark period, presumably to form two offspring cells each with 2C DNA. These cells presumably then go through meiosis II to restore the 1C nuclear state, following the pattern of conventional meiosis. The occurrence of cells with individual nuclei containing 1C, 2C, and 4C DNA has been confirmed by sorting individual cells with each DNA content onto microscope slides and photographing them (Figure 25, D-F). Importantly, and as expected, only cells with 2C or 4C DNA were found in the process of nuclear division (Figure 25, E and F). 4C nuclei in division

represent meiosis I, whereas 2C nuclei in division could represent meiosis II or mitosis (they are a similar process). These findings for *K. veneficum* are significant because, to our knowledge, actual quantification of a meiotic process in a dinoflagellate has only been reported once before. In the dinoflagellate *Prorocentrum micans*, DNA measurements by microfluorometry were used to demonstrate that vegetative cells and gametes had 1C DNA and early planozygotes had 2C DNA, which was then doubled to 4C DNA before nuclear cyclosis followed by zygote division in a  $4C\rightarrow 2C\rightarrow 1C$  DNA reduction sequence that was quantitatively determined to prove meiosis [65, 66]. Based on these data on observations and cell features, Bhaud et al*.* [65] generated a life cycle diagram for *P. micans*. With similar data and following their example, we diagram the life cycle of *Karlodinium veneficum* as it is presently understood (Figure 26).

Figure 26. Life cycle of *Karlodinium veneficum*, based on observations and DNA content measurements to date. Dotted arrows/question marks are stages that are more speculative. N indicates ploidy (inferred), whereas C indicates DNA content (determined).

Resistant, nonmotile stages commonly known as cysts have not been observed as a consistent phenomenon in any *K. veneficum* strain under any conditions. In many, but not all dinoflagellates [35], resting cysts are a product of the sexual cycle. *K. veneficum* may be heterothallic, like closely-related *Karenia brevis* [67], which might explain why sexuality is apparent in some cultured strains but not others (i.e., some cultures may have been initiated with a planozygote). To investigate whether heterothallic sexuality might lead to resting cyst formation, we have pair-wise crossed multiple *K. veneficum* strains, but no resting cysts have yet been observed in any treatment of crossed strains. Treatment of clonal and crossed strains with reduced temperatures ( $10^{\circ}$ C and  $4^{\circ}$ C) has occasionally resulted in non-motile cells that might be considered temporary cysts, but as with sister taxon *Karenia,* [67] nothing resembling these have ever been found in nature. As such, they cannot be ruled out as culture artifacts rather that *bona fide,* demonstrable and consistently repeatable life history stages. At present, it seems that *K. veneficum* is holoplanktonic, and the possibility of yet-undiscovered resting cysts, along with where *K. veneficum* cells overwinter, remains a mystery.

### **Swimming Behavior**

On swimming behavior, Ballantine [3] writes*,* 

"These organism move in a characteristic fashion. They swim forward in a jerky irregular spiral, usually with the ventral side downwards. Movement is quite rapid and the cell rotates from time to time. The transverse flagellum undulates rapidly in the girdle during movement and the longitudinal flagellum wither vibrates rapidly (during active swimming) or remains almost still, trailing behind (sluggish movement).

Figure 27. Gallery of swimming patterns observed with *K. veneficum* [69]. (a) A 3D trajectory of *K. veneficum*, color-coded with cell swimming velocity, superimposed with in-focus images sampled at every 40 time steps (0.33 s). (Insets) SEM and reconstructed image of *K. veneficum*. (b) Sample characteristic trajectories of *K. veneficum* cells. (Scale bars: 50 microns) (c) Sample trajectories of *K. veneficum* and S. major moving in unison. To the right of trajectories are shown selected in-focus images of predator and prey cells, with arrows indicating timing of image. To the left of the trajectories are shown some of the images magnified x4 with arrows indicating corresponding timing. [Reproduced with permission (Copyright (2007) National Academy of Sciences, U.S.A.].

Using digital holographic microscopy Sheng et al*.* [68] showed *K. veneficum* exhibited complex highly variable swimming behavior (Figure 27) that could be characterized by radius and pitch of helical swimming trajectories and by translational and angular velocity. *K. veneficum* moved in both left- and right-hand helices. When presented with its prey (*Storeatula major*), *K. veneficum* reduced its velocity, radius, and pitch but increased its angular velocity, changes that reduce its hydrodynamic signature while still scanning its environment as "a spinning antenna." In the nontoxic strain MD5 which we view as model for *Gymnodinium vitiligo (*PLY102*)* there was no change in swimming behavior in the presence of prey [69]. MD5 did not eat, nor did it care whether prey were present or not! [68]

### **Ecology and Toxicity in** *K. veneficum*

Among HAB species, the ability to link toxin production to growth strategies and life histories has proven generally difficult, but examples are accumulating that support the idea that toxic substances produced by phytoplankton do serve a role in the ecology of the organism. Sometimes these toxins are different from the toxins associated with public health impacts of HAB species [70], such as the allelochemicals exuded by *Karenia brevis* that are distinct from brevetoxins [70]. Among mixotrophic species, Skovgaard and Hansen [71] and Tillman [72] described prey immobilization that led to enhanced feeding in *Prymnesium parvum*. Blossom et al. [73] showed prey immobilization through secretion of a toxic mucous trap in *Alexandrium pseudogonyaulax*, which constituted a novel mode of prey capture and uptake. A follow up study [74] confirmed phagotrophy by use of this method in four of five strains of *A. pseudogonyaulax* tested, but not in any of the other eight species of *Alexandrium* tested. Xu and Kiorbe [75] demonstrated that 10 of 12 toxic dinoflagellates tested showed true grazer defense properties – that is they prevented grazing rather than toxifying predators after ingestion, an evolutionarily stable strategy.

In *K. veneficum*, evidence exists that the same toxin (karlotoxin) that is responsible for fish kills also shows grazing deterrent [76–78, 89], allelopathic [10], and prey-immobilization effects [69, 78]. Conceptually, this suggests a critical role of karlotoxin in the ecology of *K. veneficum* as a strategy for maintaining positive net population growth rate by increasing cell division rate and/or decreasing grazing losses. However, understanding how karlotoxin affects potential prey / competitors and how different growth modes (e.g., nutrient replete / deplete, phototrophic / mixotrophic) affects the cellular toxin quota of *K. veneficum* remain important questions to address in order to understand the role of karlotoxin in *K. veneficum* ecology.

Although several studies have documented the effects of KmTx on prey motility and/or survival [68, 69], none have examined the sub-lethal effects on prey photosynthesis. Exposure of a common prey item (*S. major*) to purified KmTx 1 affected cell morphology and PS II efficiency (Figure 28). Exposure to KmTx 1caused *S. major* to swell, a result consistent with the mechanism of KmTx as a non-specific pore former in membranes containing des-methyl sterols [9, 79]. This coincided in a dose-dependent manner with inhibition of PS II (e.g., Fv/Fm), as measured with a Tox-Y-Pam fluorometer. Based on the mechanism of KmTx, pore-formation in chloroplast membranes is unlikely given the lipid profile, but depolarization of the cell membrane (as evidenced by cellular swelling) may have an effect on cellular ion balances that translates to impaired photosynthesis. During a *K. veneficum* bloom KmTx levels of 100 to >1000 ng mL<sup>-1</sup> have been measured [80, 81], well above the range at which effects on cell morphology and PSII were observed. Since most toxin in living cells is cell-associated, cell-cell contact or cell lysis is likely an important factor in exposing potential prey/competitor cells to toxin *in situ*. The inset picture shows *K. veneficum* with a captured *S. major* that appears to be swollen, perhaps due to the effects of karlotoxin delivered via cellcell contact.

Changes in cellular toxin quota associated with a shift from phototrophic to mixotrophic growth were examined in *K. veneficum* strain 2778 (Figure 29). A phototrophicallymaintained culture (f/2 –Si P/10) was fed cryptophyte (*Storeatula major*) prey and tracked in

Figure 28. Dose-dependent effect of purified KmTx 1 on *S. major* (A) cell morphology and (B) PS II.

semi-continuous culture. Prey addition was controlled to allow depletion between dilution cycles. Feeding rate during mixotrophic growth averaged  $2.7 \pm 1.4$  prey predator<sup>-1</sup> d<sup>-1</sup>. Lower cellular toxin quotas and higher growth rates were observed during mixotrophic growth periods compared to phototrophic periods. Further experiments investigated whether or not this reduction in cellular toxicity was associated with cell division or simply with prey ingestion, taking advantage of the fact that for the first day after feeding a phototrophicallymaintained culture, prey ingestion typically occurs without cell division (Figure 30A). Over the first 10h of the experiment, during which *K. veneficum* strain 2278 cultures consumed cryptophytes (Figure 30B), cellular toxin levels did not differ from the phototrophic control

cultures. However, between the 24h time point and the end of the second day of the experiment, when mixotrophic cultures had grown to a higher density than the phototrophic controls, the cellular toxin level of mixotrophic cultures was lower (Figure 30C). A conclusion for this strain is that mixotrophic cells are less toxic than phototrophic cells, and this appears to be related to growth rate since toxin content did not change during the period when cryptophytes were initially consumed but *K. veneficum* cells did not divide. This conclusion contrasts with what Lin et al*.* [82] observed. They found significant toxicity (oyster larval bioassay) of both nutrient-stressed and mixotrophic cultures of *K. veneficum* (CCMP 1975). Since two different measures of toxicity were used (KmTx detection vs. bioassay) it is difficult to draw conclusions, but further investigation of the impact of mixotrophic feeding on *K. veneficum* toxicity is warranted. Lowering glycolate pools in mixotrophic growth could also explain the differences. It should be noted that *K. veneficum* has another toxic component that is not karlotoxin. The abundant fatty acid all-cis-3,6,9,12,15-octadecapentaenoic acid (18:5n-3) is highly toxic [83].

Figure 29. Growth experiment where *K. veneficum* strain CCMP 2278 that had been maintained as phototrophic was pulse fed prey cryptophytes (*Storeatula major*). Alternating phototrophic and mixotrophic growth periods were achieved by allowing prey to be grazed down to depletion before dilution of cultures with inorganic growth medium (f/2 with 1/10 P). Daily measurement of cell density  $(\bullet \& \circ)$  and KmTx (+) were made to track changes in cellular toxin quote with changes in growth mode.

Figure 30. Changes in cellular toxin quota associated with short term phototrophic vs mixotrophic growth in *K. veneficum* strain 2778.

Figure 31. *Oxyrrhis* grazing rates vs. prey density. PLY103 is *Karlodinium veneficum*, all others are cryptophytes of similar size as PLY103.

Various studies have described anti-grazing and allelopathic effects of karlotoxins on other protists with which *K. veneficum* interacts. Experiments were conducted at the MBA Citadel Hill laboratory to examine the grazing of the heterotrophic dinoflagellate, *Oxyrrhis marina*, on *K. veneficum* PLY103 as compared to other prey. *Oxyrrhis* strains PLY 697, 997A, and 2098 were tested in a preliminary experiments using cryptophyte PLY 175 as prey. PLY 697 and 997A were the same isolate maintained on bacteria (697) or *Rhodomonas* algae (997A). *Oxyrrhis* strain 2098 was used for all further experiments. Unfortunately no other strains of *K. veneficum* were available so grazing of *O. marina* on cryptophytes prey of similar size to *K. veneficum* was used as a comparison. *Karlodinium veneficum* PLY103 and cryptophyte strains PLY 544, 530, 358, 175, 23, and 29 (in ESAW complete) were used as prey at densities below 7,000 ml<sup>-1</sup>. *Oxyrrhis* density was approximately 680 ml<sup>-1</sup> in each grazing assay. Assays were conducted in triplicate in 24-well plates. All prey were examined in triplicate with and without predator. Grazing rates were calculated by dividing the difference in prey abundance between prey with predators and prey without predators after a 2 h incubation period at 15°C.

*Oxyrrhis marina* grazing rates varied for prey tested and that among the cryptophytes tested *O.* marina grazing rate trended up with prey density (Figure 31). Viewed in the context of the prey density – grazing relationship, *O. marina* grazing on PLY103 was relatively low (Figure 31), consistent with other studies finding reduced grazing of *O. marina* on toxinproducing strains of *K. veneficum* [76].

### **Global Distribution and Potential Roles of Karlotoxin in**  *Karlodinium veneficum*

*Karlodinium veneficum* was originally described as toxic and is now recognized as a harmful algal bloom (HAB) species - an ichthyotoxic dinoflagellate with a history of fishkills and other marine life moralities worldwide [49]. Karlotoxin is the causative agent of *K. veneficum*-associated fish and marine life kills [51, 84] but also has demonstrated allelopathic [76, 85], anti-grazing [78, 86, 87], and prey-immobilization effects [49, 69, 87] although recent evidence suggests allelochemicals besides karlotoxins may also be present in some strains [88]. Thus, a role for karlotoxins in the ecology of *K. veneficum* consistent with maximizing net population growth rate through increased cell division rate or decreasing losses due to grazing is suggested. However, cellular toxicity varies widely among strains, including non-toxic strains [4] that also sometimes form blooms in nature.

### *K. veneficum* **Distribution and Reported Blooms**

This section will review the distribution of *K. veneficum* globally (Figure 32), focusing on reports published since the last review [49]. It is worth noting that current global distributions of *K. veneficum*, as for other protists, likely reflect natural patterns as well as anthropogenic movements of species due to processes such as ballast water uptake and discharge (e.g., [89]- Steichen et al*.* [90] employed genetic techniques to detect *Karlodinium* and other dinoflagellates in ballast water discharged by ships in Port of Houston, Texas, USA. Additionally, contemporary models of *K. veneficum* abundance have incorporated potential

prey availability in addition to the more commonly used physical / chemical parameters that typify phytoplankton models.

The Chesapeake Bay region has a history of *K. veneficum* blooms and fish kills [51] and recent analyses using long term data sets have shed light on the ecological controls of *K. veneficum*. Li et al*.* [91] analyzed the relationship between three HABs (*Prorocentrum minimum*, *K. veneficum*, and an index of cyanobacterial HABs) and Chesapeake Bay water quality between 1991 – 2008. In comparing water quality conditions associated with *K. veneficum* blooms relative to *P. minimum* blooms, *K. veneficum* blooms tended to occur at higher SST, lower DIN, and higher DIP (e.g., lower DIN:DIP) [91]. Subsequent time series analyses [92] of water quality and phytoplankton community composition in Chesapeake Bay resulted in optimal models in which prey availability (identified as *Cryptomonas* spp. and unidentified microflagelates < 10 μm) was an important predictor of *K. veneficum* abundance in addition to the more commonly examined phyico-chemical parameters. An important outcome of both of these studies was that *K. veneficum* abundance shows a significant increase over time in the mesohaline part of Chesapeake Bay [91, 92] related to nutrients delivered in the dissolved and /or particulate form as prey.

Figure 32. Distribution of *Karlodinium veneficum* as recorded in primary literature (red) and the Ocean Biogeographic Information System [\(https://obis.org/taxon/233037\)](https://obis.org/taxon/233037) (black x's). Sources include Adolf et al. 2015 [80], Ajani et al. 2001 [121], A. Tatters (USC, pers. Comm.), Balantine 1956 [3], Bjornland and Tangen 1979 [130], Braarud 1959 [131], Busch 2016 [132], Deeds et al. 2002 [51], deSalas et al. 2005 [51], Dzhembekova et al. 2018 [134], Escobar-Morales and Hernandez-Becerril 2015 [135], Garcés et al. 2006 [33], Guallar et al. 2016 [93], Hall and Paerl 2011 [136], Hall et al. 2008 [33], Huang et al. 2019 [33], Kempton et al. 2002 [84], Li et al. 2000 [13], Li et al. 2015 [91], Lin et al. 2018 [92], Luo et al. 2018 [137], Moreno-Pino et al. 2018 [99], Siano et al. 2009 [138], Raveh et al. 2019 [100], Toldrà et al. 2018 [139], Wang et al. 2011 [94].

Other forecast models designed to predict *K. veneficum* do not consider potential prey items as predictors. Guallar et al*.* [93] used an artificial neural network to model *Karlodinium* spp. abundance in Alfacs Bay (NW Mediterranean), and area of known and recurrent *K. veneficum* blooms and ichthyotoxicity. A combination of lagged *Karlodinium* spp. abundance and environmental variables produced useful week-ahead forecast models. Although potential prey items were not tested as an input variable in these models and factors relating to freshwater inputs to the Alfac Bay stood out as strong predictors, the authors did speculate that some of the environmental drivers associated with *K. veneficum* forecasts (e.g., low light) might reflect a role of mixotrophic nutrition [93].

Wang et al*.* [94] first recorded *K. veneficum* in the East China Sea (ECS) but Dai et al. [95] presented the first record of *K. veneficum* blooms in the ECS, co-occurring with *Prorocentrum donghaiense* in seasonally temperature-stratified waters. Subsequent culture studies [96] showed that *K. veneficum* toxin inhibited (in co-culture or through addition of isolated toxin) the growth of *P. donghaiense* and that *K. veneficum* fed upon *P. donghaiense*, suggesting that feeding upon *P. donghaiense* may be an important factor supporting *K. veneficum* blooms in the ECS. Huang et al*.* [97] found *K. veneficum* in 12 of 38 samples analyzed by qPCR assay in Xiangshan Bay of the ECS, with positive hits occurring in the bottom waters (between 9-100m depth) and interpreted as possibly the result of *K. veneficum* using heterotrophic nutrition to sustain itself under the deep, low-light conditions, but this speculation requires further investigation.

The Swan River (SRE) in Western Australia is an anthropogenically impacted subtropical estuary that has experienced *K. veneficum* blooms and fish kills as far back as 1999. The cooccurrence of fish kills and *K. veneficum* blooms beginning in July 2003 prompted further study of the relationship between these conditions. Adolf et al*.* [80] reported a sequence of events including a large *K. veneficum* bloom with high toxicity levels, a stratified water column in a narrow section of the SRE with hypoxic bottom waters, and a fish kill of occurring toward the end of the *K. veneficum* bloom. The blooming population of *K. veneficum* was observed to ingest added cryptophyte prey, indicating the potential for mixotrophic nutrition, although this was not quantified nor widely observed in the bloom population. Analyses of fish gills collected at the site showed symptom of karlotoxin exposure (e.g., [98]), but the co-occurrence of *K. veneficum* with hypoxic conditions prompted questions of possible synergistic effects between these two well-known ichthyotoxic agents.

The more widespread use of molecular genetic techniques to detect *Karlodinium* spp. has resulted in additional records of its occurrence. Moreno-Pino et al*.* [99] noted presence of *Karlodinium* by NGS in Strait of Magellan near the southern tip of South America, where SST was  $2 - 5$ <sup>o</sup>C and salinity was  $27.5 - 32.5$ . Raveh et al. [100] found *K. veneficum* in 18S rRNA sequences and confirmed its presence by microscopy following bioassay additions of high nitrate well amelioration brines to oligotrophic southeast Mediterranean Sea water in winter (18 $^{\circ}$ C, 38.5 salinity) and winter (30.5 $^{\circ}$ C, 38.5 salinity) experiments. The small size and 'naked' nature of *K. veneficum* makes the availability of molecular probes for detection an important tool for those interested in understanding the distribution of this organism.

### **Top Down Forces Regulating** *K. veneficum* **Abundance**

Blooms of *K. veneficum*, as with most harmful algal bloom species (HABs), likely depend on a complex suite of physical and biological conditions favoring their growth over that of competitors. Hall et al*.* [81] and Garcés et al*.*, [47] both stress the importance of physical water conditions in explaining observed natural accumulations of *K. veneficum* (referred to as *G. corsicum* in Garcés et al*.,* [47]. Bloom initiation and growth were favored by high nutrient availability and reduced dispersal during the period of declining riverine discharge after storm events.

One possible bloom control factor for *K. veneficum* is the co-occurrence of a parasitic dinoflagellate belonging to the genus *Amoebophrya*. Members of this group were first described by the French protistologist Cachon and have been reported to infect dinoflagellates, ciliates, radiolarians, chaetognaths and siphonophores [101, 102]. Forty different free-living dinoflagellate species representing over 20 genera are estimated to be infected by *Amoebophrya spp*. [103]. *Amoebophrya ceratii* [101] was originally described as a species having a broad dinoflagellate host range, however molecular data and controlled laboratory infection experiments have shown that this is a species complex comprised of *Amoebophrya ex. K. veneficum, A. ex. Akashiwo sanguinea* and *A. ex. Gymnodinium instriatum* [104, 105].

*Amoebophrya* likely plays an important role in the ecology of estuaries and open ocean environments by consuming its host and contributing to the microbial loop [106]. While the ecology of *Amoebophrya* in specific estuarine and coastal systems has been investigated [107], the global importance of *Amoebophrya* and related organisms was not clear until the development of environmental clone libraries. These libraries revealed surprising diversity and abundance of sequences related to *Amoebophrya* in the world's oceans, particularly at depth [108–110]. This emerging lineage, dubbed the marine alveolates in environmental molecular phylogenies, roughly corresponds to the Syndiniales, as described by Cachon and Cachon [111].

Infection by *Amoebophrya* species can occur in the cytoplasm, nucleus, or both as in the case of *A. ex. K. veneficum* [112]. *Amoebophrya* species enter their host as a dinospore, grow inside the cell in a vegetative form known as a trophont, and begin to multiply within the cell to form the vermiform (or beehive) stage which ultimately causes the host to burst and release many new *Amoebophrya* dinospores [101, 102]. In order to survive and propagate, these new dinospores must find new host cells within a couple of days as they are good food for ciliates and other heterotrophic protists [113]. In contrast, dinospores of *Amoebophrya ex. K. veneficum* can remain infective for up to eleven days [112]. The infectivity rate is generally lower (90%) in laboratory experiments with *A. ex. K. veneficum* compared to experiments with *A. ex. A. sanguinea* and *A. ex. G. instriatum* (100%; [112]). It was proposed that this difference was due to toxin production by the host, however Bai et al*.* [114] showed that infection of *K. veneficum* by *Amoebophrya ex. K. veneficum* was positively correlated with host toxicity, i.e., nontoxic strains are poorly infected. Moreover, karlotoxin cell quotas remained similar between infected and uninfected hosts until parasite emergence [114]. Place et al*.* [115] found that *Amoebophrya ex. K. veneficum* contained the same dominant sterol (Gymnodinosterol, Figure 10) as *K. veneficum*. This sterol profile grants *K. veneficum* immunity from the effects of its own toxin, which lead to the hypothesis that host/parasite pairs that had a similar sterol profile would possess the same protection against karlotoxin.

Toxicity of the host species also was shown to not be a factor in the infection of natural populations of *Dinophysis* by *Amoebophrya sp.* [116, 117].

Time series sampling of *K. veneficum* and *Amoebophrya* (Figure 33) showed a tight coupling  $(R = 0.69 \text{ p} < 0.001)$  on approximately daily time scale. In time series such as this, it is difficult to say whether changes in cell abundance are due to growth, death or advection. For instance, the increase in cell abundance from day 189 – 190 would equate to a growth rate of  $>9$  d<sup>-1</sup>, which has not been observed in *K. veneficum* previously and is likely due to advection of cells to the sampling area. On the other hand, declines in cell abundance (e.g., day 190-191) are equally difficult to ascribe to advection vs. biological processes (including *Amoebophrya* infection). *Karlodinium veneficum* cultures exposed to *Amoebophrya* showed ~ 90% infection rates by 10h, and suffered drastic declines in cell abundance within 60h, [118] so a role of *Amoebophrya* in day to day population dynamics is possible. The tight coupling between *K. veneficum* and *Amoebophrya* sp. in natural populations shown here underscores the potential top-down regulation of *K. veneficum* populations in nature and needs to be considered when trying to understand population controls.

Figure 33. Time series of *K. veneficum* and *Amoebophyra ex. K. veneficum* in the Inner Harbor, Baltimore, MD.

Infection in the laboratory by *Amoebophrya ex. K. veneficum* of *K. veneficum* CCMP 1974 results in a reduction of swimming speed and turning but did not stop mobility of the host (Figure 34). This is consistent with field observations [112] which showed infected host was found deeper in the water column. The parasite swims in a left handed helix at the amazing slow speed of 2 um/sec, nearly 60 fold slower than the host, which indicates infection must occur when the host is still.

Figure 34. Joint probability density functions (PDFs) of velocity magnitude (V) and radius of helical trajectories (R) from digital holography of *Amoebophrya* ex. *K. veneficum* exposed to *K. veneficum* CCMP 1974 in laboratory. ### **Synthesis: Why Does** *K. veneficum* **(Sometimes) Form Ichthyotoxic HABs?**

"Success" among the phytoplankton requires maintenance of net population growth above losses, and the formation of dense 'blooms' by HAB species is often considered to occur as a result of an uncoupling between population growth and loss terms facilitated by interactions between the physiological capabilities of the HAB organism and the physical/chemical environment [119]. There are several described life-history strategies that are thought to contribute to uncoupling of growth and losses among the HAB-forming algae, including toxin-mediated grazer avoidance, cyst formation, diel vertical migrations, and mixotrophic nutrition. *K. veneficum* is not known to produce a resting cyst (this chapter), so the strategy involving this life history stage may not be significant for this species. Diel vertical migrations (DVM) have been observed in *K. veneficum* [81, 120] and its blooms are often associated with stratified water column conditions wherein light and nutrient sources are physically separated, suggesting an important role of DVM in *K. veneficum*'s life history. However, DVM is unlikely to distinguish *K. veneficum* from other flagellated phytoplankton, as this appears to be a common trait among HAB and non-HAB motile forms alike [81].

Karlotoxin affects susceptible cells through non-specific pore formation resulting in cytotoxicity through osmotic shock and lysis [79]. Sub-acute exposure of susceptible cells results in a variety of effects described as either allelopathic, grazing deterrent, or preyimmobilizing depending on the experimental context in which interactions between *K. veneficum,* potential prey and/or grazers are being viewed. An idea put forward by Xu and Kiørboe [75], that toxins evolved as an adaptation for grazer deterrence may have other side effects that are non-adaptive and only emerge at high cell densities, seems to fit *K. veneficum* well. Karlotoxin does fit the definition of a grazer deterrent given by Xu and Kiørboe [75] in that it deters (some) grazers before they ingest cells, and it also confers grazing protection on co-occurring non-toxic strains [76]. This idea that phytoplankton 'allelochemicals' actually evolved primarily as grazer deterrents is also consistent with findings of Jonsson et al*.* [121] who concluded that allelopathy cannot explain HAB formation.

In nature, *K. veneficum* likely experiences heavy grazing pressure from microzooplankton. Johnson et al*.* [122] studied *K. veneficum* in Chesapeake Bay and showed that grazing losses are significant for *K. veneficum* and highly correlated to grazer biomass, particularly *O. marina*. Thus, in order to bloom, growth needs to be uncoupled from grazing at least short-term (e.g., [87]). Physical factors such as freshwater flow can uncouple grazers from phytoplankton prey (e.g., [123]), while the production of grazing-deterrent toxins is likely a more reliable means. The increase in cellular toxicity associated with lower growth rates due to nutrient limitation [50, 82] is consistent with an increased role for grazing deterrence to preserve net population growth when cell division rates decline. The high cellular toxin quota of *K. veneficum* PLY103 coupled to the apparent absence of phagotrophic abilities also argues that karlotoxins evolved primarily as a grazer deterrent and perhaps play an emergent role as a means to increase prey capture rates. In practice, however, karlotoxin serves both purposes simultaneously: in three-way culture experiments with *K. veneficum*, a prey cryptophyte (*S. major*) and potential general predator (*Oxyrrhis marina*), toxic *K. veneficum* ended up dominant by avoiding *O. marina* grazing and consuming cryptophytes, whereas non-toxic *K. veneficum* was consumed by *O. marina* along with the cryptrophytes [76]. Cryptophytes are not the only prey consumed by *K. veneficum*, but they are likely an important prey item in the field for *K. veneficum* as they are too many other grazers [124], making the idea that KmTx inhibits the grazing of co-occurring heterotrophs on a common pool of prey an important advantage conferred by KmTx production.

Mixotrophic nutrition is clearly a critical component of the *K. veneficum* ecology. Several studies note the co-occurrence and feeding activity of *K. veneficum* on prey items in the field [13, 96, 125], although there are several studies in which mixotrophy is not observed or obvious during the high biomass bloom period [80, 81]. This might indicate that mixotrophy is less important to maintaining established blooms and more important to bloom initiation [76]. Along these lines, Egerton et al*.* [126] observed a rainfall event, followed by a *Cryptomonas* sp. bloom, followed by a bloom of mixotrophic *Gyrodinium instriatum* in the Chesapeake Bay region. New, dynamic models of mixotrophic *K. veneficum* growth underscore the importance of considering environmental influences that are mediated through initial effects on potential prey populations [92].

It is probably overly simplistic to look at these results and hang all of the successes of *K. veneficum* blooms on production of KmTx without considering the cost of toxin production and the known existence of non-toxic strains. If toxin production, in *K. veneficum* or other species, was costless and highly beneficial then why is toxin production not a universal trait

among phytoplankton (e.g., [75])? Chakraborty et al*.* [127] modeled PST production by *Alexandrium* spp. to demonstrate that under resource-limiting conditions the physiological cost of toxin production is non-trivial, but the benefits (e.g., grazer deterrence) outweigh the costs. Non-toxic *K. veneficum* strains are more susceptible to grazing losses and perhaps less voracious grazers [76, 76], but they are also less susceptible to infection by the potentially bloom-ending parasite, *Amoebophrya* ex. *K. veneficum* [114]. It is likely that *in situ K. veneficum* populations consist of multiple strains having distinct phenotypic and genotypic characteristics including variable toxicity as was found for *A. tamarense* [128]. Documenting this and understanding where being a non-toxic *K. veneficum* is advantageous are two important question for future research. Understanding the strategies employed by a given HAB species and the conditions that characterize blooms will aid management, preparedness and our ability to forecast HABs.

### **ACKNOWLEDGMENTS**

This is contribution #5734 from the University of Maryland Center for Environmental Science, #20–002 from the Institute of Marine and Environmental Technology. This research was funded in part by grants from OHH NIH R01ES021949-01/NSFOCE1313888 and NOAA-NOS-NCCOS-2012-2002987 to ARP, and NOAA-NOS-NCCOS NA04NOS4780272 and NA15NOS4780180 to MWP. All of the work at the MBA Citadel Hill Laboratory in Plymouth, U.K. was performed with the direct assistance of Ms. Magali Guenver, an undergraduate student from France, and with generous laboratory support of Dr. Richard Pipe and Ms. Maria Jutson. The authors thank Dr. Holly A. Bowers for qPCR work and Katrina Brooks for editorial assistance.

# **ABSTRACT**

Ciguatera poisoning results from the consumption of fish and marine invertebrates contaminated with lipid soluble toxins known as ciguatoxins (CTXs) that are produced by benthic dinoflagellates in the genera *Gambierdiscus* and *Fukuyoa*. Overall, 16 species of *Gambierdiscus* and three closely related *Fukuyoa* species are now recognized worldwide.

Occurrence data clearly highlight the current geographical expansion of these organisms from tropical and sub-tropical waters to temperate-like areas, a likely consequence of climate change. Numerous studies have examined *Gambierdiscus/ Fukuyoa* spp. *in vitro* growth responses under varying environmental factors. Results confirm that differences in both tolerance and optimum growth ranges exist not only across species, but across strains as well.

*Gambierdiscus/Fukuyoa* spp. are the potential source of at least six families of cyclic polyether compounds whose contribution to ciguatera syndrome (except for CTXs) as well as ecological relevance remain to be ascertained. Factors governing toxinogenesis in these organisms are not well understood, but several studies have provided evidence that this functional trait may depend on a combination of abiotic and biotic (including genetic) factors.

Despite the significant advances achieved in the understanding of this phenomenon, ciguatera incidents remain difficult to predict, and their recent expansion to novel areas

 $\overline{a}$ 

<sup>\*</sup> Corresponding Author's Email: mchinain@ilm.pf.

continues to pose a serious threat to the public health, lifestyle and economy of world populations. Suggested areas for future research efforts will be discussed.

**Keywords**: ciguatera, algal turfs, ecophysiology, biotic factors, toxinogenesis, impacts

### **1.INTRODUCTION**

Ciguatera poisoning represents the most common non-bacterial seafood intoxication globally, and results from the consumption of fish that have accumulated lipid soluble toxins known as ciguatoxins (CTXs) [\[1 and references therein\]](#page-1471-0). Yet, other marine organisms that are also highly prized by island communities such as bivalves (e.g.*,* giant clams), echinoderms (*e.g*., sea urchins) and gastropods (e.g., trochus) have been found to be potential vectors for human poisonings by CTXs [\[2-5\]](#page-1472-0). CTXs are produced by benthic dinoflagellates in the genus *Gambierdiscus* and *Fukuyoa* (Figure 1) that grow preferentially within mixed algal 'turfs' covering degraded coral substrates [\[6\]](#page-1472-1), although these organisms may also be found in sand, coral, detritus and other surfaces (Figure 2). CTXs enter the coral reef food web through grazing by herbivores and detritivores and are further accumulated and bio-transformed in carnivores through predation [\[7\]](#page-1472-2).

Figure 1. *Gambierdisxus* and *Fukuyoa* cells under light microscopy. (A) *Gambierdiscus toxicus* (© ILM); (B) *Fukuyoa paulensis* (© Lesley Rhodes, Cawthron Institute).

Ciguatera syndrome is characterized by a complex symptomatology, including gastrointestinal, neurological, cardiovascular and general disorders [\[8,](#page-1472-3) [9, and references](#page-1472-4)  [therein\]](#page-1472-4), that vary between individuals [\[10\]](#page-1472-5) and is often complicated by chronic manifestations lasting months to years [\[11,](#page-1472-6) [12\]](#page-1472-7). Fortunately, mortality is rare  $(\leq 0.1\%)$ , but the high morbidity of this debilitating and sometimes long-lasting illness makes it a prominent problem for recreational and subsistence fisheries worldwide. Over the past decades, the frequency and distribution of ciguatera have allegedly expanded, a likely consequence of increased human activities and climate change [\[13-18\]](#page-1472-8).

A wealth of data on the main causative agent of ciguatera, *Gambierdiscus* spp., can be found in the literature. However the resurgence of scientific interest and increasing research efforts noticeable worldwide in the past decade have led to recent advances in the understanding of this organism, particularly with respect to the discovery of novel species and novel compounds. The purpose of this book chapter is to provide an update of the current state of knowledge on the taxonomy, distribution, ecophysiology and toxicology of the ciguatera-causing dinoflagellates *Gambierdiscus* and *Fukuyoa*. A further section will deal with the global socio-economic impacts of ciguatera poisoning, in light of the recent expansion of ciguatera to novel (temperate) areas and the significant burden it represents for world populations. The concluding section will focus on some of the remaining knowledge gaps in this field of research in order to develop reliable control strategies of ciguatera poisoning.

# **2. BIODIVERSITY OF** *GAMBIERDISCUS* **AND** *FUKUYOA* **SPP.**

Species composition of *Gambierdiscus* assemblages, and particularly the presence of highly toxic species or strains in a given area, is arguably one of the main driving factors for elevated ciguatera incidence rates and severity of outbreaks [\[4,](#page-1472-9) [19,](#page-1473-0) [20\]](#page-1473-1). The accurate identification of *Gambierdiscus* species and their associated toxicity is therefore crucial to help predict the potential emergence of ciguatera risk.

Until 1995, *Gambierdiscus* was regarded as a monotypic taxon with all *Gambierdiscus* cells recorded as *G. toxicus* [\[21\]](#page-1473-2). However, the significant progress achieved over the past two decades in taxonomic studies of this genus, most notably the identification of reliable molecular markers, has allowed for the description of new species of *Gambierdiscus*, suggesting that many of the reports of *G. toxicus* in the early literature may actually concern other species. As a matter of fact, it was further concluded that the original description of *G. toxicus* by Adachi and Fukuyo (1979) [21] likely included multiple species [\[22\]](#page-1473-3), and eventually led to the description of a new epitype of *G. toxicus* in 2009 [\[23,](#page-1473-4) [24\]](#page-1473-5).

Modern taxonomy of *Gambierdiscus* species currently uses both morphological characteristics and phylogenetic analyses. Morphotaxonomy traditionally considers distinguishing characteristics such as cell shape (globular vs. lenticular), cell surface (smooth vs. areolated), cell size, or size and shape of specific thecal plates (e.g., 1p, 2', or 4" using the Kofoid tabulation system) to differentiate between isolates. These key characteristics can be found in detail in the original descriptions of *Gambierdiscus*/*Fukuyoa* species. Molecular analyses rather focus on molecular markers such as nuclear-encoded ribosomal RNA genes (5.8S, SSU and LSU rDNA), since noted plasticity in the morphology of cells can lead to inaccurate identification, particularly when comparing cultured clones to cells collected from the field [\[25\]](#page-1473-6). Different molecular techniques are currently available, including Polymerase Chain Reaction (PCR), Restriction Fragment Length Polymorphism (RFLP), Fluorescent *In Situ* Hybridization (FISH) probes or complete sequencing of the targeted genes [\[20,](#page-1473-1) [26\]](#page-1473-7).

Overall, 16 species of *Gambierdiscus* are now recognized worldwide: *G. toxicus*, *G. belizeanus*, *G. australes*, *G. pacificus*, *G. polynesiensis*, *G. caribaeus*, *G. carolinianus*, *G. carpenteri*, *G. excentricus*, *G. scabrosus*, *G. silvae*, *G. balechii*, *G. cheloniae*, *G. lapillus*, *G. honu* and *G. jejuensis* [\[21,](#page-1473-2) [23,](#page-1473-4) [25,](#page-1473-6) [27-35\]](#page-1473-8). In addition, two globular *Gambierdiscus* species have recently been reclassified as *Fukuyoa yasumotoi* and *F. ruetzleri*, with a new species described as *F. paulensis* [\[23,](#page-1473-4) [36,](#page-1474-0) [37\]](#page-1474-1). Formal classification is also pending for several unnamed genetic clades (i.e., *Gambierdiscus* sp. ribotypes and *Gambierdiscus* sp. types) which could represent new undescribed species, as it was the case for *G. silvae*, *G. scabrosus*, *G. jejuensis* and *G. balechii* previously known as *Gambierdiscus* sp. ribotype 1, *Gambierdiscus* sp. type 1, 2 and 6, respectively [\[29,](#page-1474-2) [30,](#page-1474-3) [35,](#page-1474-4) [38\]](#page-1474-5). It is likely that more species will be characterized in the coming years as more extensive samplings are conducted in areas that are still understudied such as the Indian Ocean or temperate locales.

Of note, the generalization of the molecular approach to ciguatera species identification has also fostered the development of novel detection tools operational straightforward in ciguatera risk assessment programs. Indeed, semi-quantitative PCR assays are now available for the detection and enumeration of the following species/types in environmental samples: *G. belizeanus, G. caribaeus, G. carpenteri, G. carolinianus, G. ruetzleri* and *Gambierdiscus* sp. ribotype 2 [\[26\]](#page-1473-7), *G. scabrosus*, and *Gambierdiscus* sp. type 2 and 3 [\[39\]](#page-1474-6), *G. polynesiensis, G. toxicus, G. pacificus* and *G. australes* [\[4\]](#page-1472-9), *G. lapillus* [\[40\]](#page-1474-7), and *G. excentricus* and *G. silvae* [\[41\]](#page-1474-8). Recently, Smith et al. (2017) [42] have proposed the use of metabarcoding techniques as a useful approach for the high-throughput screening of ciguatera-related harmful algal blooms (HAB) species.

### **3. GLOBAL DISTRIBUTION OF** *GAMBIERDISCUS* **AND** *FUKUYOA* **SPP.**

Numerous reports of the presence of *Gambierdiscus* in samples collected from the eastern Atlantic region, the Caribbean and Western Atlantic region, Central and Western Pacific, Southeast Asia and Indian Ocean can be found in the literature [\[24 and references therein\]](#page-1473-5). For several of these locales, the species diversity still remains unknown. As mentioned above, earlier reports of *G. toxicus* as a single cosmopolitan species with a seemingly worldwide circumtropical distribution needs to be reconsidered [\[23,](#page-1473-4) [24 and references therein,](#page-1473-5) [43,](#page-1474-9) [44\]](#page-1474-10).

*Gambierdiscus* spp. are preferentially found in tropical and sub-tropical waters of the globe between 35°N and 35°S [\[45\]](#page-1475-0), but recent studies show that *Gambierdiscus* and/or *Fukuyoa* spp. are presently established in temperate-like areas as well, including Korea [\[35,](#page-1474-4) [46\]](#page-1475-1) Japan [\[39\]](#page-1474-6), the Kermadec Islands (New-Zealand) [\[47,](#page-1750-0) [48\]](#page-1750-1), Southern Australia [\[49\]](#page-1750-2), the Northern Gulf of Mexico [\[50\]](#page-1750-3), and the Mediterranean Sea [\[51,](#page-1750-4) [52\]](#page-1750-5) (Table 1). There is concern that the geographic range of these two genera, and subsequently of ciguatera outbreaks, will continue to expand as sea surface temperatures rise [\[53,](#page-1750-6) [54\]](#page-1751-0). Indeed, cyclical weather patterns such as El Niño - which is associated with unusual warming waters in the Pacific - have resulted in spike in ciguatera cases in Kiribati, Western Samoa, Tuvalu and Cook Islands [\[55\]](#page-1751-1). Similarly, Gingold et al. (2014) [56] found an association between ciguatera poisoning (CP) incidence and warmer sea surface temperatures (SST) in the Caribbean basin. Based on water temperature projections over the coming century, a substantial shift in both the distribution and abundance of ciguatera dinoflagellates is to be expected [\[57,](#page-1751-2) [58\]](#page-1751-3), with some species becoming dominant whereas others will become less prevalent. In the long-term, however, temperatures may get too warm according to Llewellyn (2010) [59], thereby hindering *Gambierdiscus*/*Fukyoa* growth and resulting in a lower risk of ciguatera.

## **Table 1. Global distribution of** *Gambierdiscus* **and** *Fukuyoa* **species and phylotypes. For some of the locations, (\*) indicate species which were identified using solely morphological characteristics. Positive confirmation of their identity will require further phylogenetic analyses**

#### **Table 1. (Continued)**

Table 1 provides an updated summary of the current distribution of all known *Gambierdiscus* and *Fukuyoa* species. These global occurrence data were collated from studies which used either morphological and/or molecular techniques to identify species. Interestingly, in some of these locations, the presence of ciguatera-related dinoflagellates is consistent with the report of ciguatera cases decades earlier [60-63]. In addition, *Gambierdiscu*s and/or *Fukuyoa* have also been reported from other regions of the world, such as Tonga [42], several locations in Latin America such as Mexico, Cuba, Guatemala, El Salvador, Costa Rica, Colombia, etc. [64 and references therein, 65, 66], Morocco and Crete [51], Hong Kong waters [67], and the Lesser Antilles [68], nevertheless, the exact species are yet to be determined.

Occurence data suggest that some of these species seem to be limited to specific areas of the globe (i.e., *G. excentricus* and *G. scabrosus)*, whereas others are characterized by a more cosmopolitan distribution (i.e., *G. belizeanus, G. caribaeus, G. carpenteri* and *F. yasumotoi*) (Table 1), consistent with the wider range of tolerance to environmental conditions exhibited
by these species *in vitro* [69, 70] (see section 4). Nevertheless, it is likely that, with additional samplings, species now designated as specific to a region will eventually be reported from other locales.

Assessing *Gambierdicus*/*Fukuyoa* spp. abundance in the environment proves very challenging due to the high variations observed both at a temporal and spatial scale. Too, the notorious patchy distribution of these dinoflagellate even over small distances, and the differences in the algal hosts morphology which can greatly influence abundance estimates are other major impediments to an accurate assessment of population densities [71]. Despite these limitations, the literature survey conducted by Litaker et al. (2010) [44] on *Gambierdiscus* abundance data for the Atlantic and Pacific Oceans showed that 85% of the average values were  $\lt 1,000$  cells.g<sup>-1</sup> wet weight (ww) algae, while 10% of the abundance estimates fell between 1,000 and 10,000 cells. $g^{-1}$  ww algae. Such findings have led the authors to speculate that densities  $> 1,000$  cells.g<sup>-1</sup> ww algae likely correspond to localized blooms conditions that have the higher potential of causing ciguatera events. On the other hand, some studies have stressed the importance to also consider algal host-dinoflagellate associations, which may act as toxin source or sinks, depending on macroalgal palatability [72]. In other words, algae that are actively consumed by herbivores could be responsible for a high toxin flux even at low dinoflagellate densities, whereas unpalatable algae with higher dinoflagellate densities might contribute little to toxin transfer in marine food webs.

## **4. ECOPHYSIOLOGY**

*Gambierdiscus*/*Fukuyoa* spp. are regarded as benthic epiphytic organisms, but can occasionally exhibit free-swimming behavior [73-76], suggesting that they may behave as mixotrophs [77]. Although members of this genus survive as photoautotrophs, this hypothesis is consistent with recent findings that complex pathways of N and C utilization are indeed present in this taxon [77]. According to these authors, cells of *G. caribaeus* were able to sustain significant growth in the absence of light when cultured in medium supplemented with an exogenous carbon source. Nonetheless, such findings still await further confirmation since these authors used non-axenic cultures, and previous research showed that this dinoflagellate may require the presence of specific bacteria to maintain growth [78].

The life cycle of *Gambierdiscus* is still poorly documented. Early studies by Hokama et al. (1996) [79] described the succession of six distinct stages in culture: i) a motile freeswimming cell phase at the beginning of the culture, ii) a pre-cyst phase after 2 to 3 weeks, iii) a cyst phase followed by iv) a secondary cyst phase, v) a mitotic phase in which cysts divide, and vi) a terminal phase that may last up to 4-6 months preceding a new cycle. Next, Van Dolah et al. (1995) [80] demonstrated that cell division in *Gambierdiscus* was phased to the diurnal cycle, with cells dividing only during a 3h-window late in the dark phase, when grown in a 16:8 hour light:dark cycle. These authors also documented the role played by a CDC2-like kinase which, like in higher eukaryotes, was expressed constitutively in *Gambierdiscus* throughout the cell cycle but activated only during mitotis. Results of a recent study conducted on a *G. balechii* strain allowed to confirm previous findings on a circadian regulation of cell division [81] and that the life cycle of *Gambierdiscus* likely involves both asexual and sexual processes, as speculated by Taylor (1979) [82]. All these observations

(cyst-like structures and sexual reproduction) may help explain the exceptional ability of these species to adapt, survive, and even thrive in harsh environmental conditions (see following sections 4.1 and 4.2).

Compared to most planktonic dinoflagellates, *Gambierdiscus*/*Fukuyoa* spp. are considered slow-growing organisms, with growth rate never exceeding 0.5 div.d<sup>-1</sup> [19, 35, 58, 69, 83-86]. The highest growth rate ever reported for *Gambierdiscus* isolates is 0.55 div.d-1 and concerns a Hawaiian strain [87]. Whether there is a relationship between growth rate and cell potency remains unclear, although highly toxic clones in the genus *G. polynesiensis* were found to exhibit relatively low reproductive rates ( $\simeq 0.13$  div.d<sup>-1</sup>) as compared to nonciguatoxic strains [83].

### **4.1.** *Gambierdiscus/Fukuyoa* **spp. Preferred Habitats**

High densities of *Gambierdiscus*/*Fukuyoa* spp. are often observed in disturbed/degraded coral reef habitats [15-17, 44]. Indeed, Lewis (1986) [15] reported that *Gambierdiscus* grows prodigiously following both natural and man-made disturbances of coral reefs. Similarly, while studying the fluctuations of *G. toxicus* populations in a ciguateric site of French Polynesia, Chinain et al. (1999) [17] found that there was an increase in both the density and frequency of *Gambierdiscus* blooms following a severe coral bleaching episode affecting large areas of the study site. A general consensus is that the massive colonization of dead corals by macroalgae provides more substrate for the settlement of epiphytic *Gambierdiscus*/*Fukuyoa* spp. populations, as first hypothesized by Randall (1958) [88]. This may explain why reef disturbances due to extreme climatic events (*e.g*., hurricanes, heavy rains, coral bleaching) or human activities (*e.g*., dredging and filling, constructions, military activities) frequently precede ciguatoxic events [1, 13, 14, 89].

It is not clear whether *Gambierdiscus* abundances are subject to seasonality or not, as field studies sometimes showed contradictory conclusions. Chinain et al. (1999) [17] reported that *Gambierdiscus* cell densities were the highest at the beginning and end of the hot season in French Polynesia, consistent with observations from a field survey conducted in Hawaii [57]. Conversely, other studies did not observe seasonal patterns or concluded that highest densities were rather reported in the fall season [79, 90, 91]. In any case, it is likely that seasonal patterns, if any, will be primarily determined by the different temperature tolerances characterizing the various *Gambierdiscus*/*Fukuyoa* species (see the following section 4.2).

*Gambierdiscus* populations are generally more abundant in habitats where temperatures are comprised between 25 and 30 $^{\circ}$ C [17, 54]. However, early observations from the Florida Keys, U.S. Virgin Islands, Hawaii, and Queensland, that *Gambierdiscus* abundance peak at cooler temperatures seem to contradict this generalization [24 and references therein].

Like other dinoflagellates, *Gambierdiscus spp*. are sensitive to excessive agitation and show a clear preference for calm and stable environments [44, 45, 92]. There are several field observations, however, that tend to contradict this general idea: for instance, in areas such as Mayotte Island, Hawaii or Canary Islands, higher densities of *Gambierdiscus* were actually found in turbulent winward locations [28, 93, 94]. Small-scale turbulence has been shown to directly influence the physiology of some dinoflagellates by causing cell disruption, alteration of cell division and cell cycle phase duration, and even by affecting toxin production [95, 96]. Nakahara et al. (1996) [75] have observed that turbulence may cause *Gambierdiscus* cells to

quickly attach to the surface of the macrophyte. Cells are also often found attached to their algal host by a mucus thread, so as to limit cells dispersal.

*Gambierdiscus* appears to prefer environments with high, stable salinities, between 28-35 [24 and references therein, 44] but has been reported from areas with extreme lower or upper salinity values such as river outlets [65] or mangrove environments where salinity can exceed 40 [97]. There is evidence, however, that salinity preferences may significantly differ among species [24, 69] (see following section 4.2.).

Many studies have documented the apparent preference of *Gambierdiscus* for specific macroalgal hosts [24 and references therein, 68], but the exact nature of this preference remains elusive. There is some evidence that various macroalgae may supply important growth factors [75, 93, 98-100], but other factors such as algal structure and surface area, or algal class may also play a critical role [6, 72, 76, 98]. According to Bienfang et al. (2008) [45], the occurrence of *these epiphytic organisms* on many macroalgae species suggests opportunism in regard to macroalgal substrate, rather than a regulation of their abundance by specific macroalgal metabolites. Results of a study which examined the epiphytic relationship between *Gambierdiscu*s and 24 different macroalgal species seem to contradict this statement since it was shown that i) cells attached to specific algal species while avoiding others, and ii) certain algal host inhibited cells proliferation while others allowed for their growth [76]. In addition, in the environment, cell densities of epiphytic pennate diatoms on macroalgae have been shown to affect *Gambierdiscus* spp. abundance and therefore, may represent another growth determinant in the same way as sea water temperature, salinity and nutrients [101]. In any case, multiple benefits may result from the association of *Gambierdiscus* spp. with macrophytes: e.g., fixation on a substrate, protection from turbulence, shading from direct sunlight, and access to organic compounds within the thallisphere [102].

*Gambierdiscus* spp. are able to grow in shaded as well as high-lighted water habitats [50]. In shallow tropical waters, for instance, *Gambierdiscus* populations are often found attached to benthic macrophytes or to drifting algae or detritus [103] where surface irradiances can sometimes exceed 2,000 µmol photons.m<sup>-2</sup>.s<sup>-1</sup> [102]. In cultures, however, these organisms seem to be best adapted to relatively low light conditions (50-230 µmol photons. $m^2$ .s<sup>-1</sup>) and can even sustain growth at irradiances as low as 10  $\mu$ mol photons.m<sup>-2</sup>.s<sup>-1</sup>, which would allow cells to survive at depths  $> 80-100$ m in tropical environments [84, 104]. There are actually limited data studies on the vertical distribution of *Gambierdiscus*/*Fukuyoa* spp. [50, 105, 106] but early observations are consistent with *in vitro* observations since the presence of *Gambierdiscus* cells was reported at depths between 30-50m [23, 50, 93, 97]. Furthermore, recent findings clearly suggest the existence of species-specific responses to changing light regimes, with species capable of maintaining growth even when exposed to very high irradiances ( $>$  500 µmol photons.m<sup>-2</sup>.s<sup>-1</sup>) [69, 107]. Several behavioral strategies have been suggested to help this organism cope with high irradiances, including cell aggregation, mucus production, use of the three-dimensional structure of the algal host to minimize light exposure and prevent photodamage, as well as physiological responses such as the plasticity of cell size and chlorophyll content [102, 107, 108].

(A)

## **4.2.** *In Vitro* **Growth**

Data regarding *Gambierdiscus/Fukuyoa* spp. growth responses under varying environmental factors are useful to inform predictive models of their abundance, seasonality and global distribution. Early laboratory studies have primarily investigated *Gambierdiscus* sp. optima and limits for temperature, salinity and light factors. Overall, these studies generally agree with field surveys although conflicting results were sometimes reported [see 24 for a review and references therein].

The influence of ambient nutrient concentrations on *Gambierdiscus* populations remains ambiguous, since this topic had been the subject of a limited number of field studies, with sometimes contradictory conclusions [94, 105, 109]. Similarly, only two laboratory studies have sought to determine the effect of nutrients on *Gambierdiscus* growth: in the first study by Sperr and Doucette (1996) [110], the authors found that growth rates within five isolates remained constant under different N:P ratios, indicating an ability of all clones to maintain high reproductive rates under different nutritional regimes. The second study by Lartigue et al. (2009) [111] examined the effects of different nitrogen sources on the growth of two clones and concluded that nutrient physiologies likely differed between strains. Interestingly, these clones were subsequently classified as two distinct species, namely *G. caribaeus* and *Gambierdiscus* sp. ribotype 2.

As mentioned previously, most of these studies were conducted at a time when *Gambierdiscus* taxonomy was unresolved, so the extent to which growth responses may vary across the multiple species now known in *Gambierdiscus* and *Fukuyoa* genera remains to be clarified. Recent studies have started to provide growth data for the following species/phylotypes: *G. polynesiensis*, *G. australes*, *G. pacificus*, *G. belizeanus*, *G. caribaeus*, *G. carolinianus*, *G. carpenteri*, *G. silvae*, *G. scabrosus*, *F. ruetzleri*, and *Gambierdiscus* spp. types 2, 3, 4 and 5 [69, 70, 83-85, 104, 112]. Results confirm that differences in both tolerance and optimum growth ranges exist not only across species, but across strains as well [70].

# **5. TOXICOLOGY**

#### **5.1. Chemodiversity of Secondary Metabolites**

Increasing attention is paid to secondary metabolites produced by microalgae, particularly dinoflagellates due to their potential uses in the biology, biomedical and toxicological fields [113]. These compounds are also ecologically relevant since they are suspected to act as allelochemicals influencing biotic interactions (see section 5.4), and may therefore be involved in structuring microbial communities [114]. The recent development of metabolomics is furthermore a unique opportunity to investigate the chemodiversity of such dinoflagellates, in order to e.g., describe new compounds (including toxins), assess the variations of their productions in response to different stressors, or identify chemical markers at different taxonomic levels (chemotaxonomy) [115].

*Gambierdiscus/Fukuyoa* species produce several non-structurally related groups of secondary metabolites with a ladder-shaped cyclic polyether backbone: ciguatoxins (CTXs), maitotoxins (MTXs), gambieric acids (GAs), gambierol, gambieroxide and gambierones (Figures  $3 \& 4$ ). The Table 2 presents the compounds that have been detected in the different *Gambierdiscus*/*Fukuyoa* species described to date (except for the newly described *G. jejuensis* and *F. yasumotoi* species for which no information are available), through isolation or liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS) analyses. As outlined above, before 1999 and the study by Chinain et al. [25] that has introduced molecular analyses, the identification of *Gambierdiscus* species was made solely on the basis of morphological characteristics, leading to potential misidentifications. Thereby, strain identifications prior to 1999 should probably be reassessed, particularly concerning *G. toxicus*.

# **Table 2. List of polyether compounds that have been detected (through isolation or LC-MS/MS analyses) in** *Gambierdiscus***/***Fukuyoa* **genera**

**(a)**No information available for *F. yasumotoi* and *G. jejuensis*. **(b)**Trace amounts. **(c)**Compound previously identified as MTX3 and renamed 44-methylgambierone by Murray et al. (2019) [134] and Boente-Juncal et al. (2019) [135] who characterized its structure by NMR and MS experiments. **(d)**Tentative identification on the basis of low resolution LC-MS/MS analyses without reference materials. **(e)**In Pisapia et al. (2017) [129], authors presume that the study by may have misidentified 2,3-dihydroxy-P-CTX3C, as it is likely that the actual compound present was the ubiquitous 44 methylgambierone (former MTX3). <sup>(f)</sup>Five temperate *G. carpenteri* strains were found free of 44-methylgambierone (former MTX3) [142], the only ones among 89 *Gambierdiscus* strains tested by Murray et al. (2019) [134]. **(g)**Potential misidentifications, most likely *G. polynesiensis* for some Polynesian strains.

Many congeners of CTXs, comprising 13 or 14 rings transfused by ether bonds, have been isolated from dinoflagellates and/or fish [for a review see 116]. They are grouped into three sub-families according to their geographical origin, i.e., Pacific, Caribbean, and Indian CTXs (P-CTXs, C-CTXs and I-CTXs, respectively). Several P-CTXs have been detected in *Gambierdiscus*/*Fukuyoa* species, unlike C-CTXs or I-CTXs which have been found only in fish samples. To date, 11 P-CTXs (Figure 3) were definitely detected in *G. polynesiensis*  strains (TB92 and RG92 from French Polynesia, CAWD212 from Cook Islands) [32, 83, 117- 121], and/or in some *G. toxicus* strains (GII-1 and RGI-1 from French Polynesia, potential misidentifications of the species, most likely *G. polynesiensis* currently known to be the major toxic species in the South Pacific [116]) [122-126]: P-CTX4A, P-CTX4B, M-*seco*-P-CTX4A/B, P-CTX2 (52-*epi*-54-deoxy-P-CTX1B), P-CTX3 (54-deoxy-P-CTX1B), P-CTX3B, P-CTX3C, 51-hydroxy-P-CTX3C, 2-hydroxy-P-CTX3C, M-*seco*-P-CTX3C, M*seco*-P-CTX3C methyl acetal. Moreover, trace amounts of P-CTX3 (54-deoxy-CTX1B) was detected in one strain of *F. paulensis* (Dn135EHU from Mediterranean Sea) [127]. In other species of *Gambierdiscus*/*Fukuyoa*, P-CTXs were only tentatively identified on the basis of low resolution LC-MS/MS analyses without reference materials [128-130].

MTX1 (Figure 4a) is the largest non-polymeric molecule described to date in nature, with 32 ether rings and two sodiated sulfate ester groups, having a molecular weight around 3400 Da. It was detected in some *G. australes* [32, 47, 48, 117, 121, 131-133] and *G. toxicus* strains [134-136]. Two other analogues have been reported in the literature but their structures haven't been elucidated yet: MTX2, tentatively detected in some strains of *G. caribaeus*, *G. excentricus*, *G. pacificus* and *G. toxicus* [131, 136], and MTX4, recently detected exclusively in *G. excentricus* strains [131]. Another putative analogue was initially identified as MTX3 [137] but had a molecular weight much lower than other MTXs and was recently renamed 44 methylgambierone when its structure was finally fully characterized by RMN analyses (see

below) [138, 139]. It should be noted that a recent study conducted by Lewis et al. (2016) [140] indicated that several strains of *Gambierdiscus*/*Fukuyoa* produce multiple MTX congeners, actually more than four for one particular strain of *G. belizeanus,* suggesting a likely broader chemical diversity than what is known so far within MTX group.

Figure 3. Structures of the P-CTXs definitely detected in *Gambierdiscus*/*Fukuyoa* genera.

Gambieric acids (GA)-A, -B, -C and -D (Figure 4b) were isolated from a strain identified as *G. toxicus* (GII-1 from French Polynesia, potential misidentification of the species) [141] and are composed of nine contiguous ether rings and one isolated tetrahydrofuran. GA-A was also detected in trace amounts in *F. paulensis* (Dn135EHU from Mediterranean Sea) [127].

Gambierol (Figure 4c) was isolated from a strain identified as *G. toxicus* (RGI-1 from French Polynesia, potential misidentification of the species) [142]. It contains a transfused octacyclic polyether core and a skipped triene.

Gambieroxide (Figure 4d) was more recently isolated from a strain identified as *G. toxicus* (GTP2 from French Polynesia) [143]. This polyether compound comprises 12 transfused ether rings and two side chains at the extremities. Its structure is very similar to that of yessotoxin.

Figure 4. Structures of other polyether compounds isolated from *Gambierdiscus*/*Fukuyoa* genera.

Finally, gambierone (Figure 4e) was recently isolated from a *G. belizeanus* strain (CCMP401 from Caribbean Sea) [144], as well as its analogue, the 44-methylgambierone (Figure 4e) [138, 139]. The structure of this last molecule was elucidated by another team at the same time after isolation from four *G. australes* strains (Kermadec Islands) [138, 139]. Gambierones are composed of nine transfused rings, a sulfate ester group and a conjugated vinyl end. Before its structure was definitely elucidated, the 44-methylgambierone was reported as MTX3 in numerous studies and has been detected in all *Gambierdiscus*/*Fukuyoa* species analyzed to date, except for *G. jejuensis* and *F. yasumotoi* for which data are currently unavailable [32-34, 47-49, 67, 117, 121, 131, 132, 145]. An exception concerns temperate clones of *G. carpenteri* which have been found free of 44-methylgambierone [121, 145].

Further characterization of toxin profiles of all known species of *Gambierdiscus/Fukuyoa* is crucial since this information is useful to inform ciguatera risk models. Some authors even speculated that the toxin profiles in the causative dinoflagellates may contribute to shape the toxin profiles in fish [146] – which have been shown to vary across regions and fish species [123, 147].

#### **5.2. Modes of Action of Bioactive Compounds**

CTXs are by far the most studied group due to their direct involvement in ciguatera poisoning. Their major mechanism of toxicity expresses through the binding to site 5 of the  $\alpha$ -subunit of the voltage-gate sodium channels (VGSCs) on the neuronal membrane, leading to the persistent activation (opening) of VGSCs which results in cell depolarization at rest and disruption of peripheral and central nerve transmission (e.g., increase in Na<sup>+</sup> influx, enhancement of neuronal excitability, spontaneous and repetitive actions potentials) [for reviews see 148, 149]. The activation of VGSCs by CTXs has been shown to also indirectly disturb the  $Ca^{2+}$  homeostasis. Furthermore, some studies indicate that CTXs interact with other targets, such as the voltage-gated potassium channels (VGPCs), resulting in their inhibition and accentuation of the neurocellular perturbations [for reviews see 148, 149]. The multiple effects of CTXs are believed to underly the complex symptomatology observed in CP syndrome. On the contrary, the contribution of the other polyether compounds produced by *Gambierdiscus*/*Fukuyoa* genera to the clinical picture of ciguatera is not yet fully elucidated.

MTX1 is among the most potent marine toxins known to date with an  $LD_{50}$  in mice of 50 ng.kg-1 [134-136]. Its activity results in a massive calcium influx and a rapid cell death, likely due to a combination of different ion channels' modulation (e.g., nonselective cation channels, voltage-gated calcium channels, transient receptor potential channels) and altering many cellular functions, nevertheless, its primary target and mechanism of action are still unknown [for a review see 139]. MTX2 was shown to produce similar symptoms in mice to those elicited by MTX1, although with lower potency [136], whereas MTX4 was reported to exhibit a toxic effect similar to the one of MTX1 in neuroblastoma cells [131], their mechanisms of action has however not been described yet.

GA-A and GA-B are potent antifungal agents, displaying a remarkable activity against filamentous fungi, while being ineffective against yeasts [150]. GA-A is able to displace the binding of tritiated brevetoxin-3  $(\binom{3H}{-PbTx-3})$  to the site 5 of VGSCs in excitable membranes, which is also the binding site of CTXs as describe above [151]. As PbTxs, GA-A could thus be a useful pharmacological tool to study the binding of CTXs to VGSCs.

As GA-A, gambierol acts as a functional antagonist of neurotoxin site 5 on VGSCs [151- 153]. In addition, gambierol inhibits VGPCs in neurons, and two of its synthetic analogues have shown great potential for the development of therapeutic tools in autoimmune diseases [154]. Finally, gambierol and some synthetic analogues appear as promising molecules for the treatment of Alzheimer's disease (effects on *N*-methyl-d-aspartate, tau, and amyloid β expressions) [155].

Gambierones seem to share similar biological activities with CTXs. Indeed, gambierone causes VGSCs activation in a similar pattern as CTXs (appearance of sodium currents at hyperpolarized potentials), although with much less potency [144]. Likewise, both gambierone and 44-methylgambierone also induce a small rise in the cytosolic calcium concentration in human cortical neurons, as CTXs [139]. However, a decrease in cell viability in undifferentiated neuroblastoma cells is observed at higher concentrations of 44 methylgambierone, opening new research avenues on the potential therapeutic effects of this newly characterized molecule [139]. Finally, the expression of ionotropic glutamate receptor has been shown to be modified by chronic exposure of human neurons to gambierones, an alteration that could be involved in the neurological manifestations observed in human CP [139].

### **5.3. Toxin Production in** *Gambierdiscus* **and** *Fukuyoa* **spp.**

As mentioned previously, until the late 90s, *Gambierdiscus toxicus* was regarded as the sole origin of CTXs, but recent studies clearly show that this species is only slightly to nontoxic: actually, cultures of *G. toxicus* seem to produce considerable quantities of MTXs but only meager amounts, if any, of CTXs [25, 111]. Too, the lack of assay methods that clearly differentiate CTXs from MTXs in *G. toxicus* cultures may have puzzled early attempts to separate these two toxins [87, 136, 156].

Following the description of novel species in *Gambierdiscus* and *Fukuyoa* genera, many studies aimed at documenting CTXs and MTXs production in these two genera, since these two toxin groups are regarded as the primarily causes of CP (see section 5.2). To this aim, various analytical methods were used, e.g., the mouse biological assay (MBA), mode of action-based methods such as the receptor binding assay (RBA) and the cell based assay using neuroblastoma (CBA-N2a), as well as chemical methods such as LC-MS/MS [157- 159].

Tables 3 and 4 provide a tentative overview of all the toxicity data reported across species/strains and geographic locations available in the literature. However, several issues clearly limit data interpretation and comparison between studies: i) the general lack of consensus in extraction protocols and analytical methods used, ii) the fact that these results were obtained under different culture conditions and/or harvesting growth phases, iii) the use of different units to express toxin contents, and iv) several of these studies do not provide quantitative values but, instead, simply inform on the presence/absence of specific toxic compounds.

#### *5.3.1. CTXs Production*

Table 3 is a summary of the CTX-related toxicity detected in most of the *Gambierdiscus/Fukuyoa* species known to date (data not available for *F. yasumotoi* and the newly described *G. jejuensis* species).

This table highlights the significant variations observed in CTXs production across species, but also between strains from different geographic origins (intra-specific variance): this is the case for instance for a *F. ruetzleri* strain originating from the Caribbean Sea which was found to be 27-fold and 3.8-fold more toxic than strains from the Gulf of Mexico and the Atlantic Ocean, respectively (Table 3) [19]. Similarly, the CTX-related toxicity in strains of *G. balechii* from the Pacific Ocean was at least 6-fold higher than in strains from Asia. In some instances, toxic and non-toxic strains can even be observed within a given species, as evidenced in a *F. paulensis* strain isolated from the Mediterranean Sea which was found

MBA<sup>+</sup> , whereas strains originating from the Pacific and Atlantic Oceans showed no toxicity in MBA [37, 117, 127].

# **Table 3. CTX production in** *Gambierdiscus* **and** *Fukuyoa* **species/phylotypes. The units commonly used for CTX quantification are indicated in the first line of the table for each detection method, but different units can also be found in the literature: ( a ) mg.Kg-1 , (<sup>b</sup> ) cell.MU-1 , (<sup>c</sup> ) pg P-CTX1B/ P-CTX1 eqv.cell-1 , ( d ) pg C-CTX1B eqv.cell-1 , (<sup>e</sup> ) pg PbTX-3 eqv.cell-1**

**(\*)** No information available for *F. yasumotoi* and *G. jejuensis.*

Based on Table 3, toxic species can be classified into three distinct groups:

- I. a first group of species characterized by a CTXs production of the order of femtograms  $\ll 4.0x10^{-3}$  pg P-CTX3C eqv.cell<sup>-1</sup>, as assessed by CBA-N2a). This group comprises *G. belizeanus*, *G. caribaeus, G. carolinianus* and *G. carpenteri*, with the lowest toxicity recorded in a *G. belizeanus* strain collected from the Red Sea (Table 3).
- II. a second group of species which display a toxicity within the range of femtograms (>  $4.0x10^{-3}$  pg P-CTX3C eqv.cell<sup>-1</sup>) up to  $< 1$  pg P-CTX3C eqv.cell<sup>-1</sup>, which includes *G*. *australes*, *G. pacificus, G. scabrosus, G. silvae, G. toxicus*, and *Gambierdiscus* ribotype 2. An exception concerns *G. excentricus* whose toxicity ranged from 0.47 up to 1.43 pg P-CTX3C eqv.cell<sup>-1</sup> in the Atlantic Ocean, although the exact nature of the CTX analogues involved remains to be determined (Tables 2 and 3) [19, 28, 86]. Further investigations are also required to characterize the CTX profiles in *G. cheloniae*, *G. honu* and *G. lapillus* whose extracts showed a significant CTX-like activity on mice that could not be linked however to the presence of either P-CTX3B, -3C, -4A or -4B (Table 2) [32-34].
- III. a third group composed exclusively of strains of *G. polynesiensis*, a species allegedly endemic to the Pacific Ocean which is recognized as the highest CTXs producer known to date. Published toxicity data for this species range from 1.2 up to to 20.9 pg P-CTX3C eqv.cell<sup>-1</sup>, as assessed by either CBA-N2a, r-RBA or LC-MS/MS [4, 5, 25, 83, 117, 118, 160-162].

Although *G. excentricus* strains have been found to be twice to 14-fold less toxic than *G. polynesiensis* strains, these data suggest that the presence of these two species in a given area could be used as a CP high-risk biomarker, since they are the source of a CTXs reservoir that can be rapidly transferred through the trophic chain via the herbivores [160, 163].

## *5.3.2. MTXs Production*

The contribution of MTXs in CP symptomatology is still the matter of current debate: indeed, because of their low intestinal absorption due to their high molecular weight and hydrophilicity, MTXs are believed to poorly contribute to ciguatera poisoning unless gut and liver tissues of fish are consumed [164].

Table 4 summarizes the MTXs production reported in *Gambierdiscus* and *Fukuyoa* species/phylotypes. It should be noted that the putative MTX3 (p-MTX3) reported in all the studies cited in this section, corresponds in fact to 44-methylgambierone which has been recently characterized [138, 139].

Whereas CTXs production is seemingly restricted to a small number of strains/species, MTX compounds appear to be produced by a large number of *Gambierdiscus/Fukuyoa* species, sometimes in copious amounts [86, 131, 132, 165, 166]. Conversely, based on these data, three species/phylotypes seem to be unable to produce MTX compounds: *F. ruetzleri, G. belizeanus*, and *Gambierdiscus* ribotype 2, as well as *F. yasumotoi*.

So far, the highest MTX-related toxicity to mice was evidenced in a *G. toxicus* strain originating from La Réunion Island. *G. caribaeus*, *G. carpenteri*, *G. scabrosus*, and *G. silvae* were found to produce less than 10 pg MTX eqv.cell<sup>-1</sup> as assessed by CBA-N2a, while MTX production in *G. balechii*, *G. carolinianus* and *G. pacificus* produce up to 20 pg MTX

eqv.cell<sup>-1</sup>. As for *G. australes* and *G. excentricus*, both species show a wider range of MTXs production, ranging from 4.3 to 275 and 0.48 to 85.7 pg MTX eqv.cell<sup>-1</sup>, respectively (Table 4).

# **Table 4. MTX production in** *Gambierdiscus* **and** *Fukuyoa* **species/phylotypes. The units commonly used for MTX quantification are indicated in the first line of the table for each detection method, but different units can also be found in the literature: ( a ) mg.Kg-1 , (<sup>b</sup> ) pg pMTX-1.cell-1 , (<sup>c</sup> ) pg MTX4.cell-1**

#### **Table 4. (Continued)**

**(\*)** No information available for *F. yasumotoi* and *G. jejuensis.*

It has been suggested that the ability to produce CTXs and MTXs is a stable characteristic in *Gambierdiscus* strains, which is maintained even years after their isolation and acclimatation to laboratory conditions [25, 32, 47, 48, 83, 117, 131, 166, 167]. This observation has led to the speculation that toxin production is genetically determined in this dinoflagellate. However, the significant variation observed in toxicity within and among species [e.g., 19, 83, 86, 110, 131, 168, 169] suggests that this functional trait may also depend on a combination of environmental factors, both biotic and abiotic drivers, as in many other phytoplankton taxa.

### *5.3.3. Biotic Factors Influencing Toxin Production in Gambierdiscus and Fukuyoa Spp.*

#### **5.3.3.1. Genetics of Toxin Production**

In the Eukaryote kingdom, *Gambierdiscus* species are among the organisms with the largest genomes, e.g., 32.5 and 35 Gbp for *G. australes* and *G. belizeanus*, respectively [170]. However, very little is known on the biogenesis of CTXs and MTXs and even less on the genes responsible for the production of these toxins in *Gambierdiscus/Fukuyoa* genera.

CTXs and MTXs are polyether ladder compounds that have a polyketide origin. Polyketides are synthesized by specific enzymes called polyketide synthases (PKSs) through a series of condensation and reduction steps of acyl monomers. PKS enzymes are multifunctional complexes consisting of a minimal set of catalytic domains, namely ketoacylsynthase (KS), acyl transferase (AT) and acyl carrier protein (ACP), which are required for function. Three further domains ketoacylreductases (KR), dehydrases (DH) and enolreductases (ER) can be optionally present, and when present, are responsible for the broad variety of polyketide structures found in dinoflagellates [171]. Traditionally, these enzymes are classified into 3 types, according to their domain organization, in particular Type I PKSs which correspond to large multifunctional enzymes with modular or iterative activity [172, 173].

To date, the transcriptomes of several CTX-producing species of *Gambierdiscus* have been investigated: *G. polynesiensis*, *G. belizeanus*, *G. australes* and *G. excentricus* [170, 174, 175] and contigs with sequence similarity to Type I PKSs were found, as reported in other dinoflagellates [171, 176, 177]. Coincidentally, all four species also produce 44 methylgamberione [138, 139]. Of note, no differences have been highlighted in the expression of the monofunctional KS domains between these four species [174], although substantial differences exist in these strains' known toxin profiles for CTXs and MTXs: e.g., at least six P-CTX analogs have been detected in *G. polynesiensis* cultures while three unknown CTXs are suspected in *G. excentricus*; moreover, MTX1 is produced by *G. australes* vs. MTX2 and MTX4 in *G. excentricus* (Table 2), whereas low amount and no MTXs has been found in *G. polynesiensis* and *G. belizeanus*, respectively (Table 4).

Additionally, contigs with sequence similarity to type II Fatty Acid Synthase (FAS) genes were also found [174]. This differentiation of PKS and FAS pathways in *Gambierdiscus* is important, as it will likely facilitate approaches to investigate toxin biosynthesis pathways in this dinoflagellate.

In summary, the genetic basis of CTXs and MTXs synthesis is still unresolved and additionnal fundamental studies are required to further understand these perplexing pathways, in order to promote the development of novel methods for the monitoring of these harmful dinoflagellates.

#### **5.3.3.2. Growth Stage**

An earlier study showed an increase in total toxicity using MBA from the exponential to the stationnay phase for five *G. toxicus* strains originating from the Pacific and the Atlantic Oceans, regardless of N:P ratio [110]. These results are consistent with the common belief that ciguatoxins are secondary metabolites as their production is enhanced during the stationary growth phase. The variability of toxin production in *G. polynesiensis* was also evaluated at different growth stages via the MBA and r-RBA [83]. Regardless of the test used, CTXs production decline from the beginning to the end of the exponential growth phase to  $3.4 \pm 0.1$  eqv P-CTX3C pg.cell<sup>-1</sup> followed by an increase during the stationary phase up to  $11.9 \pm 0.4$  eqv P-CTX3C pg.cell<sup>-1</sup> [83]. It is noteworthy that freshly inoculated cells produce also high amounts of CTXs similarly to the ones monitored at the end of the stationary phase. For MTXs production measured by MBA, the same production pattern was observed in *G. polynesiensis* showing a toxicity of  $18 \pm 4 \times 10^{-5}$  MU.1000 cell<sup>-1</sup> and almost twice during the stationary phase at  $31 \pm 9 \times 10^{-5}$  MU.1000 cell<sup>-1</sup> reaching a maximum in freshly inoculated cells  $50 \pm 10 \text{ x}10^{-5}$  MU.1000 cell<sup>-1</sup> [83]. In *G. australes* isolated from the Macaronesian Islands, MTXs were not produced during the exponential phase, but only during the stationary phase [166].

When comparing CTXs and MTXs production in *G. polynesiensis*, the same pattern was observed for both except that CTXs were dominant in aged cells at the end of the stationary phase [83]. This CTXs production pattern was also observed in *in vitro* cultures of *G. toxicus* presenting an increase in toxicity in aged cells [111, 156, 178]. So, if one wants to compare levels of toxin production between several strains of *Gambierdiscus* spp., cells should be cultivated under the same laboratory conditions along with a harvest time at the same growth age. For several *Gambierdiscus* species, cell division seems to be slow down during the stationary phase, but the positive correlation of toxin biosynthesis with aged cells is still unclear [19, 83]. It has been hypothetized that the energy required by *Gambierdiscus,* or other toxic dinoflagellates, cannot be allocated at the same time to cell division and toxin production [70, 83, 111, 179]. Additionnally, the high toxin content measured in *G. polynesiensis* was linked to a growth rate slower than for other *Gambierdiscus* species [83] as also observed for *G. excentricus* and *G. carpenteri* [19, 70, 86]. A low growth rate with high production of intracellular toxin could also be considered as a particularly advantageous evolutionary strategy in the natural environment, to improve self-protection in reducing competition with other microalgae or to limit grazing by herbivores [19, 83, 180]. On the contrary, a positive relationship was observed between a high growth rate and "relative" high levels of CTXs production  $[0.2 - 0.697]$  pg P-CTX1B eqv.cell<sup>-1</sup> during the exponential growth phase in *G. australes* strains originating from Macaronesian Islands [166].

### **5.3.3.3. Contribution of Bacterial Flora**

Previous studies have not found an influence of associated bacteria on CTXs production in *Gambierdiscus* since the toxicity of *Gambierdiscus* strains cultured in axenic vs. xenic conditions were found to be similar, and endosymbiotic bacteria could not be observed in transmission electron microscopy (TEM) sections toxigenic cells [78, 156, 168, 181, 182]. However, a recent study by Wang et al. (2018) [180] has provided evidence that the growth and toxin production of *Gambierdiscus* spp. can be regulated by quorum sensing bacteria. Using nine different co-cultured bacteria, these authors showed that eight of them were able to enhance the growth of *Gambierdiscus* spp., suggesting nutrient supply and/or release of growth-promoting bioactive substances to this microalgae [180]. Negative and positive interactions on toxin production were also observed, depending on the bacteria co-cultured with *Gambierdiscus* [180]. Different interactions have been suspected between associated bacteria and *Gambierdiscus*: nutrient transferring, sources competition, toxic substance releasing and photosynthesis inhibition that can play a role on algal survival, acquisition of energy, cell division and the ability of *Gambierdiscus* to produce toxins [180]. Then, this algal-bacterial relationship is complex and more efforts should be made in understanding its ecological roles.

#### *5.3.4. Abiotic Factors Influencing Toxin Production in Gambierdiscus and Fukuyoa spp.*

From the first studies on *Gambierdiscus* spp., the influence of environmental factors on toxin production was questioned. Because light, temperature, salinity, pH, and nutrients foster the growth and ecological distribution of *Gambierdiscus* dinoflagellates, these factors might also impact toxin production. However, the first attempts to examine CTXs production towards environmental factors were hurdled by unresolved taxonomy in *Gambierdiscus* species [70, 79, 110, 128, 169, 183-186].

Since the 2000s, there has been a globalization of the ciguatera phenomenon due to the geographic extension of *Gambierdiscus* spp. ranges to areas previously spared from this disease (e.g., Europe), probably in response to the effects of climate change [58]. Furthermore, in a global context of climate change, a better knowledge of the environmental factors likely to influence the toxinogenesis of the microalga appears essential if one wants to be able to anticipate the severity of outbreaks varying from one region to another. In this context, the effects of environmental parameters on the growth of several *Gambierdiscus* species have been the subject of recent studies [58, 69, 84, 85, 104, 111]. These studies have shown the ability of some species to adapt to wide ranges of temperature, salinity, light or nutrients and to better understand the geographical distributions of endemic or ubiquitous *Gambierdiscus* species. However, how changes in environmental conditions can affect *Gambierdiscus* toxin production is still explored.

Regarding nutrient parameters, the total toxicity of five *G. toxicus* strains measured by MBA were not significantly influenced by increasing N:P ratio whether during the exponential phase or the stationary phase [110]. Similarly, N:P ratio did not seem to influence Na<sup>+</sup> channel activity detected at all N:P ratios for the two toxiest strains MQ2 (Atlantic ocean) and TO4 (Pacific ocean), except at ratio N:P of 5:1 where  $Na<sup>+</sup>$  channel activity recorded for  $MQ2$  strain was the highest. Conversely,  $Na<sup>+</sup>$  channel activity was detected for the three other strains only at the highest N:P ratios [110]. These authors suggested genetic differences between these strains of *G. toxicus* whereas an unresolved taxonomy was probably one of the explanations. CTXs productions of two strains of *G. toxicus* from the Caribean were not affected by organic (nitrate or ammonium) or inorganic (urea, free amino acids or putrescine) nitrogen sources [111]. The only significant effect was observed for one strain whose cells were found to contain higher CTXs levels in the stationary phase vs. the exponential phase when grown on nitrate [111].

When cells were grown at different salinities of 30, 32 and 35, the toxin profile of *G. toxicus* was modified in terms of the ratio of the most abundant CTX putative precursor [128]. In the same way, *G. carpenteri* originating from the Philippines sampled at a salinity of 30, showed a great adaptability in laboratory conditions towards a large range of various salinity levels from 26 to 41 [70]. Within this tolerable range of growth, CTXs production was optimal under the lowest salinity, i.e., 26, showing the highest cellular content of  $7.48 \pm 0.49$ pg PbTx3 eqv.cell<sup>-1</sup> followed by a decline in CTXs production starting at 29 until the highest levels of salinity tested [70]. How an increase in salinity can actually interfere with toxin biosynthesis is still unexplained. However, a possible explanation could be that the toxins acting on voltage gated sodium channels (activators or inhibitors) produced by these toxic dinoflagellates may affect osmoregulation of ion concentrations inside the cells [187].

The effect of light on *Gambierdiscus* toxins production has also been investigated. As mentioned previously, this dinoflagellate is able to grow in shaded as well as highlighted water habitats [50]. Toxin production in *G. carpenteri* was high at low light conditions and decrease slowly by 2-fold under highest light intensities [70]. Photo inhibition did not seem to occur as toxin production was still maintained under high light intensities [70]. Little is known about the link between photosynthesis and biochemical pathways needed for toxin production in dinoflagellates, although a study has shown that an increase of chlorophyll *a* content following an increase in light intensity was observed in parallel with a decrease of toxin production in *Pyrodinium bahamense* var. *compressum* [188].

When *G. carpenteri* was grown under a wide temperature range of 19-33°C, the highest toxin production was recorded at 19°C followed by a 2-fold decrease and stabilization at 27- 33°C [70]. Moreover, when its toxin production declined, an increase in growth rate was observed. It has been speculated that this negative relationship, also observed in other *Gambierdiscus* species and toxic microalgae, may be due to the adverse effects of temperature changes that could influence up and down regulation of mRNA during toxin biosynthesis [70 and reference therein].

### **5.4. Ecological Relevance of Ciguatera-Related Compounds**

The ability of microorganisms to produce and release chemicals/toxins that affect potential competitors for resources is well known among dinoflagellates [189-191]. The diversity and structural complexity of toxins synthesized by epiphytic *Gambierdiscus*/ *Fukuyoa* spp. have led to speculation that they may be allelochemic agents directed against co-occurring taxa of the thallisphere [45]. In particular, *Gambierdiscus*/*Fukuyoa* spp. are frequently found associated with other dinoflagellates in the genera *Ostreopsis*, *Prorocentrum*, *Coolia, and Amphidinium* in benthic assemblages of ciguateric biotopes [42, 192, 193]. The allelopathic effects of ciguatera-related toxins towards these taxa are still poorly documented. Earlier studies showed that *Prorocentrum concavum* and *G. toxicus* were reciprocally inhibited both in exudate-supplemented cultures and in cross-cultures, and that both exudates and CTX extracts of *G. toxicus* were able to inhibit the growth of several diatoms and chlorophytes species [for a review see 194]. A more recent study also showed that, in crossed culturing experiments, culture media preconditioned with filtered-exudates of *G. toxicus* were able to inhibit the growth of *Coolia monotis* and *Ostreopsis lenticularis* [195]. Of note, only one study has addressed the possible role of gambieric acid-A as an endogenous growth enhancer towards *G. toxicus* cultures [196].

Conversely, extracts of several benthic taxa known to co-occur with *Gambierdiscus* spp. in ciguateric biotopes, e.g., *Prorocentrum lima*, *O. lenticularis*, *C. monotis*, are able to suppress *Gambierdiscus* spp. growth or adherence capacity in the laboratory [195, 197, 198]. However, evidence shows that these allelopathic effects may be under the control of various environmental factors such as temperature or salinity (suppression or reversal of the inhibitory effects of *Ostreopsis* sp. on *G. carpenteri* growth) [198].

Since antagonist relationships of *Gambierdiscus* with co-occurring benthic dinoflagellates [17] or diatoms [101] are sometimes observed in the field, it appears interesting to pursue and develop laboratory studies in order to better characterize interspecific interactions among ciguateric phytobenthic communities and to better understand the ecological relevance of the secondary metabolites produced by *Gambierdiscus*/*Fukuyoa* species. Apart from being used to compete for space, these molecules could also eventually be used to repel grazers or repress the growth of pathogenic organisms. Moreover, to this date, lab-experiments haven't really addressed the characterizations of which secondary metabolites are responsible for these allelopathic effects.

## **6. SOCIO-ECONOMIC IMPACTS OF CIGUATERA POISONING**

Ciguatera Poisoning (CP), associated to CTXs exposure, results in a large declination of gastro-intestinal, cardio-vascular, neurological, neuropsychiatric and other systemic manifestations, which may last weeks, months or even years [9], and is considered the most commonly reported marine biotoxins related illness worldwide, with an annual incidence estimated between 50,000 and 500,000 [199]. CP is also known to be responsible for substantial human health and socio-economic impacts for populations living in endemic regions, especially from the South Pacific, and a threat for millions of costal living inhabitants. Nevertheless, the ability to assess CP socio-economic impacts prone to be challenging due to the lack of i) biological diagnosis tools, that contribute to the difficulty diagnosing CP due to the non-specific nature of symptoms, ii) global awareness, especially among the medical community, iii) specific reporting systems and, iv) systematic ciguatoxic fish screening due to expensive CTXs detection tests.

### **6.1. Ciguatera Poisoning Impact on Health-Related Expenses**

CP incidence is not easy to ascertain because of an important under-reporting in part due to the fact that persons affected often do not seek medical attention, especially in endemic regions where populations have become accustomed to heal themselves relying on traditional medicines [200, 201], and that health care workers, may have difficulties to correctly diagnose the disease, and if so, do not know or are not obliged to declare cases to authorities. Indeed, CP specific reporting systems are scarce and CP report is mandatory in only few countries (Cayman Islands, Cuba, Miami, Canary Islands, Hong Kong) [202, 203]. This has for consequence that CP under-reporting can rich 90% in some part of the world [204] and contributes to the rarefaction of studies aiming at assessing health-related costs.

Despite these difficulties, some authors estimated individual CP health expenses at USD \$1,513/reported case in Cook Islands [205]; USD \$1,613/reported case and USD \$749/unreported case in Moorea Island (French Polynesia) [206]; USD \$1,000/reported case and USD \$700/unreported case in developed countries such as Canada [207], USD \$545 in US Virgin Islands and USD \$200 in Aruba [203]. Global Public health-related costs were grossly estimated at USD \$ 19 million/year in USA tropical jurisdictions (Florida, Hawaii, Puerto Rico, Virgin Islands, Guam, American Samoa, Northern Mariana Islands) for the period 1987-1992 [208] and USD \$241,847 for the period of 2007-2013 in Moorea Island (French Polynesia) [206]. Todd (1985) [207] estimated the CP economic impact associated with medical costs and lost-labor productivity for Canada at CAD \$2.7 million/year, between 1960's and 1980's. CP economic impacts (including estimated health-related costs, and monitoring and management costs) where estimated around NZD \$396,000 in 2011 in Rarotonga (NZD \$750,000 during epidemic pick in 2006) [205].

Of note, these estimation were obtained under different contextual circumstances, such as the study period, the level of populations' dependence to marine products, social costume, access to imported food, demographic trends, hospitalization duration or number of days off work, that can interfere in calculations' extrapolation and renders comparisons difficult [54, 92, 209, 210]. It does not take in account either insurance costs purchased by certain seafood companies to cover potential ciguatera-caused damages [211], or direct arrangements for medical expenses reimbursement between seafood sellers and ciguatera affected consumers, as is customary in some Pacific Islands, such as French Polynesia. Moreover, these cost estimations are limited to the acute maganement of CP and exclude the burden of medical expenses related to chronic sequels, that can last for months or even years, and concern over 20% of the population affected [11, 12]. Finally, if CP is retalivelly easy to diagnose in endemic regions, it can prove to be complicated in temperated areas where the diagnosis can take several months, multiple specialists consultations, and expensive medical examinations (blood and urine analysis, electromyogram, scanner, Magnetic Resonance Imaging, biopsies, etc.), whose expenses can significantly weigh the costs associated to patients' management.

### **6.2. Ciguatera Poisoning Impact on Local Fisheries**

Fish contribute substantially to the livelihoods of Pacific Islands Countries and Territories (PICTs) nations whose annual fish consumption rate are among the highest in the world (between 50 to 110 kg/capita) [212]. Besides providing Pacific islanders with essential dietary proteins and animal fat, marine products also represent an important mainstay for local economies in that they contribute significantly to households incomes [213, 214]. CP therefore represents a major concern and burden for these communities and fisheries industry [215]. Of note, fish species commonly regarded as ciguatoxic fish, such as groupers, snappers, mackerels, jacks, barracudas, wrasses, parrot fish and surgeon fish, are often listed among the main species sold in many market places [9, 216].

In the Cook Islands, the increase of CP occurrence over the past two decades has progressively discouraged local fish consumption [2]. Indeed, results of a survey realized in 2006 indicated a constant decline in average daily *per capita* fish consumption rates since 1989, from 318 g in 1989 to 176 g in 2006. These results are in accordance with observations made in Tuvalu, especially in Funafuti, where the number of fish species affected by ciguatera has increased concurrently with the risk of discouraging consumers to eat marine products [217].

In the absence of global consensus and systematic CTXs detection in marine products, health autorities from endemic regions usually put bans on ciguatera emblematic species, or specimens over a certain size, based on the general assumption that a positive correlation exists between the amount of toxins and fish size. Such regulation exists since 1939 in French Polynesia and has progressively be implemented in American Samoa, Fiji, Hawaii, New Zealand, Australia, Florida, Mexico, Cuba, Puerto Rico, Gualeloupe, Reunion Islands, etc., with, nevertheless, some variations in species listed from a country to another [203, 218-222]. Some countries, such as the Dominican Republic, have also opted for temporal restrictions since they recommend avoiding certain at-risk species between the months of May and August [203].

The economic losses caused by the harvest loss associated with these restrictions have been tentatively estimated around USD \$1.1 million/year in French Polynesia [223], USD \$10 million in Caribbean [199] and over NZD \$700,000 during CP epidemic in Cook Islands according to Rongo and van Woesik (2012) [205].

### **6.3. Ciguatera Poisoning Impact on International Trade**

A typical example of how a single-CP event can lead to the permanent closure of an export industry is the one of the Republic of Kiribati, where fish trade used to be an important source of income for local fishermen (estimated over AUD \$8,000/fisherman). In 1999, a major CP outbreak occurred in Hong Kong with fish supposedly imported from Kiribati. This event resulted in the ban of all fish from Kiribati in the Hong Kong market, and in the total closure of the trade in Kiribati, which represented an annual revenue loss of AUD \$250,000 [224].

CP cases reported these past nine years in Europe by the European Rapid Alert System for Food and Feed (RASFF) where all due to fish imported mainly from Indian Ocean and South-East Asia [225].

Given that many countries do not have laboratory CTXs detection capabilities, and lack accurate species labelling and traceability procedures, and that no regulatory limits nor reference methods exist, regulation policies regarding the trade of potential ciguatoxic fish relies entirely on the appreciation of local authorities. Based on the understanding that fish are not screened on a routine basis, recommendations, mostly concern the avoidance or prohibition of specimens, particularly large predatory reef-fish that are regarded as "suspect" simply because they originate from affected areas [209].

The Council Directive 91/493/EEC of the European Community states that placing on the market "*fishery products containing biotoxins such as ciguatera toxins or muscle-paralysing toxins*" is forbidden [226], while in its Guidance for industry, the US-Food and Drug Administration (FDA) recommands that "*because ciguatoxic endemic areas are localized, primary seafood processors should recognize and avoid purchasing fish from established and emerging areas of concern*" [227].

Alternatively, other countries such as Australia (Sydney Fish Market) may choose to circumscribe the field of restrictions, by publishing several lists of bans based on different criteria: i) a list of prohibited specific species whatever their origin (chinaman or chinaman snapper, tripletail maori wrasse, humpback maori wrasse, red bass, paddle-tail or humpedback red snapper and moray eel); ii) a list of prohibited specific species from precise locations (coral trout form Fijian waters); iii) a list of prohibited locations whatever the species (Kiribati or Marshall Islands); and iv) a list of species maximum size limits [228].

#### **6.4. Ciguatera Poisoning Impact on Tourism**

Globally, travelers are poorly informed about ciguatoxic risk by the tourism industry. According to the United Nations World Tourism Organization, there were over 1.3 billion "international tourist arrivals" in 2017. This data is in constant augmentation since 2010 [229], like the risk of contracting uncommon pathologies, such as ciguatera, for a temperate region traveler due to tourist attractiveness for tropical and subtropical countries [230, 231].

Some countries show a certain reluctance to communicate on their ciguatera incidence for fear of a dramatic decrease in tourist frequentation. In at-risk areas, CP has been associated to a decrease in tourism and recreational fishing [209, 211] and represents a constent source of apprehension to hotels and restaurants industry. Indeed, if a severe poisoning event should occur, this could derive to a loss of business and a long-term stigmatization of the establishment.

In 2019, 55 countries and island territories were listed as "at-risk destinations" by the International Association for Medical Assistance to Travellers (IAMAT) [232]. For countries regarded as at high risk of ciguatera, the extent to which this ciguatoxic status may actually influence the choice of it as a travel destination in tourists' mind is not documented, as yet.

### **6.5. Ciguatera Poisoning as a Cause of Lifestyle and Tradition Upheaval**

It has been suggested that CP have impacted human migration, and fishing and dietary patterns among Pacific populations [2, 209, 233, 234].

Beyond its direct impact on fisheries, ciguatera can also lead to drastic changes in lifestyle linked to a progressive loss of food capital [204] and a forced dietary shift among local populations, resulting in a strong reliance on imported and/or canned products, with the risk of increasing sugar and fat intake. As an example, a shift in dietary habits was reported among Rarotonga residents (Cook Islands) who modified their fish consumption in favor of an increased intake of chicken and canned fish, particularly during the peak of a ciguatera outbreak [2]. Moreover, some PICTs not only observed changes in their population's diet, but also reported secondary medical consequences, such as diabetes, as an indirect aftermath of CP [214].

Finally, a survey conducted among Rarotonga communities showed that CP may also interfere and disrupt the intergenerational transmission of traditional knowledge in affected communities, particularly with regard to fishing practices [205].

#### **6.6. Ciguatera Poisoning before the Law**

With increasing CP incidence, not only appeared a loss in confidence of consumers regarding fishery industry, but also legal actions for non-compliance with regulations or requests for compensation. An example of litigation concerned a CP event involving 46 individuals attending a banquet at a restaurant, which served maori wrasse fish imported from Trunk Reef in Queensland (Australia), in 1997 [235]. One of the affected consumers made a legal claim against the restaurant, which turned against the fish supplier. As a result, both the restaurant and the supplier were declared negligent by the judge in charge [236]. In the coming years, it is expected to assist to an increase of lawsuits of this type.

According to the Food and Agriculture Organization (FAO) of the United Nations "c*iguatera dinoflagellates are predicted to become one of the increasing food safety threats due to climate change*" [237], so that a significant increase in ciguatera burden is to be expected, not only in endemic regions, but also at a global scale**.** The multiple ramifications of ciguatera thus emphasize the need for more thorough studies using a more integrated approach of CP socio-economic impacts, for improved ciguatoxic risk prevention and management.

## **CONCLUSION**

Significant advances have been achieved in the past two decades in the understanding of the ciguatera dinoflagellates *Gambierdiscus* and *Fukuyoa*. Still, ciguatera events occurrence and variability in their severity across geography remain difficult to predict.

Identifying the key-factors likely to contribute to ciguatera flare-ups is very challenging due to the multitude of potential influential factors and their interactions. Although much of the data available in the early work on *Gambierdiscus* spp. is valid for the genus, many studies will have to be redone for the various species now known to exist in *Gambierdiscus* and *Fukuyoa* genera. Too, in laboratory-based studies, experiments designed to explore the concomitant effects of two or more factors on *Gambierdiscus*/*Fukuyoa* spp. growth should be encouraged, since responses may significantly differ from those obtained in single-factor studies. Moreover, the current knowledge on these organisms needs to be reassessed through more observational field studies since natural conditions often produce responses that are different from laboratory-controlled conditions.

Furthermore, most of the studies currently available in the literature were designed to assess inter-specific variability based on the growth response of a single strain for each species, but little is known about the intra-specific variance within each species. Some authors have speculated that isolates within a given species can easily adapt to the changes of environmental conditions, and that the differences observed in growth responses and toxin production between isolates at varying environmental conditions may be habitat dependent rather than species dependent [70, 198]. This has prompted recent studies aiming at investigating the effect of fine-scale habitat heterogeneity (e.g., macroalgal cover, composition of epiphytic communities, etc.) on the dynamics of benthic harmful dinoflagellate assemblages, including *Gambierdiscus* spp. [193].

*Gambierdiscus*/*Fukuyoa* communities in a given area can comprise multiple co-occurring species that vary with respect to their toxicity. Therefore, species composition of blooms and most importantly the presence of certain highly toxic species and/or strains are likely to play a prominent role in both CFP flare-ups and severity of outbreaks [4, 17, 19]. It is thus of utmost importance to devote future research efforts to: i) fully characterize the toxin profile associated with each of the species and genotypes now known, focusing primarily on species known to produce substantial amounts of toxins, particularly *G. polynesiensis*, and *G. excentricus*; ii) clarify how these algal toxin profiles may contribute to shape the toxin profiles in ciguatoxic fish, and iii) clarify the biological activities and contribution of recently characterized compounds in ciguatera symptomatology. All these data will be useful to inform ciguatera risk models.

Future field ecology studies should also examine the role of the macroalgal community in the transfer of ciguatera toxins to higher trophic levels, particularly with regard to how algal palatability and grazing pressure from herbivores can significantly influence toxin flux injected in marine food webs [105].

Finally, field observations are increasingly showing that other epiphytic dinoflagellates often co-habit with *Gambierdiscus*/*Fukuyoa* communities in benthic assemblages of ciguatera-prone biotopes [42, 92, 192]. These benthic HAB species are known to be the potential source of other potent toxins likely to bio-accumulate in marine food webs, and whose potential contribution to ciguatera symptomatology is still poorly documented. In this

regard, the introduction of high throughput screening techniques such as metabarcoding in current monitoring programs would greatly benefit this area of research.

Undoubtedly, the greatest challenge for the ciguatera scientific community in the coming years will be to translate the recent advances in the knowledge-base of the ecology and toxicology of *Gambierdiscus*/*Fukuyoa* spp. into practical solutions for a more reliable assessment of ciguatera risk and effective mitigation programs.
