# CONTENTS OF VOLUME 1

---

<i>Editor Biographies</i>	<i>vii</i>
<i>Volume Editors</i>	<i>ix</i>
<i>Contributors to Volume 1</i>	<i>xv</i>
<i>Preface</i>	<i>xix</i>
1.01 Introduction: Significance of molecular inorganic chemistry <i>Risto S Laitinen</i>	1
<b>SECTION 1: STRUCTURE, BONDING, AND REACTIVITY IN INORGANIC MOLECULAR SYSTEMS</b>	
1.02 Main group metal coordination chemistry <i>Catherine E Housecroft and Edwin C Constable</i>	19
1.03 Low-coordinate compounds of heavier group 14–16 elements <i>Takahiro Sasamori, Vladimir Lee, Noriyoshi Nagahora, and Shogo Morisako</i>	118
1.04 Biradicals in main group chemistry: Synthesis, electronic structure, and application in small-molecule activation <i>Jonas Bresien, Liesa Eickhoff, Axel Schulz, and Edgar Zander</i>	165
1.05 Nonclassical carbenes as noninnocent ligands <i>Daniela I Bezuidenhout, George Kleinhans, and Aino J Karhu</i>	234
1.06 Frustrated lewis pairs in catalysis <i>Katarina Stefkova, Jamie L Carden, and Rebecca L Melen</i>	315
1.07 Chemistry with weakly coordinating aluminates $[\text{Al}(\text{OR}^{\text{F}})_4]^-$ and borates $[\text{B}(\text{OR}^{\text{F}})_4]^-$ : From fundamentals to application <i>Antoine Barthélemy, Philipp Dabringhaus, Eike Jacob, Hendrik Koger, David Röhner, Manuel Schmitt, Malte Sellin, and Krossing Ingo</i>	378
1.08 Noble-gas chemistry <i>Hélène PA Mercier, Mark R Bortolus, and Gary J Schrobilgen</i>	439
1.09 Syntheses and molecular structures of cyclic selenoethers and their derivatives <i>Raija Oilunkaniemi and Risto S Laitinen</i>	527
1.10 [FeFe]-Hydrogenase mimics containing heavy p block elements <i>Hassan Abul-Futouh and Wolfgang Weigand</i>	556

**SECTION 2: INTERMOLECULAR INTERACTIONS**

- 1.11 Computational modeling and characterization of secondary bonding in compounds of late p-block elements 572  
*Ignacio Vargas-Baca*
- 1.12 Halogen-bonded halogen(I) ion complexes 586  
*Jas S Ward, Khai-Nghi Truong, Mate Erdélyi, and Kari Rissanen*
- 1.13 Chalcogen bonding in supramolecular structures, anion recognition, and catalysis 602  
*Simon Kolb, Gwyndaf A Oliver, and Daniel B Werz*
- 1.14 Supramolecular chemistry of p-block elements 652  
*DS Wright and H-C Niu*
- 1.15 Metallophilic interactions 665  
*Linda H Doerrler, Cathlene Del Rosario, and Alice Fan*

**SECTION 3: INORGANIC CHAINS, RINGS, AND CAGES**

- 1.16 Molecular boron clusters 740  
*Igor B Sivaev*
- 1.17 Chain, ring, and cluster compounds of heavy group 13 elements (Al, Ga, In, Tl) 778  
*Gerald Linti and Michael Gast*
- 1.18 Aromatic compounds bearing heavy group 14 atoms in their molecular frameworks 843  
*Masaichi Saito*
- 1.19 Chain, ring, and cluster compounds of group 15 elements (P, As, Sb, Bi) 863  
*Martyn P Coles*
- 1.20 Zintl chemistry: From zintl ions to zintl clusters 903  
*Lei Qiao, John E McGrady, and Zhong-Ming Sun*
- 1.21 Polychalcogen molecules, ligands, and ions Part 1: Homo- and heteronuclear chalcogen rings 934  
*Risto S Laitinen, Raija Oilunkaniemi, Liam McGeachie, Paul F Kelly, and Roberto SP King*
- 1.22 Polychalcogen molecules, ligands, and ions Part 2: Catenated acyclic molecules, ions, and p-block element derivatives 970  
*Risto S Laitinen, Raija Oilunkaniemi, Tristram Chivers, Liam McGeachie, Paul F Kelly, and Roberto SP King*
- 1.23 Catenated compounds in group 17—polyhalides 1021  
*Lars Kloo*
- 1.24 Synthesis, carbon-polymetal bonding and applications of organometallic clusters 1050  
*Kui Xiao and Liang Zhao*

## Editors in Chief

### Jan Reedijk

**Jan Reedijk** (1943) studied chemistry at Leiden University where he completed his Ph.D. (1968). After a few years in a junior lecturer position at Leiden University, he accepted a readership at Delft University of Technology in 1972. In 1979 he accepted a call for Professor of Chemistry at Leiden University. After 30 years of service, he retired from teaching in 2009 and remained as an emeritus research professor at Leiden University. In Leiden he has acted as Chair of the Department of Chemistry, and in 1993 he became the Founding Director of the Leiden Institute of Chemistry.

His major research activities have been in Coordination Chemistry and Bioinorganic Chemistry, focusing on biomimetic catalysis, molecular materials, and medicinal inorganic chemistry. Jan Reedijk was elected member of the Royal Netherlands Academy of Sciences in 1996 and he was knighted by the Queen of the Netherlands to the order of the Dutch Lion (2008). He is also lifetime member of the Finnish Academy of Sciences and Letters and of Academia Europaea. He has held visiting professorships in Cambridge (UK), Strasbourg (France), Münster (Germany), Riyadh (Saudi Arabia), Louvain-la-Neuve (Belgium), Dunedin (New Zealand), and Torun (Poland). In 1990 he served as President of the Royal Netherlands Chemical Society.

He has acted as the Executive Secretary of the International Conferences of Coordination Chemistry (1988–2012) and served IUPAC in the Division of Inorganic Chemistry, first as a member and later as (vice/past) president between 2005 and 2018. After his university retirement he remained active as research consultant and in IUPAC activities, as well as in several editorial jobs. For Elsevier, he acted as Editor-in-Chief of the *Reference Collection in Chemistry* (2013–2019), and together with Kenneth R. Poeppelmeier for *Comprehensive Inorganic Chemistry II* (2008–2013) and *Comprehensive Inorganic Chemistry III* (2019–present). From 2018 to 2020, he co-chaired the worldwide celebrations of the International Year of the Periodic Table 2019.

Jan Reedijk has published over 1200 papers (1965–2022; cited over 58000 times;  $h = 96$ ). He has supervised 90 Ph.D. students, over 100 postdocs, and over 250 MSc research students.

### Kenneth R. Poeppelmeier

**Kenneth R. Poeppelmeier** (1949) completed his undergraduate studies in chemistry at the University of Missouri (1971) and then volunteered as an instructor at Samoa College—United States Peace Corps in Western Samoa (1971–1974). He completed his Ph.D. (1978) in Inorganic Chemistry with John Corbett at Iowa State University (1978).

He joined the catalysis research group headed by John Longo at Exxon Research and Engineering Company, Corporate Research–Science Laboratories (1978–1984), where he collaborated with the reforming science group and Exxon Chemicals to develop the first zeolite-based light naphtha reforming catalyst. In 1984 he joined the Chemistry Department at Northwestern University and the recently formed Center for Catalysis and Surface Science (CCSS). He is the Charles E. and Emma H. Morrison Professor of Chemistry at Northwestern University and a NAISE Fellow joint with Northwestern University and the Chemical Sciences and Engineering Division, Argonne National Laboratory. Leadership positions held include Director, CCSS, Northwestern University; Associate Division Director for Science, Chemical Sciences and Engineering Division, Argonne National Laboratory; President of the Chicago Area Catalysis Club; Associate Director, NSF Science and Technology Center for Superconductivity; and Chairman of the ACS Solid State Subdivision of the Division of Inorganic Chemistry.

His major research activities have been in Solid State and Inorganic Materials Chemistry focusing on heterogeneous catalysis, solid state chemistry, and materials chemistry. His awards include National Science Council of Taiwan Lecturer (1991); Dow Professor of Chemistry (1992–1994); AAAS Fellow, the American Association for the Advancement of Science (1993); JSPS Fellow, Japan Society for the Promotion of Science (1997); Natural Science Foundation of China Lecturer (1999); National Science Foundation Creativity Extension Award (2000)

and 2022); Institut Universitaire de France Professor (2003); Chemistry Week in China Lecturer (2004); Lecturer in Solid State Chemistry, China (2005); Visitantes Distinguidos, Universidad Complutense Madrid (2008); Visiting Professor, Chinese Academy of Sciences (2011); 20 years of Service and Dedication Award to Inorganic Chemistry (2013); Elected foreign member of Spanish National Academy: Real Academia de Ciencia, Exactas, Fisicas y Naturales (2017); Elected Honorary Member of the Royal Society of Chemistry of Spain (RSEQ) (2018); and the TianShan Award, Xinjiang Uygur Autonomous Region of China (2021).

He has organized and was Chairman of the Chicago Great Lakes Regional ACS Symposium on Synthesis and Processing of Advanced Solid State Materials (1987), the New Orleans National ACS Symposium on Solid State Chemistry of Heterogeneous Oxide Catalysis, Including New Microporous Solids (1987), the Gordon Conference on Solid State Chemistry (1994) and the First European Gordon Conference on Solid State Chemistry (1995), the Spring Materials Research Society Symposium on Environmental Chemistry (1995), the Advisory Committee of Intense Pulsed Neutron Source (IPNS) Program (1996–1998), the Spring Materials Research Society Symposium on Perovskite Materials (2003), the 4th International Conference on Inorganic Materials, University of Antwerp (2004), and the Philadelphia National ACS Symposium on Homogeneous and Heterogeneous Oxidation Catalysis (2004).

He has served on numerous Editorial Boards, including *Chemistry of Materials*, *Journal of Alloys and Compounds*, *Solid State Sciences*, *Solid State Chemistry*, and *Science China Materials*, and has been a co-Editor for *Structure and Bonding*, an Associate Editor for *Inorganic Chemistry*, and co-Editor-in-Chief with Jan Reedijk for *Comprehensive Inorganic Chemistry II* (published 2013) and *Comprehensive Inorganic Chemistry III* (to be published in 2023). In addition, he has served on various Scientific Advisory Boards including for the World Premier International Research Center Initiative and Institute for Integrated Cell-Material Sciences Kyoto University, the European Center SOPRANO on Functional Electronic Metal Oxides, the Kyoto University Mixed-Anion Project, and the Dresden Max Planck Institute for Chemistry and Physics.

Kenneth Poeppelmeier has published over 500 papers (1971–2022) and cited over 28000 times (h-index = 84). He has supervised over 200 undergraduates, Ph.D. students, postdocs, and visiting scholars in research.

## VOLUME EDITORS

---

Risto S. Laitinen

**Risto S. Laitinen** is Professor Emeritus of Chemistry at the University of Oulu, Finland. He received the M.Sc and Ph.D. degrees from Helsinki University of Technology (currently Aalto University). His research interests are directed to synthetic, structural, and computational chemistry of chalcogen compounds focusing on selenium and tellurium. He has published 250 peer-reviewed articles and 15 book chapters and has edited 2 books: *Selenium and Tellurium Reagents: In Chemistry and Materials Science* with Raija Oilunkaniemi (Walther de Gruyter, 2019) and *Selenium and Tellurium Chemistry: From Small Molecules to Biomolecules and Materials* with Derek Woollins (Springer, 2011). He has also written 30 professional and popular articles in chemistry. He is the Secretary of the Division of Chemical Nomenclature and Structure Representation, International Union of Pure and Applied Chemistry, for the term 2016–2023. He served as Chair of the Board of Union of Finnish University Professors in 2007–2010. In 2017, Finnish Cultural Foundation (North Ostrobothnia regional fund) gave him an award for excellence in his activities for science and music. He has been a member of Finnish Academy of Science and Letters since 2003.

Vincent L. Pecoraro

**Professor Vincent L. Pecoraro** is a major contributor in the fields of inorganic, bioinorganic, and supramolecular chemistries. He has risen to the upper echelons of these disciplines with over 300 publications (an h-index of 92), 4 book editorships, and 5 patents. He has served the community in many ways including as an Associate Editor of *Inorganic Chemistry* for 20 years and now is President of the Society of Biological Inorganic Chemistry. Internationally, he has received a Le Studium Professorship, Blaise Pascal International Chair for Research, the Alexander von Humboldt Stiftung, and an Honorary PhD from Aix-Marseille University. His many US distinctions include the 2016 ACS Award for Distinguished Service in the Advancement of Inorganic Chemistry, the 2021 ACS/SCF FrancoAmerican Lectureship Prize, and being elected a Fellow of the ACS and AAAS. He also recently cofounded a Biomedical Imaging company, VIEWaves. In 2022, he was ranked as one of the world's top 1000 most influential chemists.

Zijian Guo

**Professor Zijian Guo** received his Ph.D. from the University of Padova and worked as a postdoctoral research fellow at Birkbeck College, the University of London. He also worked as a research associate at the University of Edinburgh. His research focuses on the chemical biology of metals and metallodrugs and has authored or co-authored more than 400 peer-reviewed articles on basic and applied research topics. He was awarded the First Prize in Natural Sciences from Ministry of Education of China in 2015, the Luigi Sacconi Medal from the Italian Chemical Society in 2016, and the Outstanding Achievement Award from the Society of the Asian Biological Inorganic Chemistry in 2020. He founded Chemistry and Biomedicine Innovation Center (ChemBIC) in Nanjing University in 2019, and is serving as the Director of ChemBIC since then. He was elected to the Fellow of the Chinese Academy of Sciences in 2017. He served as Associated Editor of *Coord. Chem. Rev* and an editorial board member of several other journals.

Daniel C. Fredrickson

**Daniel C. Fredrickson** is a Professor in the Department of Chemistry at the University of Wisconsin-Madison. He completed his BS in Biochemistry at the University of Washington in 2000, where he gained his first experiences with research and crystals in the laboratory of Prof. Bart Kahr. At Cornell University, he then pursued theoretical investigations of bonding in intermetallic compounds, the vast family of solid state compounds based on metallic elements, under the mentorship of Profs. Stephen Lee and Roald Hoffmann, earning his Ph.D. in 2005. Interested in the experimental and crystallographic aspects of complex intermetallics, he then carried out postdoctoral research from 2005 to 2008 with Prof. Sven Lidin at Stockholm University. Since starting at UW-Madison in 2009, his research group has created theory-driven approaches to the synthesis and discovery of new intermetallic phases and understanding the origins of their structural features. Some of his key research contributions are the development of the DFT-Chemical Pressure Method, the discovery of isolobal bonds for the generalization of the 18 electron rule to intermetallic phases, models for the emergence of incommensurate modulations in these compounds, and various design strategies for guiding complexity in solid state structures.

Patrick M. Woodward

**Professor Patrick M. Woodward** received BS degrees in Chemistry and General Engineering from Idaho State University in 1991, an MS in Materials Science, and a Ph.D. in Chemistry from Oregon State University (1996) under the supervision of Art Sleight. After a postdoctoral appointment in the Physics Department at Brookhaven National Laboratory (1996–1998), he joined the faculty at Ohio State University in 1998, where he holds the rank of Professor in the Department of Chemistry and Biochemistry. He is a Fellow of the American Chemical Society (2020) and a recipient of an Alfred P. Sloan Fellowship (2004) and an NSF Career Award (2001). He has co-authored two textbooks: *Solid State Materials Chemistry* and the popular general chemistry textbook, *Chemistry: The Central Science*. His research interests revolve around the discovery of new materials and understanding links between the composition, structure, and properties of extended inorganic and hybrid solids.

**P. Shiv Halasyamani**

**Professor P. Shiv Halasyamani** earned his BS in Chemistry from the University of Chicago (1992) and his Ph.D. in Chemistry under the supervision of Prof. Kenneth R. Poeppelmeier at Northwestern University (1996). He was a Postdoctoral Fellow and Junior Research Fellow at Christ Church College, Oxford University, from 1997 to 1999. He began his independent academic career in the Department of Chemistry at the University of Houston in 1999 and has been a Full Professor since 2010. He was elected as a Fellow of the American Association for the Advancement of Science (AAAS) in 2019 and is currently an Associate Editor of the ACS journals *Inorganic Chemistry* and *ACS Organic & Inorganic Au*. His research interests involve the design, synthesis, crystal growth, and characterization of new functional inorganic materials.

**Ram Seshadri**

**Ram Seshadri** received his Ph.D. in Solid State Chemistry from the Indian Institute of Science (IISc), Bangalore, working under the guidance of Professor C. N. R. Rao FRS. After some years as a Postdoctoral Fellow in Europe, he returned to IISc as an Assistant Professor in 1999. He moved to the Materials Department (College of Engineering) at UC Santa Barbara in 2002. He was recently promoted to the rank of Distinguished Professor in the Materials Department and the Department of Chemistry and Biochemistry in 2020. He is also the Fred and Linda R. Wudl Professor of Materials Science and Director of the Materials Research Laboratory: A National Science Foundation Materials Research Science and Engineering Center (NSF-MRSEC). His work broadly addresses the topic of structure–composition–property relations in crystalline inorganic and hybrid materials, with a focus on magnetic materials and materials for energy conversion and storage. He is Fellow of the Royal Society of Chemistry, the American Physical Society, and the American Association for the Advancement of Science. He serves as Associate Editor of the journals, *Annual Reviews of Materials Research* and *Chemistry of Materials*.

**Serena Cussen**

**Serena Cussen** née Corr studied chemistry at Trinity College Dublin, completing her doctoral work under Yuri Gun'ko. She then joined the University of California, Santa Barbara, working with Ram Seshadri as a postdoctoral researcher. She joined the University of Kent as a lecturer in 2009. She moved to the University of Glasgow in 2013 and was made Professor in 2018. She moved to the University of Sheffield as a Chair in Functional Materials and Professor in Chemical and Biological Engineering in 2018, where she now serves as Department Head. She works on next-generation battery materials and advanced characterization techniques for the structure and properties of nanomaterials. Serena is the recipient of several awards including the *Journal of Materials Chemistry* Lectureship of the Royal Society of Chemistry. She previously served as Associate Editor of Royal Society of Chemistry journal *Nanoscale* and currently serves as Associate Editor for the Institute of Physics journal *Progress in Energy*.

Rutger A. van Santen

**Rutger A. van Santen** received his Ph.D. in 1971 in Theoretical Chemistry from the University of Leiden, The Netherlands. In the period 1972–1988, he became involved with catalysis research when employed by Shell Research in Amsterdam and Shell Development Company in Houston. In 1988, he became Full Professor of Catalysis at the Technical University Eindhoven. From 2010 till now he is Emeritus Professor and Honorary Institute Professor at Technical University Eindhoven. He is a member of Royal Dutch Academy of Sciences and Arts and Foreign Associate of the United States National Academy of Engineering (NAE). He has received several prestigious awards: the 1981 golden medal of the Royal Dutch Chemical Society; in 1992, the F.G. Chiappetta award of the North American Catalysis Society; in 1997, the Spinoza Award from the Dutch Foundation for Pure and Applied Research; and in 2001, the Alwin Mittasch Medal Dechema, Germany, among others. His main research interests are computational heterogeneous catalysis and complex chemical systems theory. He has published over 700 papers, 16 books, and 22 patents.

Emiel J. M. Hensen

**Emiel J. M. Hensen** received his Ph.D. in Catalysis in 2000 from Eindhoven University of Technology, The Netherlands. Between 2000 and 2008, he worked at the University of Amsterdam, Shell Research in Amsterdam, and Eindhoven University of Technology on several topics in the field of heterogeneous catalysis. Since July 2009, he is Full Professor of Inorganic Materials and Catalysis at TU/e. He was a visiting professor at the Katholieke Universiteit Leuven (Belgium, 2001–2016) and at Hokkaido University (Japan, 2016). He is principal investigator and management team member of the gravitation program Multiscale Catalytic Energy Conversion, elected member of the Advanced Research Center Chemical Building Blocks Consortium, and chairman of the Netherlands Institute for Catalysis Research (NIOK). Hensen was Head of the Department of Chemical Engineering and Chemistry of Eindhoven University of Technology from 2016 to 2020. Hensen received Veni, Vidi, Vici, and Casmir grant awards from the Netherlands Organisation for Scientific Research. His main interests are in mechanism of heterogeneous catalysis combining experimental and computation studies. He has published over 600 papers, 20 book chapters, and 7 patents.

Artem M. Abakumov

**Artem M. Abakumov** graduated from the Department of Chemistry at Moscow State University in 1993, received his Ph.D. in Chemistry from the same University in 1997, and then continued working as a Researcher and Vice-Chair of Inorganic Chemistry Department. He spent about 3 years as a postdoctoral fellow and invited professor in the Electron Microscopy for Materials Research (EMAT) laboratory at the University of Antwerp and joined EMAT as a research leader in 2008. Since 2015 he holds a Full Professor position at Skolkovo Institute of Science and Technology (Skoltech) in Moscow, leading Skoltech Center for Energy Science and Technology as a Director. His research interests span over a wide range of subjects, from inorganic chemistry, solid state chemistry, and crystallography to battery materials and transmission electron microscopy. He has extended experience in characterization of metal-ion battery electrodes and electrocatalysts with advanced TEM techniques that has led to a better understanding of charge–discharge mechanisms, redox reactions, and associated structural transformations in various classes of cathode materials on different spatial scales. He has published over 350 papers, 5 book chapters, and 12 patents.

Keith J. Stevenson

**Keith J. Stevenson** received his Ph.D. in 1997 from the University of Utah under the supervision of Prof. Henry White. Subsequently, he held a postdoctoral appointment at Northwestern University (1997–2000) and a tenured faculty appointment (2000–2015) at the University of Texas at Austin. At present, he is leading the development of a new graduate level university (Skolkovo Institute for Science and Technology) in Moscow, Russia, where he is Provost and the former Director of the Center for Energy Science and Technology (CEST). To date he has published over 325 peer-reviewed publications, 14 patents, and 6 book chapters in this field. He is a recipient of Society of Electroanalytical Chemistry Charles N. Reilly Award (2021).

Evgeny V. Antipov

**Evgeny V. Antipov** graduated from the Department of Chemistry at Moscow State University in 1981, received his Ph.D. in Chemistry in 1986, DSc degree in Chemistry in 1998, and then continued working at the same University as a Researcher, Head of the Laboratory of Inorganic Crystal Chemistry, Professor, Head of Laboratory of fundamental research on aluminum production, and Head of the Department of Electrochemistry. Since 2018 he also holds a professor position at Skolkovo Institute of Science and Technology (Skoltech) in Moscow. Currently his research interests are mainly focused on inorganic materials for application in batteries and fuel cells. He has published more than 400 scientific articles and 14 patents.

Vivian W.W. Yam

**Professor Vivian W.W. Yam** is the Chair Professor of Chemistry and Philip Wong Wilson Wong Professor in Chemistry and Energy at The University of Hong Kong. She received both her B.Sc (Hons) and Ph.D. from The University of Hong Kong. She was elected to Member of Chinese Academy of Sciences, International Member (Foreign Associate) of US National Academy of Sciences, Foreign Member of Academia Europaea, Fellow of TWAS, and Founding Member of Hong Kong Academy of Sciences. She was Laureate of 2011 L'Oréal-UNESCO For Women in Science Award. Her research interests include inorganic and organometallic chemistry, supramolecular chemistry, photophysics and photochemistry, and metal-based molecular functional materials for sensing, organic optoelectronics, and energy research.

Also see: <https://chemistry.hku.hk/wwym>.

David L. Bryce

**David L. Bryce** (B.Sc (Hons), 1998, Queen's University; Ph.D., 2002, Dalhousie University; postdoctoral fellow, 2003–04, NIDDK/NIH) is Full Professor and University Research Chair in Nuclear Magnetic Resonance at the University of Ottawa in Canada. He is the past Chair of the Department of Chemistry and Biomolecular Sciences, a Fellow of the Royal Society of Chemistry, and an elected Fellow of the Royal Society of Canada. His research interests include solid-state NMR of low-frequency quadrupolar nuclei, NMR studies of materials, NMR crystallography, halogen bonding, mechanochemistry, and quantum chemical interpretation of NMR interaction tensors. He is the author of approximately 200 scientific publications and co-author of 1 book. He is the Editor-in-Chief of *Solid State Nuclear Magnetic Resonance* and Section Editor (Magnetic Resonance and Molecular Spectroscopy) for the *Canadian Journal of Chemistry*. He has served as the Chair of Canada's National Ultrahigh-Field NMR Facility for Solids and is a past co-chair of the International Society for Magnetic Resonance conference and of the Rocky Mountain Conference on Magnetic Resonance Solid-State NMR Symposium. His work has been recognized with the Canadian Society for Chemistry Keith Laidler Award and with the Gerhard Herzberg Award of the Canadian Association of Analytical Sciences and Spectroscopy.

Paul R. Raithby

**Paul R. Raithby** obtained his B.Sc (1973) and Ph.D. (1976) from Queen Mary College, University of London, working for his Ph.D. in structural inorganic chemistry. He moved to the University of Cambridge in 1976, initially as a postdoctoral researcher and then as a faculty member. In 2000, he moved to the University of Bath to take up the Chair of Inorganic Chemistry when he remains to the present day, having been awarded an Emeritus Professorship in 2022. His research interests have spanned the chemistry of transition metal cluster compounds, platinum acetylide complexes and oligomers, and lanthanide complexes, and he uses laboratory and synchrotron-based X-ray crystallographic techniques to determine the structures of the complexes and to study their dynamics using time-resolved photocrystallographic methods.

Angus P. Wilkinson

**Angus P. Wilkinson** completed his bachelors (1988) and doctoral (1992) degrees in chemistry at Oxford University in the United Kingdom. He spent a postdoctoral period in the Materials Research Laboratory, University of California, Santa Barbara, prior to joining the faculty at the Georgia Institute of Technology as an assistant professor in 1993. He is currently a Professor in both the Schools of Chemistry and Biochemistry, and Materials Science and Engineering, at the Georgia Institute of Technology. His research in the general area of inorganic materials chemistry makes use of synchrotron X-ray and neutron scattering to better understand materials synthesis and properties.

# CONTRIBUTORS TO VOLUME 1

# PREFACE

---

Comprehensive Inorganic Chemistry III is a new multi-reference work covering the broad area of Inorganic Chemistry. The work is available both in print and in electronic format. The 10 Volumes review significant advances and examines topics of relevance to today's inorganic chemists with a focus on topics and results after 2012.

The work is focusing on new developments, including interdisciplinary and high-impact areas. Comprehensive Inorganic Chemistry III, specifically focuses on main group chemistry, biological inorganic chemistry, solid state and materials chemistry, catalysis and new developments in electrochemistry and photochemistry, as well as on NMR methods and diffractions methods to study inorganic compounds.

The work continues our 2013 work Comprehensive Inorganic Chemistry II, but at the same time adds new volumes on emerging research areas and techniques used to study inorganic compounds. The new work is also highly complementary to other recent Elsevier works in Coordination Chemistry and Organometallic Chemistry thereby forming a trio of works covering the whole of modern inorganic chemistry, most recently COMC-4 and CCC-3. The rapid pace of developments in recent years in all areas of chemistry, particularly inorganic chemistry, has again created many challenges to provide a contemporary up-to-date series.

As is typically the challenge for Multireference Works (MRWs), the chapters are designed to provide a valuable long-standing scientific resource for both advanced students new to an area as well as researchers who need further background or answers to a particular problem on the elements, their compounds, or applications. Chapters are written by teams of leading experts, under the guidance of the Volume Editors and the Editors-in-Chief. The articles are written at a level that allows undergraduate students to understand the material, while providing active researchers with a ready reference resource for information in the field. The chapters are not intended to provide basic data on the elements, which are available from many sources including the original CIC-I, over 50-years-old by now, but instead concentrate on applications of the elements and their compounds and on high-level techniques to study inorganic compounds.

## **Vol. 1: Synthesis, Structure, and Bonding in Inorganic Molecular Systems; Risto S. Laitinen**

In this Volume the editor presents an historic overview of Inorganic Chemistry starting with the birth of inorganic chemistry after Berzelius, and a focus on the 20th century including an overview of "inorganic" Nobel Prizes and major discoveries, like inert gas compounds. The most important trends in the field are discussed in an historic context. The bulk of the Volume consists of 3 parts, i.e., (1) Structure, bonding, and reactivity in inorganic molecular systems; (2) Intermolecular interactions, and (3) Inorganic Chains, rings, and cages. The volume contains 23 chapters.

Part 1 contains chapters dealing with compounds in which the heavy p-block atom acts as a central atom. Some chapters deal with the rich synthetic and structural chemistry of noble gas compounds, low-coordinate p-block elements, biradicals, iron-only hydrogenase mimics, and macrocyclic selenoethers. Finally, the chemistry and application of weakly coordinating anions, the synthesis, structures, and reactivity of carbenes containing non-innocent ligands, frustrated Lewis pairs in metal-free catalysis are discussed. Part 2 discusses secondary bonding interactions that play an important role in the properties of bulk materials. It includes a chapter on the general theoretical considerations of secondary bonding interactions, including halogen and chalcogen bonding. This section is concluded by the update of the host-guest chemistry of the molecules of p-block elements and by a comprehensive review of closed-shell metallophilic interactions. The third part of the Volume is dedicated to chain, ring and cage (or cluster) compounds in molecular inorganic chemistry. Separate

chapters describe the recent chemistry of boron clusters, as well as the chain, ring, and cage compounds of Group 13 and 15, and 16 elements. Also, aromatic compounds bearing heavy Group 14 atoms, polyhalogenide anions and Zintl-clusters are presented.

### **Vol. 2: Bioinorganic Chemistry and Homogeneous Biomimetic Inorganic Catalysis; Vincent L. Pecoraro and Zijian Guo**

In this Volume, the editors have brought together 26 chapters providing a broad coverage of many of the important areas involving metal compounds in biology and medicine. Readers interested in fundamental biochemistry that is assisted by metal ion catalysis, or in uncovering the latest developments in diagnostics or therapeutics using metal-based probes or agents, will find high-level contributions from top scientists. In the first part of the Volume topics dealing with metals interacting with proteins and nucleic acids are presented (e.g., siderophores, metallophores, homeostasis, biomineralization, metal-DNA and metal-RNA interactions, but also with zinc and cobalt enzymes). Topics dealing with iron-sulfur clusters and heme-containing proteins, enzymes dealing with dinitrogen fixation, dihydrogen and dioxygen production by photosynthesis will also be discussed, including bioinspired model systems.

In the second part of the Volume the focus is on applications of inorganic chemistry in the field of medicine: e.g., clinical diagnosis, curing diseases and drug targeting. Platinum, gold and other metal compounds and their mechanism of action will be discussed in several chapters. Supramolecular coordination compounds, metal organic frameworks and targeted modifications of higher molecular weight will also be shown to be important for current and future therapy and diagnosis.

### **Vol. 3: Theory and Bonding of Inorganic Non-molecular Systems; Daniel C. Fredrickson**

This volume consists of 15 chapters that build on symmetry-based expressions for the wavefunctions of extended structures toward models for bonding in solid state materials and their surfaces, algorithms for the prediction of crystal structures, tools for the analysis of bonding, and theories for the unique properties and phenomena that arise in these systems. The volume is divided into four parts along these lines, based on major themes in each of the chapters. These are: Part 1: Models for extended inorganic structures, Part 2: Tools for electronic structure analysis, Part 3: Predictive exploration of new structures, and Part 4: Properties and phenomena.

### **Vol. 4: Solid State Inorganic Chemistry; P. Shiv Halasyamani and Patrick M. Woodward**

In a broad sense the field of inorganic chemistry can be broken down into substances that are based on molecules and those that are based on extended arrays linked by metallic, covalent, polar covalent, or ionic bonds (i.e., extended solids). The field of solid-state inorganic chemistry is largely concerned with elements and compounds that fall into the latter group. This volume contains nineteen chapters covering a wide variety of solid-state inorganic materials. These chapters largely focus on materials with properties that underpin modern technology. Smart phones, solid state lighting, batteries, computers, and many other devices that we take for granted would not be possible without these materials. Improvements in the performance of these and many other technologies are closely tied to the discovery of new materials or advances in our ability to synthesize high quality samples. The organization of most chapters is purposefully designed to emphasize how the exceptional physical properties of modern materials arise from the interplay of composition, structure, and bonding. Not surprisingly this volume has considerable overlap with both Volume 3 (Theory and Bonding of Inorganic Non-molecular Systems) and Volume 5 (Inorganic Materials Chemistry). We anticipate that readers who are interested in this volume will find much of interest in those volumes and vice versa

### **Vol. 5: Inorganic Materials Chemistry; Ram Seshadri and Serena Cussen**

This volume has adopted the broad title of Inorganic Materials Chemistry, but as readers would note, the title could readily befit articles in other volumes as well. In order to distinguish contributions in this volume from

those in other volumes, the editors have chosen to use as the organizing principle, the role of synthesis in developing materials, reflected by several of the contributions carrying the terms “synthesis” or “preparation” in the title. It should also be noted that the subset of inorganic materials that are the focus of this volume are what are generally referred to as functional materials, i.e., materials that carry out a function usually through the way they respond to an external stimulus such as light, or thermal gradients, or a magnetic field.

### **Vol. 6: Heterogeneous Inorganic Catalysis; Rutger A. van Santen and Emiel J. M. Hensen**

This Volume starts with an introductory chapter providing an excellent discussion of single sites in metal catalysis. This chapter is followed by 18 chapters covering a large part of the field. These chapters have been written with a focus on the synthesis and characterization of catalytic complexity and its relationship with the molecular chemistry of the catalytic reaction. In the 1950s with the growth of molecular inorganic chemistry, coordination chemistry and organometallic chemistry started to influence the development of heterogeneous catalysis. A host of new reactions and processes originate from that time. In this Volume chapters on major topics, like promoted Fischer-Tropsch catalysts, structure sensitivity of well-defined alloy surfaces in the context of oxidation catalysis and electrocatalytic reactions, illustrate the broadness of the field. Molecular heterogeneous catalysts rapidly grew after high-surface synthetic of zeolites were introduced; so, synthesis, structure and nanopore chemistry in zeolites is presented in a number of chapters. Also, topics like nanocluster activation of zeolites and supported zeolites are discussed. Mechanistically important chapters deal with imaging of single atom catalysts. An important development is the use of reducible supports, such as  $\text{CeO}_2$  or  $\text{Fe}_2\text{O}_3$  where the interaction between the metal and support is playing a crucial role.

### **Vol. 7: Inorganic Electrochemistry; Keith J. Stevenson, Evgeny V. Antipov and Artem M. Abakumov**

This volume bridges several fields across chemistry, physics and material science. Perhaps this topic is best associated with the book “Inorganic Electrochemistry: Theory, Practice and Applications” by Piero Zanello that was intended to introduce inorganic chemists to electrochemical methods for study of primarily molecular systems, including metallocenes, organometallic and coordination complexes, metal complexes of redox active ligands, metal-carbonyl clusters, and proteins. The emphasis in this Volume of CIC III is on the impact of inorganic chemistry on the field of material science, which has opened the gateway for inorganic chemists to use more applied methods to the broad areas of electrochemical energy storage and conversion, electrocatalysis, electroanalysis, and electrosynthesis. In recognition of this decisive impact, the Nobel Prize in Chemistry of 2019 was awarded to John B. Goodenough, M. Stanley Whittingham, and Akira Yoshino for the development of the lithium-ion battery.

### **Vol. 8: Inorganic Photochemistry; Vivian W. W. Yam**

In this Volume the editor has compiled 19 chapters discussing recent developments in a variety of developments in the field. The introductory chapter overviews the several topics, including photoactivation and imaging reagents. The first chapters include a discussion of using luminescent coordination and organometallic compounds for organic light-emitting diodes (OLEDs) and applications to highlight the importance of developing future highly efficient luminescent transition metal compounds. The use of metal compounds in photo-induced bond activation and catalysis is highlighted by non-sacrificial photocatalysis and redox photocatalysis, which is another fundamental area of immense research interest and development. This work facilitates applications like biological probes, drug delivery and imaging reagents. Photochemical  $\text{CO}_2$  reduction and water oxidation catalysis has been addressed in several chapters. Use of such inorganic compounds in solar fuels and photocatalysis remains crucial for a sustainable environment. Finally, the photophysics and photochemistry of lanthanoid compounds is discussed, with their potential use of doped lanthanoids in luminescence imaging reagents.

**Vol. 9: NMR of Inorganic Nuclei; David L. Bryce**

Nuclear magnetic resonance (NMR) spectroscopy has long been established as one of the most important analytical tools at the disposal of the experimental chemist. The isotope-specific nature of the technique can provide unparalleled insights into local structure and dynamics. As seen in the various contributions to this Volume, applications of NMR spectroscopy to inorganic systems span the gas phase, liquid phase, and solid state. The nature of the systems discussed covers a very wide range, including glasses, single-molecule magnets, energy storage materials, bioinorganic systems, nanoparticles, catalysts, and more. The focus is largely on isotopes other than  $^1\text{H}$  and  $^{13}\text{C}$ , although there are clearly many applications of NMR of these nuclides to the study of inorganic compounds and materials. The value of solid-state NMR in studying the large percentage of nuclides which are quadrupolar (spin  $I > \frac{1}{2}$ ) is apparent in the various contributions. This is perhaps to be expected given that rapid quadrupolar relaxation can often obfuscate the observation of these resonances in solution.

**Vol. 10: X-ray, Neutron and Electron Scattering Methods in Inorganic Chemistry; Angus P. Wilkinson and Paul R. Raithby**

In this Volume the editors start with an introduction on the recent history and improvements of the instrumentation, source technology and user accessibility of synchrotron and neutron facilities worldwide, and they explain how these techniques work. The modern facilities now allow inorganic chemists to carry out a wide variety of complex experiments, almost on a day-to-day basis, that were not possible in the recent past. Past editions of Comprehensive Inorganic Chemistry have included many examples of successful synchrotron or neutron studies, but the increased importance of such experiments to inorganic chemists motivated us to produce a separate volume in CIC III dedicated to the methodology developed and the results obtained.

The introduction chapter is followed by 15 chapters describing the developments in the field. Several chapters are presented covering recent examples of state-of-the-art experiments and refer to some of the pioneering work leading to the current state of the science in this exciting area. The editors have recognized the importance of complementary techniques by including chapters on electron crystallography and synchrotron radiation sources. Chapters are present on applications of the techniques in e.g., spin-crossover materials and catalytic materials, and in the use of time-resolved studies on molecular materials. A chapter on the worldwide frequently used structure visualization of crystal structures, using PLATON/PLUTON, is also included. Finally, some more specialized studies, like Panoramic (in beam) studies of materials synthesis and high-pressure synthesis are present. Direct observation of transient species and chemical reactions in a pore observed by synchrotron radiation and X-ray transient absorption spectroscopies in the study of excited state structures, and ab initio structure solution using synchrotron powder diffraction, as well as local structure determination using total scattering data, are impossible and unthinkable without these modern diffraction techniques.

### Abstract

Whereas inorganic substances have been known and studied since the antiques, it is only during the 19th century that inorganic chemistry was born as an independent scientific discipline. The advances during the 20th, which have been made in inorganic molecular chemistry, have had an impact in the development of the whole field of chemistry and physical sciences. Several species with novel bonding arrangements, unprecedented structures, and unusual reactivities have been prepared comprising also compounds, which at the time were regarded impossible. The current driving force in chemical research arises from demands of materials science to establish the relationship of the molecular and electronic structures with the bulk properties of the materials. Molecular level understanding is needed to develop further electrical conductors, semiconductors, insulators, coatings, ceramics, catalysts, nanotubes, polymers, and thin films, all of which play a significant role in modern technology. The need to replace fossil fuels demands the development of environmentally friendlier energy sources in which molecular inorganic chemistry plays one of the a key roles. This chapter briefly outlines some important developments in bonding and reactivity of molecular inorganic compounds comprising (a) multiple bonding in p-block compounds, (b) secondary bonding interactions, (c) small-molecule activation, (d) weakly coordinating anions, and (e) biradicals and biradicaloids. This list is not exhaustive but serves as an introduction to the 23 chapters in Volume 1 of *Comprehensive Inorganic Chemistry III*. These chapters describe the spectacular progress in their respective fields during the recent decades.

### 1.01.1 Birth of inorganic chemistry

It is generally considered that the last person, who could fully handle and understand the whole field of chemistry, was Jöns Jacob Berzelius (1779–1848) (see Fig. 1A). Between 1822 and 1841, he published annually “Jahresbericht über die Fortschritte der physischen Wissenschaften” to review the progress in physical sciences. This series is probably the first regularly appearing review publication in chemistry (Fig. 1B).

After Berzelius, chemistry was subdivided into inorganic and organic chemistry and was gradually further divided into physical and analytical chemistry, and biochemistry. While inorganic materials have been known and investigated since the antiques, the birth of inorganic chemistry as an independent subdiscipline took place in the late 18th and early 19th century. While there are numerous scientists, who have contributed to this process, possibly the main protagonists are Antoine Lavoisier (1743–94), John Dalton (1766–1844), Friedrich Wöhler (1800–1882), Dmitri Mendeleev (1834–1907), and Alfred Werner (1866–1919).

Lavoisier [see Fig. 2A] was a co-discoverer of oxygen together with Joseph Priestley (1733–1804) and Carl Wilhelm Scheele (1742–1786). The dispute about the discovery of oxygen is well-described in the play “Oxygen” by Carl Djerassi and Roald Hoffmann.<sup>1</sup> Lavoisier repeated the experiments of Priestley and showed that “air” is composed of two components, one of which combines with metals, sustains combustion, and is the source of acidity. The names “oxygen” (Greek for acid-former) and azote (Greek for no life) for the two components in “air” are also given by Lavoisier. In 1789 Lavoisier published a book “*Traité Élémentaire de Chimie, présenté dans un ordre nouveau et d’après les découvertes modernes,*” which is considered the first textbook of modern chemistry [see Fig. 2B].

John Dalton is famous for his atomic theory of 1807 and Friedrich Wöhler for showing that the organic compound, urea ( $(\text{H}_2\text{N})_2\text{CO}$ ), can be synthesized by heating of an inorganic compound, ammonium cyanate  $(\text{NH}_4)(\text{OCN})$ , thus refuting the concept of vitalism of organic compounds. Both scientists have also made other significant advances in chemistry. For instance, Wöhler discovered several elements, such as crystalline boron and silicon. The Periodic Table that was presented by Dmitri Mendeleev in 1869 is the corner stone of modern chemistry.

**Fig. 1** (A) Jöns Jacob Berzelius (1779–1848), lithography portrait from 1836 by P.H. van den Heuvel. (B) The title page of the 1832 issue of the "Jahresbericht über die Fortschritte der physischen Wissenschaften." (A) Reproduced under the terms of the CC 0 license <https://creativecommons.org/publicdomain/zero/1.0/>.

**Fig. 2** (A) Antoine Laurent Lavoisier (1743–1794) and his wife Marie Anne Pierrette Paulze (1758–1836). Portrait by Jacques-Louis David. Metropolitan Museum of Art, USA. (B) Title page of the textbook by Lavoisier. (A) Reproduced under the terms of the CC 0 license <https://creativecommons.org/publicdomain/zero/1.0/>.

**Fig. 3** Alfred Werner (1866–1919). ETH-Bibliothek Zürich, Bildarchiv. Reproduced under the terms of the CC BY-Sa 3.0 license <https://creativecommons.org/licenses/by-sa/3.0/>.

Alfred Werner (see Fig. 3) is considered to be the father of inorganic chemistry. His main contribution is in the creation of coordination chemistry. Werner prepared numerous molecular complexes and inferred their structures. There are 228 publications credited to him in Scifinder during the years 1890–1919. He also established that complexes containing different ligands might show isomerism. His work on metal complexes culminated in the discovery of optically active isomers in octahedral complexes. He was awarded Nobel prize in 1913. A more detailed biography of his life and accomplishments has been presented in Nobel Prize lectures.<sup>2</sup>

### 1.01.2 Inorganic chemistry in the 20th century

The development of inorganic chemistry in the 20th century has been excellently reviewed by McCleverty.<sup>3</sup> As he notes, the progress often rests on the shoulders of the discoveries made in other disciplines. For instance, the advance on modern instrumental methods of analysis in the latter half of 20th century, and the birth of the digital age with the development of ever more powerful computing facilities had enabled the study of unstable species and provided for new understanding on chemical bonding and intermolecular interactions, as well as chemical reactions thus leading to materials with new functions and applications. McCleverty<sup>3</sup> has divided the 20th century highlights to those, which have been recognized by the Nobel prize, and to those, which have not.

During the history of the Nobel prize in chemistry from 1901, every major field of chemistry has seen recognition by the Nobel committee, though it is naturally a matter of opinion, how research on individual prizes should be categorized in different subdisciplines (Fig. 4).

It is important to note that development of chemistry relies significantly on the progress in Physics. The electronic structures of atoms, molecules, and materials, which form the basis of all current-day chemistry, is based on the work by the so-called Quantum ten (N. Bohr, M. Born, L. de Broglie, P. Dirac, P. Ehrenfest, A. Einstein, W. Heisenberg, P. Jordan, W. Pauli, E. Schrödinger). With the exception of Ehrenfest and Jordan, they all won Nobel prizes in physics. The early history of quantum mechanics and the key players have been reported several times (see, for instance refs. 4, 5). Their collaborations, discussions, and disagreements laid the foundation to the high-level quantum chemical computations that are currently routinely used to understand bonding and reactivity of chemical substances.

The most important discovery for inorganic chemistry has been the use of X-ray diffraction for the crystal structure determinations (M. von Laue, Nobel Prize in 1914; W. H. Bragg and W. L. Bragg, Nobel prize in 1915). The two Nobel prizes for superconductivity (H. Kamerlingh-Onnes for the discovery of superconductivity in 1913) and J. G. Bednorz and K. A. Müller for the superconductivity in ceramic materials 1987), M. Siegbahn for his work on X-ray spectroscopy (1924), J. Chadwick for the discovery of neutron (1935), and C. J. Davisson and G. P. Thomson for the discovery of electron diffraction (1937) also had a significant impact on inorganic chemistry.

The Nobel prizes in chemistry that are directly concerned with inorganic chemistry or have impact on it are shown in Table 1. The early awards involved discovery of radioactive elements and progress in nuclear physics (M. Curie in 1911, and F. Joliot and I.

**Fig. 4** The classification of Nobel prizes in different subdisciplines of chemistry.<sup>3</sup>

Joliot-Curie in 1935). The chemical interpretation of bonding and its significance in molecular structures were awarded to A. Werner (1913), L. Pauling (1954), and G. Herzberg (1971). W. N. Lipscomb received his prize in 1976 for the model of 3c-2e bonding in boranes and other electron-deficient substances. Grignard (1912) and Wittig (1979) reagents as well as the use of boron and silicon hydrides in synthetic chemistry have applications, which go beyond inorganic chemistry. The increasing computer power enabled rapid progress in the techniques of X-ray crystallography (H. A. Hauptman and J. Karle 1985), and the development of high-resolution multinuclear NMR spectroscopy (F. Bloch and E. M. Purcell 1952, and R. R. Ernst 1991). The computational methods and techniques involving molecular orbitals and density functional theory (W. Kohn and J. A. Pople 1998) have become commonplace in understanding structures and bonding of molecules and chemical reactions. Several Nobel prizes in the latter half of 20th century have been awarded for synthetic chemistry and exploration of reaction mechanisms (see **Table 1**). The advent of metallocenes (E. O. Fischer and G. Wilkinson 1973) and the routine use of the working techniques using protective atmosphere in Schlenk lines or glove boxes have been part of the rise of organometallic chemistry. The Nobel prize of Ziegler and Natta (1963) together with the discovery of organometallic catalysts have opened new vistas for the study and industrial applications of polymers.

There are several important main-group discoveries in the 20th century, which have not been awarded the Noble prize, but may have resulted in awarding Nobel prizes in a later stage, as discussed by McCleverty<sup>3</sup> and Chivers and Konu.<sup>7</sup> This is exemplified by crown-ethers<sup>8</sup> and their s-block metal complexes,<sup>9</sup> which paved the way to the Noble prize of Cram, Lehn, and Pedersen about 20 years later.

The oxidation of O<sub>2</sub> by N. Bartlett using the very reactive gas PtF<sub>6</sub> unexpectedly resulted in the formation of (O<sub>2</sub>)[PtF<sub>6</sub>].<sup>10</sup> Since the first ionization energies of O<sub>2</sub> and Xe are similar, Bartlett assumed that xenon could be oxidized using PtF<sub>6</sub>. His experiment of mixing colorless xenon and red PtF<sub>6</sub> to form immediately yellow solid is well described by him<sup>11</sup> and is shown in **Fig. 5**. This pioneering synthesis opened a rich and versatile chemistry of noble gases, which had been considered completely inert till then. It has also forced the chemists to look at the chemical bonding with new eyes. The discovery of noble-gas compound would certainly have merited the Nobel prize.

Electron counting has become a useful tool to predict and rationalize molecular structures. One of the oldest tools is VSEPR (Valence Shell Electron Pair Repulsion) model<sup>13</sup> originally formulated by Gillespie and Nyholm<sup>14</sup> based on the paper by Sidgwick and Powel.<sup>15</sup> While VSEPR is powerful in predicting molecular geometries of main group compounds, its theoretical basis has not been clear. Gillespie<sup>16</sup> has utilized the AIM approach to rationalize the justification of electron density distribution around atoms on which the geometries of the molecules are dependent. He also extended electron-counting principles to main group rings, chains, and cages, which are electron-precise or electron-rich.<sup>17</sup>

Wade's rules provide another approach to utilize electron-counting principles to deduce molecular geometry.<sup>18</sup> This methodology is best applied to so-called electron-deficient compounds and has been originally formulated for boranes. Wade's rules serve to complement Gillespie's rules for classical and electron-rich cages. While Wade's rules work also well for carboranes<sup>19</sup> and transition metal clusters,<sup>20</sup> Gillespie's rule rationalize best the p-block element cages at the right end of the Periodic Table.

Whereas main group chemistry was the principal theme in inorganic chemistry in the first half of the 20th century, the latter half saw the rapid rise of coordination chemistry of transition metal complexes followed by the advent of organometallic chemistry and supramolecular chemistry in 1980s, and bioinorganic chemistry in 1990s. Main group chemistry has, however, been and continues to be the source of fundamental discoveries that has impact in other fields of chemistry.

**Table 1** Nobel prizes awarded in themes involving inorganic chemistry.<sup>6</sup>

<i>Year</i>	<i>Nobel-prize winners</i>	<i>Justification</i>
1904	Sir W. Ramsay	Inert gaseous elements in air and their place in periodic system
1906	H. Moissan	Isolation of fluorine
1911	M. Curie	Discovery and study of radium and polonium
1912	V. Grignard P. Sabatier	Discovery of Grignard reagent Method of hydrogenating organic compounds
1913	A. Werner	Linkage of atoms of molecules
1918	F. Haber	Ammonia synthesis from the elements
1934	H. C. Urey	Discovery of heavy hydrogen
1935	F. Joliot and I. Joliot-Curie	Synthesis of new radioactive elements
1944	O. Hahn	Discovery of fission of heavy nuclei

### 1.01.3 Current trends in molecular inorganic chemistry

#### 1.01.3.1 General

The important opinion papers by Chivers and Konu,<sup>7</sup> Power,<sup>21</sup> and Yam<sup>22</sup> discuss the current state of molecular inorganic chemistry. Several species with novel bonding arrangements, unprecedented structures, and unusual reactivities have been prepared comprising also syntheses, which were earlier regarded impossible.

Chivers and Konu<sup>7</sup> have discussed the future trends in main group chemistry. The main points they enumerate are shown in **Table 2**. Some of the entries listed in the table are discussed in more detail below, as they have relevance to Volume 1 of Comprehensive Inorganic Chemistry III. There are also other emerging features of molecular inorganic chemistry that have not been mentioned by Chivers and Konu.<sup>7</sup> Some of them will also be introduced below, since they are discussed in Volume 1 of Comprehensive Inorganic Chemistry III.

### 1.01.3.2 Multiple bonding in p-block compounds

It was long considered that heavy p-block elements do not form stable multiple bonds due to the poor  $np(\pi)-np(\pi)$  ( $n \geq 3$ ) overlap. In 1981, however, West et al.<sup>23</sup> and Yoshifuji et al.<sup>24</sup> reported the preparations of tetramesityldisilene and bis(2,4,6-tri-*tert*-butylphenyl)diphosphene, respectively. Since then, the chemistry of multiply-bonded heavy Group 13–15 compounds have seen active research interest, and their preparations, structures, bonding, and reactivities have been reviewed several times, as exemplified by some of the most recent reviews.<sup>25–30</sup> The progress in this chemistry is strongly dependent on the application of sterically bulky protective groups, such as 2,4,6-tris[bis(trimethylsilyl)methyl]phenyl<sup>31</sup> and 2,4,6-tris(2-propyl)phenyl<sup>32</sup> [see **Chart 1A** and **B**].

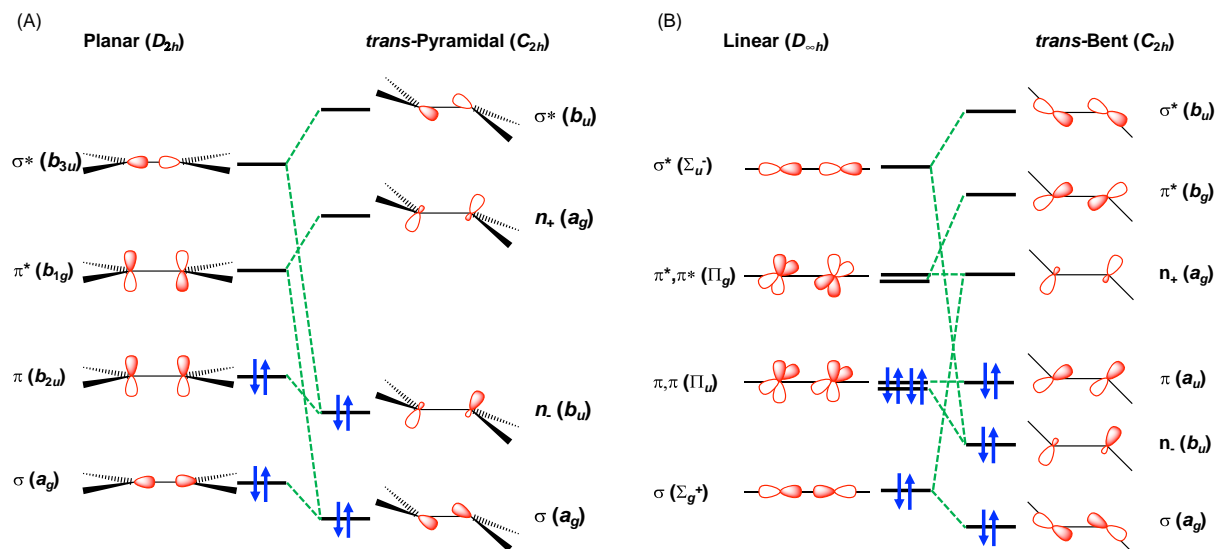

Heavy Group 14 element analogs of alkynes ( $RMMR$ ;  $M = Si, Ge, Sn, Pb$ ) have also been prepared and structurally characterized.<sup>27</sup> Their stabilization requires an even bulkier protective groups, such as terphenyl derivatives [see example in **Chart 1C**] or silyl derivatives with a very bulky substituent [see **Chart 1D**].

By contrast to the ethene derivatives in which the  $>C=C<$  moiety is planar, the  $M$  atoms in  $R_2M=MR_2$  ( $M = Si, Ge, Sn, Pb$ ;  $R =$  is the protective organic group) show pyramidal bonding geometry. In the similar fashion, while  $-C\equiv C-$  is linear, the higher congeners are bent. These differences in the bonding environments have been discussed in terms of Jahn-Teller effect<sup>27</sup> and are shown in **Fig. 6**.

In case of the heavy Group 14 elements, the distortion of the geometry from the planar ( $R_2MMR_2$ ) or the linear ( $RMMR$ ) structure can be explained by the mixing of molecular orbitals, which have different symmetries in the undistorted structures but the same symmetries in the pyramidal or bent structures. In case of disilenes, digermenes, stannenes, and plumbenes, these energy

**Chart 1** Protective organic groups in the synthesis of reactive multiply-bonded p-block compounds. (A) 2,4,6-bis[bis(trimethylsilyl)methyl]phenyl,<sup>31</sup> (B) 2,4,6-tris(2-propyl)phenyl,<sup>32</sup> (C) 2,4,6-tris[2,6-bis(2-propyl)phenyl]phenyl,<sup>33</sup> and (D) (2-propyl)bis[bis(trimethylsilyl)silyl].<sup>34</sup>

**Fig. 6** The orbital interactions upon distortion of (A) the planar structure ( $D_{2h}$ ) to *trans*-pyramidal ( $C_{2h}$ ), and (B) the linear structure ( $D_{\infty h}$ ) to *trans*-bent structure ( $C_{2h}$ ).<sup>27</sup>

levels in the planar geometry are sufficiently close to each other due to the weak bonding to enable their mixing, which leads to the lowering of energy and thus to the distortion of the structure. Since the original  $\sigma$  bonds of  $a_g$  symmetry are also weakened by the distortions, and the distortion increases, when going down the Periodic Table, the alkene analog of lead is not stable and dissociates into two monomers. The triple bond, which in organic alkynes is composed of a  $\sigma$  bond and two  $\pi$  bonds, ultimately becomes two

**Scheme 1** Examples of use of (A) Lawesson's reagent as a sulfur-transfer reagent<sup>35</sup> and (B) Woollins' reagent as a selenium-transfer reagent.<sup>36</sup>

lone pair orbitals mostly of 6s character and the Group 14 elements in this case are only linked by a single  $\sigma$ -bond. The behavior of heavy Group 15 elements is analogous to that of Group 14 elements.

Heavier Group 14 and Group 15 atoms form multiple bonds with chalcogen atoms. Lawesson's and Woollins' reagents are important members in this class of compounds. They are efficient sulfur- and selenium-transfer reagents, respectively (see **Scheme 1**).

### 1.01.3.3 Secondary bonding interactions

Secondary bonding interactions (SBIs) describe interatomic interactions, which are longer than covalent single bonds but shorter than the sums of the van der Waals radii. The term was originally coined by Alcock.<sup>37</sup> They have also been called soft-soft, closed-shell, nonbonding, semi-bonding, non-covalent, weakly bonding, or  $\sigma$ -hole interactions. In specific case of halogen, chalcogen, pnictogen (or pnicogen), and tetrel atoms, they are also known as halogen, chalcogen, pnictogen, and tetrel bonds, respectively. The SBIs are most significant in case of the heaviest p-block elements in the Periodic Table.

The halogen bond is the best-studied secondary bonding interaction of the compounds involving p-block elements<sup>38–41</sup> and has been defined by IUPAC as an attractive interaction between a positive region in the electrostatic surface potential of a halogen atom and a nucleophile.<sup>42</sup> Chalcogen bonds have also recently been defined by IUPAC<sup>43</sup> and have been reviewed on several occasions.<sup>44–47</sup> Pnictogen and tetrel bonds have seen lesser attention, but the secondary bonding interactions are important also in the solid-state lattices of heavy Group 15 and 14 compounds.<sup>48–51</sup>

Whereas halogen bonds can mainly be rationalized in terms of electrostatic  $\sigma$ -hole interactions [see **Fig. 7A**], they and, more significantly, the chalcogen bonds must be understood as combinations of orbital interactions and dispersion contributions in addition the electrostatic interactions [see **Fig. 7B**]. The covalent aspects of the secondary bonding interactions can be described as donor-acceptor interactions  $n^2(D) \rightarrow \sigma^*(E-X)$  with the lone pair orbital of the electron donor atom D overlapping with the antibonding  $\sigma^*$  orbital of the E-X bond (E = heavy p-block element; X = an electronegative atom). The strength of this 3c-4e arrangement varies from a very weak interaction to that of a hypervalent single bond. The heaviest p-block elements show strongest SBIs, because the energy difference between the  $\sigma(E-X)$  and  $\sigma^*(E-X)$  orbitals diminishes when going down the Periodic Table. At the same time, the orbital overlap diminishes, since the orbitals become more diffuse. The dispersion effects become more significant with increasing periodic number and play the major role in the interactions between the heaviest p-block elements.

SBIs affect the solid-state structures, solution behavior, and reactivities of the bulk materials. Interest in these interactions have given birth to new research areas in chemistry, such as supramolecular chemistry and crystal engineering. Since the weak intermolecular forces play an essential role in the material properties, their study has become an important emerging trend, which will also have an impact on the future research activities in inorganic chemistry.

Metallophilic interactions can also be considered to belong to the class of secondary bonding interactions. They are now well-established in chemistry with numerous reviews of different homonuclear and heteronuclear metal combinations (for some recent examples, see refs. 53–55). The complexes are generally dinuclear, but polynuclear species are also known. Their characterization relies mainly on X-ray diffraction, but currently the use of solution and solid-state spectroscopic techniques, and in particular, high-

(B) Example of the charge-transfer  $n^2 \rightarrow \sigma^*$  interaction between the Lewis base Br<sup>-</sup> and the formal Lewis acid CBr<sub>4</sub>.<sup>41</sup> (A) Adapted with permission from Politzer, P.; Murray, J. S.; Clark, T., *Phys. Chem. Chem. Phys.* **2013**, *15*, 11178–11189. © 2013, RSC. (B) Adapted with permission from Gilday, L. C.; Robinson, S. W.; Barendt, T. A.; Langton, M. J.; Mullaney, B. R.; Beer, P. D., *Chem. Rev.* **2015**, *115*, 7118–7195. © ACS. 2015.

level MO calculations have increased the understanding of these interactions. Early literature on theoretical calculations is reviewed by Pyykkö<sup>56</sup> with more recent literature discussed by Zheng et al.<sup>57</sup>

The metallophilic interactions involve neither conventional covalent bonds nor metal-metal bonds with delocalized electrons in the conduction band. The neighboring metal centers, however, lie closer to each other than the sum of their van der Waals radii. The formal metal electron configurations in these interactions are closed-shell  $d^{10}-d^{10}$  [M(I) in Group 11 or M(II) in Group 12],  $s^2-s^2$  [M(I) in Group 13, M(II) in Group 14, or M(III) in Group 15] or  $d^8-d^8$  [M(0) in Group 8, M(I) in Group 9, or M(II) in Group 10]. The metallophilic interactions are therefore also called closed-shell interactions. A few typical examples are shown in Fig. 8.

It has been suggested that the bite size of the bridging ligands (donor atom-donor atom distance) correlates with  $M \cdots M$  distance. It can be seen from Fig. 9 for dinuclear silver complexes containing nitrogen-donor ligands that there is indeed a loose correlation between the  $Ag \cdots Ag$  distance and the  $N \cdots N$  bite size. However, short  $M \cdots M$  contacts are also found in cases, when the bite size is large, as shown in Fig. 9. The metal-metal distance may also be short in case of monodentate ligands, as shown by two illustrative examples for the ligand-unsupported complexes.

The stabilization due to the close-shell  $d^{10}-d^{10}$  interaction can be explained by the simplified molecular orbital description, which is shown in Fig. 10.<sup>65</sup> The mixing of the empty  $(n+1)s$  orbital with the filled  $d$  orbitals leads to the stabilization of the bonding  $1\sigma$  orbital and to a smaller extent of the antibonding  $2\sigma$  orbital. It can be seen from Fig. 10 that the  $(n+1)s$  contribution to the  $1\sigma$  orbital is 11.0, 8.8, and 2.6% for Cu, Au, and Ag, respectively.

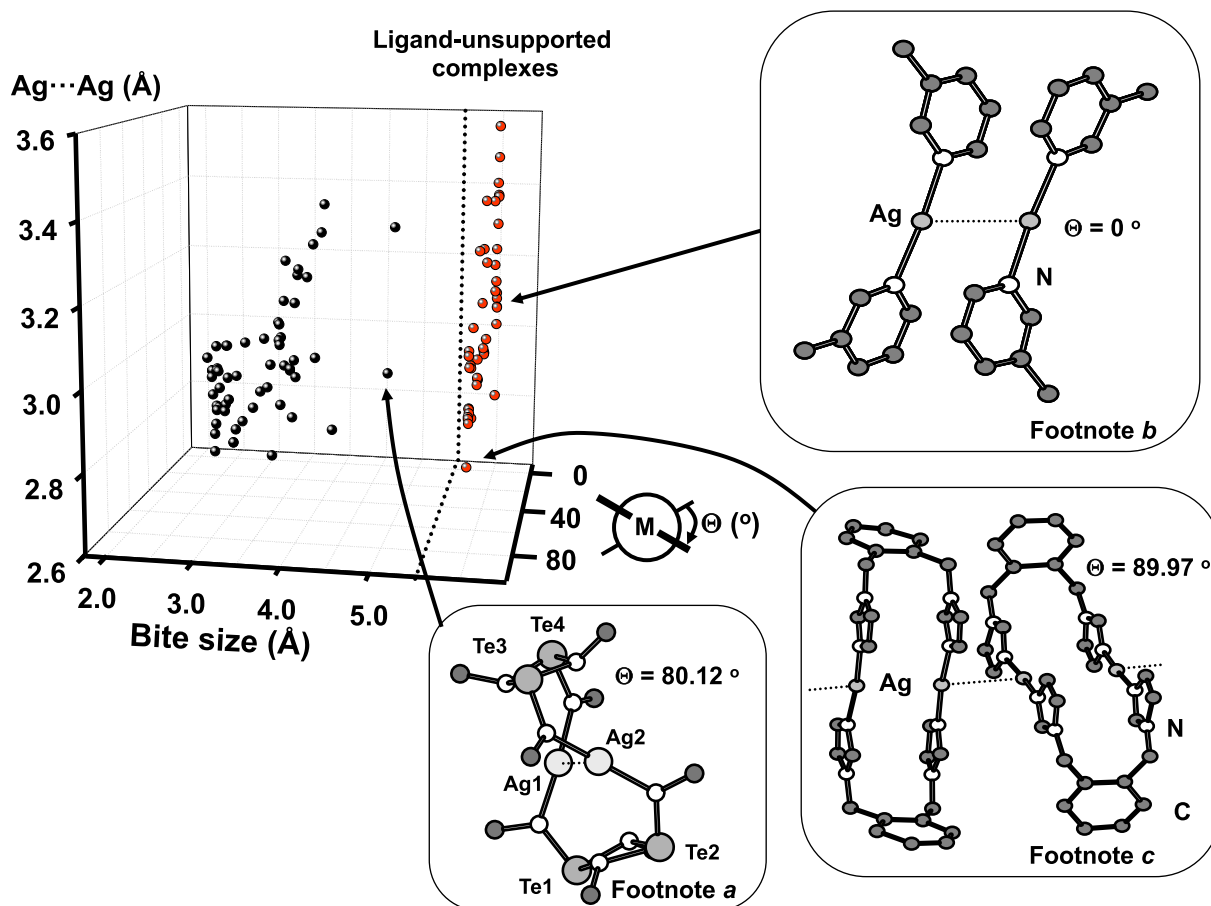

#### 1.01.3.4 Small-molecule activation

Power<sup>21</sup> has noted that the third-row or heavier p-block elements differ significantly from their second-row congeners. It has gradually been realized that the properties of their compounds are closer to those of the transition metal complexes. For instance, H<sub>2</sub> is activated under mild conditions in the same fashion by the germanium or tin analogs of alkynes as by the transition metal

**Fig. 8** Examples of metallophilic interactions in (A)  $[\text{AuPMe}_2(\text{C}_6\text{F}_4)]_2$ ,<sup>58</sup> (B)  $[\text{PtI}(\mu\text{-(PMe}_2)_2\text{CH}_2)]_2$ ,<sup>59</sup> and (C)  $[\text{Hg}_3(\mu\text{-C}_6\text{F}_4)_3]_2$ .<sup>60</sup>

complexes.<sup>66</sup> The initial step in both activations involves oxidative addition (see Fig. 11). It was argued by Power<sup>21</sup> that this is a consequence of the small energy separation between the HOMO and LUMO in the heavy p-block compounds.

Spikes et al.<sup>66</sup> have shown that  $\text{ArGeGeAr}$   $\{\text{Ar} = [2,6\text{-}^i\text{Pr}_2(\text{C}_6\text{H}_3)]_2\text{C}_6\text{H}_5\}$  reacted with  $\text{H}_2$  at ambient temperature and pressure to afford  $\text{ArHGeGeAr}$ ,  $\text{ArH}_2\text{GeGeArH}_2$ , and  $\text{ArGeH}_3$ . Their relative yields depend on the initial molar ratios of the reactants. The related reaction with  $\text{ArSnSnAr}$  gives exclusively  $\text{ArSn}(\mu\text{-H})_2\text{SnAr}$ .<sup>67</sup> Alkenes and alkynes can also be activated by multiply-bonded Group 14 compounds (for a review, see ref. 68).

Singlet carbenes can also mimic the behavior of transition metal complexes. Frey et al.<sup>69</sup> have shown that while electrophilic diaminocarbenes are inert towards molecular hydrogen, the more nucleophilic alkylaminocarbenes activate  $\text{H}_2$  under mild conditions probably involving oxidative addition in the similar manner to that in  $\text{ArMMAr}$  or in transition metal complexes (c.f. Fig. 11). Because of the higher nucleophilicity of these carbenes compared to transition metals, they have been shown to activate also ammonia affording a primary amine.<sup>69</sup>

**Fig. 11** (A) The interaction of  $\sigma(\text{H-H})$  (HOMO) of  $\text{H}_2$  with  $n_x$  (LUMO) of  $\text{ArMMAr}$  ( $M = \text{Ge}, \text{Sn}$ ;  $\text{Ar} =$  moderately bulky aromatic group), and the back-donation from  $\pi$ (HOMO) of  $\text{ArMMAr}$  to  $\sigma^*(\text{H-H})$  (LUMO) of  $\text{H}_2$ . (B) The related interaction of  $\text{H}_2$  with the d orbitals of the transition metal.<sup>21</sup> Reproduced with permission from Power, P. P., *Nature* **2010**, 463, 171–177. © 2010 McMillan Publishers Limited.

In 2006, Welch et al.<sup>70</sup> reported the first metal-free reversible activation of  $\text{H}_2$  under mild conditions by involving a bulky phosphinoborane (see **Scheme 2**). In this connection, Stephan coined the term frustrated Lewis pair to describe a situation, where due to steric reasons the Lewis acid and base cannot form an adduct.<sup>70</sup>

The orbital interaction between the FLP and  $\text{H}_2$  is shown schematically in **Fig. 12**.

The lone pair on phosphorus can donate electron density to the antibonding  $\sigma^*$  orbital of  $\text{H}_2$ , and the empty p orbital on boron can accept electron density from the bonding  $\sigma$  orbital of  $\text{H}_2$  resulting in the cleavage of the  $\text{H-H}$  bond and the formation of both  $\text{P-H}$  and  $\text{B-H}$  bonds. FLPs have opened a rapidly expanding field of transition-metal free catalysts. While hydrogenation reactions continue to play an important part in FLP reactivity, new applications involve the reduction of other small molecules such as  $\text{CO}$  and  $\text{CO}_2$ , as well as the generation of solid-state FLP catalysts, as reviewed recently.<sup>71</sup>

### 1.01.3.5 Weakly coordinating anions

p-Block elements can form polyatomic cations, such as  $\text{E}_4^{2+}$  or  $\text{E}_8^{2+}$  ( $\text{E} = \text{S}, \text{Se}, \text{Te}$ ), but they are highly electrophilic and therefore they can be isolated only by use of the anions of very strong acids like  $\text{SO}_3\text{F}^-$  or  $\text{MF}_6^-$  ( $\text{M} = \text{As}, \text{Sb}$ ) (for two reviews, see refs. 72, 73). The advent of weakly coordinating anions (WCAs) stems from the search of “noncoordinating” anions<sup>74</sup> to improve the stability of

**Scheme 2** Reversible metal-free activation of  $\text{H}_2$ .<sup>70</sup>

**Fig. 12** Simplified hypothetical orbital interactions and charge transfer in the activation of  $\text{H}_2$  by a FLP.

**Fig. 13** Crystal structure of  $[\text{Ag}_2(\text{Se}_6)(\text{O}_2\text{S})_4][\text{Al}(\text{OC}(\text{CF}_3)_3)_4]_2$ .<sup>75</sup>

materials containing such cations. However, WCAs have also had impact on areas like olefin polymerization, lithium battery technology, and ionic liquids.<sup>7</sup>  $[\text{Ag}_2(\text{Se}_6)(\text{O}_2\text{S})_4][\text{Al}(\text{OC}(\text{CF}_3)_3)_4]_2$  is an example of the use of WCAs in stabilization of otherwise unstable cations (see Fig. 13).

Krossing and Raabe<sup>74</sup> have discussed the potential candidates for WCAs. They define the requirements as chemical robustness towards electrophiles and oxidizing agents, minimal tendency for coordination, high solubility in non-polar media, pseudo gas-phase conditions in the solid state or solution, and the stabilization of weakly-bound and low-charged complexes. Several classes of compounds have been considered (see Table 3).

The number of applications of WCAs is rapidly increasing. In addition to the stabilization of low-stability cations, they can act to enhance solubility of s.c. naked  $\text{Li}^+$ -ions in non-polar solvents, which is important in  $\text{Li}^+$ -ion catalyzed organic transformations, such as in Diels-Alder reactions. Air- and moisture-stable  $[\text{Ag}(\text{PPh}_3)]^+[\text{CB}_{11}\text{H}_6\text{Br}_6]^-$  is considered to be the best catalyst for hetero Diels-Alder reactions.<sup>[76]</sup> The use of WCAs in supporting electrolytes in cyclic voltammetry enhances the solubility of the polycationic products and hinders inadvertent oxidation.<sup>[74]</sup> Other applications for salts containing WCAs include their use in low-viscosity ionic liquids, and in extraction of electrophilic metal ions.

### 1.01.3.6 Biradicals and biradicaloids

Radicals are molecular species containing an unpaired electron. They are often only transient species in the course of a chemical reaction. A radical is called stable, if the species can be isolated and stored for an extended period of time under an inert atmosphere in ambient temperature. The persistent radical is long-lived under the conditions of its generation (For a review of the stable and persistent radicals of the Group 13–17 elements, see ref. 77).

In addition to persistent radicals, biradicals have attracted increasing research attention in recent decades.<sup>74</sup> They contain two unpaired electrons in two nearly degenerate non-bonding orbitals. In the ground state, the biradicals show either the singlet or triplet spin states. While organic biradicals are very short-lived species, some related main-group biradicals may be isolated and structurally characterized by X-ray diffraction.<sup>77,78</sup> The increased stability, however, leads to the reduction of the biradical character. These kinds of species are designated as biradicaloids.<sup>78–80</sup>

The biradicaloid nature is exemplified by  $(\text{RBPR}'_2)_2$  (see Table 4).<sup>81</sup>  $(\text{PhBP}^i\text{Pr}_2)_2$  and  $(^t\text{BuBP}^i\text{Pr}_2)_2$  both have 22 valence electrons. Their  $\text{B}_2\text{P}_2$  rings are planar and the molecules show singlet biradical character with unpaired electrons localized in the two boron centers. The respective transannular  $\text{B} \cdots \text{B}$  distances of 2.563(2) and 2.559(2) Å are significantly longer than the B–B single bonds. Upon controlled modification of the substituents on boron and phosphorus, it was observed that the four-membered  $\text{B}_2\text{P}_2$  ring is folded and the transannular  $\text{B} \cdots \text{B}$  becomes shorter (see Table 4). The B–B distance is the shortest in

**Table 3** Some examples of commonly used weakly coordinating anions.<sup>74</sup>**Borate-based anions****Carborane-based anions****Fluorinated alkoxytellurates****Tellurate-based anions****Anions from Lewis acid-base reaction**

the case of  $(\text{PhBPPPh}_2)_2$  [1.835(2)] approaching that of the single bond. At the same time the folding is the most pronounced. Scheschkewitz et al.<sup>81</sup> have discussed the factors affecting the folding.

The electronic structures of the four-membered cyclic molecule  $\text{S}_2\text{N}_2$  and its isoelectronic cations  $\text{E}_4^{2+}$  ( $\text{E} = \text{S}, \text{Se}, \text{Te}$ ) have been under extensive discussion.  $\text{S}_2\text{N}_2$  is formally a  $6\pi$  aromatic molecule, but it has been shown to be only a  $2\pi$  aromatic system.<sup>82</sup> Several reports conclude that the ground-state wavefunction of  $\text{S}_2\text{N}_2$  has singlet biradical character, but there is a wide range of estimates of the weight of the contribution of the singlet biradical character in the wavefunction.<sup>83</sup>

The situation in the square-planar  $\text{E}_4^{2+}$  ( $\text{E} = \text{S}; \text{Se}, \text{Te}$ ) cation is somewhat different with that in  $\text{S}_2\text{N}_2$ . The positive charge is delocalized over all chalcogen atoms, and the two main biradical structures.

contribute equally to the wavefunction.<sup>83</sup> It was inferred that the biradical character of these cations are comparable to that of  $\text{O}_3$ .

**Table 4** The influence of the substituents on boron and phosphorus on the biradical nature of (RBPR'<sub>2</sub>)<sub>2</sub>.<sup>81</sup>

### 1.01.4 Volume 1 of Comprehensive Inorganic Chemistry III

The first edition of Comprehensive Inorganic Chemistry<sup>84</sup> contained five volumes and discussed the chemistry of the elements according to their position in the Periodic Table. First two volumes concentrated on main group chemistry, volume three described transition metals, and volumes four and five treated the chemistry of lanthanoids and actinoids. The style and approach in this five-volume book were close to that in an extended textbook. For a long time, it was the key authority in inorganic chemistry.

The second edition (CIC II) was published in 2013.<sup>85</sup> Its connection to the Periodic Table as a directing tool was looser than in the first edition. Each of the nine volumes has a specific thematic issue, as shown in Table 5. This nine-volume set was less of a textbook and resembled more closely a review publication, but it still aimed at providing a comprehensive overview on the then present state in inorganic chemistry.

The current, third edition, *Comprehensive Inorganic Chemistry III* (CIC III) continues the same topical approach to the current mainstream in inorganic chemistry as the previous version. This edition contains 10 volumes. Their topics are listed in Table 6.

**Table 5** Themes of the nine volumes in Comprehensive Inorganic Chemistry II (CIC II).<sup>84</sup>

Volume	Theme
1	Main-group elements, including noble gases
2	Transition elements, lanthanides and actinides
3	Bioinorganic fundamentals and applications: Metals in natural living systems and metals in toxicology and medicine
4	Solid-state materials, including ceramics and minerals
5	Porous materials and nanomaterials
6	Homogeneous catalytic applications
7	Surface inorganic chemistry and heterogeneous catalysis
8	Coordination and organometallic chemistry
9	Theory and methods

**Table 6** Themes in Comprehensive Inorganic Chemistry III.

Volume	Theme
1	Synthesis structure and bonding of inorganic molecular systems
2	Bioinorganic chemistry and homogeneous biomimetic inorganic catalysis
3	Theory and bonding of inorganic non-molecular systems
4	Solid-state inorganic chemistry including supramolecular
5	Inorganic materials chemistry
6	Heterogeneous inorganic catalysis
7	Inorganic electrochemistry
8	Inorganic photochemistry
9	NMR of inorganic nuclei
10	Xray, neutron and electron scattering methods in inorganic chemistry

Topics in Volume 1 of the current edition follow logically those of Volume 1 in the 2nd edition. While the principal theme in the 2nd edition was main group chemistry, the current volume of the 3rd edition addresses molecular systems as they appear both in main group and transition metal chemistry. Many themes in the 2nd edition 9 years ago are still relevant today, and many chapters provide the update of the progress during the past years, though not forgetting to give sufficient historical overview for the reader to appreciate the advent and development in any given topic. There were 40 chapters in *Comprehensive Inorganic Chemistry II* (CIC II), but the current Volume 1 contains only 23 chapters. Each chapter in CIC III therefore describes a wider range of topics than those in CIC II. The distribution of themes in the different volumes of CIC III is also different compared to CIC II. This has also affected the choice of actual chapters in any of the 10 volumes.

There are three sections in Volume 1 of CIC III:

- (1) Structure, bonding, and reactivity in inorganic molecular systems
- (2) Intermolecular interactions
- (3) Inorganic chains, rings, and cages

Section 1 contains nine chapters. There is a very comprehensive review of coordination chemistry of complexes in which the heavy p-block atom acts as a central atom. This is a vast field. Therefore, the discussion has been restricted to single-donor ligands. There are also chapters reviewing recent progress in the rich synthetic and structural chemistry of noble gas compounds, low-coordinate p-block elements, biradicals, [Fe,Fe]-hydrogenase mimics, and macrocyclic selenoethers. There has been a very rapid progress in the chemistry and application of weakly coordinating anions, and Volume 1 of CIC III provides a thorough review of the development since the publication of CIC-II. Two last chapters (*see chapters 1.08 and 1.09*) in this Section treat the preparation, structures, and reactivity of carbenes containing non-innocent ligands, and the application of frustrated Lewis pairs in metal-free catalysis.

Section 2 is concerned with secondary bonding interactions (SBI), which play an important role in the properties of bulk materials. The term SBI was originally coined by Alcock in 1960s, but nowadays this term starts to be superseded by more popular expressions like halogen, chalcogen, pnictogen (or pnicogen), and tetrel bonding. Section 2 of Volume 1 contains a separate chapter on the general theoretical considerations of the secondary bonding interactions, and then more specialized treatments of halogen and

chalcogen bonding. This section is concluded by the update of the host-guest chemistry of the molecules of p-block elements and by a comprehensive review of closed-shell  $d^{10}$ - $d^{10}$ ,  $d^8$ - $d^8$ , and  $s^2$ - $s^2$  metallophilic interactions.

Catenation continues to be one of the key characteristics in compounds of p-block elements. The third Section of Volume 1 is therefore dedicated to chain, ring, and cage (also called cluster) compounds in molecular inorganic chemistry. Separate chapters describe the recent chemistry of boron clusters, as well as the chain, ring, and cage compounds of Group 13 and 15, and 16 elements. A more specialized treatise is given on the aromatic compounds bearing heavy Group 14 atoms, Zintl-anions and -clusters, and a comprehensive account on polyhalogenide anions. This Section will be concluded by a review on organometallic clusters.

The driving force in chemical research arises from demands of materials science to develop new materials with innovative functionalities. It is important to establish the relationship of the molecular and electronic structures with the properties in the bulk material. Both new and old materials based on main group compounds show virtually unlimited number of interesting applications. Electrical conductors, semiconductors, insulators, coatings, ceramics, catalysts, nanotubes, polymers, and thin films all play a significant role in the current research in chemistry as well as in the modern technology. The increasing need to replace fossil fuels demands the development of environmentally friendlier energy sources in which molecular inorganic compounds are poised to play an important role due to their high availability and low manufacturing costs.

## Abstract

This article surveys the coordination chemistry of the main group metals (s- and p-block metals) published during the period 2000–2021. Within the p-block, metallic elements include Al–Tl for group 13, Ge–Pb for group 14, Sb and Bi for group 15, and Te for group 16. The lighter elements in groups 15 (N, P, As) and 16 (O, S, Se) typically behave as donor atoms in ligands. However, the distinction is blurred, and As(III) is included as a metal center with, for example, S- and Se-donor ligands, and Al(III) and Ga(III) complexes containing Sb-donor ligands are included. The aim of the review is to provide as comprehensive as coverage as possible so as to demonstrate different bonding modes of ligands, and the range of metal centers to which they coordinate. At the same time, the number of structurally characterized main group metal complexes is so extensive that a totally comprehensive survey has not been possible within the page constraints.

### 1.02.1 Introduction

This chapter deals with the coordination chemistry of the main group elements and covers coordination compounds of metals in group 1 (Li–Cs), group 2 (Be–Ba) and group 13 (Al–Tl), and of metals or semi-metals in group 14 (Ge–Pb), group 15 (Sb, Bi), and group 16 (Te). The lighter elements in groups 15 (N, P, As) and 16 (O, S, Se) typically behave as donor atoms in ligands. Although *Comprehensive Inorganic Chemistry II* (CIC II) was published in 2013, it did not include a chapter dealing with main group coordination chemistry and, therefore, this article covers the literature from the year 2000 to date. A number of reviews published since 2000 complement the present survey of metal coordination compounds: group 1 and 2 metals including thermodynamic aspects and metal ion sensors,<sup>1–14</sup> aluminum including speciation in solution and under physiological conditions,<sup>15–34</sup> group 13 metals Ga–Tl including precursors for chemical vapor deposition (CVD) materials,<sup>26,30–47</sup> group 14,<sup>34,48–58</sup> group 15,<sup>59–63</sup> and tellurium-centered compounds.<sup>64–67</sup> With an emphasis on ligand-types, the following reviews cover the coordination chemistry of the main group elements with phosphane, arsane and stibane ligands,<sup>68</sup> with amidinate and guanidinate ligands,<sup>69</sup> with tripodal amido ligands,<sup>70</sup> with ligands derived from (XPR<sub>2</sub>)(YPR'<sub>2</sub>)NH acids (X, Y = O, S, Se; R, R' = alkyl, aryl, OR),<sup>71</sup> with  $\alpha$ -diimine ligands,<sup>72</sup> with semicarbazone and thiosemicarbazone ligands,<sup>73,74</sup> with anionic scorpionate ligands,<sup>75</sup> with boraamidinate ligands,<sup>76</sup> with imido ligands,<sup>77–79</sup> with nitrido ligands,<sup>80</sup> with ene-diamido ligands,<sup>9</sup> with formazanate ligands (formazan = Ar<sup>1</sup>-NH-N=CR-N=N-Ar<sup>2</sup>),<sup>81</sup> with amidoborane ligands,<sup>13</sup> with bis(phosphinimino)methanide ligands,<sup>82</sup> with N-heterocyclic imines<sup>83</sup> and N-heterocyclic carbenes,<sup>84,85</sup> and with sterically demanding monodentate amide ligands.<sup>86</sup> Tan and García have reviewed the use of mechanochemical methods in main group metal chemistry.<sup>87</sup>

The literature concerning the coordination chemistry of main group elements is very extensive and we have focused our attention on compounds that are structurally characterized, and on single donor ligands. The primary source of data was the Cambridge Structural Database (CSD)<sup>88,89</sup> with searches made using Conquest v. 2021.3.0 and v. 2022.1.0<sup>88</sup> and figures drawn using Mercury 2021.3.0 and v. 2022.1.0.<sup>90</sup> We have also sourced data from the Inorganic Crystal Structure Database (ICSD, v. 4.7.1, data release 2021.2).<sup>91</sup> Coordination compounds are organized in the following sections by ligand type, with binary metal halide and hydride complexes excluded. The latter have been detailed in several reviews.<sup>92–95</sup> Compounds which include M–C bonds, including metallocene units, have been excluded. Our aim has been to provide an overview that illustrates structure-types rather than a comprehensive coverage since the latter is neither possible within the page-extent available, nor of help to the reader.

After considerable debate, we have decided not to ‘standardize’ ligand names and abbreviations to IUPAC recommendations. In part, this represents a desire to retain the nomenclature associated with the original publications and the intimate community. Ligand abbreviations used in this review are listed at the beginning of the article.

### 1.02.2 Nitrogen-donor ligands

#### 1.02.2.1 Monodentate ligands

##### 1.02.2.1.1 NH<sub>3</sub>, RNH<sub>2</sub>, R<sub>3</sub>N

Homoleptic main-group metal ammine complexes are restricted to the s-block (groups 1 and 2) metals and aluminum. One motivation for investigations of these complexes is their potential for hydrogen storage, e.g., using [Mg(NH<sub>3</sub>)<sub>6</sub>]Cl<sub>2</sub>, it is possible to store 9.1% hydrogen by weight in the form of ammonia.<sup>96</sup> The use of liquid NH<sub>3</sub> as a solvent, for example, in reactions to form Zintl ions or hydroborate clusters, is also a method by which s-block metal ammine complexes are accessed. **Fig. 1** illustrates the structures of the group 1 metal complex cations [Li(NH<sub>3</sub>)<sub>3</sub>]<sup>+</sup>,<sup>97</sup> [Li(NH<sub>3</sub>)<sub>4</sub>]<sup>+</sup>,<sup>97–102</sup> [Na(NH<sub>3</sub>)<sub>4</sub>]<sup>+</sup>,<sup>102</sup> [K(NH<sub>3</sub>)<sub>6</sub>]<sup>+</sup>,<sup>103</sup> [K<sub>2</sub>(NH<sub>3</sub>)<sub>10</sub>( $\mu$ -NH<sub>3</sub>)<sub>2</sub>]<sup>2+</sup>,<sup>104</sup> and [Rb<sub>2</sub>(NH<sub>3</sub>)<sub>4</sub>( $\mu$ -NH<sub>3</sub>)<sub>4</sub>]<sup>2+</sup>.<sup>100</sup> The increase in coordination number with size of metal ion is as expected. The 3-coordinate [Li(NH<sub>3</sub>)<sub>3</sub>]<sup>+</sup> occurs (along with [Li(NH<sub>3</sub>)<sub>4</sub>]<sup>+</sup>) in the salt Li<sub>2</sub>B<sub>12</sub>H<sub>12</sub>·7NH<sub>3</sub> and is stabilized by additional Li··H–B contacts in the solid state.<sup>97</sup> In contrast to Li<sub>2</sub>B<sub>12</sub>H<sub>12</sub>·7NH<sub>3</sub>,<sup>97</sup> Li<sub>2</sub>B<sub>12</sub>H<sub>12</sub>·10NH<sub>3</sub> contains tetrahedral [Li(NH<sub>3</sub>)<sub>4</sub>]<sup>+</sup> and NH<sub>3</sub> solvate,<sup>100</sup> and the tetrahedral [Li(NH<sub>3</sub>)<sub>4</sub>]<sup>+</sup> ion is more usual than [Li(NH<sub>3</sub>)<sub>3</sub>]<sup>+</sup>. The square-planar structure of [Na(NH<sub>3</sub>)<sub>4</sub>]<sup>+</sup> is found in the indenyl salt [Na(NH<sub>3</sub>)<sub>4</sub>][In] which forms a layered structure, in contrast to the non-layered [Li(NH<sub>3</sub>)<sub>4</sub>][In] which contains tetrahedral

**Fig. 1** Structures of group 1 metal ammine complexes: (A)  $[\text{Li}(\text{NH}_3)_3]^+$  (CSD refcode XUNYAH), (B)  $[\text{Li}(\text{NH}_3)_4]^+$  (refcode COVLUV), (C)  $[\text{Na}(\text{NH}_3)_4]^+$  (refcode XICMED), (D)  $[\text{K}(\text{NH}_3)_6]^+$  (refcode QOTQOH), (E)  $[\text{K}_2(\text{NH}_3)_{10}(\mu\text{-NH}_3)_2]^{2+}$  (refcode XEJWAL), and (F)  $[\text{Rb}_2(\text{NH}_3)_4(\mu\text{-NH}_3)_4]^{2+}$  (refcode VIHGQU).

$[\text{Li}(\text{NH}_3)_4]^+$  ions.<sup>102</sup> Ammine complexes of  $\text{K}^+$  are represented by the octahedral  $[\text{K}(\text{NH}_3)_6]^+$  and the dinuclear  $[\text{K}_2(\text{NH}_3)_{10}(\mu\text{-NH}_3)_2]^{2+}$  (Fig. 1E) in which  $\text{K}^+$  is 7-coordinate; the K–N distances for the bridging  $\text{NH}_3$  ligands are only slightly longer (3.087(2) Å) than the terminal bonds (2.933(2)–2.998(2) Å).<sup>104</sup> The  $[\text{K}(\text{NH}_3)_7]^+$  ion has also been structurally characterized (see later).<sup>105</sup> The  $[\text{Rb}_2(\text{NH}_3)_4(\mu\text{-NH}_3)_4]^{2+}$  ion (Fig. 1F) is present in  $\text{Rb}_2[\text{B}_{12}\text{H}_{12}] \cdot 8\text{NH}_3$ , whereas in  $\text{Cs}_2[\text{B}_{12}\text{H}_{12}] \cdot 6\text{NH}_3$ , the  $\text{Cs}^+$  ion is bound by only two  $\text{NH}_3$  molecules ( $\text{Cs}–\text{N} = 3.259(2)$  and  $3.125(2)$  Å) with  $\text{Cs} \cdots \text{H}–\text{B}$  contacts completing the  $\text{Cs}^+$  coordination sphere.<sup>100</sup> The competition between M– $\text{NH}_3$  coordinate bond formation and  $\text{M} \cdots \text{H}–\text{B}$  interactions is often seen in the solid-state structures of ammine s-block metal borohydride salts, and further examples are found in  $\text{Li}_2\text{B}_{12}\text{H}_{12} \cdot 4\text{NH}_3$ ,  $\text{Na}_2\text{B}_{12}\text{H}_{12} \cdot 2\text{NH}_3$  and  $\text{NaB}_{12}\text{H}_{12} \cdot 3\text{NH}_3$ ,<sup>106</sup> and in  $\text{Na}_2\text{B}_{10}\text{H}_{10} \cdot 2\text{NH}_3$  and  $\alpha\text{-Na}_2\text{B}_{10}\text{H}_{10} \cdot \text{NH}_3$ .<sup>107</sup>

As in group 1, the increased size of the group 2 metal ion on descending the group leads to higher coordination numbers (CNs). The tetrahedral  $[\text{Be}(\text{NH}_3)_4]^{2+}$  ion is present in  $[\text{Be}(\text{NH}_3)_4]_2\text{Cl}_4 \cdot 17\text{NH}_3$ . The isolation and structural characterization of this compound in 2012 by Kraus et al. provided valuable insight into similarities and differences between aqua and ammine chemistry of the  $\text{Be}^{2+}$  ion.<sup>108</sup> Fig. 2A shows the octahedral  $[\text{Mg}(\text{NH}_3)_6]^{2+}$  ion characterized in  $\text{Li}_2\text{Mg}(\text{BH}_4)_4 \cdot 6\text{NH}_3$ .<sup>109</sup> The  $[\text{Ca}(\text{NH}_3)_7]^{2+}$  ion

**Fig. 2** Structures of group 2 metal ammine complexes: (A)  $[\text{Mg}(\text{NH}_3)_6]^{2+}$  (CSD refcode HIPFIX), (B)  $[\text{Sr}(\text{NH}_3)_8]^{2+}$  (refcode IFUZE0), (C)  $[\text{Ba}(\text{NH}_3)_7]^{2+}$  (refcode NUSVAY), and (D)  $[\text{Ba}(\text{NH}_3)_9]^{2+}$  (H atoms omitted, refcode EBOYOJ).

is present in  $[\text{NH}_4(\text{NH}_3)_4][\text{Ca}(\text{NH}_3)_7]\text{As}_3\text{S}_6 \cdot 2\text{NH}_3$  which was prepared by the reduction of  $\text{As}_4\text{S}_4$  using Ca in liquid  $\text{NH}_3$ . The coordination geometry of  $[\text{Ca}(\text{NH}_3)_7]^{2+}$  is a monocapped trigonal prism,<sup>110</sup> and is structurally similar to that reported by Kolis and coworkers in  $[\text{Ca}(\text{NH}_3)_7][\text{S}_6]$ .<sup>111</sup> Heavier group 2 metal ammine complexes include those associated with the syntheses of fullerene anions in liquid  $\text{NH}_3$  by reduction of  $\text{C}_{60}$  or  $\text{C}_{70}$  with a group 2 metal. The coordination geometries of the  $[\text{Sr}(\text{NH}_3)_8]^{2+}$  ion in different salts are described as a distorted, bicapped trigonal prism (Fig. 2B)<sup>112</sup> or distorted tetragonal anti-prism.<sup>113</sup> Ammine complexes of the heavy group 2  $\text{M}^{2+}$  ions are rather sparse. The structure of  $[\text{Ba}(\text{NH}_3)_7]^{2+}$  (Fig. 2C) in  $[\text{Ba}(\text{NH}_3)_7][\text{C}_{60}] \cdot \text{NH}_3$  is a mono-capped trigonal antiprism,<sup>105,114</sup> and this coordination geometry is replicated in  $[\text{K}(\text{NH}_3)_7]^+$  and  $[\text{Sr}(\text{NH}_3)_7]^{2+}$ .<sup>105</sup> The highest CN of nine is found in  $[\text{Ba}(\text{NH}_3)_9]^{2+}$  which adopts a distorted, tricapped trigonal prismatic structure (Fig. 2D).<sup>115</sup>

In addition to their relevance for hydrogen storage, group 13 ammine complexes are of interest as precursors for III-V semiconducting materials, and are represented by the octahedral  $[\text{Al}(\text{NH}_3)_6]^{3+}$  and  $[\text{Ga}(\text{NH}_3)_6]^{3+}$  ions.<sup>116–118</sup>

Examples of main group metal complexes incorporating monodentate amino ligands are restricted to simple ligands and include complexes with bridging ethane-1,2-diamine (en), i.e., en in a bis(monodentate) bonding mode. Simple methylamine complexes include  $[\text{Pb}(\text{MeNH}_2)_6]\text{I}_2$  and  $[\text{Pb}(\text{MeNH}_2)_4]\text{I}$  formed from  $\text{PbI}_2$  in liquid  $\text{MeNH}_2$ ; the former has a cubic anti- $\text{K}_2\text{PtCl}_6$  structure. In  $[\text{Pb}(\text{MeNH}_2)_4]\text{I}$ , the  $\text{I}^-$  ion essentially fills the sixth coordination site of the Pb(II) center, but with a long Pb–I distance of 3.8801(4) Å.<sup>119</sup> Interest in these systems stems from relationships to  $\text{MeNH}_3\text{PbI}_3$  perovskite materials. Reactions of  $\text{LiGaH}_4$  with the hydrochloride of  $\text{MeNH}_2$  or  ${}^i\text{PrNH}_2$  lead to  $[\text{Ga}(\text{RNH}_2)_2\text{H}_2]\text{Cl}$  which are structurally similar,<sup>120</sup> and  $[\text{Ga}({}^t\text{BuNH}_2)_2\text{H}_2]\text{Cl}$  has also been reported.<sup>121</sup>  $[\text{Ga}(\text{MeNH}_2)_2\text{H}_2]\text{Cl}$  exhibits short N–H...Cl<sup>-</sup> contacts in the solid state (Fig. 3A).  $[\text{Ga}({}^t\text{PrNH}_2)_2\text{H}_2]^+$  reacts with  $\text{LiGaH}_4$  to yield a trigallium amino complex.<sup>120</sup>  $[\text{Ba}(\text{MeNH}_2)_3\text{Te}_3]_n$  has the layer structure shown in Fig. 3B in which the methylamine ligands protrude above and below the sheet.<sup>122</sup> A study of solvates of  $\text{Mg}(\text{BH}_4)_2$  includes  $[\text{Mg}({}^t\text{BuNH}_2)_3(\text{BH}_4)_2]$  in which the  $\text{Mg}^{2+}$  center can be described as being in a distorted trigonal bipyramidal coordination sphere with bidentate  $[\text{BH}_4]^-$  ligands bound in the axial sites (Fig. 3C); a similar structure is found for  $[\text{Mg}(\text{pip})_3(\text{BH}_4)_2]$  (pip = piperidine). When the solvent was benzylamine ( $\text{BzNH}_2$ ), the  $[\text{BH}_4]^-$  ions were non-coordinated and the octahedral  $[\text{Mg}(\text{BzNH}_2)_6]^{2+}$  cation was formed.<sup>123</sup> In  $[\text{In}(\text{BzNH}_2)_3(\text{PhCH}_2\text{CO}_2)_3]$ , the In(III) center is octahedral with a *fac*-arrangement of  $\text{BzNH}_2$  ligands.<sup>124</sup> The  $[\text{K}_2({}^t\text{BuNH}_2)_4]^{2+}$  ion (Fig. 3D) was isolated in a paramagnetic salt with the 3-oxyl-4,4,5,5-tetramethyl-2-oxoimidazolidin-1-olate anion.<sup>125</sup> Complexes of aniline are represented by  $[\text{Li}(\text{PhNH}_2)_3(\text{BH}_4)]$  which contains a tetrahedral  $\text{Li}^+$  center with a tridentate  $\text{BH}_4^-$  ion occupying one of the four coordination sites.<sup>126</sup> Mixtures of 2,6-dimethylaniline ( $\text{DmpNH}_2$ ) and  $\text{SbCl}_3$  in toluene yielded a co-crystalline mixture of  $[\text{SbCl}_3(\text{DmpNH}_2)_2]$  and  $[\text{SbCl}_3(\text{DmpNH}_2)]$  in which the Sb atoms are in square-based pyramidal and see-saw (disphenoidal) geometries, respectively.<sup>127</sup>

Monodentate, terminal en ligands coordinating to main group metal centers are found in  $[\text{Be}(\text{en})_3]\text{Cl}_2$  and  $[\text{Be}(\text{en})_3]\text{Br}_2$  (one chelating and two monodentate en). A change to  $\text{BeF}_2$  leads to a polymeric structure (see later).<sup>128</sup>

Group 1 metal complexes with  $\{\text{M}(\text{RNH}_2)_2(18\text{-crown-6})\}^+$  motifs are well represented, both with terminal and bridging amino ligands. In 1993, Dye et al. reported the sodide ( $\text{Na}^-$ ) salts  $[\text{Li}(\text{MeNH}_2)_2(18\text{-crown-6})][\text{Na}]$  and  $[\text{Li}(\text{MeNH}_2)_2(18\text{-crown-6})][\text{Na}] \cdot 3(18\text{-crown-6})$ . In the former, the  $\text{Li}^+$  ion is tetrahedrally sited with Li–N distances of 2.021 and 1.955 Å (Fig. 4A) while in the latter, the  $\text{Li}^+$  ion sits centrally in the ring (Fig. 4B) with unusually short Li–N distances of 1.733 Å and an apparently linear Li–N–C unit; a model with a three-fold disorder was suggested but residual electron density did not support the model.<sup>129</sup> While  $\text{Li}^+$  is not size-compatible with the cavity in 18-crown-6, the latter is ideally suited for  $\text{K}^+$ , as illustrated in Fig. 4C with the structure of  $[\text{K}(\text{en})_2(18\text{-crown-6})]^+$ .<sup>130</sup>  $\{\text{K}(18\text{-crown-6})\}^+$  domains connected by bridging en ligands are exemplified in 1D-polymers and cyclic arrays. The chain shown in Fig. 4D is one of two independent chains present in the salt of the  $[\text{Ge}_{16}\text{Sb}_2]^{4-}$  Zintl ion,<sup>131</sup> and other studies of Zintl ions give rise to examples of  $\{\text{K}(18\text{-crown-6})(\mu\text{-en})\}$  units in which the en ligand bridges two  $\text{K}^+$  centers or one  $\text{K}^+$  and a second metal ion.<sup>132–134</sup> A hexanuclear cyclic array (Fig. 4E) has also been structurally characterized.<sup>135</sup>

The use of en as a solvent and Li metal as a reductant in reactions to give Chevrel-like clusters has led to the assembly of an  $[\text{Li}_4(\text{en})_{10}]_n^{4n+}$  network comprising sheets of double layers (Fig. 5A) which host the Chevrel clusters.<sup>136</sup> In contrast, a 1D-coordination polymer with both bridging and chelating en ligands (Fig. 5B) is present in  $\{[\text{Li}(\text{en})_2][\text{BH}_4]\}_n$ .<sup>126</sup> Other examples of 1D- and 2D-assemblies with en ligands connecting  $\text{Li}^+$  centers have been described by Dehnen et al.<sup>137</sup> and Thiele et al.<sup>138</sup> In  $\{\text{K}_2[\text{Li}_4(\text{en})_8][\text{Ge}_{18}]\}_n$ , each  $\text{Li}^+$  center acts as a 4-connecting node to give a 3D (sra) net (Fig. 5C).<sup>139</sup> The reduction of red P by

**Fig. 3** (A) The structure of  $[\text{Ga}(\text{MeNH}_2)_2\text{H}_2]\text{Cl}$  (CSD refcode RITRUI) showing short N–H...Cl<sup>-</sup> contacts. (B) Part of one 2D-layer in  $[\text{Ba}(\text{MeNH}_2)_3\text{Te}_3]_n$  with 8-coordinate  $\text{Ba}^{2+}$ , terminal  $\text{MeNH}_2$  ligands and bridging  $\text{Te}_3^{2-}$  units (H atoms omitted, refcode JEQNAX). (C) The structure of  $[\text{Mg}({}^t\text{BuNH}_2)_3(\text{BH}_4)_2]$  (refcode LUVMAQ). (D) The  $[\text{K}_2({}^t\text{BuNH}_2)_4]^{2+}$  ion (H atoms omitted, refcode TICWIM).

**Fig. 4** The cations in (A)  $[\text{Li}(\text{MeNH}_2)_2(18\text{-crown-6})]^+ \text{Na}^-$  (CSD refcode COJDIO), (B)  $[\text{Li}(\text{MeNH}_2)_2(18\text{-crown-6})]^+ \text{Na}^- \cdot 3(18\text{-crown-6})$  (refcode COJFAI), and (C)  $[\text{K}(\text{en})_2(18\text{-crown-6})]^+$  (refcode HEVTOS). (D) Part of one chain in  $[\text{K}(18\text{-crown-6})(\mu\text{-en})]_n^+$  (refcode EWAVII), and (E) the metallohexacycle  $[\text{K}(18\text{-crown-6})(\mu\text{-en})]_6^+$  (refcode FAPLIU).

**Fig. 5** (A) Part of one sheet in the  $[\text{Li}_4(\text{en})_{10}]_n^{4n+}$  network in  $[\text{Li}_4(\text{en})_{10}][\text{Pd}_6(\mu_3\text{-Te})_8]$  (CSD refcode ZOYNOS). (B) Part of one 1D- $[\text{Li}(\text{en})_2]_n^+$  chain in the borohydride salt (refcode UBEVOM). (C) Part of the *sra* net in  $[\text{K}_2[\text{Li}_4(\text{en})_8][\text{Ge}_{18}]]_n$  represented with only the 4-connecting Li nodes; each  $\text{Li}\cdots\text{Li}$  edge is bridged by an en ligand (refcode OHUWEW).

Na in en gave  $[\text{Na}_4(\text{en})_6\text{P}_{14}]_n$  in which all en ligands bridge between pairs of  $\text{Na}^+$  centers and  $\text{P}_{14}^{4-}$  units are also interconnected by  $\text{Na}^+$  ions; each  $\text{Na}^+$  center is bound by three N and two P donors.<sup>140</sup>

Although a few examples of groups 2 and 13–15 metal complexes with bridging en ligands were reported prior to 2000,<sup>141–144</sup> structurally characterized examples in the period covered by this review are limited. An investigation of the use of liquid en as a solvent in Be coordination chemistry led to the characterization of  $[\text{Be}(\text{en})_3]\text{Cl}_2$  and  $[\text{Be}(\text{en})_3]\text{Br}_2$  (see above), and to the 1D-polymer  $[\text{BeF}_2(\text{en})]_n$  (Fig. 6A).<sup>128</sup> Moving to group 14, lead(II) complexes with bridging en ligands are illustrated by  $[\text{PbI}_2(\text{en})_2]_n$  (Fig. 6B),<sup>145</sup> and  $[\text{PbCl}_2(\text{en})_2]_n$  which is structurally similar to the iodido derivative.<sup>146</sup> The bromido analog was reported in 1996.<sup>147</sup>

**Fig. 6** Part of one 1D-chain in (A)  $[\text{BeF}_2(\text{en})]_n$  (CSD refcode IRUHOV), (B)  $[\text{PbI}_2(\text{en})_2]_n$  (refcode NOCZOV).

Our discussion of main group metal complexes with tertiary amino ligands is restricted to selected examples of those containing  $\text{Me}_3\text{N}$  and  $\text{Et}_3\text{N}$ , for which group 13 derivatives dominate. Tetrahedral  $\text{M}(\text{III})$  is typical in  $\text{R}_3\text{MNMe}_3$  ( $\text{M}$  = group 13 metal) compounds, but these organometallic derivatives, of which there are many examples, are outside the scope of this article.  $[\text{Li}(\text{NMe}_3)][\text{WMe}_7]$  is worthy of note because of the unusual environment of the  $\text{Li}^+$  ion (Fig. 7A).<sup>148</sup> Examples of group 13 coordination complexes with  $\text{Me}_3\text{N}$  or  $\text{Et}_3\text{N}$  ligands published after 2000 include  $[\text{2,6-(Dipp)}_2\text{C}_6\text{H}_3\text{OAlH}_2(\text{NMe}_3)]$  (Fig. 7B,  $\text{Al-N} = 2.0009(16) \text{ \AA}$ ),<sup>149</sup>  $[\{\text{W}(\text{CO})_5\}(\text{H}_2\text{P})\text{AlH}_2(\text{NMe}_3)]$  (Fig. 7C,  $\text{Al-N} = 2.036(3) \text{ \AA}$ ), and  $[\{\text{W}(\text{CO})_5\}(\text{H}_2\text{P})\text{GaH}_2(\text{NMe}_3)]$  (Fig. 7D,  $\text{Ga-N} = 2.039(7) \text{ \AA}$ ). The latter complexes were designed to stabilize the otherwise elusive simple phosphanylalane and -gallane. In the solid state,  $[\{\text{W}(\text{CO})_5\}(\text{H}_2\text{P})\text{AlH}_2(\text{NMe}_3)]$  exists as a monomer whereas the analogous aluminum compound is dimeric, with asymmetric  $\text{Al-H-Al}$  bridges (Fig. 7E,  $\text{Al-H} = 1.553$  and  $2.053 \text{ \AA}$ ).<sup>150</sup> A  $\text{GaH}(\text{NEt}_3)$  unit has been incorporated into the cyclosiloxane  $[(\text{OPh}_2\text{SiOSiPh}_2\text{OSiPh}_2\text{O})\text{GaH}(\text{NEt}_3)]$ .<sup>151</sup>

#### 1.02.2.1.2 $\text{R}_2\text{N}^-$ , $\text{RHN}^-$ , $\text{RN}^{2-}$

In this section, we survey main group metal complexes incorporating simple amido ( $\text{R}_2\text{N}^-$  and  $\text{RHN}^-$ ) and imido ( $\text{RN}^{2-}$ ) ligands, many of which exhibit an  $\{\text{M}_2(\mu\text{-N})_2\}$  core. There is a wide range of complexes with  $\{\text{Li}_2(\mu\text{-NR}_2)_2\}$  or  $\{\text{Li}_2(\mu\text{-NRH})_2\}$  units,<sup>152-173</sup> and Figs. 8A-C illustrate examples that exhibit 4-, 3- and 2-coordinate lithium.<sup>152,153,174</sup> The use of the sterically demanding ligands to stabilize the  $\{\text{Li}_2(\mu\text{-NR}_2)_2\}$  core without the need for terminal ligands (Fig. 8C) is notable and is observed in several examples.<sup>174,175</sup> Fig. 8D shows the structure of  $[\text{Li}_2(1,2\text{-C}_6\text{F}_2\text{H}_4)_2(\mu\text{-N}(\text{C}_6\text{F}_5)_2)_2]$  in which there are short  $\text{Li}\cdots\text{F}$  contacts ( $2.038\text{-}2.139 \text{ \AA}$ ); this increases the coordination number of  $\text{Li}$  from 4 to 6.<sup>176</sup> A related motif is found in  $[\text{Na}_2(\text{OEt}_2)_2(\mu\text{-N}(\text{C}_6\text{F}_5)_2)_2]$ , but in this case, the structure in the solid state extends into a 1D-coordination polymer by virtue of additional  $\text{Na-F-C}$  contacts;

**Fig. 7** (A) One ion pair in the solid-state structure of  $[\text{Li}(\text{NMe}_3)][\text{WMe}_7]$  (CSD refcode RETNIN). The structures of (B)  $[\text{2,6-(Dipp)}_2\text{C}_6\text{H}_3\text{OAlH}_2(\text{NMe}_3)]$  (refcode OGONAA), (C)  $[\{\text{W}(\text{CO})_5\}(\text{H}_2\text{P})\text{AlH}_2(\text{NMe}_3)]$  (refcode MIHGOZ), and (D)  $[\{\text{W}(\text{CO})_5\}(\text{H}_2\text{P})\text{GaH}_2(\text{NMe}_3)]$  (refcode MIHGUF). In (B), (C), (D), only the  $\text{M-H}$  atoms are shown; in (C) and (D), each  $\text{P}$  is a  $\text{PH}_2$  unit.

**Fig. 8** Structures of (A)  $[\text{Li}_2(\text{THF})_4(\mu\text{-NMe}_2)_2]$  (CSD refcode PAHCIO), and (B)  $[\text{Li}_2(\text{diox})_2(\mu\text{-N}(\text{CHMePh})_2)_2]$  (refcode CAZLIB). (C) Use of a sterically demanding amido ligand to stabilize 2-coordinate  $\text{Li}^+$  (refcode JOKSIM). (D) The structure of  $[\text{Li}_2(1,2\text{-C}_6\text{F}_2\text{H}_4)_2(\mu\text{-N}(\text{C}_6\text{F}_5)_2)_2]$  (refcode VUHREY). (E) The tetralithium complex  $[\text{Li}_4(\mu\text{-tmeda})_2(\mu\text{-NPh}_2)_2(\mu\text{-tmeda})]$  (refcode COBZUQ). (F) Part of the 1D-chain in  $[\{\text{Li}_2(\mu\text{-NHDipp})_2(\mu\text{-tmeda})\}_n]$  (refcode RUMRAT). Carbon-attached H atoms are omitted.

this is not discussed in the original work but is evident from inspection of the structural data (CSD refcode WIRYED).<sup>177</sup> Related to the homonuclear species described above are  $[\text{LiNa}(\text{THF})_2(\mu\text{-N}(\text{CHMePh})_2)_2]$ ,<sup>153</sup> and associated heterometallic species.<sup>178</sup> Extended systems incorporating  $\{\text{Li}_2(\mu\text{-NR}_2)_2\}$  units include  $\{[\text{Li}_2(\text{tmeda})(\mu\text{-NPh}_2)_2]_2(\mu\text{-tmeda})\}$  (Fig. 8E, tmeda = 1,2-bis(dimethylamino)ethane),<sup>179</sup> and  $\{[\text{Li}_2(\mu\text{-NHDipp})_2]_2(\mu\text{-tmeda})\}_n$  (Fig. 8F).<sup>180</sup> The use of 1,3-bis((2,6-di-isopropylphenyl)amido)methyl)benzene has led to the formation of a metallomacrocyclic containing two  $\{\text{Li}_2(\mu\text{-NR}_2)_2\}$  units.<sup>181</sup>

Complexes containing  $\{\text{Na}_2(\mu\text{-NR}_2)_2\}$  or  $\{\text{Na}_2(\mu\text{-NRH})_2\}$  units (NR<sub>2</sub> includes non-aromatic heterocycles) belonging to the same families as those described above for Li have also been reported,<sup>156,163,182–184</sup> as have potassium-based dimers.<sup>183,185–188</sup> The complex  $[\text{K}_2(\text{diox})_3(\mu\text{-NH}(2,6\text{-C}_6\text{F}_2\text{H}_3))_2]_n$  is worthy of particular note. Firstly, short K–F–C contacts (Fig. 9A) involving the fluorinated arene ring are observed which mirror those seen in  $[\text{Li}_2(\mu\text{-NHDipp})_2]_2(\mu\text{-tmeda})_n$  (Fig. 8F). Secondly, the increase in ionic radius on descending group 1 allows the accommodation of three 1,4-dioxane ligands and these, in turn, lead to the assembly of a 3D-network.<sup>189</sup> Rubidium and cesium derivatives with  $\{\text{M}_2(\mu\text{-NR}_2)_2\}$  motifs are rarer than their lighter group 1 metal analogs.  $[\text{Rb}_2(\text{tmeda})_2(\mu\text{-tmp})_2]$  (Fig. 9B) and  $[\text{Cs}_2(\text{tmeda})_2(\mu\text{-tmp})_2]$ <sup>190</sup> are structurally similar to their Na and K homologs,<sup>185</sup> but differ from that of the tmeda-solvated Li(tmp) derivative which, in the solid state, exists as  $[\text{Li}_2(\text{tmeda})(\text{tmp})(\mu\text{-tmp})]$  (Fig. 9C) with only one bridging amido ligand; note the low coordination numbers of the  $\text{Li}^+$  centers (Fig. 9C).<sup>191</sup> The reaction of Rb metal with 4-aminobenzonitrile in THF results in the formation of  $[\text{Rb}(\mu\text{-THF})_2(\mu\text{-NH}(4\text{-NCC}_6\text{H}_4))]_n$  which possesses an unusual 3D-network. Both THF and amido ligands bridge pairs of adjacent Rb atoms, and the network can be considered in terms of layers, interconnected by  $[(4\text{-NCC}_6\text{H}_4)\text{NH}]^-$  ligands which coordinate to  $\text{Rb}^+$  both through RCN and RHN<sup>−</sup> donors (Fig. 9D).<sup>166</sup>

Moving now to group 2, and the ubiquitous  $\{\text{M}_2(\mu\text{-NR}_2)_2\}$  unit is observed in  $[\text{Be}_2(\mu\text{-BH}_4)_2(\mu\text{-N}^i\text{Pr}_2)_2]$  (Fig. 10A).<sup>192</sup> However, amido beryllium derivatives remain scarce, and those of magnesium are dominant.<sup>193–209</sup> Among these examples are trimagnesium and heterometallic species. In  $[\text{Mg}_3(\text{THF})_6(\mu\text{-NHC}_6\text{F}_5)_6]$ , pairs of Mg atoms are triply bridged by amido ligands (Fig. 10B) and each  $\text{Mg}^{2+}$  ion is 6-coordinate. Interestingly, in contrast to examples described earlier in this review, e.g.,  $[\text{Li}_2(1,2\text{-C}_6\text{F}_2\text{H}_4)_2(\mu\text{-N}(\text{C}_6\text{F}_5)_2)_2]$ , there are no short  $\text{M}\cdots\text{F}$  contacts in  $[\text{Mg}_3(\text{THF})_6(\mu\text{-NHC}_6\text{F}_5)_6]$ .<sup>209</sup> On the other hand, short  $\text{Mg}\cdots\text{F}$  contacts are found in the solid-state structure of  $[\text{Mg}_2(\mu\text{-N}(\text{C}_6\text{F}_5)_2)_2(\text{N}(\text{C}_6\text{F}_5)_2)_2]$ .<sup>205</sup> Interest in alkali metal-magnesium complexes lies in their use as cooperative dimetallic catalysts, with  $^i\text{PrNMgCl}\cdot\text{LiCl}$  being described as the ‘turbo Grignard reagent.’<sup>210</sup> Examples include  $[\text{Na}_2(\text{THF})_4\text{Mg}_2(\mu\text{-Npip})_6]$  (Fig. 10C) and  $[\text{Na}_2(\text{tmeda})_2\text{Mg}(\mu\text{-Npip})_4]$  (Fig. 10D). In both, each metal ion is tetrahedrally sited and the Na–N distances are noticeably long (av. 2.46(1) Å in the former and av. 2.432(3) Å in the latter) and are described as ‘ancillary bonds.’<sup>199</sup> Related group 1–2 dimetallic species include  $[\text{Li}(\text{THF})\text{Mg}(\mu\text{-NCy}_2)_2(\text{NCy}_2)]$  in which Na and Mg are both 3-coordinate (Fig. 10E),<sup>200</sup>  $[\text{Na}(\text{tmeda})\text{Mg}(\mu\text{-N}^i\text{Pr}_2)_2(\text{N}^i\text{Pr}_2)]$ ,<sup>204</sup> and  $[\text{Li}_2(\text{THF})_4\text{Mg}_2(\mu\text{-Cl})_4(\mu\text{-N}^i\text{Pr}_2)_2]$  (Fig. 10F) which dissociates in THF solution to give  $[\text{Li}(\text{THF})_4]^+$  and  $^i\text{Pr}_2\text{NMgCl}$ -containing species.<sup>203</sup>

Amido complexes of  $\text{Ca}^{2+}$  reveal the metal in a range of coordination environments. The use of a sterically demanding β-diketimate co-ligand leads to 4-coordinate  $\text{Ca}^{2+}$  in  $[\text{Ca}_2(\text{L})_2(\mu\text{-NHBz})_2]$  (HL and the complex are shown in Fig. 11).<sup>211</sup>  $\text{CaH}_2$  reduction of isoquinoline (iQ) results in the formation of *trans*- $[\text{Ca}(\text{HiQ})_2(\text{iQ})_4]$  ( $\text{H}_2\text{iQ} = 1,2\text{-dihydroisoquinoline}$ ) and  $[\text{Ca}_3(\text{iQ})_6(\mu\text{-HiQ})_6]$  which contains a linear  $\{\text{Ca}_3(\mu\text{-NR}_2)_6\}$  core with 6-coordinate  $\text{Ca}^{2+}$ .<sup>212</sup> A similar linear  $\{\text{Ca}_3(\mu\text{-NHR})_6\}$  core is present in  $[\text{Ca}_3(\text{THF})_6(\mu\text{-NHMe})_6]$  (Mes = mesityl) which was formed by reaction of  $\text{K}[\text{MesNH}]$  with  $\text{CaI}_2$  in THF. In contrast, a change from  $\text{K}[\text{MesNH}]$  to  $\text{K}[2,6\text{-F}_2\text{C}_6\text{H}_3\text{NH}]$  resulted in the formation of the dinuclear complex  $[\text{Ca}_2(\text{THF})_5(2,6\text{-F}_2\text{C}_6\text{H}_3\text{NH})(\mu\text{-NH}(2,6\text{-F}_2\text{C}_6\text{H}_3))_3]$  (Fig. 11B).<sup>189</sup> There are no short  $\text{Mg}\cdots\text{F}$  contacts in the latter, while in  $[\text{Ca}_4(\text{N}(\text{SiMe}_3)_2)_2(\mu\text{-N}(2\text{-FC}_6\text{H}_4)_2)_6]$  (Fig. 11C),  $\text{Ca}\cdots\text{F}$  interactions are key in stabilizing a low-coordinate group 2 metal complex; related  $\text{Ba}^{2+}$

**Fig. 9** (A) Two repeating units in  $[\text{K}_2(\text{diox})_3(\mu\text{-NH}(2,6\text{-C}_6\text{F}_2\text{H}_3))_2]_n$  (CSD refcode NOBQEB). The structures of (B)  $[\text{Cs}_2(\text{tmeda})_2(\mu\text{-tmp})_2]$  (refcode VEBLEV) and (C)  $[\text{Li}_2(\text{tmeda})(\text{tmp})(\mu\text{-tmp})]$  (refcode YAPCOH). (D) Part of the 3D-network in  $[\text{Rb}(\mu\text{-THF})_2(\mu\text{-NH}(4\text{-NCC}_6\text{H}_4))]_n$  (all H atoms omitted, refcode FEXLIE).

**Fig. 10** The structures of (A)  $[\text{Be}_2(\mu\text{-BH}_4)_2(\mu\text{-N}^i\text{Pr}_2)_2]$  (only H atoms in  $[\text{BH}_4]^-$  ligands are shown, CSD refcode AQADAX), (B)  $[\text{Mg}_3(\text{THF})_6(\mu\text{-NHC}_6\text{F}_5)_6]$  (only amido H atoms are shown, refcode YOHTOF), (C)  $[\text{Na}_2(\text{THF})_4\text{Mg}_2(\mu\text{-Npip})_6]$  (refcode POFREK), (D)  $[\text{Na}_2(\text{tmeda})_2\text{Mg}(\mu\text{-Npip})_4]$  (refcode POFRIO), (E)  $[\text{Li}(\text{THF})\text{Mg}(\mu\text{-NCy}_2)_2(\text{NCy}_2)]$  (refcode QOLFEC) and (F)  $[\text{Li}_2(\text{THF})_4\text{Mg}_2(\mu\text{-Cl})_4(\mu\text{-N}^i\text{Pr}_2)_2]$  (refcode TUYGUQ).

**Fig. 11** The structures of (A) the  $\beta$ -diketimine HL, and  $[\text{Ca}_2(\text{L})_2(\mu\text{-NHBz})_2]$  (only amido H atoms are shown, CSD refcode LIYYUO), (B)  $[\text{Ca}_2(\text{THF})_5(2,6\text{-F}_2\text{C}_6\text{H}_3\text{NH})(\mu\text{-NH}(2,6\text{-F}_2\text{C}_6\text{H}_3))_3]$  (only amido H atoms shown, refcode NOBQUR), and (C)  $[\text{Ca}_4(\text{N}(\text{SiMe}_3)_2)_2(\mu\text{-N}(2\text{-FC}_6\text{H}_4)_2)_6]$  (refcode POJXAQ).

complexes were also reported.<sup>213</sup> The tendency for higher coordination numbers is seen in  $[\text{Ca}_4(\text{THF})_8(\mu\text{-NHPH})_8]$  which contains 6-coordinate  $\text{Ca}^{2+}$  centers in a  $\{(\text{THF})_3\text{Ca}(\mu\text{-N})_3\text{Ca}(\text{THF})(\mu\text{-N})_2\text{Ca}(\text{THF})(\mu\text{-N})_3\text{Ca}(\text{THF})_3\}$  motif.<sup>214</sup> Related strontium and barium derivatives  $[\text{Sr}(\text{THF})_2(\mu\text{-NHPH})_2]_n$  (Fig. 12A) and  $[\text{Ba}_2(\text{THF})_3(\mu\text{-NHPH})_4]_n$  (Fig. 12B) are polymeric with 6-coordinate metal ions and increasing interactions to the phenyl ring  $\pi$ -systems with increasing size of the group 2 metal.<sup>214</sup>

For group 13, we again see complexes based on dimetallic  $\{\text{M}_2(\mu\text{-NR}_2)_2\}$  cores with Al-containing species predominating over complexes of the heavier metals.<sup>215–228</sup> There are many simple dinuclear complexes in the  $[\text{M}_2\text{X}_4(\mu\text{-NR}_2)_2]$  and  $[\text{M}_2\text{X}_4(\mu\text{-NHR})_2]$  families, and their typical structures are illustrated by that of  $[\text{Al}_2\text{Cl}_4(\mu\text{-NEt}_2)_2]$  (Fig. 13A). An interesting related complex is  $[\text{Al}_2\text{H}_2(\text{NHDipp})(\text{NMe}_2\text{Et})(\mu\text{-NHDipp})(\mu\text{-NDipp})]$  in which both amido and imido ligands bridge the  $\text{Al}_2$ -unit (Fig. 13B). This was prepared by reaction of  $\text{H}_3\text{Al}\cdot\text{NMe}_2\text{Et}$  with  $\text{DippNH}_2$ , and is one of a series of associated compounds reported by Bauer et al.<sup>215</sup> Chivers reported a series of heterometallic compounds formed from reactions of  $\text{MAlH}_4$  ( $\text{M} = \text{Li}, \text{Na}$ ) with  $\text{RH}_2\text{N}$  ( $\text{R} = ^i\text{Bu}, ^i\text{Pr}, 4\text{-tolyl}$ ).  $[\text{LiAl}(\text{NH}^i\text{Pr})_4]_n$  and  $[\text{NaAl}(\text{NH}^i\text{Pr})_4]_n$  (Fig. 13C) are 1D-polymers in the solid state, while  $[\text{Li}(\text{THF})_4][\text{Al}(\text{NH}(4\text{-tolyl}))_4]$  contains discrete ions.<sup>229</sup>

Chloroamides of low-valence group 14 elements include monomers and cyclic products with bridging chlorido and amido ligands. In 2007, Khrustalev et al. reported the thermally stable metal(II) complexes  $[\text{Ge}_2\text{Cl}_2(\mu\text{-NEt}_2)_2]$  (Fig. 14A) and  $[\text{Sn}_2\text{Cl}_2(\mu\text{-NMe}_2)_2]$  which were the first crystallographically characterized group 14 metal(II) chlorides with small alkylamino ligands. The Ge(II) and Sn(II) derivatives are structurally similar. However, the  $\text{Sn}_2\text{N}_2$  rhombus is planar (crystallographically imposed) whereas the  $\text{Ge}_2\text{N}_2$  rhombus has a butterfly configuration with internal dihedral angle of  $167^\circ$ ; Ge–N bond lengths are 2.034(2) and 2.073(2) Å, and Sn–N = 2.267(4) and 2.229(4) Å.<sup>230</sup> In  $[\text{Ge}_2\text{Cl}_2(\mu\text{-NEt}_2)_2]$  and  $[\text{Sn}_2\text{Cl}_2(\mu\text{-NMe}_2)_2]$ , the chlorido ligands are in a mutually *anti* arrangement.<sup>230</sup> In contrast, they are in a *syn*-arrangement in  $[\text{Sn}_2\text{Cl}_2(\mu\text{-NHDipp})_2]$ ,<sup>231</sup> and in  $[\text{Pb}_2\text{Cl}_2(\mu\text{-NHDipp})_2]$ .<sup>232</sup> Other examples of tin(II) amido complexes include  $[\text{Sn}_2\text{L}_2(\mu\text{-NMe}_2)_2]$  (HL is a salicylaldimine, e.g., Fig. 14B) which have been investigated for use in *rac*-lactide polymerization,<sup>233</sup>  $[\text{Sn}_2(\text{Me}_2\text{NC}(\text{S})\text{NPh})_2(\mu\text{-NMe}_2)_2]$  (Fig. 14C) which acts as a single source precursor for the deposition of phase-pure films of  $\text{SnS}$ ,<sup>234</sup> and  $[\text{Sn}_2(\text{OR})_2(\mu\text{-NMe}_2)_2]$  complexes (e.g., Fig. 14D) which have been applied to the synthesis of  $\text{SnO}_x$  nanowires.<sup>235</sup>

The first Sb(III) aziridinides were reported in 2017. The reaction between  $\text{Sb}(\text{NMe}_2)_3$  and aziridine ( $\text{HAzn}$ ) yielded  $[\text{Sb}_2(\text{Azn})_4(\mu\text{-NAzn})_2]$  (Fig. 15A) which exhibits a ‘weak’ dimeric structure in the solid state (for the bridging ligands, Sb–N = 2.084(1) and

**Fig. 12** Parts of the 1D-polymer chains in (A)  $[\text{Sr}(\text{THF})_2(\mu\text{-NHPh})_2]_n$  (CSD refcode VIMYOG) and (B)  $[\text{Ba}_2(\text{THF})_3(\mu\text{-NHPh})_4]_n$  (CSD refcode VIMYOG). H atoms omitted except for NH.

**Fig. 13** Structures of (A)  $[\text{Al}_2\text{Cl}_4(\mu\text{-NEt}_2)_2]$  (refcode SUDKUZ), and (B)  $[\text{Al}_2\text{H}_2(\text{NHDipp})(\text{NMe}_2\text{Et})(\mu\text{-NHDipp})(\mu\text{-NDipp})]$  (CSD refcode PUZSOS). (C) Part of one 1D-polymer chain in  $[\text{NaAl}(\text{NH}'\text{Pr})_4]_n$  (refcode PEGZAD).

**Fig. 14** The structures of (A)  $[\text{Ge}_2\text{Cl}_2(\mu\text{-NEt}_2)_2]$  (CSD refcode KIJVAB), (B) an example of a  $[\text{Sn}_2\text{L}_2(\mu\text{-NMe}_2)_2]$  (refcode DUGHIX) complex where HL is a salicylalimine, (C)  $[\text{Sn}_2(\text{Me}_2\text{NC}(\text{S})\text{NPh})_2(\mu\text{-NMe}_2)_2]$  (refcode RACPET), (D)  $[\text{Sn}_2(\text{O}(2\text{-MeC}_6\text{H}_4))_2(\mu\text{-NMe}_2)_2]$  (refcode VAYRIY). All H atoms are omitted.

**Fig. 15** The structures of (A)  $[\text{Sb}_2(\text{Azn})_4(\mu\text{-NAzn})_2]$  (CSD refcode HAPSEZ) and (B) part of the 1D-polymer in  $[\text{Li}_3\text{Sb}(\mu_3\text{-Cl})_2(\mu\text{-Azn})_4(\text{THF})_2]_n$  (Li, dark purple, Sb, pale purple; refcode HAPSAV). (C) General structure of an  $\text{E}_4(\mu_3\text{-NR})_4$  cubane, and (D) the cubane  $[\text{Sn}_3\text{Se}_3\text{Li}(\text{THF})(\mu_3\text{-N}^t\text{Bu})_4]^-$  (refcode FERVEE). H atoms are omitted.

2.534(2) Å).  $[\text{Sb}_2(\text{Az}_n)_4(\mu\text{-NAz}_n)_2]$  could not be accessed by reacting  $\text{SbCl}_2$  with  $\text{Li}[\text{Az}_n]$ , but instead, a reaction in THF produced the polymeric  $[\text{Li}_3\text{Sb}(\mu_3\text{-Cl})_2(\mu\text{-Az}_n)_4(\text{THF})_2]_n$  (Fig. 15B).<sup>236</sup> Neutral bismuth amides, e.g.,  $\text{Bi}(\text{N}(\text{SiMe}_3)_2)_3$ , and a bismuth thioamide were investigated as volatile Bi-containing precursors for bismuth oxide materials.<sup>237</sup> Cationic Bi amido derivatives  $[\text{Bi}(\text{NR}_2)_2\text{L}_n]^+$  ( $\text{R}=\text{Me}$ ,  $^i\text{Pr}$ ,  $\text{Ph}$ ;  $\text{L}$  = neutral ligand) have also been described. However, in the  $[\text{BPh}_4]^-$  salts, transfer of  $\text{Ph}$  from  $\text{Bi}$  to  $\text{Bi}$  was observed; use of fluorinated tetraarylborate counterions yielded more stable cationic bismuth amides.<sup>238</sup>

The imido ( $\text{RN}^{2-}$ ) group is isoelectronic with an oxido  $\text{O}^{2-}$  ligand, and main group metal clusters involving  $\text{M}-\text{NR}-\text{M}$  bridging units are well represented and reviewed.<sup>77-79</sup> Although strictly organometallic,  $[\text{Sb}_2\text{Ph}_2(\mu\text{-N}^t\text{Bu})_2]$  is a representative example of a simple imido complex.<sup>239</sup> Imido cubanes  $[\text{E}_4(\mu_3\text{-NR})_4]$  (Fig. 15C) are represented by  $[\text{M}_4(\mu_3\text{-NGeMe}_3)_4]$  ( $\text{M} = \text{Ge}$ ,  $\text{Sn}$ ,  $\text{Pb}$ ) and  $[\text{Sn}_4(\mu_3\text{-NSnMe}_3)_4]$ ,<sup>240</sup>  $[\text{Sn}_3\text{Mg}(\mu_3\text{-N}^t\text{Bu})_4]$  and  $[\text{Sn}_3\text{Li}(\mu_3\text{-N}^t\text{Bu})_4]^-$ ,<sup>241</sup> and  $[\text{Sn}_3\text{X}_3\text{Li}(\text{THF})(\mu_3\text{-N}^t\text{Bu})_4]^-$  ( $\text{X} = \text{Se}$ ,  $\text{Te}$ ; Fig. 15D).<sup>242</sup>

### 1.02.2.1.3 Nitriles

We have restricted our discussion of nitrile ( $\text{RC}\equiv\text{N}$ ) complexes to homoleptic compounds and other simple species. For  $\text{Li}^+$ , tetrahedral coordination is typical, e.g., in salts of  $[\text{Li}(\text{NCMe})_4]^+$ ,<sup>243-247</sup> in  $[\text{Li}_2(\text{NCMe})_4(\mu\text{-Br})_2]$  (Fig. 16A),<sup>248</sup> and in the 1D-coordination polymer  $[\text{Li}(\text{NCMe})_2(\mu\text{-Cl})]_n$  (Fig. 16B).<sup>249,250</sup>  $\{[\text{Li}(\mu\text{-NCCH}_2\text{CH}_2\text{CN})_2][\text{N}(\text{SO}_2\text{F})_2]\}_n$  is an example of a network built up from  $\text{Li}^+$  and a dinitrile (Fig. 16C); the compound is of interest for its high Li-ion conductivity.<sup>251</sup> The coordination environments of  $\text{Na}^+$  in apparently simple complex cations with  $\text{MeCN}$  ligands are surprisingly varied. Both octahedral  $[\text{Na}(\text{NCMe})_6]^+$ ,<sup>252</sup> and 5-coordinate  $[\text{Na}(\text{NCMe})_5]^+$  ions have been structurally characterized.<sup>253-255</sup> The  $\text{Na}^+$  ion displays a square-planar coordination geometry in  $\text{trans-}[\text{Na}(\text{NCMe})_2(\text{OEt}_2)]^+$ <sup>256</sup>; note that this complements the square-planar  $[\text{Na}(\text{NH}_3)_4]^+$  ion described earlier. An unusual  $[\text{Na}(\text{NCMe})_2]^+$  cation with a non-linear geometry has been reported in  $[\text{Na}(\text{NCMe})_2][\eta^7\text{-(MeOCH}_2\text{CH}_2)_2\text{C}_2\text{B}_{10}\text{H}_{10}\text{Er}]_2$ , but as Fig. 16D illustrates, the  $\text{Na}^+$  ion is also closely associated with the carbaborane counterion.<sup>257</sup> Just as  $[\text{Na}(\text{NCMe})_2]^+$  deceptively displays  $\text{CN} = 2$ , the 3-coordinate  $\text{K}^+$  ion present in the tripodal cobalt(II) complex depicted in Fig. 17A exhibits close contacts to arene rings in the complex anion.<sup>258</sup> This and the octahedral  $[\text{K}(\text{NCMe})_6]^+$  ion<sup>259</sup> are among the few structurally characterized homoleptic acetonitrile complexes of  $\text{K}^+$ . A further example in which the low coordination number of the group 1 metal ion is ambiguous is  $[\text{Cs}_2(\mu\text{-CNMe})_2]^{2+}$  where the apparently open coordination sites of  $\text{Cs}^+$  are occupied by virtue of close  $\text{Cs}\cdots\text{Cl}$  or  $\text{Cs}\cdots\text{Br}$  contacts with the counterion.<sup>260</sup>

A number of  $[\text{M}\{\text{C}(\text{CN})_3\}_2]_n^{n-}$  coordination networks containing the group 1 metals have been reported. They possess metal-ocene counterions and are notable for melting in a range 102–239 °C; the dimensionality of the net depends on the size of the organometallic cation. An example is shown in Fig. 17B.<sup>261</sup>

Simple acetonitrile complexes of all the group 2 metals are represented. Tetrahedral coordination prevails in  $\text{RCN}$  complexes of beryllium, exemplified by  $[\text{BeBr}_2(\text{NCMe})_2]$ ,<sup>262</sup>  $[\text{Be}(\text{OSO}_2\text{CF}_3)_2(\text{NCMe})_2]$ ,<sup>263</sup> and  $[\text{BeCl}_2(\text{NCPh})_2]$ .<sup>264</sup> Treatment of  $\text{Be}$  powder with  $\text{I}_2$  in  $\text{MeCN}$  led to the formation of  $[\text{Be}_3(\mu_3\text{-O})_3(\text{MeCN})_6\{\text{Be}(\text{MeCN})_3\}_3]\text{I}_6$  and an active role of trace amounts of  $\text{BeO}$  in this reaction has been suggested. The cation has an essentially planar  $\text{Be}_6\text{O}_3$ -core (Fig. 17C).<sup>265</sup> On going to  $\text{Mg}^{2+}$ , octahedral coordination

**Fig. 16** (A) The structure of  $[\text{Li}_2(\text{NCMe})_4(\mu\text{-Br})_2]$  (CSD refcode SAWSUE01). (B) Part of the 1D-chain in  $[\text{Li}(\text{NCMe})_2(\mu\text{-Cl})]_n$  (refcode XENHAZ01). (C) Part of the 3D-network (viewed down the  $a$ -axis) in the  $[\text{N}(\text{SO}_2\text{F})_2]^-$  salt of  $[\text{Li}(\mu\text{-NCCH}_2\text{CH}_2\text{CN})_2]_n^+$  (refcode FAHDUR). (D) The  $[\text{Na}(\text{NCMe})_2]^+$  cations in  $[\text{Na}(\text{NCMe})_2][\eta^7\text{-(MeOCH}_2\text{CH}_2)_2\text{C}_2\text{B}_{10}\text{H}_{10}\text{Er}]_2$  with only B–H–Er H atoms shown (refcode IRIZEO).

**Fig. 17** (A) The ion-pair in  $[\text{K}(\text{NCMe})_3]^+[\text{Co}(\text{NCMe})(\text{L-tripod})]^-$  (CSD refcode GIGGUW) and the structure of  $\text{H}_3\text{L-tripod}$ . (B) Part of the  $[\text{K}(\text{C}(\text{CN})_3)_2]_n^-$  3D-net in the  $[\text{CpRu}(\text{C}_6\text{H}_5\text{Me})]^+$  salt (refcode LOMZEV). (C) The structure of the  $[\text{Be}_3(\mu_3\text{O})_3(\text{MeCN})_6\{\text{Be}(\text{MeCN})_3\}_3]^{6+}$  cation (refcode INILUN).

dominates as in  $[\text{Mg}(\text{NCMe})_6]^{2+}$ ,<sup>266–272</sup> and *trans*- $[\text{Mg}(\text{OH}_2)_4(\text{NCMe})_2]^{2+}$ .<sup>273</sup> Higher CNs are expected on descending group 2 and are indeed observed in  $[\text{Ca}(\text{NCMe})_8]^{2+}$  (CN = 8),<sup>268</sup>  $[\text{Ca}(\text{NCS})_2(\text{NCMe})_5]$  (CN = 7),<sup>274</sup>  $[\text{Ca}(\text{NCMe})_2(\text{OH}_2)_5]^{2+}$  (CN = 7),<sup>275</sup>  $[\text{Ca}(\text{NCMe})_3(15\text{-crown-5})]^{2+}$  (CN = 8, Fig. 18A),<sup>276</sup>  $[\text{Ca}(\text{NCMe})_2(18\text{-crown-6})]^{2+}$  (CN = 8),<sup>277</sup>  $[\text{Ca}(\text{NCMe})_3(18\text{-crown-6})]^{2+}$  (CN = 9, Fig. 18B),<sup>278</sup>  $[\text{Ca}(\text{NCMe})_4(\text{THF})_4]^{2+}$  (CN = 8),<sup>278</sup>  $[\text{Sr}(\text{NCMe})_8]^{2+}$  (CN = 8),<sup>268</sup>  $[\text{Sr}(\text{NCMe})_3(18\text{-crown-6})]^{2+}$  (CN = 9),<sup>278</sup> and  $[\text{Ba}(\text{NCMe})_8(\text{OH}_2)]^{2+}$  (CN = 9).<sup>260</sup> Fig. 17B showed part of the  $[\text{K}\{\text{C}(\text{CN})_3\}_2]_n^{n-}$  3D-net in which cavities are occupied by cations. In contrast, the neutral  $[\text{Ca}\{\text{C}(\text{CN})_3\}_2]_n$  forms an interpenetrating 3D-network (Fig. 18C) with octahedral  $\text{Ca}^{2+}$  centers connected by  $[\text{C}(\text{CN})_3]^-$  ligands. On going from  $[\text{Ca}\{\text{C}(\text{CN})_3\}_2]_n$  to  $[\text{Ba}\{\text{C}(\text{CN})_3\}_2(\text{OH}_2)_2]_n$ , the coordination number of the group 2 metal increases from 6 to 9 (a capped tetragonal antiprism). The 3D-network is unusual, with  $\text{Ba}^{2+}$  ions linked both by trinitrile and aqua ligands (Fig. 18D).<sup>279</sup>

Group 13 metal complexes with simple nitrile ligands are restricted to those of aluminum, if organometallics are excluded. A number of examples of octahedral  $[\text{Al}(\text{NCMe})_5\text{X}]^{2+}$  complexes with X = Cl or Br have been reported since 1979,<sup>280–287</sup> but these dications have been described as being ‘rather uncommon.’<sup>286</sup> The  $\text{Al}^{3+}$  center retains octahedral coordination in  $[\text{Al}_2(\mu\text{-OH})_2(\text{NCPH})_8]^{4+}$ ,<sup>284</sup> and  $[\text{Al}_2(\mu\text{-OH})(\mu\text{-O}_2\text{C}^t\text{Bu})_2(\text{NCPH})_6]^{3+}$ .<sup>288</sup> For the later main groups, examples of simple nitrile metal complexes reported since 2000 are relatively few: *cis*- $[\text{Ge}(\text{NCCH}_2\text{F})_2\text{F}_4]$ ,<sup>289</sup> *cis*- $[\text{Sn}(\text{NCMe})_2\text{Cl}_4]$ ,<sup>290,291</sup> *cis*- $[\text{Sn}(\text{NCMe})_2\text{Br}_4]$ ,<sup>292</sup> *cis*- $[\text{Sn}(\text{NCMe})_2\text{Cl}_4]$ ,<sup>290</sup> *cis*- $[\text{Sn}(\text{NC}^i\text{Pr})_2\text{Cl}_4]$ ,<sup>290</sup>  $[\text{Sn}(\text{NCMe})_6]^{2+}$ ,<sup>293</sup>  $[\text{Sn}(\text{NCMe})_5]^{2+}$ ,<sup>176</sup> and *cis*- $[\text{Te}(\text{NCMe})_2\text{Cl}_4]$ .<sup>294</sup> In the case of  $[\text{Sn}(\text{NCMe})_5]^{2+}$  and  $[\text{Sn}(\text{NCMe})_6]^{2+}$ , such examples of tin(II) dications without close contacts to the counterion are uncommon.<sup>176,293</sup>

#### 1.02.2.1.4 $\text{N}_3^-$ , N-bonded $\text{CN}^-$ , $\text{NCO}^-$ , $\text{NCS}^-$ , $\text{NCSe}^-$

As in previous sections, we focus on homoleptic main group metal complexes and other simple derivatives to give an overview of typical bonding modes of  $\text{N}_3^-$ ,  $\text{CN}^-$ ,  $\text{NCO}^-$ ,  $\text{NCS}^-$  and  $\text{NCSe}^-$ . We first consider azido complexes, investigations of which are motivated by their classification as high-energy materials. For groups 1 and 2, a number of crown ether complexes incorporate axial  $\text{N}_3^-$  ligands as exemplified by  $[\text{Li}(12\text{-crown-4})(\text{N}_3)]$  (with a linear Li–N–N–N unit),<sup>295</sup>  $[\text{Rb}(18\text{-crown-6})(\text{N}_3)(\text{OH}_2)]$  (with an Rb–N–N angle of  $134.7(2)^\circ$  and hydrogen-bonded pairs of molecules, Fig. 19A),<sup>295</sup>  $[\text{Cs}_2(18\text{-crown-6})_2(\mu\text{-N}_3)_2]$ ,<sup>295</sup>  $[\text{Cs}(18\text{-crown-6})(\mu\text{-N}_3)]_n$  (Fig. 19B),<sup>295</sup>  $[\text{K}(18\text{-crown-6})(\text{N}_3)(\text{OPPh}_3)]$ ,<sup>296</sup>  $[\text{Ba}_2(18\text{-crown-6})_2(\text{MeOH})_2(\mu\text{-N}_3)_3]$  (10-coordinate  $\text{Ba}^{2+}$ , Fig. 19C),<sup>297</sup>  $[\text{Sr}(15\text{-crown-5})(\text{N}_3)_2]$ ,<sup>297</sup> and  $[\text{Sr}(15\text{-crown-5})(\text{NO}_3\text{-}\kappa^2)(\mu\text{-N}_3)]_n$  (9-coordinate  $\text{Sr}^{2+}$ , Fig. 19C).<sup>297</sup> In  $[\text{K}(18\text{-crown-6})(\mu\text{-N}_3)]_n$  the azido ligand forms a near-linear bridge between the two metal atoms (K–N–N =  $174.3^\circ$ , U–N–N =  $167.8^\circ$ ).<sup>298</sup> This is one representative example of an  $\text{N}_3^-$  bridging ligand linking a group 1 metal ion to a second metal; in

**Fig. 18** The structures of (A)  $[\text{Ca}(\text{NCMe})_3(15\text{-crown-5})]^{2+}$  (CSD refcode CIPFOZ) and (B)  $[\text{Ca}(\text{NCMe})_3(18\text{-crown-6})]^{2+}$  (refcode FUDCAJ). (C) Part of the interpenetrating nets in  $[\text{Ca}\{\text{C}(\text{CN})_3\}_2]_n$  (refcode DOJVUU). (D) The coordination environment of  $\text{Ba}^{2+}$  in  $[\text{Ba}\{\text{C}(\text{CN})_3\}_2(\text{OH}_2)_2]_n$  (refcode DOJWAB).

**Fig. 19** (A) Structure of one hydrogen-bonded pair of  $[\text{Rb}(18\text{-crown-6})(\text{N}_3)(\text{OH}_2)]$  molecules (CSD refcode TEDKUJ). (B) Part of the 1D-coordination polymer in  $[\text{Cs}(18\text{-crown-6})(\mu\text{-N}_3)]_n$ .<sup>295</sup> (C) Structure of  $[\text{Ba}_2(18\text{-crown-6})_2(\text{MeOH})_2(\mu\text{-N}_3)_3]$  (refcode WIZCEO) and (D) part of the 1D-chain in  $[\text{Sr}(15\text{-crown-5})(\text{NO}_3)(\mu\text{-N}_3)]_n$  (refcode WIZCAK).

**Fig. 20** Structures of (A)  $[\text{Be}_4\text{Br}_4(\mu\text{-N}_3)_6]^{2-}$  (CSD refcode TANHAS), (B)  $[\text{Te}(\text{N}_3)_5]^-$  (refcode BELZUO), (C)  $[\text{Te}(\text{N}_3)_6]^{2-}$  (refcode BEMBAX), (D)  $[\text{Ge}(\text{N}_3)_3]^-$  (refcode JUCROQ), (E)  $[\text{Ga}_2\text{Cl}_6(\mu\text{-N}_3)]^-$  (refcode LUHRIQ), and (F)  $[\text{In}_2\text{Cl}_4(\text{THF})_4(\mu\text{-N}_3)_2]$  (refcode LOFVAD).

some cases the azido unit bridges the two metals as shown in Fig. 19C, while in others, it binds to both metal centers through one terminal N atom.<sup>299–308</sup>

In group 2, in addition to the tetrahedral  $[\text{Be}(\text{N}_3)_4]^{2-}$  ion which was the first structurally characterized homoleptic beryllium azide,<sup>309</sup> Be offers a number of interesting azido complexes. The dimer  $[\text{Be}_2(\text{N}_3)_4(\mu\text{-OSiMe}_3)_2]^{2-}$  contains terminal  $\text{N}_3^-$  ligands with the typical bent geometry ( $\text{Be-N-N} = 134.5(4)$  and  $120.0(4)^\circ$ )<sup>310</sup> which is also observed in  $[\text{BeCl}(\text{N}_3)\text{L}]$  where  $\text{L} = (\text{R,R})\text{-N,N'}$ -di-isopropylcyclohexyl-1,2-diamine.<sup>311</sup>  $[\text{Be}_4\text{Cl}_4(\mu\text{-N}_3)_6]^{2-}$  and  $[\text{Be}_4\text{Br}_4(\mu\text{-N}_3)_6]^{2-}$  (Fig. 20A) are isostructural and contain tetrahedral  $\text{Be}_4$  units, edge-bridged by azido ligands.<sup>312,313</sup> As we move into the p-block, the number of simple azido complexes reported since 2000 increases on moving from group 13 to 15. It is noteworthy that neutral  $[\text{As}(\text{N}_3)_5]$  and  $[\text{Sb}(\text{N}_3)_5]$  were reported for the first time in 2004 and were prepared by treatment of  $\text{AsF}_5$  or  $\text{SbF}_5$  in  $\text{SO}_2$  with excess  $\text{Me}_3\text{SiN}_3$ .<sup>314</sup> Limited examples of non-organometallic compounds are found in group 16, and these include the homoleptic complexes  $[\text{Se}(\text{N}_3)_6]^{2-}$ ,<sup>315</sup>  $[\text{Te}(\text{N}_3)_5]^-$  (Fig. 20B),<sup>316</sup> and  $[\text{Te}(\text{N}_3)_6]^{2-}$  (Fig. 20C).<sup>317</sup> A summary of homoleptic group 15 polyazides was provided in 2013 by Haiges et al.<sup>318</sup> Homoleptic azides of the p-block metals that have been isolated and characterized since 2000 are  $[\text{M}(\text{N}_3)_3]$  ( $\text{M} = \text{Ga}, \text{In}, \text{Tl}$ ),<sup>319</sup>  $[\text{Ga}(\text{N}_3)_5]^{2-}$ ,<sup>319</sup>  $[\text{M}(\text{N}_3)_6]^{3-}$  ( $\text{M} = \text{In}, \text{Tl}$ ),<sup>319</sup> coordinatively unsaturated metal(II)  $[\text{M}(\text{N}_3)_3]^-$  ( $\text{M} = \text{Ge}, \text{Sn}$ ) (Fig. 20D),<sup>320,321</sup> octahedral  $[\text{Ge}(\text{N}_3)_6]^{2-}$ ,<sup>322</sup> octahedral  $[\text{Sn}(\text{N}_3)_6]^{2-}$ ,<sup>323</sup> octahedral  $[\text{As}(\text{N}_3)_6]^-$ ,<sup>324,325</sup> octahedral  $[\text{Sb}(\text{N}_3)_6]^-$ ,<sup>314,325,326</sup> octahedral  $[\text{Bi}(\text{N}_3)_6]^{3-}$ ,<sup>327,328</sup> square-based pyramidal  $[\text{Sb}(\text{N}_3)_5]^{2-}$ ,<sup>326</sup> square-based pyramidal  $[\text{Bi}(\text{N}_3)_5]^{2-}$ ,<sup>327</sup> and  $[\text{Bi}(\text{N}_3)_4]^-$  which forms a chain structure by virtue of weak intermolecular  $\text{Bi}\cdots\text{N}$  interactions.<sup>327</sup> While retaining a see-saw (disphenoidal) coordination geometry at As or Sb, the structures of  $[\text{As}(\text{N}_3)_4]^-$  and  $[\text{Sb}(\text{N}_3)_4]^-$  are cation dependent and show variations in the azido ligand conformations.<sup>318,329</sup> Haiges et al. state that ‘the experimental observation of five distinct single conformers for the same type of anion is unprecedented’. The differences arise from small changes in packing energies and cation–anion interactions in the solid state.<sup>318</sup> Salts of both  $[\text{As}(\text{N}_3)_4]^+$  and  $[\text{Sb}(\text{N}_3)_4]^+$  with As(V) and Sb(V) have been reported; while kinetically stable, they explode violently under conditions of thermal shock. In contrast, the As(III) and Sb(III) compounds  $[\text{Me}_4\text{N}][\text{As}(\text{N}_3)_4]$  and  $[\text{Ph}_4\text{P}][\text{Sb}(\text{N}_3)_4]$  exhibit relatively high stabilities.<sup>325</sup>

Additional simple azido complexes include  $[\text{M}(\text{N}_3)_3(\text{NCMe})]$  ( $\text{M} = \text{Ga}, \text{In}$  with tetrahedral metal center),<sup>319</sup>  $[\text{Ga}_2\text{Cl}_6(\mu\text{-N}_3)]^-$  (Fig. 20E),<sup>330</sup> tetrahedral  $[\text{GaH}_2(\text{N}_3)(\text{qu})]$  ( $\text{qu} = \text{quinuclidine}$ ),<sup>331</sup>  $[\text{In}_2\text{Cl}_4(\text{THF})_4(\mu\text{-N}_3)_2]$  (Fig. 20F),<sup>332</sup> trigonal bipyramidal  $[\text{Ga}(\text{N}_3)_2\{(\text{Et}_2\text{NCH}_2\text{CH}_2)_2\text{N}\}]$  used as a CVD precursor to GaN,<sup>333</sup> octahedral  $[\text{InCl}(\text{N}_3)_2\text{py}_3]$  with a *trans*-arrangement of azido ligands,<sup>334</sup> octahedral  $[\text{Ge}(\text{N}_3)_4(\text{phen})]$  (Fig. 21A),<sup>322,335</sup> octahedral  $[\text{GeCl}_2(\text{N}_3)_2(\text{tmeda})]$  with a *trans*-arrangement of azido ligands,<sup>336</sup> and octahedral *trans*- $[\text{Sn}(\text{N}_3)_4(\text{py})_2]$  and  $[\text{Sn}(\text{N}_3)_4(\text{phen})]$ .<sup>323</sup> Like lead(II) azide, tin(II) azide is shock sensitive and explosive. However, the adducts  $[\text{Sn}(\text{N}_3)_2(\text{py})_2]$  and  $[\text{Sn}(\text{N}_3)_2(4\text{-Mepy})_2]$  (4-Mepy = 4-methylpyridine) are shock- and friction-insensitive and are stable at 298 K under an atmosphere of the respective Lewis base. They possess see-saw (disphenoidal) geometries with azido ligands in the equatorial sites.<sup>321</sup> The dinuclear complex  $[\text{Pb}_2(\text{phen})_4(\mu\text{-N}_3)_4]$  with 8-coordinate Pb(II) exhibits two different azido bridging modes (Fig. 21B) with  $\text{Pb-N-N}$  angles in the range  $104.8\text{--}121.9^\circ$ ,<sup>337</sup> whereas in  $[\text{Pb}_2(\text{phen})_4(\text{NCS})_2(\mu\text{-N}_3)_2]$ , each bridging azido ligand binds to two Pb(II) centers through one terminal N-atom.<sup>338</sup> The Pb(II) coordination sphere suggests the presence of a sterically active lone-pair.<sup>339–342</sup>

The octahedral As(V) and Sb(V) complexes  $[\text{M}(\text{dmap})(\text{N}_3)_5]$  ( $\text{M} = \text{As}, \text{Sb}$ ) have been isolated and it was established that formation of the base adducts led to kinetic stabilization of highly explosive main group metal polyazides.<sup>343</sup> The As(III) and Sb(III) complexes  $[\text{AsCl}(\text{N}_3)_2\text{py}]$  and  $[\text{SbCl}_2(\text{N}_3)(\text{py})_2]$  have disphenoidal and square-based pyramidal geometries, respectively.<sup>344</sup> The homoleptic polyazides  $\text{As}(\text{N}_3)_3$ ,  $\text{Sb}(\text{N}_3)_3$  and  $\text{Bi}(\text{N}_3)_3$  are stabilized by anion formation (as described above) or by the formation of adducts such as  $[\text{As}(\text{bpy})(\text{N}_3)_3]$ ,  $[\text{Sb}(\text{bpy})(\text{N}_3)_3]$ ,  $[\text{Bi}(\text{bpy})(\text{N}_3)_5]^{2-}$  and  $[\text{Bi}_2(\text{bpy})_4(\text{N}_3)_4(\mu\text{-N}_3)_2]$ .<sup>327</sup> The Bi(III) center in  $[\text{Bi}(\text{N}_3)_5(\text{dmsO})]^{2-}$  is octahedrally sited.<sup>329</sup> Fig. 21C shows the structure of  $[\text{Bi}_4\{^t\text{BuC}(\text{PrN})_2\}_4(\text{N}_3)_4(\mu\text{-N}_3)_4]$  which features both terminal and bridging azido ligands; this is one in a series of amidinatobismuth(III) diazides  $[\text{LBi}(\text{N}_3)_2]$  made by reactions between  $\text{LBiX}_2$  ( $\text{X} = \text{Cl}, \text{I}$ ) and  $\text{AgN}_3$ .<sup>345</sup> In  $[\text{Sb}_2(\text{N}_3)_2(\mu\text{-N}^t\text{Bu})_2]$ , each Sb(III) center is in a trigonal pyramidal environment and the azido ligands are directed over the  $\text{Sb}_2\text{N}_2$  rhombus (Fig. 21D).<sup>346</sup>

$\beta$ -Diketimate derivatives include tetrahedral  $[\text{Al}(\text{N}_3)_2\{\text{HC}(\text{CMeN}^i\text{Pr})_2\}]$  (Fig. 21E)<sup>347</sup>  $[\text{Ga}(\text{N}_3)_2\{\text{HC}(\text{CMeN}^i\text{Pr})_2\}]$ <sup>348</sup> and  $[\text{Ga}(\text{N}_3)_2\{\text{HC}(\text{CMeNPh})_2\}]$ ,<sup>349</sup> and the 3-coordinate metal(II) species  $[\text{Ge}(\text{N}_3)\text{L}]$  ( $\text{HL} = \text{H}_2\text{C}(\text{CMeNDipp})_2$ ) (Fig. 21F),<sup>350</sup> and  $[\text{Sn}(\text{N}_3)\text{L}]$  ( $\text{HL}$  with  $\text{Ar} = \text{Mes}$ ).<sup>351</sup>

**Fig. 21** Structures of (A)  $[\text{Ge}(\text{N}_3)_4(\text{phen})]$  (refcode BUHQOM), (B)  $[\text{Pb}_2(\text{phen})_4(\mu\text{-N}_3)_4]$  (refcode MUMBUS), (C)  $[\text{Bi}_4\text{t}^{\text{BuC}}(\text{PrN})_2)_4(\text{N}_3)_4(\mu\text{-N}_3)_4]$  with the amidinato 'Pr substituents omitted for clarity (refcode CEJTOC), (D)  $[\text{Sb}_2(\text{N}_3)_2(\mu\text{-N}^{\text{tBu}})_2]$  (refcode RANBUD), (E)  $[\text{Al}(\text{N}_3)_2(\text{HC}(\text{CMeN}^{\text{Pr}})_2)]$  (GSD refcode LUCKEC), and (F)  $[\text{Ge}(\text{N}_3)_4\text{L}]$  (HL =  $\text{H}_2\text{C}(\text{CMeNDipp})_2$ , refcode OHUXIZ).

We now move to N-bonded cyanido ligands. There are few, if any, simple examples containing monodentate N-bonded cyanido ligands coordinated to main group metals. However, there is an extremely interesting subclass of compounds containing cyanido-metallate ligands which can act as monodentate or polydentate N-donors to main group metals, and thus contain bridging CN ligands with the C typically bonded to a d-block metal center. This class of compound will not be discussed extensively, but we present examples of  $\{\text{M}(\text{CN})_n\}$  metalloligands of various denticities coordinated to main group metal centers. Monodentate metalloligands coordinating to main group metal centers are less well represented than higher denticity analogs. An investigation of copper(I)-catalyzed silylation reactions with silyboranes has given rise to the isolation of  $[\text{K}(18\text{-crown-6})][\text{Cu}(\text{CN})(\text{SiMe}_2\text{Ph})]$  in which the cation and anion interact through a bent  $\text{K}-\text{N}\equiv\text{C}-\text{Cu}$  bridge ( $\text{K}-\text{N} = 2.830(4) \text{ \AA}$ ,  $\text{K}-\text{N}\equiv\text{C} = 112.7(3)^\circ$  for one of two independent ion pairs); a change in crystallization conditions leads to a dimer in which the  $\text{K}-\text{N}\equiv\text{C}-\text{Cu}$  bridge is less bent ( $\text{K}-\text{N}\equiv\text{C} = 151.5(2)^\circ$ ).<sup>352</sup> Bidentate metalloligands include linear  $[\text{Ag}(\text{CN})_2]^-$  and  $[\text{Au}(\text{CN})_2]^-$ , although a monodentate mode is observed in  $[\text{Pb}(\text{OH}_2)(\text{bbp})_2\{\text{Au}(\text{CN})_2\}_2]$  (Fig. 22A).<sup>353</sup>  $[\text{Ag}(\text{CN})_2]^-$  coordinates in a bidentate manner to  $\text{Li}^+$  in  $[\text{Li}(\text{NCMe})_2(\mu\text{-Ag}(\text{CN})_2)]_n$ ,<sup>354</sup>  $\text{K}^+$  in  $[\text{K}(18\text{-crown-6})(\mu\text{-Ag}(\text{CN})_2)]_n$  (Fig. 22B),<sup>355</sup> and  $\text{Pb}^{2+}$  in  $[\text{Pb}(\text{tpy})(\mu\text{-Ag}(\text{CN})_2)_2]_n$  (Fig. 22C);  $[\text{Pb}(\text{tpy})(\mu\text{-Au}(\text{CN})_2)_2]_n$  is structurally analogous to the Ag(I) complex.<sup>356</sup> Other examples incorporating bridging  $[\text{Au}(\text{CN})_2]^-$  include  $[\text{Pb}(\text{bpy})_2(\mu\text{-Au}(\text{CN})_2)_2]_n$ ,<sup>356</sup>  $[\text{Pb}(\text{phen})_2(\mu\text{-Au}(\text{CN})_2)_2]_n$ ,<sup>356</sup> and  $[\text{K}(\mu\text{-bpy})(\mu\text{-Au}(\text{CN})_2)_2]_n$  which has a layered structure.<sup>357</sup> Numerous examples of square-planar Au(III), Pd(II) and Pt(II) cyanido derivatives acting as metalloligands to main group metals are known. With L = dibenzo-18-crown-6,  $[\text{Ba}_2\text{L}_2(\text{OH}_2)_3(\text{MeOH})_2\{\text{Pt}(\text{CN})_4\}_2]$  is a discrete molecule (Fig. 22D) featuring one monodentate and one bridging  $[\text{Pt}(\text{CN})_4]^{2-}$ .<sup>358</sup> Other examples of hypodentate  $[\text{Pt}(\text{CN})_4]^{2-}$  ligands are found in the 1D-polymer  $[\text{Ba}(18\text{-crown-6})(\text{OH}_2)_2(\mu\text{-Pt}(\text{CN})_4)]_n$  (bidentate  $[\text{Pt}(\text{CN})_4]^{2-}$ ),<sup>359</sup> the discrete molecule  $[\text{K}_2(18\text{-crown-6})_2(\mu\text{-Pt}(\text{CN})_4)]$  (bidentate  $[\text{Pt}(\text{CN})_4]^{2-}$  with a *trans*-arrangement of  $\text{K}^+$  ions),<sup>360</sup> and the 2D-network  $[\text{Ba}(\text{azacrown})(\mu_3\text{-Pt}(\text{CN})_4)]_n$  where the azacrown is 1,4,10,13-tetraoxa-7,16-diazacyclooctadecane (tridentate  $[\text{Pt}(\text{CN})_4]^{2-}$ ).<sup>361</sup> Tridentate  $[\text{M}(\text{CN})_4]^{2-}$  connecting  $\text{Ba}^{2+}$  or  $\text{Sr}^+$  centers is observed in  $[\text{Ba}(\text{DMF})_4(\mu_3\text{-Ni}(\text{CN})_4)]_n$ ,  $[\text{Sr}(\text{DMF})_4(\mu_3\text{-Ni}(\text{CN})_4)]_n$ ,  $[\text{Sr}(\text{DMF})_4(\mu_3\text{-Pd}(\text{CN})_4)]_n$ , and  $[\text{Sr}(\text{DMF})_4(\mu_3\text{-Pt}(\text{CN})_4)]_n$ . In contrast, in  $[\text{Ba}(\text{DMF})_3(\mu_4\text{-Pd}(\text{CN})_4)]_n$  and  $[\text{Ba}(\text{DMF})_3(\mu_4\text{-Pt}(\text{CN})_4)]_n$ ,  $[\text{M}(\text{CN})_4]^{2-}$  is tetradentate.<sup>362</sup> We return to tetradentate metalloligands later.

Bidentate cyanido metalloligands are further represented by  $[\text{Pd}(\text{ppy})(\text{CN})_2]^-$  which coordinates to Tl(I) in  $[\text{TlPd}(\text{ppy})(\text{CN})_2]_n$  to produce a 2D-network featuring Pd–Tl donor–acceptor metal–metal bonds (Fig. 22E); the  $\text{Tl}-\text{N}\equiv\text{C}$  angles are  $149.8(9)$  and  $110.5(7)^\circ$ .<sup>363</sup> Related to  $[\text{Pd}(\text{ppy})(\text{CN})_2]^-$  is  $[\text{Pt}(4\text{-Meppy})(\text{CN})_2]^-$  which acts as a bidentate ligand, binding  $\text{K}^+$  to give the motif shown in Fig. 22F; the structure propagates into a sheet with additional coordinated  $\text{H}_2\text{O}$  and acetone, and the  $\{\text{Pt}(4\text{-Meppy})(\text{CN})_2\}$  units are arranged in stacked pairs (Fig. 22F) with a  $\text{Pt}\cdots\text{Pt}$  separation of  $3.2785(7) \text{ \AA}$ .<sup>364</sup> The discrete molecule  $[\text{Pb}_2(\text{HBpz}_3)_2(\text{OCMe}_2)_2(\mu\text{-Pt}(\text{CN})_2(4\text{-MeC}_6\text{H}_4\text{C}\equiv\text{C}))_2]$  features a near-linear  $\text{Pb}-\text{N}\equiv\text{C}-\text{Pt}-\text{C}\equiv\text{N}-\text{Pb}$  unit.<sup>365</sup> In  $[\text{K}(\mu\text{-OH}_2)\{\mu\text{-AuCl}_2(\text{CN})_2\}_2]_n$ , *trans*- $[\text{AuCl}_2(\text{CN})_2]^-$  binds  $\text{K}^+$  ions to give a network with both short  $\text{K}-\text{NC}$  and  $\text{K}-\text{Cl}$  contacts; related bromido and iodido compounds also form extended structures by virtue of  $\text{K}-\text{NC}$  coordinate bonds and with additional weak  $\text{X}\cdots\text{X}$  contacts between  $[\text{AuX}_2(\text{CN})_2]^-$  units.<sup>366</sup> On moving from Au(III) to Hg(II), the square-planar metal environment is retained but the

**Fig. 22** (A) The structure of  $[\text{Pb}(\text{OH}_2)(\text{bbp})_2\{\text{Au}(\text{CN})_2\}_2]$  (CSD refcode CAFREJ), (B) part of the 1D-chain in  $[\text{K}(18\text{-crown-6})(\mu\text{-Ag}(\text{CN})_2)]_n$  (refcode EJELUA), and (C) the building block in the 2D-network in  $[\text{Pb}(\text{tpy})(\mu\text{-Ag}(\text{CN})_2)]_n$  (refcode KISDUM). (D) The structure of  $[\text{Ba}_2\text{L}_2(\text{OH}_2)_3(\text{MeOH})_2\{\text{Pt}(\text{CN})_4\}_2]$  (L = dibenzo-18-crown-6) with the crown ether shown in stick representation for clarity (refcode EBALUR). (E) Part a 2D-net in  $[\text{TlPd}(\text{ppy})(\text{CN})_2]_n$  (refcode REJHOF). (F) The building block in the 2D-sheet in solvated  $[\text{KPt}(4\text{-Meppy})(\text{CN})_2]$  (refcode AHIGUV). (g) Part of the 3D-assembly in  $[\text{K}(\mu\text{-OH}_2)\{\mu\text{-HgCl}(\text{CN})_2\}]_n$  (refcode HAYHAT).

propensity for Cl–Hg–Cl bridges leads to an extended array in  $[\text{K}(\mu\text{-OH}_2)\{\mu\text{-HgCl}(\text{CN})_2\}]_n$  comprising alternating  $\{\text{Hg}(\mu\text{-Cl})\}_n$  and K-containing sheets interconnected by bridging  $\text{CN}^-$  ligands (Fig. 22G).<sup>367</sup>

Many hypodentate  $[\text{M}(\text{CN})_n]^{x-}$  and related ligands act in a bidentate mode toward main group metals. Representative examples are the discrete molecular  $[\text{K}_2(18\text{-crown-6})_2\{\mu\text{-Rh}(\text{CN})_3(\text{CO})\}]$  with a *trans*-arrangement of coordinated  $\{\text{K}(18\text{-crown-6})\}^+$  units,<sup>368</sup> and the 1D-coordination polymer  $[\text{Ba}(\text{OH}_2)_5(\mu\text{-OH}_2)\{\mu\text{-Ru}(\text{bpy})(\text{CN})_4\}]_n$  which features a central  $\{\text{Ba}(\mu\text{-OH}_2)\}_n$  chain decorated with bridging  $\{\text{Ru}(\text{bpy})(\text{CN})_4\}$  units (Fig. 23A). The latter heterometallic complex was one of a series investigated to evaluate the effect that the interaction of the *cis*-cyanido ligands with different metal cations has on the <sup>3</sup>MLCT luminescence of  $[\text{Ru}(\text{bpy})(\text{CN})_4]^{2-}$ .<sup>369</sup> Similarly, binding of metal cations to the cyanido ligands of  $[\text{Os}(\text{diimine})(\text{CN})_4]^{2-}$  complexes enhances the emission;  $[\text{Na}(\mu\text{-OH}_2)\{\mu\text{-Os}(\text{phen})(\text{CN})_4\}]_n^{n-}$  (Fig. 23B) is an example of the resulting polynuclear assemblies.<sup>370</sup> With a goal of devising structural models for the iron subsite in  $[\text{NiFe}]$ -hydrogenases, Whaley et al. reported the structure of  $[\text{K}_2(18\text{-crown-6})_2\{\mu\text{-HfFe}(\text{CN})_3(\text{CO})_2\}]$  in which *trans*-cyanido ligands in  $[\text{HfFe}(\text{CN})_3(\text{CO})_2]^{2-}$  link two  $\text{K}^+$  centers.<sup>371</sup> The following assemblies incorporate octahedral  $[\text{M}(\text{CN})_6]^{x-}$  or  $[\text{M}(\text{CN})_5\text{NO}]^{x-}$  metalloligands in bridging modes between two metal centers:  $[\text{K}_2(18\text{-crown-6})_2\{\mu\text{-Ru}(\text{CN})_6\}]^-$  (Fig. 23C) and its Os(III) analog,<sup>372</sup>  $[\text{Li}(\text{OH}_2)_2\{\mu\text{-Co}(\text{CN})_6\}]_n^{2n-}$  (Fig. 23D),<sup>373</sup>  $[\text{Ba}(\text{phen})_3(\text{OH}_2)\{\mu\text{-Fe}(\text{CN})_5\text{NO}\}]$  (in which  $\text{Ba}^{2+}$  and  $\text{Fe}^{2+}$  centers are linked into a 1D-coordination polymer via *trans* CN and NO ligands),<sup>374</sup>  $[\text{Ca}_2(\text{phen})_4(\text{OH}_2)_6\{\mu\text{-Fe}(\text{CN})_6\}]^+$ ,<sup>375</sup>  $[\text{Sr}_2(\text{phen})_4(\text{O}_2\text{CCF}_3)(\text{OH}_2)_3\{\mu\text{-Fe}(\text{CN})_6\}]$  and  $[\text{Ca}_2(\text{phen})_4(\text{O}_2\text{CCF}_3)_2(\text{OH}_2)_2\{\mu\text{-Co}(\text{CN})_6\}]$ .<sup>376</sup>

Trigonal planar  $[\text{Cu}(\text{CN})_3]^{2-}$  is a rare example of a tridentate, but not hypodentate, metalloligand binding to main group metals.  $[\text{Li}_2(\text{THF})_3\{\mu_3\text{-Cu}(\text{CN})_3\}]_n$  possesses the 2D-network shown in Fig. 24A; both the  $\text{Cu}^+$  ions and  $\{\text{Li}_2\}^{2+}$  units are 3-connecting nodes in the net.<sup>377</sup> In  $[\text{K}_2(18\text{-crown-6})_2\{\mu\text{-Cu}(\text{CN})_3\}]$ , the  $[\text{Cu}(\text{CN})_3]^{2-}$  ligand is bidentate (Fig. 24B).<sup>352</sup> Examples in which hypodentate ligands act in a tridentate mode include  $[\text{K}(\text{OH}_2)\{\mu_3\text{-AuCl}_4\}]_n$  (3D-network),<sup>378</sup>  $\{\text{Li}|\text{Li}(\text{O}_2\text{H})(\mu_3\text{-W}(\text{CN})_6(\text{bpy}))\}_n$  (Fig. 24C),<sup>379</sup>  $[\text{K}\{\mu_3\text{-Fe}(\text{CN})_3(\text{CO})_3\}]_n$  (Fig. 24D) and  $[\text{Na}(\text{OH}_2)\{\mu_3\text{-Co}(\text{CN})_6\}]_n^{2n-}$  (both with layer structures).<sup>380,381</sup>

Examples of  $[\text{M}(\text{CN})_4]^{2-}$  and  $[\text{M}(\text{CN})_6]^{n-}$  ions that act as tetradentate ligands are found in  $[\text{K}_2(\text{phen})_2\{\mu_4\text{-Pt}(\text{CN})_4\}]_n$  (2D-sheet),<sup>382</sup>  $[\text{K}_2\{\mu_4\text{-Zn}(\text{CN})_4\}]_n$  (in which  $\text{K}^+$  has CN = 8),<sup>383</sup>  $[\text{Ba}(\text{DMF})_3\{\mu_4\text{-Pd}(\text{CN})_4\}]_n$  (2D-sheet),<sup>362</sup> the imidazolium salt of  $[\text{Na}(\text{OH}_2)\{\mu_4\text{-Co}(\text{CN})_6\}]_n^{2n-}$  (with non-coordinated cyanides being mutually *trans*),<sup>384</sup> the pyridinium salt of  $[\text{Na}(\text{OH}_2)\{\mu_4\text{-Co}(\text{CN})_6\}]_n^{2n-}$  (with non-coordinated cyanides *cis*, Fig. 24E), and  $[\text{Me}_3\text{NOH}]_2[\text{KCo}(\text{CN})_6]$  (a perovskite material in which the  $\{\text{Co}^{\text{III}}(\text{CN})_6\}$  unit is in a  $\mu_4$ -mode).<sup>385</sup> In a second phase of the latter, the  $[\text{Co}(\text{CN})_6]^{3-}$  metalloligand is hexadentate and  $[\text{Me}_3\text{NOH}]^+$  ions are hosted within a 3D-network of cubic cages.<sup>385</sup> Pentadentate metalloligands are observed in the  $[\text{Me}_2\text{NH}_2]^+$  salt of  $[\text{Na}\{\mu_5\text{-Fe}(\text{CN})_5(\text{NO})\}]_n^{n-}$  (3D-network and a hybrid high-temperature ferroelectric material),<sup>386</sup> and the  $[\text{MeNH}_3]^+$  salt of  $[\text{Na}(\text{OH}_2)\{\mu_5\text{-Fe}(\text{CN})_5(\text{NO})\}]_n^{n-}$  (2D-double sheets, Fig. 25A).<sup>387</sup> There are many examples in which  $[\text{M}(\text{CN})_6]^{n-}$  ions act as hexadentate ligands forming 3D-networks with exploitable dielectric, ferroelectric or magnetic properties. Representative examples are the  $[\text{MeNH}_3]^+$  salt of  $[\text{Na}\{\mu_6\text{-Co}(\text{CN})_6\}]_n^{2n-}$ ,<sup>388</sup> salts of  $[\text{K}\{\mu_6\text{-Co}(\text{CN})_6\}]_n^{2n-}$ ,<sup>385,389,390</sup> and  $[\text{Rb}\{\mu_6\text{-Co}(\text{CN})_6\}]_n^{2n-}$  (Fig. 25B),<sup>391</sup> salts of  $[\text{K}\{\mu_6\text{-Fe}(\text{CN})_6\}]_n^{2n-}$  (Fig. 25C),<sup>392–394</sup> the mixed valence Co(II)/Co(III)  $[\text{KCo}_2(\text{ox})(\text{OH}_2)_3\{\mu_6\text{-Co}(\text{CN})_6\}]_n$ ,<sup>395</sup> the Prussian blue analog  $[\text{Ga}\{\mu_6\text{-Fe}(\text{CN})_6\}]_n$ ,<sup>396</sup> the guanidinium salt of  $[\text{Ca}\{\mu_6\text{-Co}(\text{CN})_6\}]_n^{n-}$ ,<sup>397</sup> the  $[\text{H}_3\text{O}]^+$  salt of

**Fig. 23** The structures of (A) part of the 1D-chain in  $[\text{Ba}(\text{OH}_2)_5(\mu\text{-OH}_2)\{\mu\text{-Ru}(\text{bpy})(\text{CN})_4\}]_n$  (CSD refcode RIBUCUD), (B) part of the 1D-chain in  $[\text{Na}(\mu\text{-OH}_2)\{\mu\text{-Os}(\text{phen})(\text{CN})_4\}]_n^{n-}$  (refcode QITCUS), (C)  $[\text{K}_2(18\text{-crown-6})_2\{\mu\text{-Ru}(\text{CN})_6\}]_n^{-}$  (refcode OSINOU), and (D) part of the 1D-polymer chain in  $[\text{Li}(\text{OH}_2)_2\{\mu\text{-Co}(\text{CN})_6\}]_n^{2n-}$  (refcode PODFEV).

**Fig. 24** (A) Part of the 2D-network in  $[\text{Li}_2(\text{THF})_3\{\mu\text{-Cu}(\text{CN})_3\}]_n$  (CSD refcode GOKXIP); for clarity, the THF molecules are depicted in stick representation. The structures of (B)  $[\text{K}_2(18\text{-crown-6})_2\{\mu\text{-Cu}(\text{CN})_3\}]_n$  (refcode HAXZEO), (C) part of the anionic 2D-net in  $[\text{Li}][\text{Li}(\text{O}_2\text{H})\{\mu_3\text{-W}(\text{CN})_6(\text{bpy})\}]_n$  (refcode BUNJIG), (D) part of a 2D-sheet in  $[\text{K}\{\mu_3\text{-Fe}(\text{CN})_3(\text{CO})_3\}]_n$  (refcode CADYAI), and (E) part of a 2D-sheet in  $[\text{Na}(\text{OH}_2)\{\mu_4\text{-Co}(\text{CN})_6\}]_n^{n-}$  (refcode QUGCECO1).

$[\text{Ca}(\text{OH}_2)_2\{\mu_6\text{-Co}(\text{CN})_6\}]_n^{n-}$ ,<sup>398</sup> the  $[\text{NH}_4]^+$  salts of  $[\text{Sr}\{\mu_6\text{-Fe}(\text{CN})_6\}]_n^{2n-}$ ,<sup>399</sup> and  $[\text{Sr}(\text{OH}_2)_2\{\mu_6\text{-Fe}(\text{CN})_6\}]_n^{2n-}$ ,<sup>400</sup> the  $[\text{NH}_4]^+$  salt of  $[\text{Ba}(\text{OH}_2)_3\{\mu_6\text{-Fe}(\text{CN})_6\}]_n^{2n-}$ ,<sup>401</sup> and salts of  $[\text{K}\{\mu_6\text{-Cr}(\text{CN})_6\}]_n^{2n-}$ .<sup>402,403</sup> The guanidinium salt of  $[\text{K}_2(\text{OH}_2)_6\{\mu_6\text{-Fe}(\text{CN})_6\}]_n^{2n-}$  possesses a 2D-structure with a central layer of  $\{\text{Fe}^{\text{III}}(\text{CN})_6\}$  units interconnecting peripheral *fac*- $\{\text{K}(\text{OH}_2)_3\}$  units.<sup>404</sup>

The final group of pseudo-halides that we consider are  $\text{NCO}^-$ ,  $\text{NCS}^-$  and  $\text{NCSe}^-$  ligands, and we include examples of terminally N-bonded, bridging N-bonded, and bridging N,X-bound ( $\text{X} = \text{O}, \text{S}, \text{Se}$ ) ligands. The structure of  $\text{Cs}[\text{NCO}]$  is related to that of  $\text{KN}_3$  with disordered  $\text{NCO}^-$  ligands in  $\text{Cs-NCO/OCN-Cs}$  bridging sites.<sup>405</sup> Reactions between 3,4-dicyano-1,2,5-chalcogenadiazoles ( $\text{L}_\text{S}$ ,  $\text{L}_\text{Se}$  and  $\text{L}_\text{Te}$ , Fig. 26A) and pseudohalides  $\text{XCN}^-$  ( $\text{X} = \text{O}, \text{S}, \text{Se}, \text{Te}$ ) produced a series of donor-acceptor complexes demonstrating both terminal and bridging modes of the ligands to and between main group metals. These include  $[\text{K}(18\text{-crown-6})(\text{L}_\text{Te})(\mu\text{-NCO})]$ ,  $[\text{K}(18\text{-crown-6})(\text{L}_\text{Te})(\text{NCS})]$  and  $[\text{K}(\text{L}_\text{Te})(\text{NCSe})]$  (Fig. 26A).<sup>406</sup> An investigation of *ortho*-cupration using non cyanide reagents looked at the reaction of  $\text{CuOCN}$  with  $\text{Li}[\text{tmp}]$ . Both lithiocuprates and lithium-only complexes were characterized, and Fig. 26B shows the structure of  $[\text{Li}_6(\text{THF})_4(\text{tmp})_4(\mu\text{-NCO})_2]$  in which the N of each  $\text{NCO}^-$  interacts with three Li centers.<sup>407</sup> Group 2 metal complexes are represented by  $[\text{Mg}(\text{tpp})(\text{NCO})]^-$  (with a terminally N-bound ligand),<sup>408</sup> *trans*- $[\text{Mg}(\text{py})_4(\text{NCO})_2]$  (terminally N-bound  $\text{NCO}^-$ ),<sup>409,410</sup> and a trimer containing a cyclic  $\{\text{Mg}_3(\mu\text{-NCO})_3\}$  core (Fig. 26C).<sup>411</sup>

**Fig. 25** (A) Part of one double sheet in the  $[\text{MeNH}_3]^+$  salt of  $[\text{Na}(\text{OH}_2)\{\mu_5\text{-Fe}(\text{CN})_5(\text{NO})\}]_n^-$  (CSD refcode EHEBOL). Part of the 3D-nets in (B) the  $[\text{MeNH}_3]^+$  salt of  $[\text{Rb}\{\mu_6\text{-Co}(\text{CN})_6\}]_n^-$  (refcode AXUDII), and (C) the  $[\text{Me}_3\text{NOH}]^+$  salt of  $[\text{K}\{\mu_6\text{-Fe}(\text{CN})_6\}]_n^-$  (refcode CATXED).

**Fig. 26** (A) Top: ligands  $L_S$ ,  $L_{Se}$  and  $L_{Te}$ ; bottom, left to right: structures of  $[\text{K}(18\text{-crown-6})(L_{Te})(\mu\text{-NCO})]$  (CSD refcode BIHQOB),  $[\text{K}(18\text{-crown-6})(L_{Te})(\text{NCS})]$  (refcode BIQUH) and  $[L_{Te}(\text{NCS})]^-$  in the  $\text{K}^+$  salt (refcode BIHRES). (B) The structure of  $[\text{Li}_6(\text{THF})_4(\text{tmp})_4(\mu\text{-NCO})_2]$  (refcode HASKUK). (C) The structure of  $[\text{Me}_2\text{Al}(\mu\text{-OSiMe}_3)_2\text{Mg}(\text{THF})_2(\mu\text{-NCO})_3]$  (refcode WEJREJ); the  $\text{NCO}^-$  ligands are disordered and only one site for each is shown.

Moving to the p-block and compounds exhibiting N-bound terminal  $\text{NCX}^-$  ligands include the  $\beta$ -ketiminate derivative  $[\text{Al}\{\text{OCMeCHCMeNDipp}\}_2(\text{NCO})]$ ,<sup>412</sup> the tetrahedral  $[\text{LAlX}_2]$  complexes in which  $\text{HL} = \text{HC}\{\text{MeC}(\text{NDipp})\}_2$ ,  $\text{X} = \text{NCO}$  or  $\text{NCS}$  (the first examples of species in which two pseudohalide ligands are bound to  $\text{Al}^{3+}$ , Fig. 27A).<sup>413</sup> Note that in 1996, Assmann et al. reported  $[\text{In}(\text{pc})(\text{NCO})_2]^-$  with two terminal  $\text{NCO}^-$  ligands bound to  $\text{In}^{3+}$ .<sup>414</sup> In the centrosymmetric  $[\text{Ga}_2(\text{dpp-bian})_2(\text{NCO})_2]$  (which contains *dpp-bian* radicals, Fig. 27B), the  $\text{Ga-N-C}$  angle is  $149.2(4)^\circ$ ,<sup>415</sup> compared to  $167.9(1)$  and  $171.8(1)^\circ$  in  $[\text{Al}\{\text{OCMeCHCMeNDipp}\}_2(\text{NCO})]$ . A *trans*-arrangement of  $\text{NCO}^-$  ligands is found in  $[\text{Ge}(\text{tmtaa})(\text{NCO})_2]$  (*H*<sub>2</sub>tmtaa is defined in Fig. 27C) in which the  $\text{Ge-N-C}$  angles are  $160.9(2)$  and  $136.7(2)^\circ$ .<sup>416</sup> Similarly, bent geometries are observed in related  $\text{Ge}(\text{IV})$  complexes,<sup>417</sup> and in *trans*- $[\text{Sn}(\text{pc})(\text{NCO})_2]^{2-}$  ( $\text{Sn-N-C} = 140.9^\circ$ ).<sup>418</sup>

Large numbers of N-bonded thiocyanato derivatives of main group metals are known and we focus on selected examples reported after 2000. Angles designated  $\text{M-N-C}$  refer to terminally attached  $\text{NCS}^-$  ligands. Lithium is tetrahedrally sited in  $[\text{Li}(2,9\text{-Me}_2\text{phen})(\text{NCS})(\text{MeOH})]$  (the  $\text{LiNCS}$  unit is close to linear),<sup>419</sup> while the  $\text{Na}^+$  center in  $[\text{Na}(2,9\text{-Me}_2\text{phen})_2(\text{NCS})]$  is in a distorted trigonal bipyramidal environment; the  $\text{Na-N-C}$  angle is  $156.5(3)^\circ$ .<sup>420</sup> In  $[\text{Na}(18\text{-crown-6})(\text{THF})(\text{NCS})]$ , the  $\text{NaNCS}$  unit is approximately linear, while in  $[\text{Na}(15\text{-crown-5})(\text{NCS})]$ , the  $\text{Na-N-C}$  angle is  $133.6(5)^\circ$ .<sup>421</sup> In  $[\text{Li}(18\text{-crown-6})(\text{OH}_2)(\text{NCS})]$ , the  $\text{Li}^+$  binds to three of the six O-donors of the crown ether and is 5-coordinate<sup>422</sup>; this contrasts with the tetrahedral environment found in  $[\text{Li}(\text{MeNH}_2)_2(18\text{-crown-6})]^+$  (Fig. 4A). Examples with group 2 metals include the tetrahedral  $[\text{Be}(\text{NCS})_4]^{2-}$  anion (linear  $\text{BeNCS}$  units),<sup>423</sup> octahedral *trans*- $[\text{Mg}(\text{THF})_4(\text{NCS})_2]$  ( $\text{Mg-N-C} = 163.6^\circ$ ),<sup>424</sup> octahedral *cis*- $[\text{Mg}(\text{phen})_2(\text{NCS})_2]$  ( $\text{Mg-N-C} = 165.63(16)^\circ$ ),<sup>425</sup> octahedral  $[\text{Ca}(\text{NCS})_6]^{4-}$  (*ca.* linear  $\text{CaNCS}$ ),<sup>426</sup> octahedral *cis*- $[\text{Ca}(\text{OH}_2)_2(\text{NCS})_4]^{2-}$  (*ca.* linear  $\text{CaNCS}$ ),<sup>427</sup>  $[\text{Ca}(\text{N-CMe})_5(\text{NCS})_2]$  and  $[\text{Ca}(\text{OH}_2)(\text{dme})_2(\text{NCS})_2]$  with close to linear  $\text{CaNCS}$  units,<sup>274</sup>  $[\text{Ca}(\text{dme})_3(\text{NCS})_2]$  ( $\text{Ca-N-C} = 156.9(2)^\circ$ ),<sup>274</sup> and the 9-coordinate barium complex  $[\text{Ba}(L_{\text{diazacrown}})(\text{OH}_2)(\text{NCS})_2]$  ( $L_{\text{diazacrown}} = N,N'$ -bis(4-aminobenzyl)-4,13-diaza-18-crown-6) with a  $\text{Ba-N-C}$  angle of  $132.0^\circ$ .<sup>428</sup> Thiocyanato complexes of group 13 metals include octahedral  $[\text{Al}(\text{NCS})_6]^{3-}$  (*ca.* linear  $\text{AlNCS}$  units),<sup>429</sup> *mer*- $[\text{Ga}(\text{OH}_2)_3(\text{NCS})_3]$  (which co-crystallizes with 18-crown-6 and has approximately linear  $\text{GaNCS}$  units, Fig. 27D),<sup>430</sup> *trans*- $[\text{Ga}(\text{iQ})_2(\text{NCS})_4]^-$  (*ca.* linear  $\text{GaNCS}$ ),<sup>431</sup> octahedral  $[\text{In}(\text{NCS})_6]^{3-}$  ( $\text{In-N-C}$  angles in the range  $162.7\text{--}176.2^\circ$ ),<sup>432</sup> and *cis*- $[\text{In}(\text{OH}_2)_4(\text{NCS})_2]^+$  and *trans*- $[\text{In}(\text{OH}_2)_2(\text{NCS})_4]^-$  which occur in the salt

**Fig. 27** (A) Structure of  $[\text{LaI}(\text{NCO})_2]$  where  $\text{HL} = \text{HC}(\text{MeC}(\text{NDipp}))_2$  (CSD refcode QIGWIP). (B) Schematic diagram and structure of  $[\text{Ga}_2(\text{dpp-bian})_2(\text{NCO})_2]$  (refcode XEWMIY). (C) Structures of  $\text{H}_2\text{tmtaa}$  and the  $\text{Ge}(\text{IV})$  complex  $[\text{Ge}(\text{tmtaa})(\text{NCO})_2]$  (refcode DABHEU). (D) The structure of *mer*- $[\text{Ga}(\text{OH}_2)_3(\text{NCS})_3]$  (refcode EFOSAU).

$[\text{In}(\text{OH}_2)_4(\text{NCS})_2][\text{In}(\text{OH}_2)_2(\text{NCS})_4]^-$ .<sup>433</sup> The anion *trans*- $[\text{In}(\text{OH}_2)_2(\text{NCS})_4]^-$  has also been characterized in the 4,4'-bipyridinium salt.<sup>434</sup>

Group 14 germanium and tin complexes are represented by the  $\text{NCS}^-$  analog of  $[\text{Ge}(\text{tmtaa})(\text{NCO})_2]$  (see Fig. 27C),<sup>435</sup> and the trigonal pyramidal  $[\text{SnCl}(\text{NCS})_2]^-$  ( $\text{Sn}-\text{N}-\text{C} = 149.5(4)$  and  $139.5(4)^\circ$ ).<sup>436</sup> Lead(II) thiocyanate derivatives are exemplified by  $[\text{Pb}(\text{18-crown-6})(\text{NCS})_2]^+$  ( $\text{Pb}-\text{N}-\text{C} = 130.8(7)^\circ$ ),<sup>437</sup>  $[\text{Pb}(\text{phen})(\text{NCS})(\text{NO}_2-\kappa^2)]$ ,<sup>438</sup> and  $[\text{Pb}(5,5'\text{-Me}_2\text{bpy})(\text{NCS})_2]$  (Fig. 28A) and  $[\text{Pb}(4,4'\text{-(MeO)}_2\text{bpy})(\text{NCS})_2]$  (Fig. 28B) both of which show four 'normal'  $\text{Pb}-\text{N}$  bonds and three weak  $\text{Pb}\cdots\text{S}$  contacts to adjacent molecules in the solid state.<sup>439</sup> The coordination geometries for  $\text{Pb}(\text{II})$  (Fig. 28A and B) are indicative of the presence of a stereochemically active lone pair,<sup>439</sup> and this is, in general, a much discussed topic for  $\text{Pb}(\text{II})$ .<sup>339-342</sup> Terminal  $\text{NCS}^-$  ligands in

**Fig. 28** The structures of (A)  $[\text{Pb}(5,5'\text{-Me}_2\text{bpy})(\text{NCS})_2]$  (CSD refcode RAXGUU), (B)  $[\text{Pb}(4,4'\text{-(MeO)}_2\text{bpy})(\text{NCS})_2]$  (refcode RAXHAB), (C)  $[\text{Bi}(\text{THF})(\text{NCS})_5]^{2-}$  (refcode CIYKED), (D)  $[\text{K}_2(\text{benzo-15-crown-5})_2(\mu\text{-NCS})_2]$  (refcode FIXJOM), (E)  $[\text{Na}_2(\text{NCS})_2(\text{OH}_2)_2(\mu\text{-NCS})_2]^{2-}$  (refcode LACDOJ), and (F)  $[\text{K}(\text{18-crown-6})(\mu\text{-SCN})\text{In}(\text{NCS})_5]^{2-}$  (refcode RUDTIU).

[Pb<sub>2</sub>(phen)<sub>4</sub>(NCS)<sub>2</sub>(μ-N<sub>3</sub>)<sub>2</sub>] exhibit Pb–N–C angles of 147.1(3)°. In contrast to the N-bonded NCS<sup>−</sup> ligands in the complexes above, Saghatforoush et al. observe S-bonded thiocyanates in [Pb(4-ClC<sub>6</sub>H<sub>4</sub>tpy)(SCN)<sub>2</sub>].<sup>440</sup>

Homoleptic Sb(NCS)<sub>3</sub> and Bi(NCS)<sub>3</sub> are formed in reactions of SbF<sub>3</sub> or BiF<sub>3</sub> with Me<sub>3</sub>Si(SCN) and were crystallized as THF adducts. The thiocyanato ligands are N-bonded in [Sb(THF)(NCS)<sub>3</sub>]. In [(Ph<sub>3</sub>P)<sub>2</sub>N]<sub>2</sub>[Sb(NCS)<sub>5</sub>], the [Sb(NCS)<sub>5</sub>]<sup>2−</sup> ion has a square-pyramidal structure with N-bonded NCS<sup>−</sup> ligands (Sb–N–C angles are in the range 140.1(3)–169.1(3)°). Both N- and S-bonded thiocyanato ligands occur in the [(Ph<sub>3</sub>P)<sub>2</sub>N]<sup>+</sup> salt of [Bi(THF)(NCS)<sub>5</sub>]<sup>2−</sup> (Fig. 28C) with Bi–N–C angles of 173.8(5), 123.9(5) and 159.5(5)°.<sup>441</sup>

Different modes of bonding are observed for bridging thiocyanates, paralleling the modes described above for bridging NCO<sup>−</sup>. An N-bound mode (referring to either terminal or bridging NCO<sup>−</sup>) is seen, for example, in [K<sub>2</sub>(benzo-15-crown-5)<sub>2</sub>(μ-NCS)] (Fig. 28D),<sup>442</sup> and [Na<sub>2</sub>(NCS)<sub>2</sub>(OH<sub>2</sub>)<sub>2</sub>(μ-NCS)]<sup>2−</sup> with both terminal and bridging NCS<sup>−</sup> (Fig. 28E). In [K(18-crown-6)(μ-SCN)In(NCS)<sub>5</sub>]<sup>2−</sup>, one thiocyanate ligand bridges between K<sup>+</sup> and In<sup>3+</sup> centers, S-bound to K and N-bound to In (Fig. 28F).<sup>443</sup> Doubly bridged pairs of Pb(II) centers are seen in the 1D-coordination polymer [PbL<sub>2</sub>(μ-SCN)<sub>2</sub>]<sub>n</sub> (L = 5,6-bis(furan-2-yl)-3-(pyridin-2-yl)-1,2,4-triazine).<sup>444</sup> Further examples of bridging NCS<sup>−</sup> ligands that coordinate through both N- and S-donors are detailed in Section 1.02.7.1.3.

Complexes containing NCSe<sup>−</sup> ligands are far less well represented than their NCO<sup>−</sup> and NCS<sup>−</sup> counterparts. Selenocyanate-containing species related to those shown in Fig. 26A have been reported by Semenov et al.<sup>406</sup> The tetrahedral complex [Be(DMF)<sub>2</sub>(NCSe)<sub>2</sub>] (angle Be–N–C = 176.8(5)°) was the first example of a structurally characterized selenium-containing beryllium compound; it was prepared by reaction of BeCl<sub>2</sub> and KSeCN in DMF/THF.<sup>445</sup> [In(Me<sub>2</sub>NCH<sub>2</sub>CMe<sub>2</sub>S)<sub>2</sub>(NCSe)] is trigonal bipyramidal with the NCSe<sup>−</sup> ligand in an equatorial site, and the linear In–N–C–Se unit is crystallographically imposed; this and related compounds are of interest as single precursors for indium chalcogenides.<sup>446</sup>

### 1.02.2.1.5 Monodentate heterocyclic ligands

The variety of heterocyclic ligands is vast, and for an introduction to their main group metal coordination compounds, we focus only on pyridine (py), pyrazine (pyz), pyrimidine (pym), imidazole (Him) and pyrazole (Hpz) ligands (Scheme 1), exemplified by homoleptic and other simple species. Heterocyclic ligands also feature in other complexes considered in this review but where

**Scheme 1** Heterocyclic ligands discussed in this section.

the emphasis of the discussion is on a different ligand. The section is organized by heterocyclic ligand, starting with pyridine.

#### 1.02.2.1.5.1 Pyridine

Pyridine often occurs as an axial ligand in main group metal complexes in which macrocyclic ligands occupy the equatorial sites, e.g., [Na(18-crown-6)(py)<sub>2</sub>]<sup>+</sup>,<sup>447–454</sup> [K(18-crown-6)(py)<sub>2</sub>]<sup>+</sup>,<sup>455–457</sup> [Mg(15-crown-5)(py)<sub>2</sub>]<sup>2+</sup>,<sup>458</sup> porphyrinato complexes,<sup>459–468</sup> phthalocyanato complexes,<sup>469,470</sup> corrole derivatives,<sup>471–485</sup> corphycene derivatives,<sup>486</sup> or complexes in which tetradentate Schiff base ligands define a plane in the coordination sphere of the metal.<sup>487</sup>

The role of pyridine as a solvent probably explains the large number of derivatives of the main group metals. Simple pyridine complexes of lithium are represented by tetrahedral [Li(py)<sub>4</sub>]<sup>+</sup>,<sup>488–494</sup> tetrahedral [Li(OH<sub>2</sub>)<sub>2</sub>(py)<sub>2</sub>]<sup>+</sup>,<sup>495</sup> tetrahedral [Li(OH<sub>2</sub>)Cl(py)<sub>2</sub>],<sup>496</sup> trigonal planar [Li(py)<sub>2</sub>{N(SiMe<sub>3</sub>)(SiPh<sub>3</sub>)}],<sup>497</sup> the dimer [Li<sub>2</sub>(py)<sub>4</sub>(μ-NHPh)<sub>2</sub>],<sup>171</sup> tetrahedral [Li(py)<sub>3</sub>(PHR)] adducts and related dimers [Li<sub>2</sub>(py)<sub>2</sub>(μ-PHR)<sub>2</sub>] with 3-coordinate Li<sup>+</sup>,<sup>498</sup> and dimeric [Li<sub>2</sub>(py)<sub>4</sub>(μ-OAr)<sub>2</sub>] e.g., Ar = various arene substituents.<sup>499,500</sup> When the reaction of LiN(SiMe<sub>3</sub>)<sub>2</sub> and HOCH<sub>2</sub><sup>t</sup>Bu was carried out in pyridine, the cubane [Li<sub>4</sub>(py)<sub>3</sub>(μ<sub>3</sub>-OCH<sub>2</sub><sup>t</sup>Bu)<sub>4</sub>] was

**Fig. 29** The structures of (A) [Li<sub>4</sub>(py)<sub>3</sub>(μ<sub>3</sub>-OCH<sub>2</sub><sup>t</sup>Bu)<sub>4</sub>] (CSD refcode ACIYAM), (B) part of the 1D-polymer chain in [LiCl(py)]<sub>n</sub> (refcode L1CLPY02), (C) [Na(py)<sub>4</sub>]O(2,6-<sup>t</sup>Bu<sub>2</sub>C<sub>6</sub>H<sub>3</sub>) (refcode FIKJUG), (D) the cubane [Na<sub>4</sub>(py)<sub>6</sub>(μ<sub>3</sub>-OC<sub>6</sub>H<sub>4</sub>Pr)<sub>4</sub>] (refcode FIKKIV), and the 2-<sup>t</sup>PrC<sub>6</sub>H<sub>4</sub> groups drawn in stick representation for clarity, and (E) the [Be<sub>8</sub>(py)<sub>4</sub>(μ-NH<sub>2</sub>)<sub>12</sub>(μ<sub>4</sub>-O)]<sup>2+</sup> cation in the iodide salt (refcode DUJYAL).

isolated in which one Li was not solvated due to steric hindrance (Fig. 29A).<sup>501</sup> This contrasts with cubanes such as  $[\text{Li}_4(\text{py})_4(\mu_3\text{-OC}_6\text{H}_4\text{OMe})_4]$  in which all four Li atoms carry a terminal py ligand.<sup>500</sup> Also worthy of note is the 1D-polymeric structure of  $[\text{LiCl}(\text{py})]_n$  (Fig. 29B).<sup>488</sup> There have been few reports since 2000 of homoleptic  $[\text{M}(\text{py})_n]^+$  ( $\text{M} = \text{Na}, \text{K}, \text{Rb}, \text{Cs}$ ) complexes. In terms of simple complexes,  $[\text{Na}(18\text{-crown-6})(\text{py})_2]^+$  and  $[\text{K}(18\text{-crown-6})(\text{py})_2]^+$  are ubiquitous (see above). An apparently low CN is found in  $[\text{Na}(\text{py})_2]^+$  but the vacant coordination sites are occupied by  $\text{B-H}\cdots\text{Na}$  interactions with a carbaborane cluster<sup>502</sup>; this mirrors ambiguous low CNs discussed earlier in this review. A distorted octahedral  $[\text{K}(\text{py})_6]^+$  ion has been reported, but in a composite environment associated with a dicerium-based, so-called, 'letter-box' complex.<sup>503</sup>  $\text{NaBH}_4$  crystallizes from pyridine as the 5-coordinate  $[\text{Na}(\text{py})_3(\text{BH}_4\text{-}\kappa^2)]$  although association of these units via additional  $\text{Na-H-B}$  bridges leads to the assembly of a 1D-chain in the solid state.<sup>449</sup> Related to this is a  $\{\text{Na}(\text{py})_4(\text{BH}_4)\}$  unit in which the  $\text{BH}_4^-$  ion is part of an extended  $\{\text{BH}_4\text{-U}(\mu\text{-BH}_4)\text{-U-BH}_4\}$  motif.<sup>504</sup> Members of the series  $[\text{Na}(\text{py})_x(\text{OAr})]_n$  have been studied in detail.  $[\text{Na}(\text{py})_4\{\text{O}(2,6\text{-}^t\text{Bu}_2\text{C}_6\text{H}_3)\}]$  is trigonal pyramidal (Fig. 29C),<sup>505</sup> and  $\{\text{Na}_4\text{O}_4\}$  cubanes with Na-coordinated py ligands are of different types:  $[\text{Na}_4(\text{py})_4(\mu_3\text{-OR})_4]$  with 4-coordinate Na and  $[\text{Na}_4(\text{py})_6(\mu_3\text{-OR})_4]$  with 4- and 5-coordinate Na (Fig. 29D).<sup>505</sup>

Moving to group 2, beryllium forms a number of simple complexes with pyridine and examples with tetrahedral Be environments are  $[\text{Be}(\text{py})_4]^{2+}$ ,<sup>506,507</sup>  $[\text{BeCl}_3(\text{py})]^-$ ,<sup>508</sup>  $[\text{BeCl}_2(\text{py})_2]$ ,<sup>264</sup>  $[\text{BeBr}(\text{py})_3]^+$ ,<sup>509</sup> and  $[\text{BeCl}(\text{py})(\text{NHPPH}_3)_2]^+$ .<sup>510</sup> An investigation of Be(II) species formed in acidic liquid ammonia led to the isolation of  $[\text{Be}_8(\text{py})_4(\mu\text{-NH}_2)_{12}(\mu_4\text{-O})]_2$  and confirmed that the  $\{\text{Be}_4(\mu_4\text{-O})\}^{6+}$  unit can be stabilized without bidentate  $\text{O}, \text{O}'$ -ligands; Fig. 29E illustrates the structure of the unusual  $[\text{Be}_8(\text{py})_4(\mu\text{-NH}_2)_{12}(\mu_4\text{-O})]^{2+}$  cluster.<sup>511</sup> While CN = 6 is common in simple pyridine-containing complexes of  $\text{Mg}^{2+}$ , lower CNs are also encountered, for example, in trigonal planar  $[\text{Mg}\{\text{N}(\text{SiMe}_3)(\text{SiMe}_2^t\text{Bu})\}_2(\text{py})]$ ,<sup>512</sup> tetrahedral  $[\text{Mg}\{\text{N}(\text{SiMe}_3)_2\}_2(\text{py})_2]$ ,<sup>200</sup> tetrahedral  $[\text{Mg}\{\text{N}(\text{SiMe}_3)(\text{Mes})\}_2(\text{py})_2]$ ,<sup>512</sup> the tetrahedral bis(diphenylphosphanyl)amido complex  $[\text{Mg}\{\text{N}(\text{PPh}_2)_2\}_2(\text{py})_2]$ ,<sup>513</sup> and the 5-coordinate  $[\text{Mg}\{\text{O}(2,6\text{-Me}_2\text{C}_6\text{H}_3)\}_2(\text{py})_3]$  which contains sterically demanding  $\text{ArO}^-$  ligands.<sup>514</sup> The compound  $[\text{Mg}(\text{py})_6][\text{BH}_4]_2$  crystallizes as *trans*- $[\text{Mg}(\text{BH}_4\text{-}\kappa^2)_2(\text{py})_4] \cdot 2\text{py}$ .<sup>123</sup> Taking each  $[\text{BH}_4\text{-}\kappa^2]^-$  ligand as occupying a single coordination site, this can be considered to belong to a well-established family of octahedral Mg(II) complexes which includes *trans*- $[\text{MgCl}_2(\text{py})_4]$ ,<sup>515,516</sup> *trans*- $[\text{Mg}(\text{O}_2\text{CCF}_3)_2(\text{py})_4]$ ,<sup>517</sup> and *trans*- $[\text{Mg}(\text{NCO})_2(\text{py})_4]$ .<sup>409,410</sup> The octahedral *trans*- $[\text{Mg}(\text{NC}_5\text{H}_6)_2(\text{py})_4]$  (Fig. 30A) was formed by treating  $[\text{Mg}(\text{SiPh}_3)_2(\text{THF})_2]$  with neat pyridine,<sup>518</sup> and a related bis(4-allylpyridin-1(4H)-yl) derivative of Ca (Fig. 30B) was formed by reacting bis(allyl)calcium with an excess of py.<sup>519</sup> Simple octahedral complexes of  $\text{Ca}^{2+}$  include *trans*- $[\text{CaBr}_2(\text{py})_4]$ ,<sup>520</sup> and *trans*- $[\text{Ca}\{\text{Si}(\text{SiHMe}_2)_3\}_2(\text{py})_4]$ ,<sup>521</sup> while in  $[\text{Ca}(\text{S}_2\text{COEt-}\kappa^2)_2(\text{py})_3]$ , the  $\text{Ca}^{2+}$  center is 7-coordinate.<sup>522</sup> Lower CNs are represented by the tetrahedral  $[\text{Ca}\{\text{N}(\text{SiMe}_3)(\text{SiMe}_2^t\text{Bu})\}_2(\text{py})_2]$  which contains very bulky amido ligands.<sup>523</sup> Earlier we pointed to the role of py as an axial ligand in  $[\text{ML}(\text{py})_2]$  or  $[\text{ML}(\text{py})]$  species where L is a macrocyclic ligand. The structure of  $[\text{Ca}(\text{tpp}^t\text{Bu})(\text{py})_3]$  is interesting in having three py ligands bound to a  $\text{Ca}^{2+}$  center which resides above the porphyrin  $\text{N}_4$ -donor set (Fig. 30C).<sup>459</sup> Simple complexes of pyridine and the later group 2 metals are represented by the 5-coordinate  $[\text{M}\{\text{O}(2,6\text{-}^t\text{Bu}_2\text{C}_6\text{H}_3)\}_2(\text{py})_3]$  for  $\text{M} = \text{Sr}$  or  $\text{Ba}$ ,<sup>524</sup> the distorted octahedral *trans*- $[\text{Sr}\{\text{O}(2,6\text{-}^t\text{Bu}_2\text{C}_6\text{H}_3)\}_2(\text{py})_4]$  and *trans*- $[\text{M}\{\text{ODipp}\}_2(\text{py})_4]$  ( $\text{M} = \text{Sr}, \text{Ba}$ ),<sup>524</sup>  $[\text{Sr}_2(\text{py})_6\{\text{O}(2,6\text{-Me}_2\text{C}_6\text{H}_3)\}_2\{\mu\text{-O}(2,6\text{-Me}_2\text{C}_6\text{H}_3)\}_2]$ ,<sup>524</sup>  $[\text{Ba}_2(\text{py})_5\{\text{O}(2,6\text{-Me}_2\text{C}_6\text{H}_3)\}_2\{\mu\text{-O}(2,6\text{-Me}_2\text{C}_6\text{H}_3)\}_3]$  (Fig. 30D),<sup>524</sup> and  $[\text{Ba}_3(\text{py})_6\{\mu\text{-O}(2,6\text{-Me}_2\text{C}_6\text{H}_3)\}_6]$  in which each Ba has CN = 6.<sup>524</sup>

Restricting the discussion to non-organometallic complexes leaves a relatively small number of simple complexes of group 13 metals with pyridine ligands. Examples of monomeric species include tetrahedral  $[\text{AlCl}_3(\text{py})]$ ,<sup>525</sup>  $[\text{AlBr}_3(\text{py})]$ ,<sup>526</sup>  $[\text{GaX}_3(\text{py})]$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ),<sup>526</sup>  $[\text{GaHCl}_2(\text{py})]$  and related derivatives with substituted py ligands,<sup>527</sup>  $[\text{GaCl}_2(\text{py})\{\text{N}(\text{SiMe}_3)_2\}]$ ,<sup>528</sup>  $[\text{InBr}_3(\text{py})]$ ,<sup>529</sup> trigonal bipyramidal  $[\text{M}(\text{CN})_3(\text{py})_2]$  ( $\text{M} = \text{Ga}, \text{Tl}$ ) with axial py ligands,<sup>530</sup> 5-coordinate  $[\text{In}(\text{py})_2(\text{SeC}_6\text{F}_5)_3]$  with axial py ligands,<sup>531</sup> and octahedral *trans*- $[\text{AlF}_2(\text{py})_4]^+$ ,<sup>525,532</sup> *trans*- $[\text{AlCl}_2(\text{py})_4]^+$ ,<sup>284</sup> *trans*- $[\text{AlBr}_2(\text{py})_4]^+$ ,<sup>532</sup> and *trans*- $[\text{AlCl}_4(\text{py})_2]^-$ .<sup>284</sup> The octahedral cation *trans*- $[\text{AlH}_2(\text{py})_4]^+$  has been isolated in the salt  $[\text{Al}(\text{NC}_5\text{H}_6)_4][\text{AlH}_2(\text{py})_4]$  in which  $\text{C}_5\text{H}_6\text{NH}$  is 1,4-dihydropyridine; however, each Al-H site in the anion is disordered with an approximately 0.15 Al-OH superimposition.<sup>533</sup> Examples for the heavier group 13 metals in octahedral environments are  $[\text{GaF}_3(\text{py})_2(\text{OH}_2)]$  with a *trans*-arrangement of py ligands,<sup>534</sup> *mer*- $[\text{InBr}_3(\text{py})_3]$ ,<sup>529</sup> *mer*- $[\text{InI}_3(\text{py})_3]$ ,<sup>535</sup>  $[\text{InCl}(\text{N}_3)_2(\text{py})_3]$ ,<sup>334</sup> and *mer*- $[\text{In}(\text{CN})_3(\text{py})_3]$ .<sup>530</sup> Dimeric species are represented by  $[\text{Al}_2\text{Cl}_2(\text{py})_2(\mu\text{-PSi}^t\text{Pr}_3)_2]$  with an  $\text{Al}_2\text{Cl}_6$ -type structure,<sup>536</sup> and  $[\text{In}_2\text{Br}_4(\text{py})_4(\mu\text{-Br})_2]$  with octahedral In(III) centers and *trans*-py ligands.<sup>529</sup> The compounds  $\text{GaEX}$  ( $\text{E} = \text{S}, \text{Se}$  and  $\text{X} = \text{Cl}, \text{Br}$ ) have been prepared from  $\text{Ga}_2\text{E}_3$  and  $\text{Ga}_2\text{X}_6$ , and cyclic trimers  $[\text{Ga}_3\text{X}_3(\mu\text{-E})_3]$  have been isolated from pyridine solutions of  $\text{GaEX}$ ; each Ga(III) center in a trimer is tetrahedrally sited.<sup>537</sup>

**Fig. 30** Structures of (A) *trans*- $[\text{Mg}(\text{NC}_5\text{H}_6)_2(\text{py})_4]$ , (B) *trans*- $[\text{Ca}(\text{NC}_5\text{H}_5\text{R})_2(\text{py})_4]$  with  $\text{R} = \text{allyl}$  (refcode GUYQEX; for clarity, H atoms are only shown in the allyl group), (C)  $[\text{Ca}(\text{tpp}^t\text{Bu})(\text{py})_3]$  (CSD refcode QIVGIL; for clarity, the porphyrin framework is shown in stick representation), and (D)  $[\text{Ba}_2(\text{py})_5\{\text{O}(2,6\text{-Me}_2\text{C}_6\text{H}_3)\}_2\{\mu\text{-O}(2,6\text{-Me}_2\text{C}_6\text{H}_3)\}_3]$  (refcode FEMCEH).

Moving to group 14, the tin(IV) compound *trans*-[Sn(N<sub>3</sub>)<sub>4</sub>(py)<sub>2</sub>] was one of the first charge-neutral Lewis base adducts of Sn(N<sub>3</sub>)<sub>4</sub> and is stable in air over a period of days. It is noteworthy for having (in 2015) the highest temperature (305 °C) of onset of exothermic deposition of any group 14 polyazide, including Pb(N<sub>3</sub>)<sub>2</sub>.<sup>323</sup> Other M(IV) complexes include *trans*-[GeF<sub>4</sub>(py)<sub>2</sub>].<sup>538,539</sup> The metal(II) derivatives [SnBr<sub>2</sub>(py)<sub>2</sub>],<sup>540</sup> [Sn(NCO)<sub>2</sub>(py)<sub>2</sub>],<sup>541</sup> [Sn(N<sub>3</sub>)<sub>2</sub>(py)<sub>2</sub>],<sup>321</sup> [Sn(py)<sub>2</sub>(SeC<sub>6</sub>F<sub>5</sub>)<sub>2</sub>] and [Pb(py)<sub>2</sub>(SeC<sub>6</sub>F<sub>5</sub>)<sub>2</sub>],<sup>531</sup> [Pb(py)<sub>2</sub>(SePh)<sub>2</sub>],<sup>542</sup> [Pb(py)<sub>2</sub>{S(2,6-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>)<sub>2</sub>}<sub>2</sub>],<sup>543</sup> and [Pb(py)<sub>2</sub>(SC<sub>6</sub>F<sub>5</sub>)<sub>2</sub>],<sup>544</sup> have disphenoidal (see-saw) geometries with axial py ligands. Interest in some of these lead(II) complexes is as precursors to PbE (E = chalcogen) materials. In [SnBr<sub>2</sub>(py)<sub>2</sub>], close Sn⋯Br contacts (3.65 Å) interconnect molecules into 1D-chains (Fig. 31A). In this case, the Sn–Br⋯Sn angle is close to 180°, and this contrasts with the weak bridging interactions in the related [SnBr<sub>2</sub>(py)(THF)] (Fig. 31B).<sup>540</sup> [Pb(μ-Cl)<sub>2</sub>(py)<sub>2</sub>]<sub>n</sub> comprises infinite 1D-chains in the solid state with octahedral Pb(II).<sup>545</sup>

Octahedral [SbCl<sub>5</sub>(py)] is one of only a limited number of adducts of SbCl<sub>5</sub>.<sup>546</sup> For M(III), examples are the octahedral [BiCl<sub>5</sub>(py)]<sup>2-</sup>,<sup>547</sup> [BiI<sub>5</sub>(py)]<sup>2-</sup>,<sup>548</sup> and [BiBr<sub>4</sub>I<sub>2</sub>(py)]<sup>2-</sup> with disordering of the Br and I sites.<sup>549</sup> Bi(III) appears to be in a square-based pyramidal environment in [Bi(py)<sub>2</sub>(SC<sub>6</sub>Cl<sub>5</sub>)<sub>3</sub>]. However, this last description is ambiguous due to the presence of a third py ligand with a long Bi⋯N distance of 3.983(9) Å, and a similar {5 + 1} coordination pattern is observed in [Bi(py)<sub>3</sub>(SC<sub>6</sub>F<sub>5</sub>)<sub>3</sub>].<sup>550</sup> No such short contacts occur in the crystal structure of [SbCl<sub>2</sub>(N<sub>3</sub>)(py)<sub>2</sub>] which is square-based pyramidal with py ligands mutually *cis* in the basal plane. The latter was prepared by reaction of SbCl<sub>3</sub>, Me<sub>3</sub>SiN<sub>3</sub> and py, while in a similar reaction using AsCl<sub>3</sub>, the isolated product was the 4-coordinate [AsCl(N<sub>3</sub>)<sub>2</sub>(py)].<sup>344</sup> Reactions of SbCl<sub>3</sub> and pyridine under vacuum resulted in the formation of compounds formulated as [(SbCl<sub>3</sub>)<sub>4</sub>(py)<sub>4</sub>] and [(SbCl<sub>3</sub>)<sub>3</sub>(py)<sub>5</sub>]. In the solid state, the former comprises {SbCl<sub>2</sub>(py)<sub>2</sub>} units bridged by an {Sb<sub>2</sub>Cl<sub>6</sub>(μ-Cl)<sub>2</sub>} motif (Fig. 31C). ‘[(SbCl<sub>3</sub>)<sub>3</sub>(py)<sub>5</sub>]’ consists of two 5-coordinate [SbCl<sub>3</sub>(py)<sub>2</sub>] complexes and [SbCl<sub>3</sub>(py)] with a disphenoidal geometry; the three molecules associate through Sb⋯Cl interactions.<sup>551</sup> Prokudina et al. reported a series of [Sb<sub>x</sub>Br<sub>y</sub>py<sub>z</sub>] complexes containing 5-coordinate Sb(III) complexes in which the sixth coordination site is occupied by an additional Sb⋯Br contact. The simplest of these is the dimer shown in Fig. 31D (Sb–N = 2.384(6) and 2.395(6) Å) with asymmetric Br–Sb⋯Br bridges.<sup>552</sup> The analogous iodo-bridged dimer has also been reported and a related complex is [Sb<sub>3</sub>I<sub>9</sub>(py)<sub>4</sub>] (Fig. 31E).<sup>553</sup> These compounds were prepared from pyridine and SbI<sub>3</sub> under vacuum, and other members of the series are the disphenoidal (see-saw) shaped [SbI<sub>2</sub>(py)<sub>2</sub>]<sup>+</sup> cation (the counterion for which is [Sb<sub>2</sub>I<sub>7</sub>(py)]<sub>n</sub><sup>-</sup> comprising a 1D-chain), [Sb<sub>2</sub>I<sub>6</sub>(py)<sub>2</sub>] (Fig. 31F), and [Sb<sub>6</sub>I<sub>18</sub>(py)<sub>6</sub>] (Fig. 31G).<sup>553</sup> A CN of 7 is found in [BiCl<sub>3</sub>(py)<sub>4</sub>]; in the pentagonal bipyramidal structure, the py ligands occupy equatorial sites.<sup>554</sup> Seven-coordinate Bi(III) is also found in the 1D-polymeric [Bi(N<sub>3</sub>)(py)<sub>2</sub>(μ-N<sub>3</sub>)<sub>2</sub>]<sub>n</sub>.<sup>555</sup>

Complexes in which pyridine is coordinated to Se and Te include pyramidal [SeO<sub>2</sub>(py)],<sup>556</sup> disphenoidal [Te(py)<sub>2</sub>(<sup>t</sup>BuNCHMeCHMeN<sup>t</sup>Bu)]<sup>2+</sup>. The latter was the first example of a monodentate pyridine-type donor coordinated to Te(IV).<sup>557</sup>

#### 1.02.2.1.5.2 Pyrazine and pyrimidine

Pyrazine (pyz) and pyrimidine (pym) are isomers (Scheme 1) and coordination complexes of the main group metals with pyz reported since 2000 far exceed those with pym. The spatial arrangement of the two nitrogen lone pairs in pyrazine contribute to its ubiquitous choice as a bridging ligand, and the examples included in this section are representative of its coordination to main group metal ions. Some comparisons with analogous pyridine species by reference to the previous section may be helpful to the reader. Like pyridine, pyrazine may occur as an axial ligand in porphyrinato complexes,<sup>558</sup> but it is more often associated with the assembly of 1D-coordination polymers with [M(porph)] (H<sub>2</sub>porph = general porphyrin) building blocks.<sup>559–561</sup> In the

**Fig. 31** The structures of (A) [SnBr<sub>2</sub>(py)<sub>2</sub>] with intermolecular Sn⋯Br contacts (CSD refcode VUTTAG), (B) [SnBr<sub>2</sub>(py)(THF)] showing intermolecular Sn⋯Br contacts (refcode VUTSUZ), (C) [(SbCl<sub>3</sub>)<sub>4</sub>(py)<sub>4</sub>] (refcode MIQMOR), (D) [Sb<sub>2</sub>Br<sub>6</sub>(py)<sub>4</sub>] (refcode XAFQEE), (E) [Sb<sub>3</sub>I<sub>9</sub>(py)<sub>4</sub>] (refcode UNAHAV), (F) [Sb<sub>2</sub>I<sub>6</sub>(py)<sub>2</sub>] (refcode UNAGEY), and (G) [Sb<sub>6</sub>I<sub>18</sub>(py)<sub>6</sub>] (refcode UNAGIC).

discussion below, the preferences for the formation of discrete molecular species in which pyz is terminally bound, discrete oligomeric complexes, or polymeric assemblies are highlighted.

For the s-block metals, complexes with pyz and pym are represented by the 3D-network  $[\text{Na}(\mu_4\text{-ClO}_4)(\mu\text{-pyz})]_n$  (consisting of  $\{\text{Na}(\mu_4\text{-ClO}_4)\}_n$  sheets interconnected by bridging pyz ligands),<sup>562</sup> and heterometallic assemblies in which pyz bridges between  $\text{Na}^+$  and  $\text{Re(V)}$ ,<sup>563</sup> or  $\text{Na}^+$  and  $\text{Ru(III)}$ ,<sup>564</sup> and pym bridges between  $\text{Na}^+$  and  $\text{Ru(III)}$ .<sup>565</sup> As part of a wider investigation of series of  $[\text{BH}_4]^-$ -containing coordination polymers, Kadota et al. reported the 2D-networks present in  $[\text{M}(\text{BH}_4\text{-}\kappa^2)(\mu\text{-pyz})_2]_n$  ( $\text{M} = \text{Mg, Ca}$ ); a (4,4) net is defined by 4-connecting  $\text{Mg}^{2+}$  or  $\text{Ca}^{2+}$  nodes linked by pyz ligands, and terminal  $[\text{BH}_4]^-$  ligands complete the octahedral coordination at each metal.<sup>566</sup> Other  $\text{Mg}^{2+}$  pyrazine complexes involve  $[\text{Mg}(\text{porph})]$  units (see above).

We turn now to the p-block metals. Timoshkin and coworkers<sup>567</sup> have investigated the solid-state structures of group 13 metal halide complexes with pyz and have structurally characterized  $[\text{Al}_2\text{Br}_6(\mu\text{-pyz})]$  (Fig. 32A),  $[\text{Ga}_2\text{Cl}_6(\mu\text{-pyz})]$  (with tetrahedral M), and the 1D-polymers  $[\text{AlBr}_3(\mu\text{-pyz})]_n$  and  $[\text{GaCl}_3(\mu\text{-pyz})]_n$  in which the M(III) center is 5-coordinate.<sup>567,568</sup> The analogous polymer  $[\text{GaBr}_3(\mu\text{-pyz})]_n$  (Fig. 32C) has also been reported.<sup>568</sup>  $\text{GaI}_3$  (which is a weaker Lewis acid than  $\text{AlBr}_3$ ,  $\text{GaCl}_3$  or  $\text{GaBr}_3$ ) forms the tetrahedral monomer  $[\text{GaI}_3(\text{pyz})]$ .<sup>567</sup> A structure related to  $[\text{Al}_2\text{Br}_6(\mu\text{-pyz})]$  (Fig. 32A) is found for  $[\text{In}_2\text{Cl}_6(\text{DMSO})_4(\mu\text{-pyz})]$  (Fig. 32B) but the higher CN of 6 for In vs 4 for Al allows additional DMSO coordination. If DMSO solvent is replaced by aqueous EtOH, reaction of  $\text{InCl}_3$  and pyz yields a 1D-ladder (Fig. 32D) with octahedral In(III) and a *mer*-arrangement of N-donors.<sup>569</sup> A similar polymer was confirmed for  $[\text{Tl}_2\text{Cl}_6(\mu\text{-pyz})_3]_n$ .<sup>568</sup> An interesting comparison is in the products of the reactions of  $\text{InX}_3$  ( $\text{X} = \text{Cl, Br}$ ) and pyrimidine or pyrazine in EtOH. The former leads to the discrete octahedral *mer*- $[\text{InCl}_3(\text{OH})(\text{Hpym})_2]^+$  (hydroxide salt), while for pyz, the 1D-polymer  $[\text{InBr}_3(\text{OH}_2)(\mu\text{-pyz})]_n$  was isolated.<sup>568</sup>

Krossing and coworkers have succeeded in isolating gallium(I) species with monodentate pyz; use of the sterically demanding and weakly coordinating  $[\text{Al}(\text{OR}^f)_4]^-$  anion ( $\text{R}^f = \text{C}(\text{CF}_3)_3$ ) was a key factor. The trigonal pyramidal  $[\text{Ga}(\text{pyz})_3]^+$  was the first 3-coordinate, non-chelated, homoleptic N-donor complex of Ga(I). The addition of one equivalent of pyz to  $[\text{Ga}(\text{pyz})_3][\text{Al}(\text{OR}^f)_4]$  led, unexpectedly, to the isolation of  $\{[\text{Ga}(\mu\text{-pyz})_2(\text{pyz})][\text{Al}(\text{OR}^f)_4]\}_n$ . The formation of monomer or polymer is dependent upon both the concentration of pyz and the temperature of crystallization.<sup>570</sup>

The tin(IV) complex *trans*- $[\text{SnCl}_4(\text{pyz})_2]$  is a discrete molecular species in the solid state.<sup>571</sup> The  $[\text{Sn}(\text{NCMe})_6]^{2+}$  cation was mentioned in Section 1.02.2.1.3, and use of the  $[\text{Al}(\text{OR}^f)_4]^-$  anion led to the tin(II) cation being relatively isolated from the counterion in the solid state. Two MeCN ligands in  $[\text{Sn}(\text{NCMe})_6]^{2+}$  can be replaced by pyz to give *cis*- $[\text{Sn}(\text{pyz})_2(\text{NCMe})_4]^{2+}$  ( $\text{Sn-N}_{\text{pyz}} = 2.373(4)$  and  $2.421(3)$  Å) with three of the MeCN ligands being only weakly bound ( $\text{Sn-N} = 2.713(4)$ – $2.863(4)$  Å).<sup>293</sup>  $[\text{Pb}\{\text{S}(2,6\text{-Me}_2\text{C}_6\text{H}_3)\}_2(\mu\text{-pyz})]_n$  forms a 1D-coordination polymer (Fig. 32G),<sup>543</sup> while in  $[\text{Pb}_2(\mu\text{-Br})_4(\mu\text{-pyz})]_n$  all ligands are in bridging modes giving a double-layer structure (Fig. 32H); each Pb(II) center is in a square-based pyramidal environment.<sup>572</sup>  $[\text{Pb}(\mu\text{-I})_2(\mu\text{-pyz})]_n$  comprises a (4,4) net with Pb(II) acting as 4-connecting nodes; alternate edges of each  $\text{Pb}_4$  rhombus are bridged by pyz or two  $\text{I}^-$  ligands.<sup>573</sup>

Pyrazine complexes of the group 15 metals focus on Sb and Bi. In addition to the discrete molecule  $[\text{Sb}_2\text{F}_{10}(\mu\text{-pyz})]$ ,<sup>574</sup> group 15 metal(III) halides form a number of extended arrays with pyz.  $[\text{SbCl}_3(\mu\text{-pyz})]_n$  is a 1D-chain with Sb(III) in a square-pyramidal environment, indicative of a stereochemically active lone pair. In contrast, the compounds  $[\text{Sb}_2\text{X}_6(\mu\text{-pyz})_3]_n$  ( $\text{X} = \text{Cl, I}$ ) assemble into 3D-networks with each Sb(III) center (*fac*-arrangement of N-donors) acting as a 3-connecting node. The structures are described as ‘dense frameworks’<sup>575</sup>; inspection of the crystallographic data (CDS refcodes KUNXUP and KUNYAW) reveals that both  $[\text{Sb}_2\text{X}_6(\mu\text{-pyz})_3]_n$  ( $\text{X} = \text{Cl, I}$ ) have interpenetrating 3D-nets (Fig. 33A). The reaction between  $\text{BiI}_3$  and pyz yields  $[\text{Bi}(\mu\text{-I})_3(\mu\text{-pyz})]_n$ .

**Fig. 32** Structures of (A)  $[\text{Al}_2\text{Br}_6(\mu\text{-pyz})]$  (CSD refcode HIJBOT), (B)  $[\text{In}_2\text{Cl}_6(\text{DMSO})_4(\mu\text{-pyz})]$  (refcode NIBLOA). (C) Part of the 1D-chain in  $[\text{GaBr}_3(\mu\text{-pyz})]_n$  (refcode NIWTIX). (D) Part of the 1D-ladder in  $[\text{In}_2\text{Cl}_6(\mu\text{-pyz})_3]_n$  (refcode NIBMAN) indicating the direction of chain propagation. Part of (E) a 1D-chain in  $[\text{Pb}\{\text{S}(2,6\text{-Me}_2\text{C}_6\text{H}_3)\}_2(\mu\text{-pyz})]_n$  (refcode GAGXOC), and (F) one double-layer in  $[\text{Pb}_2(\mu\text{-Br})_4(\mu\text{-pyz})]_n$  (refcode MOTSET).

**Fig. 33** (A) The interpenetrating networks in  $[\text{Sb}_2\text{Cl}_6(\mu\text{-pyz})_3]_n$  (CSD refcode KUNXUP) showing only the 3-connecting Sb nodes; the diagram was constructed using Mercury 2021.3.0.<sup>90</sup> (B) Part of the 2D-net in  $[\text{Bi}(\mu\text{-l})_3(\mu\text{-pyz})]_n$  (refcode VUPMAX). (C) Part of the  $[\text{Bi}_2\text{Cl}_6(\mu\text{-Cl})_2(\mu\text{-pyz})]_n^{2n-}$  1D-chain (refcode KEKTIG); the direction of chain propagation is clarified with the arrows.

$\text{pyz})]_n$  with the 2D-network shown in **Fig. 33B**; the (4,4) net is defined by nodes at the centers of the  $\{\text{Bi}_2\text{I}_6\}$  units.<sup>576</sup> In contrast, the reaction between  $\text{BiI}_3$ ,  $\text{Bu}_4\text{NI}$  and  $\text{pyz}$  produces the  $[\text{Bu}_4\text{N}]^+$  salt of 1D-polymer  $[\text{Bi}_2\text{Cl}_6(\mu\text{-Cl})_2(\mu\text{-pyz})]_n^{2n-}$  (**Fig. 33C**).<sup>577</sup>

#### 1.02.2.1.5.3 Imidazole

Imidazole (**Scheme 1**) complexes of the s-block metal ions are represented by octahedral  $[\text{Mg}(\text{Him})_6]^{2+}$  and *trans*- $[\text{Mg}(\text{Him})_4(\text{OH}_2)_2]^{2+}$ , the structures of which have been determined from powder X-ray diffraction data using full-profile Rietveld refinement methods.<sup>578</sup> The single crystal structure of *trans*- $[\text{Mg}(\text{Him})_4(\text{OH}_2)_2]\text{Cl}_2$  has also been reported ( $\text{Mg-N} = 2.2281(10)$  and  $2.1611(10)$  Å).<sup>579</sup> Using solvent-free conditions, Zurawski et al. prepared the group 2 coordination polymers  $[\text{Mg}(\text{im})_2(\text{Him})_3]_n$  and  $[\text{M}(\text{im})_2(\text{Him})_2]_n$  ( $\text{M} = \text{Ca}, \text{Sr}, \text{Ba}$ ) with structural dependence on the size of the metal ion. In the Mg and Ca complexes, metal ions are octahedrally sited, but whereas  $[\text{Mg}(\text{im})_2(\text{Him})_3]_n$  (**Fig. 34A**) is a 1D-polymer,  $[\text{Ca}(\text{im})_2(\text{Him})_2]_n$  and  $[\text{Sr}(\text{im})_2(\text{Him})_2]_n$  form (4,4) nets with each  $\text{M}^{2+}$  ion coordinated to *trans*-terminal Him ligands and four bridging  $\text{im}^-$  ligands. A  $\text{CN} > 6$  is favored for  $\text{Ba}^{2+}$  and metal ions are connected into a 1D-chain by bridging  $\text{im}^-$  ligands which coordinate in an  $\eta^5$ -manner to one  $\text{Ba}^{2+}$  and via an  $\text{M-N}$   $\sigma$ -bond to the next (**Fig. 34B**).<sup>580</sup> Note the presence of Him as a terminal ligand, but the conjugate base in bridging sites. Imidazole also occurs as an axial ligand in  $[\text{Mg}(\text{porph})]$  complexes, for example,  $[\text{Mg}(\text{tppBr})(\text{Him})]$ ,<sup>581</sup> in  $[\text{Mg}_2(\text{Him})_4(\text{HOAc})_2(\mu\text{-OAc})_2(\mu\text{-O})]$ ,<sup>582</sup> *fac*- $[\text{Ca}(\text{Him})(\text{OH}_2)_3(\text{O}_2\text{CC}_6\text{H}_4\text{NO}_2)_2]$  and *trans*- $[\text{Ca}(\text{Him})_2(\text{OH}_2)_2(\text{O}_2\text{CC}_6\text{H}_4\text{NO}_2)_2]$ .<sup>583</sup>

As part of an investigation of Him as a structure-directing agent in the assembly of metal-organic frameworks (MOFs), the octahedral  $[\text{In}(\text{Him})_6]^{3+}$  (as the nitrate salt) was isolated.<sup>584</sup> An interesting approach to MOF synthesis capitalizes on the fact that both gallium metal and imidazole are low melting. Thus  $[\text{Ga}_2(\text{Him})(\text{im})_6]_n$  was isolated from a melt with Ga being oxidized to Ga(III) during the reaction.  $[\text{Ga}_2(\text{Him})(\text{im})_6]_n$  comprises a 3D-network, with two independent, octahedral Ga(III) centers, in  $\{\text{Ga}(\text{im})_6\}$  and  $\{\text{Ga}(\text{im})_5(\text{Him})\}$  environments, respectively. The net has a (3,6) topology constructed from two Kagomé nets which share connectivity points (**Figs. 34C** and **D**).

#### 1.02.2.1.5.4 Pyrazole

In this section, we consider main group metal complexes with  $\text{Hpz}$  (**Scheme 1**) or  $\text{pz}^-$  ligands. Complexes with tris(pyrazolyl) borate ligands are described in **Section 1.02.2.3**. As for imidazole complexes, there is a dominance of s-block and group 13 metal complexes rather than the later main group metals. There is a range of 1H-pyrazole-3-carboxylate and 1H-pyrazole-3,5-

**Fig. 34** Parts of the 1D-chains in (A)  $[\text{Mg}(\text{im})_2(\text{Him})_3]_n$  (CSD refcode CAVTEA) and (B)  $[\text{Ba}(\text{im})_2(\text{Him})_2]_n$  (refcode CAVTUQ); only the N–H hydrogen atoms are shown. (C) The 3D-network in  $[\text{Ga}_2(\text{Him})(\text{im})_6]_n$  (view down the  $a$ -axis) showing only the Ga nodes, and (D) the same lattice viewed to show the two interconnected Kagomé nets (refcode YUWHOO).

**Fig. 35** Structures of (A)  $[\text{Li}_2(\text{Hpz-3,5-}^t\text{Bu}_2)_2\{\mu\text{-(pz-3,5-}^t\text{Bu}_2)_2\}]$  (CSD refcode YEBBOX, only the NH H atoms displayed), (B)  $[\text{Mg}(\text{Hpz-3,5-}^t\text{Bu}_2)(\text{pz-3,5-}^t\text{Bu}_2)_2]$  and (C)  $[\text{Mg}_2(\text{Hpz-3,5-}^i\text{Pr}_2)_2(\text{pz-3,5-}^i\text{Pr}_2)_2\{\mu\text{-(pz-3,5-}^i\text{Pr}_2)_2\}]$  showing intramolecular hydrogen bonds (refcodes MIRMEF and XETXAW, only the NH H atoms are shown). (D) The building block in  $[\text{Ca}(\text{OH}_2)_3(\text{Hpz-4-SO}_3)_2]_n$  (refcode OLITIM). (E) Structure of  $\text{trans-}[\text{GaCl}_2(\text{Hinz})_4]^+$  (refcode TAHPAV, with only NH H atoms shown).

dicarboxylate ligands that act as N,O-chelates to main group metal ions,<sup>585–595</sup> but in this section, we focus on N-bonded pyrazole ligands in simple complexes.

The  $\text{Li}^+$  ion in  $[\text{Li}(\text{Hpz-4-CO}_2)(\text{OH}_2)_3]$  is tetrahedrally sited, with N-bound  $[\text{Hpz-4-CO}_2]^-$ .<sup>596</sup> In  $[\text{Li}_2(\text{Hpz-3,5-}^t\text{Bu}_2)_2\{\mu\text{-(pz-3,5-}^t\text{Bu}_2)_2\}]$ , the bridging pyrazolato ligands exhibit different bonding modes to the two  $\text{Li}^+$  centers as depicted in Fig. 35A. This is one of a series of complexes formed in reactions of  $\text{Hpz-3,5-Me}_2$  or  $\text{Hpz-3,5-}^t\text{Bu}_2$  with  $\text{RLi}$ ,  $\text{Na}$  or  $\text{K}$ .<sup>597</sup> The reaction between  $\text{BeCl}_2$  and  $\text{Hpz}$  in  $\text{Et}_2\text{O}$  produced tetrahedral  $[\text{BeCl}_2(\text{Hpz})(\text{OEt}_2)]$  ( $\text{Be-N} = 1.717(4) \text{ \AA}$ ); with two equivalents of  $\text{Hpz}$ , the isolated product was  $[\text{Be}_2(\text{Hpz})_2\text{Cl}_2(\mu\text{-OEt}_2)_2]$ .<sup>264</sup> An interesting feature of the sterically crowded tetrahedral  $[\text{Mg}(\text{Hpz-3,5-}^t\text{Bu}_2)_2(\text{pz-3,5-}^t\text{Bu}_2)_2]$  is the presence of hydrogen bonds between pairs of  $\text{Hpz-3,5-}^t\text{Bu}_2$  and  $[\text{pz-3,5-}^t\text{Bu}_2]^-$  ligands (Fig. 35B,  $\text{N-H}\cdots\text{N} = 2.7448(17) \text{ \AA}$ , angle  $\text{N-H}\cdots\text{N} = 153(3)^\circ$ ).<sup>598</sup> A similar feature occurs in  $[\text{Mg}_2(\text{Hpz-3,5-}^i\text{Pr}_2)_2(\text{pz-3,5-}^i\text{Pr}_2)_2\{\mu\text{-(pz-3,5-}^i\text{Pr}_2)_2\}]$  (Fig. 35C).<sup>599</sup> Octahedral group 2 metal complexes include  $[\text{Mg}(\text{Hpz-5-th})_4(\text{pz-5-th})_2]$ ,<sup>600</sup>  $[\text{Ca}(\text{Hpz-3,5-Me}_2)_4(\text{pz-3,5-Me}_2)_2]$ ,<sup>601</sup> and  $[\text{Sr}(\text{Hpz-3,5-Me}_2)_4(\text{pz-3,5-Me}_2)_2]$ .<sup>601</sup> Reactions of pyrazole-4-sulfonic acid ( $\text{Hpz-4-SO}_3\text{H}$ ) with  $\text{Na}_2\text{CO}_3$ ,  $\text{K}_2\text{CO}_3$ ,  $\text{CaCO}_3$  and  $\text{BaCO}_3$  under aqueous conditions lead to metal sulfonate networks (the first containing  $\text{Hpz-4-SO}_3^-$ ) which consist of inorganic–organic layered structures. For example, in  $[\text{Ca}(\text{OH}_2)_3(\text{Hpz-4-SO}_3)_2]_n$ , one  $[\text{Hpz-4-SO}_3]^-$  ligand is N-bound and the other O-bound; the structure propagates through additional O–Ca bonds with each  $\text{Ca}^{2+}$  being 7-coordinate (Fig. 35D).<sup>602</sup> This study is complemented by assemblies between  $\text{Hpz-4-SO}_3\text{H}$  and  $\text{Rb}^+$ ,  $\text{Cs}^+$ ,  $\text{Mg}^{2+}$  and  $\text{Sr}^{2+}$ .<sup>603</sup>

Complexes with group 13 metal ions are illustrated by tetrahedral  $[\text{GaCl}_3(\text{Hpz-3,5-Ph}_2)_2]$ ,<sup>604</sup> octahedral  $\text{trans-}[\text{GaCl}_2(\text{Hpz})_4]^+$ ,<sup>605</sup>  $\text{trans-}[\text{AlCl}_2(\text{Hinz})_4]^+$  and  $\text{trans-}[\text{GaCl}_2(\text{Hinz})_4]^+$  (Fig. 35E)<sup>606</sup>; we include these indazole derivatives because of their close relationship to their pyrazole analogs.

## 1.02.2.2 Bidentate ligands

### 1.02.2.2.1 Diamines

We restrict our discussion of main group metal complexes containing chelating diamine ligands to those with *en*, *pn*, *pda*, *tmeda* and *tmpda* ligands (Scheme 2). Complexes featuring bridging or monodentate *en* were covered in Section 1.02.2.1.1. The use of *tmeda* as a solvent results in its incorporation as a ligand into a wide range of complexes, in particular those of the s-block metals. In 2021, Buchner and Müller investigated the use of *en* as an alternative solvent to liquid  $\text{NH}_3$  in beryllium chemistry.<sup>128</sup>

Homoleptic  $[\text{ML}_x]^{n+}$  are represented by tetrahedral  $[\text{Be}(\text{en})_2]^{2+}$  and  $[\text{Be}(\text{en})(\text{en-N})_2]^{2+}$  (Fig. 36A),<sup>128</sup> octahedral  $[\text{Mg}(\text{en})_3]^{2+}$ ,<sup>607–611</sup>  $[\text{Ca}(\text{en})_3]^{3+}$ ,<sup>612,613</sup>  $[\text{In}(\text{en})_3]^{3+}$ ,<sup>614–616</sup>  $[\text{Tl}(\text{en})_3]^{3+}$ ,<sup>617</sup> and  $[\text{Ge}(\text{en})_3]^{2+}$ .<sup>618,619</sup> In contrast to a CN of 6 in

**Scheme 2** Chelating diamines included in Section 1.02.2.2.1.

**Fig. 36** Structures of (A) the  $[\text{Be}(\text{en})(\text{en}-M)_2]^{2+}$  cation in the chloride salt (CSD refcode IRUJIR), and (B) the  $[\text{Ba}_2(\text{en})_4(\mu\text{-pn})]^{4+}$  cation with 9-coordinate  $\text{Ba}^{2+}$  (refcode TOMTOG). (C) Part of the 1D-chain in  $[\text{Sn}(\text{en})(\mu\text{-S})_2]_n$  (refcode QUKPUI). (D) In  $[\text{Pb}(\text{pda})_2][\text{NO}_3]_2$ , one  $\text{NO}_3^-$  ion interacts with the cation ( $\text{Pb}\cdots\text{O} = 3.177(3), 3.090(3)$  Å, refcode FAKYUN).

$[\text{Mg}(\text{en})_3]^{2+}$ , the larger  $\text{Ca}^{2+}$  ion forms the 8-coordinate  $[\text{Ca}(\text{en})_4]^{2+}$ . The latter was formed with selenium-based anions under superheated and supercritical solvothermal conditions in en.<sup>620</sup> A further increase in CN is observed on going to  $[\text{Ba}_2(\text{en})_4(\mu\text{-pn})]^{4+}$  (Fig. 36B).<sup>621</sup> Mixed amine/halido and related complexes are illustrated by tetrahedral  $[\text{AlBr}_2(\text{en})]^+$ ,  $[\text{AlI}_2(\text{en})]^+$  and  $[\text{GaI}_2(\text{en})]^+$ ,<sup>622</sup> octahedral *cis*- $[\text{In}(\text{OAc})_2(\text{en})_2]^+$  with monodentate acetate ligands,<sup>623</sup> and octahedral  $[\text{Ge}(\text{en})(\text{OH})_4]$ .<sup>618</sup> The centrosymmetric  $[\text{In}_2(\text{en})_4(\mu\text{-S})_2]^{2+}$ ,<sup>608</sup>  $[\text{In}_2(\text{en})_4(\mu\text{-Se})_2]^{2+}$ ,<sup>624</sup>  $[\text{In}_2(\text{en})_4(\mu\text{-Te})_2]^{2+}$ ,<sup>625</sup> and  $[\text{In}_2(\text{en})_4(\mu\text{-OH})_2]^{4+}$ ,<sup>626</sup> contain octahedrally sited In(III). The  $[\text{Pb}(\text{en})_2]^{2+}$ ,  $[\text{Pb}(\text{pda})_2]^{2+}$ , and  $[\text{Pb}(\text{tmeda})_2]^{2+}$  cations were isolated in salts containing  $[\text{Ag}_2\text{I}_6]^{4-}$  anions with cation $\cdots$ anion interactions through  $\text{Pb}\cdots\text{I}$  contacts. Note the lower CN in  $[\text{Pb}(\text{tmeda})]^{2+}$  vs  $[\text{Pb}(\text{en})_2]^{2+}$  caused by the greater steric hindrance of tmeda.<sup>627</sup> In the solid-state structure of  $[\text{Pb}(\text{en})(\text{NO}_3)(\text{MeCO}_2\text{-}\kappa^2)]$ , the Pb(II) center is 5-coordinate with a geometry that suggests the presence of a stereochemically active lone pair; there are also close  $\text{Pb}\cdots\text{O}$  contacts to the coordinated  $\text{NO}_3^-$  ligand of an adjacent molecule.<sup>628</sup> 1D-coordination polymers featuring interconnected  $\{\text{M}(\text{en})\}$ ,  $\{\text{M}(\text{en})\text{X}_2\}$  or  $\{\text{M}(\text{en})_2\}$  units are represented by  $[\text{Li}(\text{en})_2]_n^{n+}$  with both bridging and chelating en (Fig. 5B),<sup>126</sup>  $[\text{Tl}(\text{en})_2(\mu\text{-CN})]_n^{2n+}$  with a *trans* arrangement of bridging cyanido ligands,<sup>629</sup>  $[\text{Sn}(\text{en})(\mu\text{-S})_2]_n$  (Fig. 36C),<sup>630</sup>  $[\text{Pb}(\text{en})_2(\mu\text{-en})]_n$  (Fig. 6B),<sup>145</sup>

Perhaps surprisingly, simple main group metal complexes containing chelating pn (Scheme 2) are very limited in number, with one of the few structurally characterized examples being octahedral  $[\text{Mg}(\text{pn})\text{L}_2]$  in which  $\text{HL} = 2,2,6,6$ -tetramethylheptane-3,5-dione.<sup>631</sup> There are significantly more examples of complexes with pda (Scheme 2), and this is most likely indicative of a preference for 5- over 6-membered chelate rings. However, few homoleptic complexes have been reported.  $[\text{Pb}(\text{pda})_2]^{2+}$  in salts with  $[\text{Ag}_2\text{I}_6]^{4-}$  anions was mentioned above.<sup>627</sup> Fig. 36D depicts the structure of the  $[\text{Pb}(\text{pda})_2]^{2+}$  cation in the nitrate salt. The ubiquitous ‘gap’ in the coordination sphere for lead(II) is partly occupied by weak contacts to one nitrate ion.<sup>632</sup>

A wide variety of coordination and organometallic compounds is formed between tmeda and the s- and p-block metals, in particular  $\text{Li}^+$ . Some  $\{\text{Li}(\text{tmeda})\}^+$  complexes which also incorporate amido and imido ligands were described in Section 1.02.2.1.2. The steric hindrance imparted by the  $\text{NMe}_2$  units in tmeda does not preclude the formation of tetrahedral  $[\text{Li}(\text{tmeda})_2]^+$  (representative examples are cited),<sup>633–649</sup> while in  $[\text{Li}(\text{tmeda})\{\text{N}(\text{CHMePh})_2\}]$ <sup>153</sup>  $[\text{Li}(\text{tmeda})\{\text{O}(2,6\text{-tBu}_2\text{-4-MeC}_6\text{H}_2)\}]$ ,<sup>650</sup> and  $[\text{Li}(\text{tmeda})\{\text{NPh}(\text{CH}^i\text{Pr}_2)\}]$ ,<sup>651</sup> Li is in a trigonal planar environment. An investigation of dichalcogenidoimidodiphosphinate anions (Scheme 3a) has included structural data for  $[\text{Li}(\text{tmeda})\{\text{N}(\text{tPr}_2\text{PSe})_2\}]$  and  $[\text{Li}(\text{tmeda})\{\text{N}(\text{tPr}_2\text{PTe})_2\}]$  as well as the mixed

**Scheme 3** (A) General families of dichalcogenidoimidodiphosphinate anions.<sup>652</sup> (B) Structure of the  $[\text{Ph}_2\text{PCH}(\text{BH}_3)\text{P}(\text{BH}_3)\text{Ph}_2]^-$  ligand.

**Fig. 37** Structures of (A)  $[\text{Na}(\text{tmeda})_2]^+$  (CSD refcode CIVWIO), (B)  $[\text{Li}_4(\text{tmeda})_2(\mu\text{-tmeda})(\mu\text{-B}_3\text{Me}_2\text{N}_3\text{H}_2)_4]$  (refcode CAPTAP), (C)  $[\text{Sr}_2(\text{tmeda})_2(\text{Me}_2\text{N}(\text{BH}_3)_2)_2]$  (refcode TAHWOS), and (D)  $[\text{In}_6\text{I}_8(\text{tmeda})_4]$  (refcode XIQWAW). In (C) and (D), tmeda is shown in stick representation for clarity.

S/Te and Se/Te analogs; the Li<sup>+</sup> ion is tetrahedrally sited.<sup>652</sup> The [Na(tmeda)<sub>2</sub>]<sup>+</sup> ion appears to have first been structurally characterized in 1983,<sup>653</sup> and the Na<sup>+</sup> ion is in a planar environment (Fig. 37A).<sup>654,655</sup> This mirrors the structural preference found in, for example, [Na(NH<sub>3</sub>)<sub>4</sub>]<sup>+</sup> (Fig. 1C). The axial sites are occupied by MeCN ligands in *trans*-[Na(tmeda)<sub>2</sub>(NC<sup>t</sup>Bu)<sub>2</sub>]<sup>+</sup>.<sup>656</sup> A similar coordination environment is found in [K(tmeda)<sub>2</sub>(Ph<sub>2</sub>PCH(BH<sub>3</sub>)P(BH<sub>3</sub>)Ph<sub>2</sub>)<sub>n</sub>] (see Scheme 3B for the ligand); the axial sites of the {K(tmeda)<sub>2</sub>}<sup>+</sup> unit are occupied by B–H–K interactions to produce a 1D-polymeric structure in the solid state.<sup>657</sup> The K<sup>+</sup> ion is large enough to accommodate three chelating tmeda ligands; [K(tmeda)<sub>3</sub>]<sup>+</sup> has a distorted octahedral structure.<sup>658</sup>

Tetrahedral [M(tmeda)X<sub>2</sub>] derivatives include [Be(tmeda)X<sub>2</sub>] (X = Br, I),<sup>509,659</sup> [M(tmeda){N(SiMe<sub>3</sub>)<sub>2</sub>}<sub>2</sub>] (M = Mg, Sr),<sup>660</sup> [Mg(tmeda)(BH<sub>4</sub>-κ<sup>3</sup>)<sub>2</sub>] (pseudo-tetrahedral with tridentate BH<sub>4</sub><sup>−</sup> ligands),<sup>661</sup> [Mg(tmeda)(NHSi<sup>t</sup>Pr<sub>3</sub>)<sub>2</sub>] (which has large Mg–N–Si bond angles of 139.2(1)<sup>o</sup>),<sup>662</sup> [Mg(tmeda){O(2,6-<sup>t</sup>Bu<sub>2</sub>C<sub>6</sub>H<sub>3</sub>)<sub>2</sub>}<sub>2</sub>],<sup>195</sup> [Ca(tmeda){N(SiMe<sub>3</sub>)<sub>2</sub>}<sub>2</sub>],<sup>663</sup> [Ca(tmeda)(N<sup>t</sup>Pr<sub>2</sub>)<sub>2</sub>],<sup>663</sup> [Ba(tmeda){N(SiMe<sub>3</sub>)<sub>2</sub>}<sub>2</sub>],<sup>664</sup> [AlBr<sub>2</sub>(tmeda)]<sup>+</sup>,<sup>622</sup> and [GaCl<sub>2</sub>(tmeda)]<sup>+</sup>.<sup>622</sup>

Complexes with CN = 5 are exemplified by the square-based pyramidal [K(tmeda)<sub>2</sub>{Si(SiMe<sub>3</sub>)<sub>3</sub>}],<sup>665</sup> trigonal bipyramidal [Mg(tmeda)Br<sub>2</sub>(THF)],<sup>666</sup> [Sr(tmeda)(NPh<sup>t</sup>Pr)<sub>2</sub>(THF)],<sup>667</sup> [In(tmeda)I<sub>3</sub>],<sup>668</sup> and [Sb(tmeda)F<sub>3</sub>]<sup>669</sup>; the latter is unstable unless at low temperatures under inert conditions. Examples of octahedral species include *trans*-[MgBr<sub>2</sub>(tmeda)<sub>2</sub>],<sup>670</sup> *trans*-[CaI<sub>2</sub>(tmeda)<sub>2</sub>],<sup>671</sup> *trans*-[AlH<sub>2</sub>(tmeda)<sub>2</sub>]<sup>+</sup>,<sup>672</sup> [In(tmeda)Cl<sub>4</sub>],<sup>668</sup> [Ge(tmeda)X<sub>4</sub>] (X = F, Cl, Br),<sup>336,538</sup> and [Ge(tmeda)Cl<sub>2</sub>(N<sub>3</sub>)<sub>2</sub>] (with *trans* azido ligands).<sup>336</sup>

Dimers with {M<sub>2</sub>(tmeda)<sub>2</sub>(μ-X)} motifs are represented by [Li<sub>2</sub>(tmeda)<sub>2</sub>(μ-Cl)<sub>2</sub>],<sup>250</sup> [Li<sub>2</sub>(tmeda)<sub>2</sub>(μ-Br)<sub>2</sub>],<sup>673,674</sup> [Li<sub>2</sub>(tmeda)<sub>2</sub>(μ-OMes)<sub>2</sub>] (note there is a change to a monomer when the ArO<sup>−</sup> ligand is more bulky, see above),<sup>650</sup> a series of [Li<sub>2</sub>(tmeda)<sub>2</sub>{μ-OSArR}<sub>2</sub>] dimers (prepared by lithiation of ArRS=O by <sup>n</sup>BuLi in tmeda),<sup>675</sup> [Li<sub>2</sub>(tmeda)<sub>2</sub>(μ-E<sup>n</sup>Bu)<sub>2</sub>] (E = Se, Te),<sup>676</sup> [M<sub>2</sub>(tmeda)<sub>2</sub>(μ-HBEt<sub>3</sub>)<sub>2</sub>] (M = Na, K),<sup>677</sup> [Na<sub>2</sub>(tmeda)<sub>2</sub>(μ-NPh<sup>t</sup>Pr)<sub>2</sub>],<sup>183</sup> [Rb<sub>2</sub>(tmeda)<sub>2</sub>{μ-N(SiMe<sub>3</sub>)<sub>2</sub>}<sub>2</sub>],<sup>660</sup> and [Ge<sub>2</sub>(tmeda)<sub>2</sub>Cl<sub>2</sub>(μ-Cl)<sub>2</sub>] (in which Ge(II) is in a trigonal pyramidal environment with asymmetrical Ge–Cl⋯Ge bridges).<sup>678</sup>

A number of other species are worthy of note. Reaction of the borazine B<sub>3</sub>Ph<sub>3</sub>N<sub>3</sub>H<sub>3</sub> with LiMe/Li/tmeda in Et<sub>2</sub>O leads to [Li(tmeda)(μ-Ph<sub>3</sub>B<sub>3</sub>N<sub>3</sub>H<sub>2</sub>)Li](tmeda).<sup>679</sup> Similarly, trimethylborazine is deprotonated when treated with BuLi in tmeda giving rise to [Li<sub>4</sub>(tmeda)<sub>2</sub>(μ-tmeda)(μ-B<sub>3</sub>Me<sub>2</sub>N<sub>3</sub>H<sub>2</sub>)<sub>4</sub>] (Fig. 37B).<sup>680</sup> The reactions of Li, Na or K with MesPCL<sub>2</sub> yields MPHMe<sub>s</sub>; for M = Na, the tmeda adduct is the 1D-coordination polymer [Na(tmeda)(μ-PHMe<sub>s</sub>)<sub>n</sub>].<sup>681</sup> An [Mg<sub>3</sub>Cl<sub>5</sub>]<sup>+</sup> unit is stabilized by tmeda in the triangular [Mg<sub>3</sub>(tmeda)<sub>3</sub>(μ-Cl)<sub>3</sub>(μ<sub>3</sub>-Cl)<sub>2</sub>]<sup>+</sup>.<sup>682,683</sup> Sr<sup>2+</sup> is 11-coordinate in [Sr<sub>2</sub>(tmeda)<sub>2</sub>{Me<sub>2</sub>N(BH<sub>3</sub>)<sub>2</sub>}<sub>2</sub>] (Fig. 37C) and was characterized as part of an investigation of complexes of Sr for use as CVD precursors.<sup>684</sup> The [Me<sub>2</sub>N(BH<sub>3</sub>)<sub>2</sub>]<sup>−</sup> ligand coordinates to Ba<sup>2+</sup> through four B–H–Ba interactions in the 10-coordinate [Ba(tmeda){Me<sub>2</sub>N(BH<sub>3</sub>)<sub>2</sub>}<sub>2</sub>].<sup>685</sup> The dissolution of solid indium(I) iodide in a mixture of toluene and tmeda led to the isolation of crystals of [In<sub>6</sub>I<sub>8</sub>(tmeda)<sub>4</sub>] (Fig. 37D) which is the first example of a neutral indium sub-halide cluster complex; thermal decomposition of the latter gave [In<sub>2</sub>I<sub>4</sub>(tmeda)<sub>2</sub>].<sup>686</sup> Dissolving InBr in toluene/tmeda produced [In<sub>2</sub>Br<sub>4</sub>(tmeda)<sub>2</sub>], the transformation being reversible; storing the solution at low temperature resulted in crystals of [InBr(tmeda)] which, in the solid state, associates as a weakly bound dimer with an In⋯In = 3.678(2) Å.<sup>687</sup> Reaction of Pb(SAr)<sub>2</sub> with (Ar = 2,6-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>) with tmeda leads to [Pb(tmeda)(SAr)][Pb(SAr)<sub>3</sub>] in which there are close S⋯Pb contacts between the two units.<sup>688</sup>

### 1.02.2.2 Imidoamidate and guanidinate ligands

The general structures of imidoamidate and guanidinate anions are shown in Scheme 4. As in previous sections, we can only provide selected examples of their main group metal complexes, and we focus on relatively simple structures with compounds containing M–C bonds being excluded. Many imidoamidate and guanidinate complexes are of interest for their catalytic properties.<sup>69,689,690</sup>

Scheme 4 suggests that imidoamidates are pre-designed as chelating ligands and of the very many such complexes, examples with group 2 metals are tetrahedral [Mg{<sup>t</sup>BuC(NMes)<sub>2</sub>}<sub>2</sub>],<sup>691</sup> 5-coordinate [Mg(THF){HC(NDipp)<sub>2</sub>}<sub>2</sub>],<sup>692</sup> distorted octahedral *cis*-[Ca(THF)<sub>2</sub>{BzC(N<sup>t</sup>Bu)<sub>2</sub>}<sub>2</sub>],<sup>693</sup> *trans*-[Mg(THF)<sub>2</sub>{MeC(NCy)<sub>2</sub>}<sub>2</sub>],<sup>694</sup> and the dimer [Mg<sub>2</sub>(OEt<sub>2</sub>)<sub>2</sub>{MesC(NCy)<sub>2</sub>}<sub>2</sub>(μ-Br)<sub>2</sub>].<sup>695</sup> However, it is important to recognize that a range of other bonding modes is also possible, and we illustrate these with complexes of the s-block metals; a monodentate mode is exemplified in [GaH<sub>2</sub>(quin){HC(NDipp)<sub>2</sub>}]<sup>696</sup> which is discussed later. A combination of chelation and bridging is found in [Li<sub>2</sub>(OEt<sub>2</sub>)<sub>2</sub>{μ-PhC(NSiMe<sub>3</sub>)(N<sup>n</sup>Pr)}<sub>2</sub>] (Fig. 38A)<sup>697</sup> and in a range of other dilithium species.<sup>698–703</sup> A simple bridging mode is exemplified in the dilithium complexes [Li<sub>2</sub>(THF)<sub>2</sub>{μ-THF}{μ-HC(N(4-MeC<sub>6</sub>H<sub>4</sub>))<sub>2</sub>}<sub>2</sub>] (Fig. 38B) and [Li<sub>2</sub>{μ-HC(N(4-MeC<sub>6</sub>H<sub>4</sub>))<sub>2</sub>}<sub>3</sub>],<sup>704</sup> while in [Li<sub>2</sub>(THF)<sub>2</sub>{μ-HC(N(2-FC<sub>6</sub>H<sub>4</sub>))<sub>2</sub>}<sub>2</sub>], the imidoamidate bridging mode is supplemented by CF–Li interactions similar to those depicted in Fig. 8D.<sup>705</sup> The dimer [Mg<sub>2</sub>{MeC(N<sup>t</sup>Pr)<sub>2</sub>}<sub>2</sub>{μ-MeC(N<sup>t</sup>Pr)<sub>2</sub>}<sub>2</sub>] exhibits both chelating and bridging imidoamidates.<sup>706</sup> Fig. 38C depicts an example of another bridging motif, illustrated with the structure of [K<sub>2</sub>{μ-PhC(NCHMePh)<sub>2</sub>}<sub>2</sub>].<sup>707</sup> In the coordination polymer [Na(THF)<sub>2</sub>{μ-<sup>t</sup>BuC(NH)(NDipp)}<sub>n</sub>], the imidoamidate anion acts as a ditopic ligand (Fig. 38D),<sup>708</sup> and a similar structure is observed in [Li(THF)<sub>2</sub>{μ-PhC(NH)(N(2-<sup>t</sup>PrC<sub>6</sub>H<sub>4</sub>))}]<sub>n</sub>.<sup>709</sup>

**Scheme 4** The general structures of imidoamidate (also called amidinate, left) and guanidinate (middle) ligands, and the structure of guanidine (H<sub>5</sub>Gu).

**Fig. 38** Structures of (A)  $[\text{Li}_2(\text{OEt}_2)_2\{\text{PhC}(\text{NSiMe}_3)(\text{N}^i\text{Pr})_2\}]_2$  (CSD refcode AGOJOV; Et<sub>2</sub>O shown in stick representation for clarity), (B)  $[\text{Li}_2(\text{THF})_2(\mu\text{-THF})\{\text{HC}(\text{N}(4\text{-MeC}_6\text{H}_4))_2\}]_2$  (refcode AGONAL; THF shown in stick representation), (C)  $[\text{K}_2\{\mu\text{-PhC}(\text{NCHMePh})_2\}]_2$  (refcode AQISAV), (D) part of a chain in  $[\text{Na}(\text{THF})_2\{\mu\text{-}^t\text{BuC}(\text{NH})(\text{NDipp})\}]_n$  (refcode AROXUC, THF in stick representation, and only NH H atoms shown).

Other s-block metal complexes with imidoamidate ligands which demand attention include  $[\text{Mg}\{(4\text{-MeC}_6\text{H}_4)\text{C}(\text{NDipp})_2\}]_2$ . This is a rare example of square-planar  $\text{Mg}^{2+}$  which is not imposed by a porphyrinato environment<sup>710</sup>; a further example of square-planar  $\text{Mg}^{2+}$  is the guanidinate complex  $[\text{Mg}\{(\text{C}_2\text{N})\text{C}(\text{NMe}_5)_2\}]_2$ .<sup>711</sup> Beryllium complexes with imidoamidate ligands are sparse, and are represented by the tetrahedral  $[\text{BeCl}_2\{\text{PhC}(\text{NSiMe}_3)_2\}]_2$ ,<sup>508</sup> and  $[\text{Be}\{\text{EtC}(\text{NDipp})_2\}]_2$ ,<sup>712</sup> and the centrosymmetric dimer  $[\text{Be}_2(\mu\text{-OEt})_2\{^t\text{BuC}(\text{NDipp})_2\}]_2$ .<sup>712</sup>

Lithio derivatives are typical precursors to p-block metal complexes. For example, treatment of  $[\text{Li}\{\text{PhC}(\text{NSiMe}_3)_2\}]$  with  $\text{GeCl}_2$  leads to  $[\text{GeCl}\{\text{PhC}(\text{NSiMe}_3)_2\}]$ ,<sup>713</sup> reaction of  $[\text{Li}\{(4\text{-}^t\text{BuC}_6\text{H}_4)\text{C}(\text{NDipp})_2\}]$  with  $\text{SnCl}_2$  yields  $[\text{SnCl}\{(4\text{-}^t\text{BuC}_6\text{H}_4)\text{C}(\text{NDipp})_2\}]$ ,<sup>714</sup> and reaction of  $\text{SnCl}_2$  with  $[\text{Li}\{^m\text{BuC}(\text{NCy})_2\}]$  gives  $[\text{SnCl}\{^m\text{BuC}(\text{NCy})_2\}]$ .<sup>715</sup> In each case, the imidoamidate ligand is chelating. Reaction of  $[\text{Li}\{^t\text{BuC}(\text{N}^i\text{Pr})_2\}]$  with  $\text{GaI}_3$  produces  $[\text{GaI}_2\{^t\text{BuC}(\text{N}^i\text{Pr})_2\}]$ , while with  $\text{GaI}$ , the product is the trigallium species shown in Fig. 39A; replacing the C<sup>t</sup>Bu unit in the imidoamidate ligand by CMe redirects the assembly to a tetragallium complex.<sup>716</sup>

**Fig. 39** Structures of (A)  $[\text{Ga}_3\text{I}_2\{^t\text{BuC}(\text{N}^i\text{Pr})_2\}]_3$  (CSD refcode FUBHES), (B)  $[\text{AlCl}_2\{\text{DippC}(\text{N}^i\text{Pr})_2\}]$  (refcode AGEMUU), (C)  $[\text{Al}\{\text{PhC}(\text{NPh})_2\}]_3$  (refcode QETBAS, in space-filling representation), (D)  $[\text{Ge}_6\{\text{PhC}(\text{N}^t\text{Bu})_2\}]_4$  (refcode GIHZOO), (E)  $[\text{Pb}\{\text{HC}(\text{NDipp})_2\}]_2$  (refcode GODWUS), and (F)  $[\text{Bi}\{\text{HC}(\text{NMe}_5)_2\}]_3$  (refcode PIHHYI). In (E) and (F), ligands are shown in stick representation for clarity.

**Scheme 5** Examples of imidoamidates with two metal-binding domains.

Derivatives of group 13 metals are well represented. The use of sterically demanding Dipp substituents which provide 'bowl-shaped' ligands (e.g., in the Al(III) complex shown in Fig. 39B) has been described by Arnold.<sup>717</sup> The same tetrahedral  $\{\text{AlCl}_2\text{N}_2\}$  motif is found in  $[\text{AlCl}_2\{\text{PhC}(\text{N}^t\text{Pr})_2\}_2]$ , and this derivative has been used as a precursor for the synthesis via salt metathesis of complexes with Al–M bonds.<sup>718</sup> Cole et al. showed that the reaction of  $[\text{GaH}_3(\text{quin})]$  with one equivalent of  $\text{H}_2\text{C}(\text{NDipp})_2$  resulted in the formation of tetrahedral  $[\text{GaH}_2(\text{quin})\{\text{HC}(\text{NDipp})_2\}]$  in which the imidoamidate ligand is monodentate; the fact that the quin ligand is not displaced is explained in terms of its strong Lewis basicity.<sup>696</sup> Examples of 5-coordinate  $\{\text{MX}(\text{imidoamidate})_2\}$  complexes include  $[\text{AlH}\{\text{PhC}(\text{N}^t\text{Bu})_2\}_2]$ ,<sup>719</sup>  $[\text{InX}\{\text{PhC}(\text{N}^t\text{Bu})_2\}_2]$  (X = Cl, Br),<sup>720</sup> and  $[\text{InCl}\{\text{MeC}(\text{N}^t\text{Pr})_2\}_2]$ .<sup>721</sup> With less sterically crowded ligands, octahedral tris-chelates can be accommodated, e.g., in  $[\text{Al}\{\text{MeC}(\text{N}^t\text{Pr})_2\}_3]$ ,<sup>722</sup>  $[\text{M}\{\text{HC}(\text{NSiMe}_3)_2\}_3]$  (M = Al, Ga),<sup>723</sup> and  $[\text{In}\{\text{MeC}(\text{N}^t\text{Pr})_2\}_3]$ .<sup>721</sup> Interestingly, even with the relatively sterically encumbered  $[\text{PhC}(\text{NPh})_2]^-$  ligand, interlocking of the phenyl substituents (Fig. 39C) allows three ligands to be accommodated in  $[\text{Al}\{\text{PhC}(\text{NPh})_2\}_3]$ .<sup>724</sup> Ligands such as those shown in Scheme 5 allow the formation of dinuclear complexes, e.g., coordinating to two  $\{\text{AlX}_2\}$  units.<sup>725</sup>

Imidoamidate complexes of Ge(II) and Sn(II) are well established, and examples prepared from lithium derivatives were mentioned earlier. Many feature halido or amido ligands and possess 3-coordinate molecular structures, e.g.,  $[\text{GeCl}\{\text{PhC}(\text{N}^t\text{Bu})_2\}]$ ,<sup>726</sup>  $[\text{SnCl}\{\text{PhC}(\text{N}^t\text{Bu})_2\}]$ ,<sup>727</sup> and  $[\text{M}\{\text{N}(\text{SiMe}_3)_2\}\{\text{PhC}(\text{N}^t\text{Bu})_2\}]$  with M = Ge or Sn (which are catalysts for phenyl isocyanate cyclization).<sup>728</sup> Reduction of  $[\text{GeCl}\{\text{PhC}(\text{N}^t\text{Bu})_2\}]$  by K in THF results in the formation of  $[\text{Ge}_2\{\text{PhC}(\text{N}^t\text{Bu})_2\}_2]$  which contains an unsupported Ge–Ge bond.<sup>726</sup> In  $[\text{Ge}(\mu\text{-O}_3\text{SCF}_3)\{\text{PhC}(\text{N}^t\text{Bu})_2\}]_n$ , the triflate ions bridge between pairs of Ge centers to give a 1D-polymer decorated with chelating imidoamidate ligands.<sup>727</sup> Yeong et al. reported two interesting complexes with  $\text{Ge}_2\text{Sn}_2$  and  $\text{Ge}_4$  cores supported by imidoamidate ligands and bearing low-valent  $\text{Ge}\{\text{PhC}(\text{N}^t\text{Bu})_2\}$  substituents (Fig. 39D); a theoretical investigation confirmed planar charge-separated core-structures.<sup>729</sup> With the use of the sterically demanding  $[\text{RC}(\text{NDipp})_2]^-$  ligands (R = H, <sup>t</sup>Bu), it has been possible to isolate the thermally stable Pb(II) complexes  $[\text{Pb}\{\text{HC}(\text{NDipp})_2\}_2]$  (with a geometry indicative of a stereochemically active lone pair on Pb, Fig. 39E) and  $[\text{PbCl}\{\text{BuC}(\text{NDipp})_2\}]_2$  (in which pairs of molecules are weakly associated through  $\text{Pb}\cdots\text{Cl}$  interactions,  $\text{Pb}\cdots\text{Cl} = 2.571(2)$ ,  $\text{Pb}\cdots\text{Cl} = 3.260(2)$  Å).<sup>730</sup>

Imidoamidate complexes of the heavier group 15 elements are represented by  $[\text{SbCl}_2\{\text{BuC}(\text{N}^t\text{Pr})_2\}]$ ,  $[\text{SbCl}_2\{\text{BuC}(\text{NCy})_2\}]$ ,  $[\text{SbCl}_2\{\text{BuC}(\text{NDipp})_2\}]$ ,  $[\text{BiCl}_2\{\text{BuC}(\text{NDipp})_2\}]$  and  $[\text{Bi}_2\text{Cl}_2(\mu\text{-Cl})_2\{\text{BuC}(\text{N}^t\text{Pr})_2\}_2]$  and this series illustrates the influence of both the metal and ligand on the coordination geometry.<sup>731</sup> In  $[\text{Bi}\{\text{HC}(\text{NMes})_2\}_3]$  (Fig. 39F), two NC(H)N units are roughly coplanar while the third lies perpendicular to this plane, leaving a vacant coordination site below the plane.<sup>732</sup>

Guanidates (Scheme 3) offer the same donor set as imidoamidates with the peripheral  $\text{NR}_2$  (R ≠ H) unit remaining non-coordinated. Similar families of metal complexes with the two ligands types are thus expected and are observed. Within group 1, we observe mononuclear complexes with simple chelating guanidinate ligands,<sup>733</sup> as well as dinuclear species in which the guanidinate acts simultaneously in chelating and bridging modes (e.g., Fig. 40A).<sup>169,702,734–741</sup> A simple bridging mode of a guanidinate ligand is illustrated in  $[\text{Li}_2(\text{THF})_2\{\mu\text{-Me}_2\text{NC}(\text{NPh})(\text{NSiMe}_3)\}_2]$ .<sup>741</sup> In the solid state and in the absence of a donor solvent, [Li

**Fig. 40** Structures of (A)  $[\text{Li}_2(\text{OEt}_2)_2\{\text{Et}_2\text{NC}(\text{NPh})(\text{N}(2,6\text{-Me}_2\text{C}_6\text{H}_3)\}_2)]_2$  (CSD refcode CUHQUT), (B)  $[\text{Li}\{\text{Me}_2\text{NC}(\text{N}^t\text{Bu})_2\}_4]$  (refcode HATZAF), (C)  $[\text{Mg}_2\{\text{Pr}_2\text{NC}(\text{NDipp})_2\}_2]$  (refcode JISWIS), (D)  $[\text{Sn}\{(\text{Me}_3\text{Si})_2\text{NC}(\text{N}(4\text{-Me}_6\text{C}_6\text{H}_4)\}_2)]_2$  (refcode APIHUE), and (E)  $[\text{SnCl}\{(\text{Me}_3\text{Si})_2\text{NC}(\text{N}^t\text{Pr})_2\}]$  (refcode HUKQAI).

$\{\text{Me}_2\text{NC}(\text{N}^t\text{Bu})_2\}$ ] exists as the tetramer shown in Fig. 40B in which each guanidinate acts as a ditopic ligand, bridging two Li centers.<sup>737</sup>

Just as with imidoamidates, there is a variety of group 2 metal complexes of guanidinate with CN = 5 or 6. These include  $[\text{M}(\text{OEt})_2\{\text{(Me}_3\text{Si)}_2\text{NC}(\text{NCy})_2\}_2]$  (M = Ca, Sr),<sup>742</sup>  $[\text{Mg}(\text{THF})\{\text{(Me}_3\text{Si)}_2\text{NC}(\text{N}^i\text{Pr})_2\}_2]$ ,<sup>743</sup> and the dimer  $[\text{Mg}_2(\text{THF})_2\{\text{(Me}_3\text{Si)}_2\text{NC}(\text{NCy})_2\}_2(\mu\text{-Cl})_2]$ .<sup>744</sup> Green et al. have demonstrated that the reduction of  $[\text{Mg}_2(\text{OEt})\{\text{Pr}_2\text{NC}(\text{NDipp})_2\}_2(\mu\text{-I})_2]$  (which contains sterically demanding Dipp substituents) with metallic K results in the formation of the Mg(I) complex  $[\text{Mg}_2\{\text{Pr}_2\text{NC}(\text{NDipp})_2\}_2]$  with an unsupported Mg–Mg bond (Fig. 40C, Mg–Mg = 2.8508(12) Å).<sup>745</sup> The sterically crowded  $[\text{Pr}_2\text{NC}(\text{NDipp})_2]^-$  forms severely distorted 4-coordinate  $[\text{ML}_2]$  complexes with  $\text{Ca}^{2+}$  and  $\text{Sr}^{2+}$ .<sup>746</sup> Kays and coworkers have reported the formation of a series of Mg(II) complexes incorporating the sterically demanding ligand  $[\text{Cy}_2\text{NC}(\text{NMe}_s)_2]^-$ . These include  $[\text{MgI}\{\text{Cy}_2\text{NC}(\text{NMe}_s)_2\}]$  which was isolated in the form of the cubane  $[\text{Mg}_4\{\text{Cy}_2\text{NC}(\text{NMe}_s)_2\}_4(\mu_3\text{-I})_4]$  and the dimer  $[\text{Mg}_2\{\text{Cy}_2\text{NC}(\text{NMe}_s)_2\}_2(\text{OEt})_2(\mu\text{-I})_2]$ .<sup>711</sup> Of particular note is  $[\text{Mg}\{\text{(Cy}_2\text{N})\text{C}(\text{NMe}_s)_2\}_2]$  with sterically demanding ligands with surround a square-planar  $\text{Mg}^{2+}$  center. Significantly, this preference is not wholly due to steric constraints because the 5-coordinate THF adduct  $[\text{Mg}(\text{THF})\{\text{Cy}_2\text{NC}(\text{NMe}_s)_2\}_2]$  has also been structurally characterized. Moving to the larger group 2 metals allows the CN to increase to 6 in  $[\text{M}(\text{THF})_2\{\text{Cy}_2\text{NC}(\text{NMe}_s)_2\}_2]$  (M = Ca, Sr), while for  $\text{Ba}^{2+}$ , there is a preference for  $\text{Ba}^{2+} \cdots \pi_{\text{arene}}$  interactions in  $[\text{Ba}\{\text{Cy}_2\text{NC}(\text{NMe}_s)_2\}_2]$ .<sup>711</sup> A CN of 6 is also exemplified in *cis*- $[\text{M}(\text{THF})_2\{\text{Ph}_2\text{NC}(\text{N}^i\text{Pr})_2\}_2]$  (M = Ca, Sr) and *trans*- $[\text{Ca}(\text{THF})_2\{\text{(Me}_3\text{Si)}_2\text{NC}(\text{NCy})_2\}_2]$ .<sup>747</sup>

Tetrahedral group 13 metal  $[\text{MX}_2(\text{guanidinate})]$  complexes are represented by  $[\text{AlCl}_2\{\text{Pr}_2\text{NC}(\text{NCy})_2\}]$ ,<sup>718</sup>  $[\text{GaCl}_2\{\text{Pr}_2\text{NC}(\text{N}^i\text{Pr})_2\}]$ ,<sup>736</sup>  $[\text{Al}\{\text{NHDipp}\}_2\{\text{(Me}_3\text{Si)}_2\text{NC}(\text{NCy})_2\}]$ ,<sup>748</sup> and  $[\text{GaI}_2\{\text{Cy}_2\text{NC}(\text{NDipp})_2\}]$ .<sup>749</sup> The dimer  $[\text{Al}_2\text{Cl}_4\{\mu\text{-}\{\text{Me}_2\text{NC}(\text{NMe})_2\}\}_2]$  is an interesting example in which the guanidinate ligand adopts a bridging mode in preference to the halide ligands.<sup>750</sup> Five-coordinate complexes of the type  $[\text{MX}(\text{guanidinate})_2]$  (M = Al, Ga; X = H, halide,  $\text{NR}_2$ ) with square-pyramidal structures have been detailed.<sup>734,736,751,752</sup> In group 13, octahedral tris(chelates) are found for sterically non-congested ligands,<sup>753,754</sup> and have been assessed as precursors for  $\text{In}_2\text{O}_3$  thin films.<sup>753,754</sup> By using the sterically congested guanidinate ligands  $[\text{Cy}_2\text{NC}(\text{NDipp})_2]^-$  and  $[\text{Pr}_2\text{NC}(\text{NDipp})_2]^-$ , Jones et al. were able to isolate the air-sensitive, but thermally stable, Ga(I) and In(I)  $[\text{ML}]$  complexes; DFT calculations reveal that these complexes should behave as good  $\sigma$ -donor and weak  $\pi$ -acceptor metalloligands.<sup>749,755</sup>

Group 14 metal(II) complexes include 4- and 3-coordinate Sn(II) guanidinate formed, respectively, from reactions of  $\text{R-N}=\text{C}=\text{N-R}'$  with  $[\text{Sn}\{\text{N}(\text{SiMe}_3)_2\}_2]$  or  $[\text{SnCl}\{\text{N}(\text{SiMe}_3)_2\}]$ ; Fig. 40D shows the structure of  $[\text{Sn}\{\text{(Me}_3\text{Si)}_2\text{NC}(\text{N}(4\text{-MeC}_6\text{H}_4))_2\}_2]$  as an example.<sup>756</sup> Similar structures are found for  $[\text{Sn}\{\text{(Me}_3\text{Si)}_2\text{NC}(\text{N}^i\text{Pr})_2\}_2]$ ,<sup>757</sup>  $[\text{Sn}\{\text{(Me}_3\text{Si)}_2\text{NC}(\text{NCy})_2\}_2]$ ,<sup>757</sup>  $[\text{Sn}\{\text{Me}_2\text{NC}(\text{NCy})_2\}_2]$ ,<sup>758</sup> and  $[\text{Sn}\{\text{CyHNC}(\text{NCy})_2\}_2]$ .<sup>759</sup> This structure type is also represented in Sn(II) complexes with one amidinate and one guanidinate ligand, the first example of which appeared in 2014.<sup>760</sup> The structure of  $[\text{SnCl}\{\text{(Me}_3\text{Si)}_2\text{NC}(\text{N}^i\text{Pr})_2\}]$  (Fig. 40E)<sup>757</sup> is typical of  $[\text{MX}(\text{guanidinate})]$  complexes (M<sup>II</sup> = Ge, Sn, Pb).<sup>758,761–763</sup> The oxidative addition of  $\text{Ph}_2\text{E}_2$  (E = S, Se, Te) to  $[\text{Sn}\{\text{Me}_2\text{NC}(\text{NCy})_2\}_2]$  results in the formation of Sn(IV) complexes, e.g.,  $[\text{Sn}(\text{TePh})_2\{\text{Me}_2\text{NC}(\text{NCy})_2\}_2]$ , which have been applied as precursors to SnE nanocrystals.<sup>764</sup> Reactions between elemental S or Se with  $[\text{Sn}^{\text{II}}\{\text{Me}_2\text{NC}(\text{NCy})_2\}_2]$  also result in oxidative addition to yield  $[\text{Sn}^{\text{IV}}(\text{E}_4)\{\text{Me}_2\text{NC}(\text{NCy})_2\}_2]$  in which  $\text{S}_4^{2-}$  or  $\text{Se}_4^{2-}$  ligands adopt chelating modes.<sup>758</sup> Reactions of  $[\text{Ge}^{\text{II}}(\text{N}(\text{SiMe}_2)_2)\{\text{Pr}_2\text{NC}(\text{N}(2,6\text{-Me}_2\text{C}_6\text{H}_3))_2\}_2]$  with elemental S or Se yield the tetrahedral  $[\text{Ge}^{\text{IV}}\text{E}(\text{N}(\text{SiMe}_2)_2)\{\text{Pr}_2\text{NC}(\text{N}(2,6\text{-Me}_2\text{C}_6\text{H}_3))_2\}_2]$  containing  $\text{E}^{2-}$  (E = S, Se) ligands, whereas analogous reactions with the Sn(II) analogs lead to  $[\text{Ge}^{\text{IV}}(\text{E}_4)(\text{N}(\text{SiMe}_2)_2)\{\text{Pr}_2\text{NC}(\text{N}(2,6\text{-Me}_2\text{C}_6\text{H}_3))_2\}_2]$  with chelating  $\text{E}_4^{2-}$  as described above.<sup>765</sup> Treatment of  $\text{SnCl}_4$  with triisopropylguanidine yields  $[\text{SnCl}_2\{\text{PrHNC}(\text{N}^i\text{Pr})_2\}]$  which adopts the expected tetrahedral geometry.<sup>759</sup> Earlier in this section, we described the use of sterically demanding  $[\text{RC}(\text{NDipp})_2]^-$  ligands (R = H,  $^t\text{Bu}$ ) to isolate thermally stable imidoaminate Pb(II) complexes. Related to this are the dimers  $[\text{PbCl}\{\text{DippHNC}(\text{NDipp})_2\}_2]$  and  $[\text{PbCl}\{\text{Cy}_2\text{NC}(\text{NDipp})_2\}_2]$ .<sup>730</sup>

For the group 15 metals, 4-coordinate  $[\text{M}^{\text{III}}\text{X}_2(\text{guanidinate})]$  complexes are represented by  $[\text{MCl}_2\{\text{Cy}_2\text{NC}(\text{NDipp})_2\}]$  (M = As, Sb), and  $[\text{SbI}_2\{\text{Cy}_2\text{NC}(\text{NDipp})_2\}]$ , all with distorted disphenoidal structures, consistent with a stereochemically active lone pair on the metal center.<sup>766</sup> Reduction of  $[\text{AsCl}_2\{\text{Cy}_2\text{NC}(\text{NDipp})_2\}]$  using  $\text{KC}_8$  yielded the dimeric  $[\text{As}_2\{\mu\text{-}\{\text{Cy}_2\text{NC}(\text{NDipp})_2\}_2\}]$  with a planar  $\text{As}_2\text{N}_4$  framework (Fig. 41A).<sup>766</sup> The tris(chelate)  $[\text{Bi}\{\text{Me}_2\text{NC}(\text{N}^i\text{Pr})_2\}_3]$  has the structure shown in Fig. 41B with the coordination sphere consistent with the presence of a stereochemically active lone pair.<sup>767</sup>

Before leaving guanidinate metal complexes, we should mention s-block metal complexes which incorporate conjugate bases of guanidine ( $\text{H}_5\text{Gu}$ ). The very strong basicity of  $[\text{H}_4\text{Gu}]^-$  coupled with moisture sensitivity of its compounds have served as barriers to the isolation of group 1 metal salts.<sup>768</sup>  $[\text{Li}(\text{H}_4\text{Gu})]_n$  was the last of the alkali metal guanidates to be isolated (from guanidine and Li in liquid  $\text{NH}_3$  under pressure, or from solid guanidine and LiH) and structurally characterized. Each  $\text{Li}^+$  center is tetrahedrally bound by one  $\text{NH}_2$  and three  $\text{NH}$  units.<sup>768</sup>  $[\text{Na}(\text{H}_4\text{Gu})]_n$  and  $[\text{K}(\text{H}_4\text{Gu})]_n$  have been prepared from  $\text{H}_5\text{Gu}$  and either Na or K in liquid  $\text{NH}_3$  at  $P \approx 10$  atm and ambient temperature. In the  $\text{Na}^+$  salt, each metal center is tetrahedrally sited, whereas  $\text{K}^+$  coordination environments in  $[\text{K}(\text{H}_4\text{Gu})]_n$  are irregular.<sup>769</sup> While the structures of  $[\text{Li}(\text{H}_4\text{Gu})]_n$  and  $[\text{Na}(\text{H}_4\text{Gu})]_n$  are similar, they differ in that 1D-chains of linked  $\text{LiN}_4$ -tetrahedra are found in the latter contrasting with what are described as ‘edge-sharing tetrahedra’ in the  $\text{Li}^+$  salt; analysis of the structure illustrates an overall sheet assembly (Fig. 41C).<sup>768</sup> Crystalline  $[\text{Rb}(\text{H}_4\text{Gu})]_n$  and  $[\text{Cs}(\text{H}_4\text{Gu})]_n$  (prepared using the liquid  $\text{NH}_3$  route described above) possess the same structure type (Fig. 41D).<sup>770</sup> Group 2 metal guanidates are represented by  $[\text{Ca}(\text{H}_3\text{Gu})]_n$  (prepared in liquid  $\text{NH}_3$  by a similar strategy as described above) and  $[\text{Sr}(\text{H}_3\text{Gu})]_n$  which are isostructural<sup>771</sup>; note that in each compound, guanidine is doubly-deprotonated. In contrast, the barium compound  $[\text{Ba}(\text{H}_4\text{Gu})_2]_n$  contains the  $[\text{H}_4\text{Gu}]^-$  ligand. A liquid ammonia route in an autoclave was again used and precise stoichiometric amounts of reactants are essential for the isolation of phase-pure  $[\text{Ba}(\text{H}_4\text{Gu})_2]_n$ ; each  $\text{Ba}^{2+}$  ion is 8-coordinate and the assembly extends to give a 2D-sheet structure. In Fig. 41E, the different *syn* and *anti*-conformations of the  $[\text{H}_4\text{Gu}]^-$  ligands are highlighted in red.<sup>772</sup>

**Fig. 41** Structures of (A)  $[\text{As}_2\{\mu\text{-}(\text{Cy}_2\text{NC}(\text{NDipp})_2)_2\}]_2$  (CSD refcode JEWRUZ) and (B)  $[\text{Bi}(\text{Me}_2\text{NC}(\text{N}'\text{Pr})_2)_3]$  (refcode OSENEI). (C) Part of the sheet structure of  $[\text{Li}(\text{H}_4\text{Gu})]_n$  viewed down the crystallographic  $b$ -axis (refcode KUTFEQ). (D) Part of the 3D-structure of  $[\text{Rb}(\text{H}_4\text{Gu})]_n$  viewed down the  $b$ -axis (refcode XUNJEX). (E) Part of one sheet in  $[\text{Ba}(\text{H}_4\text{Gu})]_n$  viewed down the  $c$ -axis, and emphasizing in red that both *syn*- and *anti*-conformations of the ligand are present (refcode VUDKAJ01).

**Scheme 6** General structures of  $\beta$ -diketiminato ligands. The abbreviation  $[\text{Nacnac}]^-$  and  $[\text{Me}_2\text{N-Nacnac}]^-$  are used in the text (here and in later sections) with Ar specified.

### 1.02.2.2.3 $\beta$ -Diketiminates

$\beta$ -Diketiminato ligands are widely used both in main group coordination and organometallic compounds, and a number of derivatives have already been included in earlier sections. The examples below are necessarily selective, and have been chosen to illustrate (i) coordination to metals from each of the s- and p-block groups, and (ii) structural dependence on the size of the N-substituents. The general  $\beta$ -diketiminato structure is shown in **Scheme 6**;  $[\text{Nacnac}]^-$  is commonly used as an abbreviation for the general class shown at the right of **Scheme 6**, and sterically demanding  $[\text{Nacnac}]^-$  ligands are employed to kinetically stabilize extremely reactive low-oxidation state main group metal complexes.<sup>773</sup>

Lithiation of  $\text{HNacnac}$  (Ar = 2,6- $\text{F}_2\text{C}_6\text{H}_3$ ) in  $\text{Et}_2\text{O}$  or THF yields the 3-coordinate  $[\text{Li}(\text{OEt}_2)(\text{Nacnac})]$  or  $[\text{Li}(\text{THF})(\text{Nacnac})]$ , respectively, whereas reaction in pentane leads to the dinuclear complex shown in **Fig. 42A**. In this dimer, each  $[\text{Nacnac}]^-$  ligand

**Fig. 42** Structures of (A)  $[\text{Li}_2(\text{Nacnac})_2]$  with Ar = 2,6- $\text{F}_2\text{C}_6\text{H}_3$  (CSD refcode HEFSUI), (B)  $[\text{Mg}_2(\text{Nacnac})_2(\mu\text{-AIH}_4\text{NMe}_3)_2]$  (refcode FEGJUJ), (C)  $[\text{Ca}_2(\text{THF})_2(\text{Nacnac})_2(\mu\text{-Cl})_2]$  (Ar = Dipp) (refcode DIVTEI), and (D)  $[\text{Mg}_3(\text{Nacnac})_2(\mu\text{-F})_3]$  (Ar = Mes, refcode HEMGOY).

is in both chelating and bridging modes, and one F atom of each ligand forms an F $\cdots$ Li interaction, reminiscent of similar interactions described earlier (e.g., Fig. 8D).<sup>774</sup>

Beryllium  $\beta$ -diketiminate complexes are represented by the trigonal planar [BeX(Nacnac)] (Ar = Mes; X = Br, I),<sup>659</sup> trigonal planar [BeBr(-Nacnac)] (Ar = Dipp),<sup>659</sup> trigonal planar [BeX{HC(CPh)<sub>2</sub>(NDipp)<sub>2</sub>}] (X = Cl, I),<sup>775</sup> and tetrahedral [BeBr(OEt<sub>2</sub>)(Nacnac)] (Ar = Ph).<sup>659</sup> THF reacts with [BeI{HC(CPh)<sub>2</sub>(NDipp)<sub>2</sub>}] in a ring-opening insertion reaction to yield [Be(O(CH<sub>2</sub>)<sub>4</sub>I){HC(CPh)<sub>2</sub>(NDipp)<sub>2</sub>}].<sup>775</sup> The extremely bulky TROP substituent (derived from tropone) has been incorporated into [Nacnac]<sup>-</sup> (Ar = TROP) and the asymmetric [Nacnac]<sup>-</sup> (Ar<sub>1</sub> = TROP, Ar<sub>2</sub> = Dipp). Complexes of Li<sup>+</sup> exhibit a 1:1 stoichiometry, and reactions of the two [Li(Nacnac)] complexes with MgI<sub>2</sub> in Et<sub>2</sub>O led to the 3-coordinate [MgI(Nacnac)] (Ar = TROP) and the highly distorted 4-coordinate [MgI(OEt<sub>2</sub>)(Nacnac)] (Ar<sub>1</sub> = TROP, Ar<sub>2</sub> = Dipp).<sup>776</sup> Tetrahedral Mg(II) complexes with  $\beta$ -diketiminate ligands include [MgCl(THF)(Nacnac)] (Ar = Dipp),<sup>777</sup> and [MgI(OEt<sub>2</sub>)(Nacnac)] with an asymmetric  $\beta$ -diketiminate (Ar<sub>1</sub> = CHMePh, Ar<sub>2</sub> = Dipp).<sup>778</sup> In contrast to the mononuclear [MgCl(THF)(Nacnac)] (Ar = Dipp)<sup>777</sup> and [MgIL(Nacnac)] (Ar = Mes, L = THF, OEt<sub>2</sub>),<sup>779</sup> dimeric structures are found for [Mg<sub>2</sub>(Nacnac)<sub>2</sub>( $\mu$ -I)<sub>2</sub>] (Ar = Mes),<sup>779</sup> [Mg<sub>2</sub>(Nacnac)<sub>2</sub>( $\mu$ -Cl)<sub>2</sub>] (Ar = 2,6-Et<sub>2</sub>C<sub>6</sub>H<sub>3</sub>),<sup>780</sup> and [Mg<sub>2</sub>(Nacnac)<sub>2</sub>( $\mu$ -Cl)<sub>2</sub>] (Ar = Dipp).<sup>781</sup> Bonyhady et al. made a detailed study of the varying steric effects of the N-Ar groups in the  $\beta$ -diketiminate ligands in these latter families of complexes.<sup>779</sup> [Mg<sub>2</sub>(Nacnac)<sub>2</sub>( $\mu$ -Cl)<sub>2</sub>] (Ar = 2,6-Et<sub>2</sub>C<sub>6</sub>H<sub>3</sub>) reacts with NaAlH<sub>4</sub> in Et<sub>2</sub>O to produce [Mg<sub>2</sub>(OEt<sub>2</sub>)<sub>2</sub>(Nacnac)<sub>2</sub>( $\mu$ -AlH<sub>4</sub>)<sub>2</sub>], and with AlH<sub>3</sub>(NMe<sub>3</sub>) to yield [Mg<sub>2</sub>(Nacnac)<sub>2</sub>( $\mu$ -AlH<sub>4</sub>NMe<sub>3</sub>)<sub>2</sub>] (Fig. 42B).<sup>780</sup> The calcium analog of [MgCl(THF)(Nacnac)] is a dimer (Fig. 42C) and is structurally similar to the F<sup>-</sup> and I<sup>-</sup> derivatives, and to [Ca<sub>2</sub>(NH<sub>3</sub>)<sub>4</sub>(Nacnac)<sub>2</sub>( $\mu$ -NH<sub>2</sub>)<sub>2</sub>] (Ar = Dipp). The common precursor to these compounds is [Ca(NSiMe<sub>3</sub>)(THF)(Nacnac)] (Ar = Dipp).<sup>782</sup> Hydrodehalogenation of aromatic halides using [Sr<sub>2</sub>(THF)<sub>2</sub>(Nacnac)<sub>2</sub>( $\mu$ -H)<sub>2</sub>] (Ar = 2,6-(3-pentyl)<sub>2</sub>C<sub>6</sub>H<sub>3</sub>) is a route to the halido derivatives [Sr<sub>2</sub>(THF)<sub>2</sub>(Nacnac)<sub>2</sub>( $\mu$ -X)<sub>2</sub>] with X = F, Cl, Br, I.<sup>783</sup> Earlier, we described the Mg(I) imidoaminate complex [Mg<sub>2</sub>{<sup>i</sup>Pr<sub>2</sub>NC(NDipp)<sub>2</sub>}<sub>2</sub>] which possesses an Mg-Mg bond (Fig. 40C); Green et al. have also prepared analogous complexes containing [Nacnac]<sup>-</sup> ligands with sterically demanding Ar groups.<sup>745</sup> Addition of a C-F bond across the Mg-Mg bond in [Mg<sub>2</sub>(Nacnac)<sub>2</sub>] occurs rapidly in solution to produce a new family of F-containing Grignard reagents<sup>784,785</sup>; among the compounds isolated was the trimer shown in Fig. 42D.<sup>785</sup>

A wide range of tetrahedral [MX<sub>2</sub>( $\beta$ -diketiminate)] complexes is known in which M(III) = Al, Ga, or In, and representative examples include [MF<sub>2</sub>(Nacnac)] (Ar = Dipp, M = Al or Ga),<sup>786</sup> [AlI<sub>2</sub>{HC(CR)<sub>2</sub>(NMe)<sub>2</sub>}] (R = Me, <sup>i</sup>Pr),<sup>787</sup> [GaCl<sub>2</sub>(Nacnac)] and [GaCl(OSiMe<sub>3</sub>)(Nacnac)] (Ar = Dipp),<sup>788</sup> [GaCl<sub>2</sub>{HC(CPh)<sub>2</sub>(NPh)<sub>2</sub>}],<sup>789</sup> [Ga<sub>2</sub>(Nacnac)] (Ar = 2,6-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>),<sup>790</sup> [InI<sub>2</sub>(Nacnac)] (Ar = Ph),<sup>791</sup> [AlCl<sub>2</sub>{PhC(CH)<sub>2</sub>(NDipp)<sub>2</sub>}] and related Al, Ga and In complexes,<sup>792</sup> [AlBr<sub>2</sub>{PhC(CPh)<sub>2</sub>(NDipp)<sub>2</sub>}] and related compounds,<sup>793</sup> [AlCl<sub>2</sub>{Ph<sub>2</sub>PC(CMe)<sub>2</sub>(NDipp)<sub>2</sub>}],<sup>794</sup> [GaCl(NR)(Nacnac)] (Ar = Dipp),<sup>795</sup> and [InI<sub>2</sub>(Nacnac)] (Ar = Dipp) and related derivatives.<sup>796</sup> The reaction of [AlCl<sub>2</sub>(Nacnac)] (Ar = C<sub>6</sub>F<sub>5</sub>) with BCl<sub>3</sub> followed by H<sub>2</sub>O produced the first example of a stable oxoborane monomer [O=B(Nacnac)] which is stabilized by B=O  $\rightarrow$  AlCl<sub>3</sub> adduct formation.<sup>797</sup>  $\beta$ -Diketimidate analogs of the ligands shown in Scheme 5 have been used to access dimetallic species in the families [AlX<sub>2</sub>{bis( $\beta$ -diketiminate)}] (X = Cl, Br, I).<sup>798</sup> The hydrolysis of [AlClI(Nacnac)] (Ar = Dipp) led first to [Al<sub>2</sub>Cl<sub>2</sub>(Nacnac)<sub>2</sub>( $\mu$ -OH)<sub>2</sub>] and then to [Al(OH)<sub>2</sub>(Nacnac)].<sup>799</sup> Oxidative addition of SiBr<sub>4</sub> to the Ga(I) derivative [Ga(Nacnac)] (Ar = Dipp) gives [GaBr(SiBr<sub>3</sub>)(Nacnac)]; at 60 °C, the product was [GaBr(Nacnac)]<sub>2</sub>SiBr<sub>2</sub>, while in the presence of CO, [GaBr(Nacnac)]<sub>2</sub>Si(CO)] (a silylene carbonyl that is stable at room temperature) was isolated.<sup>800</sup> Compounds incorporating a non-bridged M-M bond include [In<sub>2</sub>Cl<sub>2</sub>(Nacnac)<sub>2</sub>] (Ar = Dipp, In-In = 2.8343(7) Å),<sup>801</sup> [In<sub>2</sub>Br<sub>2</sub>(Nacnac)<sub>2</sub>] (Ar = Mes),<sup>720</sup> and [In<sub>2</sub>Cl<sub>2</sub>{PhC(CH)<sub>2</sub>(NDipp)<sub>2</sub>}<sub>2</sub>].<sup>792</sup>

The Ge(IV) compound [GeCl<sub>2</sub>{PhC(CH)<sub>2</sub>(NDipp)<sub>2</sub>}(OGeCl<sub>3</sub>)] (Fig. 43A) is formed in the reaction of the lithium  $\beta$ -diketiminate and (GeCl<sub>3</sub>)<sub>2</sub>O.<sup>802</sup> [SnBr<sub>3</sub>(Nacnac)] and [SnI<sub>3</sub>(Nacnac)] (Ar = Dipp) possess square-based pyramidal structures with the  $\beta$ -diketiminate ligand occupying two basal sites.<sup>803</sup> We move now to low oxidation state complexes of the group 14 metals. A combination of structural and calculational data suggest that [GeX(Nacnac)] (Ar = Ph; X = Cl, I, OMe) is best described by a structure comprising [Ge(Nacnac)]<sup>+</sup> weakly coordinated with the X<sup>-</sup> unit.<sup>804</sup> Sterically demanding N-bonded aryl groups such as 2,6-<sup>i</sup>Pr<sub>2</sub>C<sub>6</sub>H<sub>3</sub> (Dipp) are often used to stabilize low oxidation state group 14 metal  $\beta$ -diketiminate complexes,<sup>805-814</sup> and Fig. 43B and C illustrate two examples. [GeX(Nacnac)] and [SnX(Nacnac)] complexes with less sterically demanding NAr units (e.g., Ar = Mes, Ph) are also known.<sup>351,815</sup> Tam et al. showed that the reactions of Li[Nacnac] (Ar = Ph, 4-<sup>i</sup>PrC<sub>6</sub>H<sub>4</sub> or 2,6-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>) with PbCl<sub>2</sub> yielded the corresponding [PbCl(Nacnac)] complexes, and that, in the solid state, [PbCl(Nacnac)] with

**Fig. 43** Structures of (A) [GeCl<sub>2</sub>{PhC(CH)<sub>2</sub>(NDipp)<sub>2</sub>}(OGeCl<sub>3</sub>)] (CSD refcode IHIRIB), (B) [GeCl{BzC(CMe)<sub>2</sub>(NDipp)<sub>2</sub>}] (refcode ACEPIJ), and (C) [PbCl(Nacnac)] with Ar = Dipp (refcode CIJQES). (D) Part of the 1D-chain in [PbCl(Nacnac)]<sub>n</sub> (Ar = Ph, refcode DABCIV).

Ar = Ph exists as a 1D-polymer (Fig. 43D). In contrast, intermolecular  $\text{Pb}\cdots\pi$  contacts are observed in  $[\text{PbCl}(\text{Nacnac})]$  with Ar = 2,6-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>.<sup>816</sup>

Representative  $\beta$ -diketiminate complexes of the heavier group 15 elements include  $[\text{AsI}_2\{\text{PhC}(\text{CH})_2(\text{NDipp})_2\}]$ ,<sup>817</sup>  $[\text{SbX}_2\{\text{PhC}(\text{CH})_2(\text{NDipp})_2\}]$  (X = Cl, Br; each structure is derived from a square-based pyramid with a stereochemically active lone pair in one basal site),<sup>818</sup>  $[\text{SbCl}_2(\text{Nacnac})]$  (Ar = Mes; disphenoidal geometry with axial Cl),<sup>819</sup>  $[\text{Bi}_2\text{X}_2(\text{THF})\{\text{PhC}(\text{CH})_2(\text{NDipp})_2\}(\mu\text{-X})_2]$  (X = Cl, Br),<sup>820</sup> and  $[\text{Bi}_2\text{I}_2\{\text{PhC}(\text{CH})_2(\text{NDipp})_2\}(\mu\text{-I})_2]$ .<sup>820</sup>

### 1.02.2.2.4 Triazenide ligands

In Section 1.02.2.2.2, we considered metal complexes of imidoamidate ligands (Scheme 3). Replacement of the central CR unit by a (formally) isoelectronic N leads to the family of triazenide ligands (Scheme 7). Gyton et al. have made a direct comparison of the structures and physical properties of a series of s-, p- and d-block metal complexes containing  $[\text{DippN}_3\text{Dipp}]^-$  and  $[\text{DippN}(\text{CH})\text{NDipp}]^-$ ; this detailed study provides an excellent base from which to develop an understanding of the similarities and differences of triazenide and imidoamidate complexes of a given metal ion.<sup>821</sup>

Many complexes of symmetrical  $[\text{RN}_3\text{R}]^-$  ligands with the alkali metals have unexceptional structures which feature chelating  $[\text{RN}_3\text{R}]^-$ , with CN increasing with the size of the metal ion. Examples include  $[\text{Li}(\text{OEt}_2)\{(2,6\text{-Mes}_2\text{C}_6\text{H}_3)\text{N}_3(2,6\text{-Mes}_2\text{C}_6\text{H}_3)\}]$  (trigonal planar),<sup>822</sup>  $[\text{Li}(\text{OEt}_2)_2\{(2,6\text{-Mes}_2\text{C}_6\text{H}_3)\text{N}_3(3\text{-MeC}_6\text{H}_4)\}]$  (tetrahedral),<sup>823</sup>  $[\text{Li}(\text{OEt}_2)_2(\text{DippN}_3\text{Dipp})]$  and  $[\text{Li}(\text{THF})_2(\text{DippN}_3\text{Dipp})]$  (both tetrahedral),<sup>821</sup>  $[\text{Na}(\text{THF})_3(\text{DippN}_3\text{Dipp})]$  (CN = 5),<sup>821</sup>  $[\text{M}(\text{dme})_2(\text{DippN}_3\text{Dipp})]$  (M = Na, K; CN = 6),<sup>821</sup>  $[\text{Na}(15\text{-crown-5})(\text{PhN}_3\text{Ph})]$  (CN = 7),<sup>824</sup>  $[\text{Na}(15\text{-crown-5})(\text{DippN}_3\text{Dipp})]$  (CN = 7),<sup>821</sup> and  $[\text{K}(18\text{-crown-6})(\text{DippN}_3\text{Dipp})]$  (CN = 8).<sup>821</sup> Of particular note is  $[\text{Li}(\text{ArN}_3\text{Ar})]$  (Ar = 2,6-Mes<sub>2</sub>C<sub>6</sub>H<sub>3</sub>) in which there are no additional donors bound to Li<sup>+</sup> and the metal ion is sandwiched between two mesityl rings; similar complexes with heavier alkali metal ions have also been reported.<sup>825</sup> Metal  $\cdots\pi$  interactions feature in a number of triazenide complexes with very bulky aryl substituents, and we discuss these further below.

A departure from monomeric group 1 metal complexes is found in the 1D-coordination polymer  $[\text{K}_2(\text{THF})_3(\text{DippN}_3\text{Dipp})_2]_n$  in which the triazenide ligand is in a bridging mode and the arene ring is involved in  $\text{K}^+\cdots\pi$  interactions; the crystal structure suffers from a complicated disorder/desolvation phenomenon.<sup>821</sup> However, the bonding mode of  $[\text{DippN}_3\text{Dipp}]^-$  in  $[\text{K}_2(\text{THF})_3(\text{DippN}_3\text{Dipp})_2]_n$  is similar to that observed in the heterometallic complex  $[\text{K}(\text{THF})_3(\mu\text{-DippN}_3\text{Dipp})\text{Ba}(\text{THF})\{\text{N}(\text{SiMe}_3)_2\}_2]$  (Fig. 44A).<sup>826</sup> As with imidoamidates and guanidates (Figs. 38A and 40A), triazenides may act both in chelating and bridging modes within the same dilithium species.<sup>827</sup> In contrast, in  $[\text{K}_2(\text{THF})_4(\mu\text{-MesN}_3\text{Mes})_2]$  and  $[\text{K}_2(\text{dme})_2(\mu\text{-MesN}_3\text{Mes})_2]$ , each N<sub>3</sub>-unit symmetrically bridges a K<sub>2</sub>-unit ( $\text{K}\cdots\text{K} = 3.5613(8)$  and  $3.4678(5)$  Å, respectively), coordinating through the outer N atoms to each K<sup>+</sup> to form an octahedral K<sub>2</sub>N<sub>4</sub>-core.<sup>828</sup>

As with group 1, chelating  $[\text{RN}_3\text{R}]^-$  and a general increase in CN on descending the group are seen for the group 2 metals. In the following examples, sterically demanding substituents play an important stabilizing role, and the ability of the 2-(2,4,6-<sup>i</sup>Pr<sub>3</sub>C<sub>6</sub>H<sub>2</sub>)C<sub>6</sub>H<sub>4</sub> and other aryl substituents to participate in  $\text{M}\cdots\pi$  interactions should be noted (see below): tetrahedral  $[\text{Mg}(\text{THF})(\text{ArN}_3\text{Ar}')]^-$  (Ar = 2,6-Mes<sub>2</sub>C<sub>6</sub>H<sub>3</sub>, Ar' = 2-(2,4,6-<sup>i</sup>Pr<sub>3</sub>C<sub>6</sub>H<sub>2</sub>)C<sub>6</sub>H<sub>4</sub>),<sup>829</sup> square-based pyramidal  $[\text{Mg}(\text{OEt}_2)(\text{DippN}_3\text{Dipp})_2]$ ,<sup>830</sup> octahedral *trans*- $[\text{Mg}(\text{THF})_2(\text{MesN}_3\text{Mes})_2]$ ,<sup>828</sup>  $[\text{Ca}(\text{THF})_2\{\text{N}(\text{SiMe}_3)_2\}(\text{DippN}_3\text{Dipp})]$  (CN = 5),<sup>826</sup> *trans*-

**Scheme 7** Structure of a general triazenide ligand  $[\text{RN}_3\text{R}]^-$  which is isoelectronic with an imidoamidate ligand (center). Right: structure of the sterically hindered triazenide ligand  $[\text{DippN}_3\text{Dipp}]^-$ .

**Fig. 44** Structures of (A)  $[\text{K}(\text{THF})_3(\mu\text{-DippN}_3\text{Dipp})\text{Ba}(\text{THF})\{\text{N}(\text{SiMe}_3)_2\}_2]$  (CSD refcode AGEGOJ), (B)  $[\text{Sr}(\text{C}_6\text{F}_5)(\text{ArN}_3\text{Ar}')]^-$  (Ar = 2,6-Mes<sub>2</sub>C<sub>6</sub>H<sub>3</sub>, Ar' = 2-(2,4,6-<sup>i</sup>Pr<sub>3</sub>C<sub>6</sub>H<sub>2</sub>)C<sub>6</sub>H<sub>4</sub>; refcode KAVNOL), (C)  $[\text{K}(\text{ArN}_3\text{Ar})]$  with Ar = 2-(2,4,6-<sup>i</sup>Pr<sub>3</sub>C<sub>6</sub>H<sub>2</sub>)C<sub>6</sub>H<sub>4</sub> (refcode MELPEZ), (D)  $[\text{Ti}_2(\text{DippN}_3\text{Dipp})_2]$  (refcode NADQOC).

[Ca(THF)<sub>2</sub>(MesN<sub>3</sub>Mes)<sub>2</sub>] (a distortion in the coordination sphere is caused by intramolecular face-to-face  $\pi$ -stacking),<sup>828</sup> [Ca<sub>2</sub>(THF)<sub>4</sub>{N(SiMe<sub>3</sub>)<sub>2</sub>}(DippN<sub>3</sub>Dipp)<sub>2</sub>( $\mu$ -I)<sub>2</sub>] (CN = 6),<sup>826</sup> [Sr(THF)<sub>3</sub>{N(SiMe<sub>3</sub>)<sub>2</sub>}(DippN<sub>3</sub>Dipp)] (CN = 6),<sup>826</sup> [Sr(THF)<sub>2</sub>(DippN<sub>3</sub>Dipp)<sub>2</sub>] (CN = 6), and [Sr(tmeda)(MesN<sub>3</sub>Mes)<sub>2</sub>] (CN = 6).<sup>828</sup> Vinduš and Niemeyer have made an extensive study of hetero and homoleptic Mg<sup>2+</sup> triazenides, and among these is [Mg(ArN<sub>3</sub>Ar)<sub>2</sub>] (Ar = 2,6-(3,5-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>)<sub>2</sub>C<sub>6</sub>H<sub>3</sub>) in which Mg<sup>2+</sup> is in a square-planar environment.<sup>831</sup> Niemeyer and coworkers have designed sterically hindered triazenides incorporating the 2-(2,4,6-*i*-Pr<sub>3</sub>C<sub>6</sub>H<sub>2</sub>)C<sub>6</sub>H<sub>4</sub> substituent; such a ligand envelops the metal ion to which it is coordinated. A critical factor is the design of the 2-(2,4,6-*i*-Pr<sub>3</sub>C<sub>6</sub>H<sub>2</sub>)C<sub>6</sub>H<sub>4</sub> substituent with the pendant aryl unit oriented so as to facilitate the M $\cdots\pi$  contacts. [MgI(THF)(ArN<sub>3</sub>Ar')] (Ar = 2,6-Mes<sub>2</sub>C<sub>6</sub>H<sub>3</sub>, Ar' = 2-(2,4,6-*i*-Pr<sub>3</sub>C<sub>6</sub>H<sub>2</sub>)C<sub>6</sub>H<sub>4</sub>) was mentioned above,<sup>829</sup> and a related complex is [MgI(OEt<sub>2</sub>)(ArN<sub>3</sub>Ar')].<sup>831</sup> The ligand also encloses Ca<sup>2+</sup>, Sr<sup>2+</sup> or Ba<sup>2+</sup> in a cavity with stabilizing M $\cdots\pi$  interactions as depicted for [Sr(C<sub>6</sub>F<sub>5</sub>)(ArN<sub>3</sub>Ar')] (Ar = 2,6-Mes<sub>2</sub>C<sub>6</sub>H<sub>3</sub>, Ar' = 2-(2,4,6-*i*-Pr<sub>3</sub>C<sub>6</sub>H<sub>2</sub>)C<sub>6</sub>H<sub>4</sub>) in Fig. 44B; although these pentafluorophenyl derivatives are organometallic, we include them because of the innovative triazenide ligand design strategy.<sup>829</sup> Similar M $\cdots\pi$  interactions also feature in [K(ArN<sub>3</sub>Ar)], [Cs(ArN<sub>3</sub>Ar)] and [Tl(ArN<sub>3</sub>Ar)] with Ar = 2-(2,4,6-*i*-Pr<sub>3</sub>C<sub>6</sub>H<sub>2</sub>)C<sub>6</sub>H<sub>4</sub> (Fig. 44C).<sup>827,832</sup>

Typical group 13 M(III) triazenide complexes are 5-coordinate and include [AlH(MesN<sub>3</sub>{2,6-(4-MeC<sub>6</sub>H<sub>4</sub>)<sub>2</sub>C<sub>6</sub>H<sub>3</sub>})<sub>2</sub>],<sup>833</sup> and [MX(DippN<sub>3</sub>Dipp)<sub>2</sub>] (M = Ga, In, Tl; X = Cl, Br, I, H).<sup>821</sup> The dihydrido derivative [AlH<sub>2</sub>(THF){MesN<sub>3</sub>(2,6-Mes<sub>2</sub>C<sub>6</sub>H<sub>3</sub>)}] is stabilized by the extreme steric demands of the ligand.<sup>833</sup> [Ga<sub>2</sub>I<sub>2</sub>(DippN<sub>3</sub>Dipp)<sub>2</sub>] contains a Ga–Ga bond and is formally a gallium(II) compound.<sup>821</sup> Trischelates can be accessed using non-sterically crowded substituents, for example, [In(PhN<sub>3</sub>Ph)<sub>3</sub>].<sup>834</sup> Reaction of TlOEt and H[DippN<sub>3</sub>Dipp] yields [Tl(DippN<sub>3</sub>Dipp)] which has a dimeric structure in the solid state (Fig. 44D, Tl $\cdots$ Tl = 3.4612(5) Å)<sup>821</sup>; this motif is seen regularly for thallium(I) triazenide complexes.

Triazenide complexes of the group 14 and 15 metals are relatively sparse. The M(II) derivatives [M(DippN<sub>3</sub>Dipp)<sub>2</sub>] (M = Ge, Sn, Pb)<sup>835</sup> are structurally similar to their imidoamidate analogs, and the sterically demanding [MesN<sub>3</sub>Mes]<sup>−</sup> was used to stabilize [MCl(MesN<sub>3</sub>Mes)] and [MH(MesN<sub>3</sub>Mes)] (M = Ge, Sn).<sup>836</sup>

#### 1.02.2.2.5 2,2'-Bipyridine and 1,10-phenanthroline

Main group metal complexes of bpy and phen, especially the former, are abundant. Whereas phen is preorganized for chelation, bpy must undergo a conformational change (Scheme 8); the resulting 5-membered chelate ring is highly favored.

We have recently surveyed the structural diversity of main group metal complexes containing bpy, phen and tpy,<sup>837</sup> and also bpy complexes of the group 1 metals.<sup>838</sup> Rather than repeat this discussion here, we refer the reader to these reviews.

**Scheme 8** The ligand phen is preorganized for chelation, but bpy undergoes a conformational change to form a chelate ring.

#### 1.02.2.3 Tridentate ligands

##### 1.02.2.3.1 Triamines: Open-chain

Open-chain tridentate N-donor ligands are typified by those in Scheme 9 which depicts the parent amine N<sup>1</sup>-(2-aminoethyl) ethane-1,2-diamine (dien), a general derivative, and the commonly encountered N<sup>1</sup>-(2-*N,N*-dimethylaminoethyl)-N<sup>1</sup>,N<sup>2</sup>,N<sup>2</sup>-trimethylethane-1,2-diamine (pmdeta). Upon coordination, the formation of 5-membered chelate rings is favored and the large numbers of main group metal complexes containing this family of amines precludes all but a brief overview. Complexes of the s-block metals, in particular lithium, are especially numerous.

**Scheme 9** Typical open-chain tridentate N-donor ligands. The abbreviations derive from the non-IUPAC names diethylenediamine and *N,N,N',N'*-pentamethyldiethylenetriamine.

**Scheme 10** Forms of the conjugate base of 2-methylpyridine, abbreviated to [2-Mepy-H]<sup>−</sup>.

**Fig. 45** Structures of (A)  $[K(\text{pmdeta})(\text{N}(\text{SiMe}_2\text{Ph})_2)_2]$  (CSD refcode HUXPIA), (B)  $[\text{Mg}_2(\text{pmdeta})(\text{N}(\text{SiMe}_3)_2)_2(\mu\text{-H})_2]$  (refcode GOWHOS, only the  $\mu\text{-H}$  atoms are shown), and (C)  $[\text{GeCl}(\text{pmdeta})]^+$  (refcode FULZUI). Parts of the 1D-chains in (D)  $[\text{Pb}(\text{dien})(\mu\text{-S}_2\text{C}_6\text{H}_4)]_n$  (refcode HAVDAL) and (E)  $[\text{Pb}(\text{dien})(\mu\text{-N}_3)]_n$  (refcode HPEXHIK).

Lithium typically exhibits CN = 4 or 5 in complexes with bichelating *pmdeta*. Representative examples are  $[\text{Li}(\text{pmdeta})(\text{NH}\text{-Dipp})]$ ,<sup>180</sup>  $(R,R)\text{-}[\text{Li}(\text{pmdeta})\{\text{N}(\text{CHMePh})_2\}]$ ,<sup>839</sup>  $[\text{Li}(\text{pmdeta})(2\text{-Mepy-H})]$  (see **Scheme 10**),<sup>840</sup>  $[\text{Li}(\text{pmdeta})(\text{THF})]^+$ ,<sup>646</sup>  $[\text{Li}(\text{pmdeta})\{\text{O}(2,6\text{-}^i\text{Bu}_2\text{-4-MeC}_6\text{H}_2)\}]$ ,<sup>650</sup>  $[\text{Li}(\text{pmdeta})\{\text{N}(\text{SnMe}_3)_2\}]$ ,<sup>841</sup>  $[\text{Li}(\text{pmdeta})(\text{TFSI-}\kappa^2)]$ ,<sup>842</sup>  $[\text{Li}(\text{pmdeta})(\text{BH}_4\text{-}\kappa^2)]$ ,<sup>843</sup>  $[\text{Li}_2(\text{pmdeta})_2(\mu\text{-Cl})_2]$ ,<sup>680,844</sup> and  $[\text{Li}_2(\text{pmdeta})_2(\mu\text{-O}_3\text{SCF}_3\text{-}1\kappa\text{O}^1\text{:}2\kappa\text{O}^2)_2]$ .<sup>845</sup>

For sodium, a CN = 5 is illustrated by  $[\text{Na}_2(\text{pmdeta})_2(\mu\text{-OH}_2)_2]^{2+}$ ,<sup>846</sup> and CN = 6 is seen in, for example,  $[\text{Na}(\text{pmdeta})_2]^+$ .<sup>847</sup> In contrast to the tetrahedral  $[\text{Li}(\text{pmdeta})(2\text{-Mepy-H})]$  with N-bound  $[2\text{-Mepy-H}]^-$ , the  $\text{K}^+$  analog is a dimer with bridging  $[2\text{-Mepy-H}]^-$  ligands tending to an azaallylic (**Scheme 10**) mode of coordination.<sup>840</sup> As we have noted earlier in this review (e.g., **Fig. 44A** and C),  $\text{M}^+\cdots\pi$  interactions may influence the structures of complexes of the heavier s-block elements. Such is the case in  $[\text{K}(\text{pmdeta})\{\text{N}(\text{SiMe}_2\text{Ph})_2\}_2]$  (**Fig. 45A**).<sup>848</sup>

Tetrahedral coordination for  $\text{Be}^{2+}$  is exemplified in  $[\text{BeX}(\text{pmdeta})]^+$  ( $\text{X} = \text{Cl}, \text{I}$ ).<sup>509,849</sup> In related halide derivatives,  $\text{Mg}^{2+}$  exhibits a CN = 5 in  $[\text{MgBr}_2(\text{pmdeta})]$ <sup>850</sup> and  $[\text{Mg}(\text{OMes})_2(\text{pmdeta})]$ .<sup>851</sup> Whereas the reaction of  $[\text{Mg}\{\text{N}(\text{SiMe}_3)_2\}_2]$  with  $\text{PhSiH}_3$  yields a poorly defined precipitate, the addition of neutral ligands such as *pmdeta* leads to well-defined complexes; **Fig. 45B** shows one example in which the  $\text{Mg-H}$  bonding is largely ionic in character.<sup>852</sup> As expected, the metal ion coordination number increases down group 2, and an example of CN = 7 is found in  $[\text{Sr}(\text{pmdeta})\{\text{HC}(\text{CO}_2\text{Me})_2\}_2]$ .<sup>853</sup>

Group 13 metal complexes with dien and *pmdeta* include the trigonal bipyramidal  $[\text{AlH}_2(\text{pmdeta})]^+$ ,<sup>854</sup> and octahedral *fac*- $[\text{M}(\text{dien})_2]^{3+}$  ( $\text{M} = \text{In}, \text{Tl}$ ).<sup>855,856</sup> Group 14  $\text{M}(\text{II})$  complexes include  $[\text{GeCl}(\text{pmdeta})]^+$  (**Fig. 45C**) and its bromido analog.<sup>678</sup> In the 1D-coordination polymer  $[\text{Pb}(\text{dien})(\mu\text{-S}_2\text{C}_6\text{H}_4)]_n$  (**Fig. 45D**), the  $\text{PbN}_3$ -unit is close to planar and the thiolate ligands are mutually *trans*,<sup>857</sup> whereas in  $[\text{Pb}(\text{dien})(\mu\text{-N}_3)]_n$  (**Fig. 45E**), the dien ligand can be described as binding in a *fac*-mode and the azido ligands are *cis*.<sup>858</sup> Note that this description is based upon a pseudo-octahedral  $\text{Pb}(\text{II})$  with a stereochemically active lone pair (**Figs. 45D** and E). A comparison of the five structures in **Fig. 45** illustrates the conformational flexibility of the dien and *pmdeta* ligands.

### 1.02.2.3.2 Triamines: Tripodal ligands and tris(pyrazolyl)borates

In addition to a general representation of a tripodal-type ligand, **Scheme 11** defines the tripodal ligands described in this section. It also shows the structure of the tris(pyrazolyl)borate ( $\text{HBpz}_3^-$ ) ligand and defines a general substituted tris(pyrazolyl)borate ligand. Typically, tripodal ligands coordinate in a *fac*-mode with all three 'arms' involved in binding a metal ion. Note that such chelating donors are also known as scorpionate ligands, and in 2015, Reglinski and Spicer reviewed their p-block metal coordination compounds.<sup>75</sup> Thallium(I) and potassium salts of tris(pyrazolyl)borate ligands are commonly encountered, and a recent study has highlighted the use of  $^{11}\text{B}$  NMR spectroscopy to follow the synthesis of  $\text{K}^+$  salts and determine compound purity.<sup>859</sup>

The reaction of  $\text{H}_2\text{tripod}^1$  ( $\text{R} = \text{Me}$  or  $^i\text{Bu}$ , **Scheme 11**) with  $^i\text{BuLi}$  produces lithium amides which exhibit dimeric structures in the solid state; the  $\text{Li}_4\text{N}_4$  core possesses a ladder-like assembly (**Fig. 46A**).<sup>860</sup> The ability of amido ligands to bridge between metal centers facilitates the formation of heterometallic species, illustrated by  $[\text{Li}(\text{OEt}_2)\text{AlCl}(\text{tripod}^1)]$  (**Fig. 46B**).<sup>861</sup> Reaction of  $[\text{Li}_4(\text{tripod}^1)_2]$  ( $\text{R} = \text{Me}$ ) with  $\text{TlCl}$  led to  $[\text{Tl}_2(\text{tripod}^1)]$  and in the solid state, pairs of molecules associate through a weak  $\text{Tl}\cdots\text{Tl}$  interaction ( $\text{Tl}\cdots\text{Tl} = 3.500(2)$  Å).<sup>860</sup> Thallium(I) derivatives have also been formed directly. For example, the ligands  $\text{tripod}^3$  with  $\text{R} = \text{Me}$  or  $^i\text{Bu}$ ,  $\text{Ar} = 2\text{-}^i\text{PrC}_6\text{H}_4$  react with  $\text{Tl}[\text{BAR}^{\text{F}}_4]$  to give the  $[\text{BAR}^{\text{F}}_4]^-$  salt of  $[\text{Tl}(\text{tripod}^3)]^+$ . There are no short cation $\cdots$ anion contacts in the solid state, and the cation forms dimers with  $\text{Tl}\cdots\text{Tl}$  distances of 3.649(4) Å ( $\text{R} = \text{Me}$ ) and 3.7862(2) Å ( $\text{R} = ^i\text{Bu}$ , **Fig. 46C**).<sup>862</sup>

The  $\text{Ge}(\text{II})$  complex  $[\text{Ge}(\text{tripod}^4)]^-$  (**Fig. 46D**) was structurally characterized as the  $[\text{Na}(\text{THF})_5]^+$  salt;  $[\text{Ge}(\text{tripod}^4)]^-$  utilizes its Ge-centered lone pair to act as a ligand to metal centers such as  $\text{Cu}(\text{I})$  and  $\text{Fe}(0)$ .<sup>863</sup> The larger  $\text{Pb}(\text{II})$  can accommodate two  $\text{tripod}^5$  (**Scheme 11**) ligands as shown in **Fig. 46E**, with the metal center in a distorted octahedral environment.<sup>864</sup> Examples from the group 15 metals include  $[\text{Sb}(\text{tripod}^4)]$  with a structure similar to  $[\text{Ge}(\text{tripod}^4)]^-$  (**Fig. 46D**); the compound crystallizes as a benzene solvate and a  $\text{C}_6\text{H}_6$  molecule sits between the  $\text{Sb}$  atoms of two adjacent  $[\text{Sb}(\text{tripod}^4)]$  molecules ( $\text{Sb}\cdots\text{benzene}_{\text{centroid}} =$

**Scheme 11** General types of tripodal ligands. The substituents are specified in the text with reference to these general structures.

**Fig. 46** Structures of (A) [Li<sub>4</sub>(tripod<sup>1</sup>)<sub>2</sub>] with R = <sup>t</sup>Bu (CDS refcode QAQXEL), (B) [Li(OEt<sub>2</sub>)AlCl(tripod<sup>2</sup>)] (refcode RIQGAA), (C) [Ti<sub>2</sub>(tripod<sup>3</sup>)<sub>2</sub>]<sup>2+</sup> (R = <sup>t</sup>Bu, Ar = 2-<sup>i</sup>PrC<sub>6</sub>H<sub>4</sub>; refcode BIKGAF), (D) [Ge(tripod<sup>4</sup>)]<sup>-</sup> (refcode FISGOG), and (E) [Pb(tripod<sup>5</sup>)<sub>2</sub>]<sup>2+</sup> (refcode OTEDOH).

**Fig. 47** Structures of (A) [Li{HB(RR'pz)<sub>3</sub>}] (R = Me, R' = <sup>t</sup>Bu; CSD refcode CEZSOR), (B) [Li<sub>2</sub>{HB(RR'pz)<sub>3</sub>}<sub>2</sub>] (R = R' = Me; refcode IYIQOY), (C) [Mg{HB(RR'pz)<sub>3</sub>}<sub>2</sub>] (R = R' = <sup>i</sup>Pr) (refcode EKOTIK), (D) [HB(RR'pz)<sub>3</sub>]Ga(Gal)<sub>2</sub>Ga[HB(RR'pz)<sub>3</sub>] (R = R' = Me; refcode KAJWID), and (E) the weakly associated dimer [Ti{HB(RR'pz)<sub>3</sub>}<sub>2</sub>] with R = H, R' = Ph (refcode ASADAZ).

3.648 Å). [Sb(tripod<sup>4</sup>)] was used as a building block in conjunction with pyridine-based ligands to produce a number of supramolecular assemblies.<sup>865</sup>

Complexes with tetrahedral Li<sup>+</sup> bound by one tris(pyrazolyl)borate and one other monodentate donor include [Li{HB(RR'pz)<sub>3</sub>}(Hpz-3,5-Me<sub>2</sub>)] (R = R' = Me, see **Scheme 11**),<sup>866</sup> [Li{HB(RR'pz)<sub>3</sub>}(OH<sub>2</sub>)] (R = H or Me, R' = 'Bu),<sup>867</sup> [Li{HB(RR'pz)<sub>3</sub>}(NCMe)] (R = Me, R' = 'Bu),<sup>867</sup> and [Li{HB(RR'pz)<sub>3</sub>}(THF)] (R = H, R' = Me).<sup>868</sup> Less common is 3-coordinate Li<sup>+</sup> as found in [Li{HB(RR'pz)<sub>3</sub>}] (R = Me or H, R' = 'Bu; **Fig. 47A**).<sup>867</sup> A departure from these monomeric assemblies occurs in [Li<sub>2</sub>{HB(RR'pz)<sub>3</sub>}]<sub>2</sub> (R = R' = Me) in which two pz arms of each ligand coordinate to different Li<sup>+</sup> centers, and the third pz unit is in a bridging mode (**Fig. 47B**); each Li<sup>+</sup> maintains a tetrahedral geometry.<sup>869</sup> A further structural variation is achieved by using *B*-fluorenyl substituted tris(pyrazolyl)borates; in [Li(RBpz<sub>3</sub>)<sub>2</sub>] (R = fluorenyl), two pz rings of each ligand coordinate to Li<sup>+</sup> (giving a tetrahedral geometry) leaving a pendant third arm.<sup>870</sup> With bulky substituents in the 3-positions of the pz rings, Na<sup>+</sup> also tends to form 4-coordinate complexes, for example, [Na{HB(RR'pz)<sub>3</sub>}L] (R = Ph; R' = CF<sub>3</sub>; L = H<sub>2</sub>O, THF),<sup>871</sup> [Na{HB(RR'pz)<sub>3</sub>}(OEt<sub>2</sub>)] (R = R' = CF<sub>3</sub>),<sup>871</sup> and [Na{HB(RR'pz)<sub>3</sub>}(THF)] (R = Me, R' = <sup>n</sup>C<sub>3</sub>F<sub>7</sub>),<sup>872</sup> although CN = 5 with a square-based pyramidal arrangement of donors is found in [Na<sub>2</sub>{HB(RR'pz)<sub>3</sub>}]<sub>2</sub>(μ-OH<sub>2</sub>)<sub>2</sub> (R = Me; R' = CF<sub>3</sub>).<sup>871</sup> Two tris(pyrazolyl)borate ligands can be accommodated if the pyrazole 3-substituents are not sterically demanding, e.g., in [Na{HB(RR'pz)<sub>3</sub>}]<sub>2</sub><sup>-</sup> (R = R' = Me).<sup>873</sup> Octahedral Na<sup>+</sup> is also observed in [Na<sub>2</sub>{HB(RR'pz)<sub>3</sub>}]<sub>2</sub>(μ-OCMe<sub>2</sub>)<sub>3</sub> (R = R' = Me) with bridging acetone ligands,<sup>874</sup> and a similar structural motif is found in [K<sub>2</sub>{HB(RR'pz)<sub>3</sub>}]<sub>2</sub>(μ-OH<sub>2</sub>)<sub>3</sub> (R = R' = Me, X = Cl; see **Scheme 11**).<sup>875</sup> We noted above the monomeric structure of [Na{HB(RR'pz)<sub>3</sub>}(THF)] (R = Me, R' = <sup>n</sup>C<sub>3</sub>F<sub>7</sub>). In contrast, in [Cs{HB(RR'pz)<sub>3</sub>}]<sub>n</sub> (R = Me, R' = <sup>n</sup>C<sub>3</sub>F<sub>7</sub>), the perfluoropropyl substituents engage in Cs⋯F contacts (range 3.10–3.72 Å) producing a 1D-chain in the solid state; this was the first structurally characterized tris(pyrazolyl)borate of cesium.<sup>872</sup> The single crystal structure of [K{HB(RR'pz)<sub>3</sub>}(NCMe)<sub>3</sub>] (R = H, R' = Ph) reveals an apparent vacancy in the coordination sphere of K<sup>+</sup> and inspection of the structural data (CSD refcode USUSIN) shows that molecules are aligned into chains with K⋯HB separations of 3.47 Å.<sup>859</sup>

Moving to group 2, beryllium complexes of tris(pyrazolyl)borates are exemplified by tetrahedral [BeX(HBpz<sub>3</sub>)] (X = F, Cl, Br, I),<sup>876</sup> and [Be(THF)(HBpz<sub>3</sub>)].<sup>877</sup> The Mg<sup>2+</sup> ion is large enough to accommodate two tris(pyrazolyl)borate ligands (**Scheme 11**), as exemplified in [Mg(HBpz<sub>3</sub>)<sub>2</sub>],<sup>878–880</sup> [Mg{(4-Br-C<sub>6</sub>H<sub>4</sub>)Bpz<sub>3</sub>}]<sub>2</sub>,<sup>881</sup> [Mg{HB(RR'pz)<sub>3</sub>}]<sub>2</sub> (R = R' = Me),<sup>880</sup> [Mg{HB(RR'pz)<sub>3</sub>}]<sub>2</sub> (R = R' = Me, X = Cl; see **Scheme 11**),<sup>880</sup> and [Mg{HB(RR'pz)<sub>3</sub>}]<sub>2</sub> (R = R' = 'Pr) (**Fig. 47C**).<sup>882</sup> However, incorporating sterically demanding substituents adjacent to the metal-binding site typically prevents the coordination of two tripodal ligands to Mg<sup>2+</sup>, for example, in [MgX{HB(RR'pz)<sub>3</sub>}] (R = Me, R' = 'Bu; X = F, Cl, Br, I).<sup>883</sup> The Ca, Sr and Ba analogs of [Mg{HB(RR'pz)<sub>3</sub>}]<sub>2</sub> (R = R' = 'Pr) (**Fig. 47C**) have also been structurally characterized,<sup>882</sup> as have [Sr(HBpz<sub>3</sub>)<sub>2</sub>] and [M{HB(RR'pz)<sub>3</sub>}]<sub>2</sub> (M = Ca, Sr, Ba; R = R' = Et).<sup>884</sup> Complexation of [HBpz<sub>3</sub>]<sup>-</sup> with Ba<sup>2+</sup> leads to the unusual dimer [Ba<sub>2</sub>(HBpz<sub>3</sub>)<sub>4</sub>] in which two ligands bind in the typical *fac*-mode and two are bridging with a combination of σ- and η<sup>5</sup>-pz-Ba interactions.<sup>884</sup> In [Ca{HB(RR'pz)<sub>3</sub>}]<sub>2</sub> (R = Me, R' = 'Bu), the steric bulk of the 'Bu groups results in a 5-coordinate Ca<sup>2+</sup> with one ligand arm non-coordinated<sup>885</sup>; the same coordination behavior is seen in [Ca{HB(RR'pz)<sub>3</sub>}]<sub>2</sub> (R = H, R' = 'Bu).<sup>886</sup> Interestingly, in [Ca{HB(RR'pz)<sub>3</sub>}]<sub>2</sub> (R = Me, R' = Ph), the spatially demanding phenyl rings engage in inter-ligand face-to face π-interactions and octahedral coordination is retained.<sup>887</sup> Both [Ca{HB(RR'pz)<sub>3</sub>}]<sub>2</sub>(N(SiMe<sub>3</sub>)<sub>2</sub>) (R = H, R' = 'Bu),<sup>888</sup> and [Ca{HB(RR'pz)<sub>3</sub>}(ODipp)] (R = H, R' = 'Bu) contain tetrahedral Ca<sup>2+</sup>.<sup>889</sup> One interest in such species is their activity in lactide ring-opening polymerization.<sup>889</sup> Thermolysis of [Ca(H<sub>2</sub>Bpz<sub>2</sub>)<sub>2</sub>(THF)<sub>2</sub>] leads to the formation of [Ca(HBpz<sub>3</sub>)<sub>2</sub>] and [Ca(HBpz<sub>3</sub>)(BH<sub>4</sub>)]; the latter reacts with THF to give *fac*-[Ca(HBpz<sub>3</sub>)(THF)<sub>2</sub>(BH<sub>4</sub>)] and a tetranuclear [Ca<sub>4</sub>(HBpz<sub>3</sub>)<sub>4</sub>(THF)<sub>4</sub>(μ-BH<sub>4</sub>)<sub>4</sub>] with the Ca centers forming a rhomboid.<sup>890</sup>

Among the many contributions from Parkin and coworkers to the field of tris(pyrazolyl)borate coordination chemistry is a series of compounds containing Ga–Ga bonds. These include [Ga<sub>2</sub>{HB(RR'pz)<sub>3</sub>}]<sub>2</sub> (R = R' = Me), [{HB(RR'pz)<sub>3</sub>}Ga–GaX<sub>3</sub>] (X = Cl, I; R = R' = Me) and [{HB(RR'pz)<sub>3</sub>}Ga(GaI<sub>2</sub>)<sub>2</sub>Ga{HB(RR'pz)<sub>3</sub>}] (R = R' = Me; **Fig. 47D**); the octahedral [Ga{HB(RR'pz)<sub>3</sub>}]<sub>2</sub><sup>+</sup> (R = R' = Me) has also been structurally characterized.<sup>891</sup> In the Ga(III) complex [GaH{HB(RR'pz)<sub>3</sub>}]<sub>2</sub><sup>+</sup> (R = Me, R' = 'Bu), the hydrido ligand is protected within a sheath of 'Bu substituents.<sup>892</sup> Monomeric In(I) complexes are exemplified by [In{HB(RR'pz)<sub>3</sub>}] (R = R' = Me; R = Me, R' = 'Bu).<sup>892</sup> The coordination chemistry of tris(pyrazolyl)borate thallium(I) species is an extensive area which was reviewed by Janiak in 1997,<sup>893</sup> and is included in a 2015 review by Reglinski and Spicer.<sup>75</sup> The following examples are necessarily selective. Thallium(I) complexes of [HB(RR'pz)<sub>3</sub>]<sup>-</sup> with R = H, R' = Ph and [HB(RR'pz)<sub>2</sub>(R''R''pz)]<sup>-</sup> (see **Scheme 11**) with R = R'' = R''' = Me, R' = Ph, possess dimeric structures in the solid state. The former dimer (**Fig. 47E**) is supported by a weak Tl⋯Tl interaction (3.853(1) Å), and in both complexes weak CH⋯π contacts are important packing interactions. This investigation also includes a comparison of previously reported tris(pyrazolyl)borate complexes of thallium(I), giving a useful entry into this area.<sup>894</sup> The incorporation of bulky substituents in the pyrazole 3-position prevents the formation of Tl⋯Tl close contacts in the solid state, e.g., in [Tl{HB(RR'pz)<sub>3</sub>}] (R = Me, R' = Bz),<sup>895</sup> [Tl{HB(RR'pz)<sub>3</sub>}] (R = 'Bu, R' = 4-MeC<sub>6</sub>H<sub>4</sub>),<sup>896</sup> [Tl{HB(RR'pz)<sub>3</sub>}] (R = H, R' = CHPh<sub>2</sub>),<sup>897</sup> [Tl{HB(RR'pz)<sub>3</sub>}] (R = H, R' = Mes),<sup>898</sup> and [Tl{HB(RR'pz)<sub>3</sub>}] (R = 'Pr, R' = adamantan-1-yl).<sup>899</sup>

Group 14 metal(IV) complexes are represented by [Ge{HB(RR'pz)<sub>3</sub>}(N<sub>3</sub>)<sub>3</sub>] (R = R' = Me) (which was prepared by oxidation of [Ge{HB(RR'pz)<sub>3</sub>}(N<sub>3</sub>)] using HN<sub>3</sub>),<sup>900</sup> and octahedral [SnCl<sub>3</sub>{HB(RR'pz)<sub>3</sub>}] (R = R' = Me).<sup>901</sup> The use of sterically non-demanding ligands proved critical in the formation of lead(II) compounds, exemplified by the dimer [Pb<sub>2</sub>{HB(RR'pz)<sub>3</sub>}]<sub>2</sub>(μ-NCS)<sub>2</sub>] (R = R' = Me) and the 2D-coordination network [Pb(HBpz<sub>3</sub>)<sub>2</sub>(μ-NCS)]<sub>n</sub>.<sup>902</sup>

A combination of the size of Bi(III) and lack of steric hindrance in the unsubstituted [HBpz<sub>3</sub>]<sup>-</sup> allows the formation of the 8-coordinate [BiCl(HBpz<sub>3</sub>)<sub>2</sub>(pz)]. This was the first example of a pyrazolylborate complex of a group 15 metal.<sup>903</sup> In [BiCl<sub>2</sub>{HB(RR'pz)<sub>3</sub>}] (R = R' = Me), the Bi(III) center is in square-based pyramidal environment with dimer assembly by virtue

**Scheme 12** General structures of representative pincer-type ligands with three N-donors.

of long Bi...Cl interactions (3.234(3) Å); the highly electrophilic  $[\text{Bi}\{\text{HB}(\text{RR}'\text{pz})_3\}]^{2+}$  cation is an active catalyst for alkene hydro-silylation.<sup>904</sup> Tris(pyrazolyl)borates are tridentate  $\sigma$ -donor ligands, and have been used to investigate the *trans*-influence in Bi(III) compounds in the presence of other ligands with different nucleophilicities. Among the series of complexes studied are  $[\text{Bi}\{\text{HB}(\text{RR}'\text{pz})_3\}_2]$  ( $\text{R} = \text{R}' = \text{Me}$ ),  $[\text{BiCl}_3\{\text{HB}(\text{RR}'\text{pz})\}]$  ( $\text{R} = \text{R}' = \text{Me}$ ), and  $[\text{Bi}_2\text{Cl}_2\{\text{HB}(\text{RR}'\text{pz})\}_2(\mu\text{-O}_3\text{SCF}_3\text{-}1\kappa\text{O}^1\text{:}2\kappa\text{O}^2)]$  ( $\text{R} = \text{R}' = \text{Me}$ ).<sup>905</sup>

### 1.02.2.3.3 Pincer ligands

Typical pincer ligand families are shown in **Scheme 12**. However, it should be noted that the ligands are redox active allowing access to a multiplicity of oxidation- and charge-states. The examples in this section are necessarily selective and aim to provide an entry into the relevant literature.

The reaction of MeLi with  $\text{im}_2\text{py}$  ( $\text{R} = \text{Me}$ ,  $\text{R}' = \text{Dipp}$ ) unexpectedly resulted in methylation of the pyridine N atom to give 'Li  $\{\text{im}_2(\text{C}_5\text{H}_3\text{NMe})\}'$ ; the structure of the crystallized product reveals two different units, one with Li-bound THF and one with a Li...C contact as shown in **Fig. 48A**. The methylation is reversible upon heating, and characterization of  $[\text{Li}(\text{im}_2\text{py})(\text{THF})]$  confirmed  $\text{Li}^+$  in a distorted square-planar environment.<sup>906</sup> In  $[\text{K}_2(\text{OEt}_2)_4(\text{pyr}_2\text{py})]$  ( $\text{R} = \text{Ph}$ ,  $\text{R}' = \text{Mes}$ , see **Scheme 12**), two  $\{\text{K}(\text{OEt}_2)_2\}$  units are bridged by an  $[\text{pyr}_2\text{py}]^{2-}$  ligand as shown in **Fig. 48B**.<sup>907</sup> Jones and coworkers have reported a series of group 2 metal complexes of  $\text{im}_2\text{py}$  with  $\text{R} = \text{Ph}$ ,  $\text{R}' = \text{Dipp}$  (see **Scheme 12**) in which the  $\text{im}_2\text{py}$  ligand is neutral, singly or doubly reduced. These complexes include  $[\text{MgI}_2(\text{im}_2\text{py})]$ ,  $[\text{CaI}_2(\text{im}_2\text{py})]$  and  $[\text{MgI}(\text{im}_2\text{py})]$  (with a radical anion ligand and approximately square-planar  $\text{Mg}^{2+}$ ).<sup>908</sup> Marks and coworkers have reported  $[\text{MgCl}_2(\text{im}_2\text{py})]$  ( $\text{R} = \text{Me}$ ,  $\text{R}' = \text{ferrocenyl}$ ) along with analogous d-block

**Fig. 48** Structures of (A)  $[\text{Li}_2\{\text{im}_2(\text{C}_5\text{H}_3\text{NMe})\}_2(\text{THF})]$  (CSD refcode CALSOY) with a schematic of 'Li  $\{\text{im}_2(\text{C}_5\text{H}_3\text{NMe})\}'$ , (B)  $[\text{K}_2(\text{OEt}_2)_4(\text{pyr}_2\text{py})]$  (refcode GOYNOA), (C)  $[\text{PbBr}_2(\text{H}_2\text{Bzim}_2\text{py})]$  (only the NH H atoms are shown; refcode CAFQEI), (D)  $[\text{Pb}_2(\text{HBzim}_2\text{py})_2(\mu\text{-boa})]$  (refcode EHEYOG), and (E)  $[\text{Pb}(\text{im}_2\text{py})_3]$  ( $\text{R} = \text{H}$ ,  $\text{R}' = \text{Ph}$ ; refcode HOXQER).

metal compounds; combined experimental and computational data indicate that coordination of the im<sub>2</sub>py ligand results in mixing of the ferrocenyl d-orbitals with the π\* orbitals of the im<sub>2</sub>py unit.<sup>909</sup>

Trigonal bipyramidal group 13 metal M(III) complexes containing pincer ligands of the general type [MX<sub>2</sub>(pincer)] with X<sup>-</sup> ligand in equatorial sites are exemplified by [MCl<sub>2</sub>(im<sub>2</sub>py)] (M = Al, Ga; R = Ph, Me, R' = Dipp),<sup>910,911</sup> and [GaCl<sub>2</sub>(R<sub>2</sub>bzim<sub>2</sub>py)] (R = Bz, CH<sub>2</sub>CH=CH<sub>2</sub>).<sup>911</sup> In the blue-emitting complex [InCl<sub>2</sub>(OH<sub>2</sub>)(Hbzim<sub>2</sub>py)],<sup>912</sup> and [InCl(O<sub>3</sub>SCF<sub>3</sub>)<sub>2</sub>(im<sub>2</sub>py)] (R = Ph, R' = 2,6-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>),<sup>913</sup> the In(III) center is octahedrally sited. Berden and coworkers have reported bis(imino)pyridine ligand-based mixed valent (MV) complexes of Al(III) which feature electron donating and electron withdrawing substituents on the ligands, allowing access to species with [Al(L<sup>-</sup>)(L<sup>2-</sup>)] and [Al(L<sup>2-</sup>)(L<sup>3-</sup>)] charge states,<sup>914</sup> and related water-stable MV compounds have been prepared by reactions of reduced bis(imino)pyridine ligands with Al(III), Ga(III) and In(III) salts.<sup>915</sup> Related to this is a reaction of [(pz<sub>2</sub>py)AlCl<sub>2</sub>(THF)]<sup>+</sup> (R = CH<sub>2</sub><sup>i</sup>Pr, R' = <sup>i</sup>Pr, see **Scheme 12**) involving 2-electron reduction and single-ligand protonation to give [(pz<sub>2</sub>py)AlCl<sub>2</sub>]; each electron- and H<sup>+</sup>-transfer process is ligand-centered.<sup>916</sup> An attempt to form Ga(I) coordination compounds using the sterically demanding bis(imino)pyridine ligands im<sub>2</sub>py (R = Ph, R' = Dipp or 2,5-<sup>t</sup>Bu<sub>2</sub>C<sub>6</sub>H<sub>3</sub>) resulted instead in the Ga(III) complexes [Ga<sub>2</sub>(im<sub>2</sub>py)][Ga<sub>4</sub>]; the neutral radical [Ga<sub>2</sub>(im<sub>2</sub>py)] was also isolated.<sup>917</sup>

For group 14 M(II), the familiar (see earlier discussions) geometry with a stereochemically active lone pair is illustrated for pincer-type ligands by [GeCl(im<sub>2</sub>py)]<sup>+</sup> (R = Me, R' = Dipp),<sup>918,919</sup> [MCl(im<sub>2</sub>py)]<sup>+</sup> (M = Ge, Sn; R = H, R' = ferrocenyl),<sup>920</sup> [SnCl(im<sub>2</sub>py)]<sup>+</sup> (R = Me, R' = Dipp),<sup>921,922</sup> [SnBr(im<sub>2</sub>py)]<sup>+</sup> (R = H, R' = Dipp),<sup>923</sup> [SnX(im<sub>2</sub>py)]<sup>+</sup> (X = Cl, Br; R = Ph, R' = 2,5-<sup>t</sup>Bu<sub>2</sub>C<sub>6</sub>H<sub>3</sub>),<sup>924</sup> and [Pb(NCS)(im<sub>2</sub>py)]<sup>+</sup> (R = Me, R' = 2,6-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>).<sup>902</sup> The reduction of [GeCl(im<sub>2</sub>py)]<sup>+</sup> (R = Me, R' = Dipp) with KC<sub>8</sub> yielded the 3-coordinate Ge(0) derivative [GeCl(im<sub>2</sub>py)] which possesses a singlet ground state and partial Ge–N multiple-bond character.<sup>918</sup> In the triflate salt of [SnCl(im<sub>2</sub>py)]<sup>+</sup>, there is ion pairing in the solid state with an Sn<sub>cat</sub>–O<sub>triflate</sub> separation of 3.042(2) Å, and in [Sn(O<sub>3</sub>SCF<sub>3</sub>)<sub>2</sub>(im<sub>2</sub>py)], both triflate ions coordinate to the Sn(II) center.<sup>921</sup> In a detailed study of Ge(II) and Sn(II) complexes, Flock et al. observed that the triflate salt of [Sn(im<sub>2</sub>py)]<sup>2+</sup> (R = H, R' = Dipp) crystallizes with two independent, neutral molecules in the asymmetric unit; one has CN = 5 (as just described), and the second is 6-coordinate with an additional THF ligand.<sup>923</sup> The same coordination geometry as in [Sn(O<sub>3</sub>SCF<sub>3</sub>)<sub>2</sub>(im<sub>2</sub>py)] is observed in [PbBr<sub>2</sub>(H<sub>2</sub>Bzim<sub>2</sub>py)] (**Fig. 48C**, see **Scheme 12** for the ligand); the latter is one of a series of H<sub>2</sub>Bzim<sub>2</sub>py derivatives of Pb(II) reported by Thompson et al. which has included a correlation of structural parameters with the <sup>207</sup>Pb NMR chemical shift span parameter, Ω.<sup>353</sup> A similar coordination environment is found in [Pb<sub>2</sub>(ONO<sub>2</sub>)<sub>2</sub>(H<sub>2</sub>Bzim<sub>2</sub>py)<sub>2</sub>(μ-adip)], although each CO<sub>2</sub><sup>-</sup> unit of the bridging ligand is bidentate, giving a CN of 7 for each Pb(II).<sup>925</sup> In contrast, in [Pb<sub>2</sub>(HBzim<sub>2</sub>py)<sub>2</sub>(μ-boa)] (**Fig. 48D**) which contains monodeprotonated [HBzim<sub>2</sub>py]<sup>-</sup> ligands, the outer axial site of each Pb(II) center is occupied by a stereochemically active lone pair.<sup>926</sup> Reactions of lead(II) triflate with im<sub>2</sub>py (R = H, R' = Ph) in MeCN solution produced [Pb(im<sub>2</sub>py)<sub>x</sub>] (x = 1–3) while crystal growth by layering produced only [Pb(im<sub>2</sub>py)<sub>3</sub>] with 9-coordinate Pb(II) (**Fig. 48E**); the ligands are arranged so that there is efficient inter-ligand π-stacking of phenyl substituents. Interestingly, when im<sub>2</sub>py (R = H, R' = Ph) was replaced by im<sub>2</sub>py (R = H, R' = 4-HOC<sub>6</sub>H<sub>4</sub>), only single crystals of [Pb(O<sub>3</sub>SCF<sub>3</sub>)<sub>2</sub>(im<sub>2</sub>py)] were obtained.<sup>927</sup>

Group 15 metal(III) complexes with pincer ligands are represented by [BiI(pyr<sub>2</sub>py)] (R = R' = <sup>t</sup>Bu, or R = Ph, R' = Mes) and [SbI(pyr<sub>2</sub>py)] (R = Ph, R' = Mes) in which the 3-coordinate M(III) is protected by sterically hindered substituents <sup>t</sup>Bu or Mes; Turner has reported a detailed study of the reduction of these species with strong metal reductants.<sup>907</sup> Low oxidation compounds include the 3-coordinate As(I) complex [As(im<sub>2</sub>py)]<sup>+</sup> (R = Me, R' = Dipp).<sup>928</sup> The first diiminopyridine complexes of S, Se and Te have been reported; the triflate salts of [Se(im<sub>2</sub>py)]<sup>2+</sup> and [Te(im<sub>2</sub>py)]<sup>2+</sup> (R = H, R' = Dipp) are air-stable, and notably, the analogous sulfur complex was also isolated.<sup>929</sup> Reactions of group 16 element halides with im<sub>2</sub>py (R = H, R' = Dipp) have also been reported, and include the structures of salts of the square-planar [SeX(im<sub>2</sub>py)]<sup>+</sup> (X = Cl, Br) cations.

### 1.02.2.3.4 2,2':6',2''-Terpyridines

For a coverage of the coordination chemistry of main group metal complexes containing 2,2':6',2''-terpyridine (tpy) ligands, we direct the reader to our recent review of the field.<sup>837</sup>

### 1.02.2.4 Polydentate open-chain, macrocyclic and cage ligands

Main group metal complexes of polydentate open-chain, macrocyclic and cryptand N-donor ligands are plentiful, and for the open-chain ligands, we have restricted the overview to compounds that can be regarded as representative 'parent' ligands. **Scheme 13** shows ligand types that are included. The macrocyclic tetraamine tacn (**Scheme 13**) is the building block for a wide range of mixed donor polydentate ligands including DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) and related ligands, metal complexes of which have significant applications in, for example, biomedical imaging.<sup>41,930,931</sup> Porphyrinato and phthalocyanato main group metal complexes have been adequately reviewed elsewhere.<sup>53,932–938</sup>

Use of the tetradentate ligand Me<sub>6</sub>trien (**Scheme 13**) directs a *cis* configuration in [Ca(Me<sub>6</sub>trien)(PPh<sub>2</sub>)<sub>2</sub>]; this is very air and moisture sensitive, and as a result, *cis*-[Ca(Me<sub>6</sub>trien)(PPh<sub>2</sub>)(OPPh<sub>2</sub>)] was also isolated.<sup>939</sup> In [Sr(tetraen)(<sup>t</sup>Bu<sub>2</sub>acac)<sub>2</sub>], the Sr<sup>2+</sup> ion has CN = 9; this is one of a series of Sr(II) related complexes containing both polyamine and β-diketonate ligands.<sup>940</sup> Examples of group 13 M(III) complexes include the 6-coordinate [In<sub>2</sub>(trien)<sub>2</sub>(μ-Se)<sub>2</sub>]<sup>2+</sup>,<sup>624</sup> [In<sub>2</sub>(trien)<sub>2</sub>(μ-Te)<sub>2</sub>]<sup>2+</sup>,<sup>625</sup> and *cis*-[Tl(trien)(CN)<sub>2</sub>]<sup>+</sup>.<sup>629</sup> In [Pb(tetraen)][Ag<sub>2</sub>L<sub>4</sub>]<sub>n</sub>, the Pb<sup>2+</sup> center is bound by the pentadentate tetraen ligand (**Scheme 13**) and has three Pb⋯I cation⋯anion contacts giving an overall CN of 8.<sup>627</sup>

**Fig. 49** Structures of (A)  $[\text{Na}(\text{R}_4\text{tacd})]^+$  ( $\text{R} = \text{Bz}$ ; CSD refcode JOTRAO), (B)  $[\text{Ca}_3(\text{Me}_3\text{tacd-H})_2(\mu_3\text{-H})_2]^+$  (refcode FAXCOY), (C)  $[\text{Ca}(\text{THF})_2(\text{H}_2\text{L}_{\text{compart}})]^+$  (refcode KAFHAD, only the pyrrole H atoms are shown), (D)  $[\text{Ge}(\text{Me}_4\text{tacd})]^{2+}$  (only the hydrido H atoms are shown; refcode DUSKEJ), (E)  $[\text{Ba}(\text{H}_5\text{aza}(2.2.2)\text{crypt})]^+$  (refcode HAGNOT), and (F)  $[\text{K}(\text{N}_9\text{-azacrypt})]^+$  (refcode HIFCIL).

Moving on to the macrocyclic ligands shown in **Scheme 13**, and group 1 metal complexes are exemplified by  $[\text{Li}(\text{THF})(\text{Me}_4\text{tacd})]$  with 5-coordinate  $\text{Li}^+$ ,<sup>941</sup>  $[\text{M}(\text{THF})_n(\text{Me}_3\text{Rtacd})]$  ( $\text{M} = \text{Li}, \text{Na}, n = 1$ ;  $\text{M} = \text{K}, n = 2$ ) containing the hypervalent  $\text{R} = \text{SiH}_2\text{Ph}_2$  group,<sup>942</sup> the peroxolato complexes  $[\text{Li}(\text{O}_2\text{CMe}_2\text{Ph})(\text{Me}_4\text{tacd})]$ ,  $[\text{K}(\text{O}_2\text{CMe}_2\text{Ph})(\text{PhCMe}_2\text{OOH})_2(\text{Me}_4\text{tacd})]$  and  $[\text{K}(\text{O}_2\text{CMe}_2\text{Ph})(\text{PhCMe}_2\text{OOH})_3(\text{Me}_4\text{tacd})]$  (which are stabilized in the solid state by strong hydrogen bonds from  $\text{PhCMe}_2\text{OOH}$  solvate molecules),<sup>943</sup> and the square-based pyramidal  $[\text{Na}(\text{Me}_3\text{tacd})]$ .<sup>944</sup> The trisodium complex  $[\text{Na}_3(\text{Me}_3\text{tacd-H})_3]$  is structurally related to  $[\text{Ca}_3(\text{Me}_3\text{tacd-H})_3(\mu_3\text{-H})_2]^+$  described below.<sup>942</sup> In  $[\text{Na}(\text{R}_4\text{tacd})]^+$  with  $\text{R} = \text{Bz}$ , the benzyl substituents provide a caged environment for the  $\text{Na}^+$  ion with  $\text{Na}^+ \cdots \pi$  contacts (**Fig. 49A**).<sup>945</sup> While the  $[\text{K}(18\text{-crown-6})]^+$  cation is ubiquitous, analogous N-donor ligands (i.e., O atoms in 18-crown-6 replaced by NH or NR) have been much less studied. In 2015, Reid and coworkers reported the preparation and structures of  $[\text{K}\{\text{Me}_6[18]\text{aneN}_6\}]^+$  as well as the  $\text{Li}^+$ ,  $\text{Na}^+$ ,  $\text{Rb}^+$  and  $\text{Cs}^+$  congeners. In  $[\text{K}\{\text{Me}_6[18]\text{aneN}_6\}]^+$ , the  $\text{K}^+$  ion sits within the plane of the six N-donors, while in  $[\text{Rb}\{\text{Me}_6[18]\text{aneN}_6\}]^+$ , the  $\text{Rb}^+$  ion is displaced from the plane; the macrocycle adopts a puckered conformation in  $[\text{Li}\{\text{Me}_6[18]\text{aneN}_6\}]^+$  with  $\text{Li}^+$  in a distorted octahedral environment. This investigation also includes the structures of  $[\text{Na}(\text{THF})(\text{Me}_4\text{tacd})]^+$  (square-based pyramidal  $\text{Na}^+$ ) and  $[\text{K}(\text{Me}_3\text{tacd})_2]^+$  ( $\text{K}^+$  octahedrally sited).<sup>946</sup>

Group 2 metal complexes include the square-based pyramidal  $[\text{Mg}(\text{BH}_4)(\text{Me}_4\text{tacd})]^+$ ,<sup>947</sup>  $[\text{MgCl}(\text{Me}_4\text{tacd})]^+$  (formed by treating  $[\text{Mg}_2(\text{Me}_4\text{tacd})_2(\mu\text{-H})_2]^{2+}$  with  $[\text{NEt}_3\text{H}]\text{Cl}$ ),<sup>948</sup>  $[\text{M}\{\text{N}(\text{SiMe}_3)_2\}(\text{Me}_3\text{tacd-H})]$  ( $\text{M} = \text{Mg}, \text{Ca}$ ),<sup>949</sup>  $[\text{Mg}(\text{pyridin-1}(4\text{H})\text{-yl})(\text{Me}_3\text{tacd})]$ ,<sup>518</sup> and the 7-coordinate  $[\text{Ca}(\text{THF})_2\text{I}(\text{Me}_4\text{tacd})]^+$ .<sup>950</sup> Reaction of  $\text{Me}_3\text{tacd}$  (**Scheme 13**) with  $[\text{Ca}\{\text{N}(\text{SiMe}_3)_2\}_2(\text{THF})_2]$  followed by treatment with  $\text{Ph}_2\text{SiH}_2$  resulted in the formation of  $[\text{Ca}_3(\text{Me}_3\text{tacd-H})_3(\mu_3\text{-H})_2]^+$  (**Fig. 49B**) in which  $[\text{Me}_3\text{tacd-H}]^-$  is the conjugate base of  $\text{Me}_3\text{tacd}$ ; this was the first example of a cationic calcium hydride and was found to be active in the catalytic hydrosilylation and hydrogenation of 1,1-diphenylethene.<sup>951</sup> Related complexes are  $[\text{Sr}_3(\text{Me}_3\text{tacd-H})_3(\mu_3\text{-H})_2]^+$ ,<sup>952</sup>  $[\text{Ca}_2(\text{Me}_4\text{tacd})_2(\mu\text{-H})_3]^+$ ,<sup>953</sup> and  $[\text{Ca}_2(\text{THF})(\text{Me}_4\text{tacd})_2(\mu\text{-H})_2]^{2+}$ .<sup>950,954</sup> The hydrido ligands in  $[\text{Ca}_2(\text{THF})(\text{Me}_4\text{tacd})_2(\mu\text{-H})_2]^{2+}$  exhibit nucleophilic behavior and the complex is a precursor to a series of dicalcium derivatives retaining  $\{\text{Ca}(\text{Me}_4\text{tacd})\}$  units.<sup>950</sup> Mukherjee et al. have reported a series of  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ , and  $\text{Sr}^{2+}$  silylamide complexes assembled upon an  $\text{Me}_3\text{tacd}$  framework.<sup>955</sup> The Schiff base compartmental ligand  $\text{H}_4\text{L}_{\text{compart}}$  shown in **Scheme 13** accommodates one or two  $\text{Ca}^{2+}$  ions in  $\text{N}_4$ -donor sites in the complexes  $[\text{Ca}(\text{THF})_2(\text{H}_2\text{L}_{\text{compart}})]^+$  (**Fig. 49C**) and  $[\text{Ca}_2(\text{THF})_2(\mu\text{-THF})(\text{L}_{\text{compart}})]$ , as well as one  $\text{Ca}^{2+}$  and one  $\text{Li}^+$  in  $[\text{LiCa}(\text{THF})(\mu\text{-THF})(\text{HL}_{\text{compart}})]$ ; the bowl-shaped conformation of the ligand is noteworthy.<sup>956</sup>

Group 13 metal *tacd* derivatives include the octahedral  $[\text{GaCl}_2(\text{tacd})]^+$  in which the *tacd* ligand directs a *cis* configuration.<sup>957</sup> The reaction of  $[\text{AlH}_2(\text{Me}_3\text{tacd-H})]$  with  $\text{BPh}_3$  in THF gave  $[\text{Al}(\text{O}^t\text{Bu})(\text{Me}_3\text{tacd-H})][\text{HBPh}_3]$  by ring-opening of THF.<sup>958</sup> In  $[\text{GaCl}(\text{H}_2\text{-tabht})]$  (see **Scheme 13** for  $\text{H}_4\text{tabht}$ ), the Ga(III) center is in a square-based pyramidal environment.<sup>959</sup>

Everett et al. have explored reactions of  $[\text{GeCl}_2(\text{diox})]$  with neutral azamacrocyclic ligands, and  $[\text{Ge}(\text{Me}_4\text{tacd})]^{2+}$  is representative of the structurally characterized products; **Fig. 49D** shows that the Ge(II) atom lies above the plane of the four N donors in  $[\text{Ge}(\text{Me}_4\text{tacd})]^{2+}$ ,<sup>960</sup> and a similar coordination geometry is seen for the Pb(II) center in  $[\text{Pb}(\text{R}_2\text{tacd})]^{2+}$  ( $\text{R} = \text{Bz}$ ; see **Scheme 13** for  $\text{R}_2\text{tacd}$ ).<sup>961</sup>

The introduction into macrocyclic ligands such as *tacd* of pendant arms bearing N-donor domains provides a means of increasing the CN of a metal ion bound within the ligand cavity and thereby enhances the stability of the complex with respect to ligand dissociation. The following references give selected examples of such main group metal complexes incorporating purely N-donor ligands.<sup>962–968</sup>

**Scheme 13** Representative 'parent' open-chain, macrocyclic and caging polydentate ligands. In the text, deprotonated Me<sub>3</sub>tacc is represented as Me<sub>3</sub>tacc-H, etc.

**Scheme 14** Formation of the cryptand derivative reported by Gerus et al.<sup>972</sup>

Finally in this section, we consider representative examples of s-block metal ions encapsulated within caging ligands with an emphasis on azacryptands. Cryptands including azacryptands play a crucial role in the synthesis of alkali and electrides.<sup>969</sup> The first barium sodide [Ba{H<sub>5</sub>aza(2.2.2)crypt}]<sup>+</sup>Na<sup>-</sup> was prepared from Ba, Na, and H<sub>6</sub>aza(2.2.2)crypt (**Scheme 13**) in NH<sub>3</sub>-MeNH<sub>2</sub> solution; **Fig. 49E** shows the [Ba{H<sub>5</sub>aza(2.2.2)crypt}]<sup>+</sup> complex.<sup>970</sup> Alkali metal cations template the assembly of the N<sub>9</sub>-azacryptand (N<sub>9</sub>-azacrypt, **Scheme 13**), and the Pb(II) complex has also been described; **Fig. 49F** shows the structure of [K(N<sub>9</sub>-azacrypt)]<sup>+</sup>.<sup>971</sup> The reactions of the hexaazamacrocycle shown in **Scheme 14** with 2,6-bis(bromomethyl)pyridine or 2,6-bis[(tosyloxy)methyl]pyridine in the presence of Na<sub>2</sub>CO<sub>3</sub> or K<sub>2</sub>CO<sub>3</sub> under basic conditions yielded enantiopure azacryptates of Na<sup>+</sup> or K<sup>+</sup>.<sup>972</sup>

## 1.02.3 Phosphorus-donor ligands

### 1.02.3.1 Monodentate ligands

#### 1.02.3.1.1 RPH<sub>2</sub>, R<sub>2</sub>PH, R<sub>3</sub>P including P,P-ligands in monodentate or bridging modes

In this section, monodentate phosphane ligands belonging to the classes RPH<sub>2</sub>, R<sub>2</sub>PH, and R<sub>3</sub>P will be discussed along with ditopic ligands such as R<sub>2</sub>PCH<sub>2</sub>CH<sub>2</sub>PR<sub>2</sub> which can coordinate in a monodentate manner to a metal center. The latter category includes those with ligands which bridge between two main group metals. Complexes of main group metals with RPH<sub>2</sub> ligands are restricted to organometallic species and are outside the scope of this review. Simple derivatives of p-block metals containing R<sub>2</sub>PH ligands are also sparse. Group 13 M(III) compounds with R<sub>2</sub>PH ligands are represented by [MBr<sub>3</sub>(PH<sup>t</sup>Bu<sub>2</sub>)] (M = Al, Ga, In),<sup>973</sup> and complexes featuring a Ga–Ga bond include [Ga<sub>2</sub>Br<sub>4</sub>(PHCy<sub>2</sub>)<sub>2</sub>] (formed from [GaBr(THF)<sub>n</sub>] and PHCy<sub>2</sub>),<sup>974</sup> and [Ga<sub>2</sub>I<sub>4</sub>(PHR<sub>2</sub>)<sub>2</sub>] (R = Cy, <sup>t</sup>Bu).<sup>975</sup> Although one could argue that phosphane selenides are not metal coordination compounds, we include them because, in this review, we treat Se as a semimetal. In SePHPh<sub>2</sub><sup>976,977</sup> and SePH<sup>t</sup>Bu<sub>2</sub>,<sup>978</sup> P–H⋯Se hydrogen bonds dominate packing interactions in the solid state, but are not observed in SePH(CH<sub>2</sub>CH<sub>2</sub>Ph)<sub>2</sub>.<sup>979</sup>

Compared to those with RPH<sub>2</sub> and R<sub>2</sub>PH ligands, coordination compounds with tertiary phosphanes are more abundant, and complexes of the p-block metals predominate over those in the s-block. Buchner et al. have reported the synthesis and crystal structure of tetrahedral [BeCl<sub>2</sub>(PMe<sub>3</sub>)<sub>2</sub>] which has been used as a precursor to <sup>n</sup>Bu<sub>2</sub>Be.<sup>980</sup> While reaction of [BeI<sub>2</sub>(OEt<sub>2</sub>)<sub>2</sub>] with dppm yielded [BeI<sub>2</sub>(dppm-κ<sup>1</sup>)<sub>2</sub>] (Fig. 50A),<sup>659</sup> that with dppe led to the 1D-coordination polymer [BeI<sub>2</sub>(μ-dppe)]<sub>n</sub>.<sup>981</sup> A similar structure to that shown in Fig. 50A is also found for [BeCl<sub>2</sub>(dppm-κ<sup>1</sup>)<sub>2</sub>].<sup>982</sup>

The reactions of AlX<sub>3</sub> (X = Cl, Br, I) with PMe<sub>3</sub> lead to the formation of [AlX<sub>3</sub>(PMe<sub>3</sub>)] or [AlX<sub>3</sub>(PMe<sub>3</sub>)<sub>2</sub>] depending on the ratio of reagents used; with the bisphosphane Cy<sub>2</sub>PCH<sub>2</sub>CH<sub>2</sub>PCy<sub>2</sub>, dinuclear [AlCl<sub>3</sub>]<sub>2</sub>(μ-Cy<sub>2</sub>PCH<sub>2</sub>CH<sub>2</sub>PCy<sub>2</sub>) was the sole product while with the less sterically demanding Me<sub>2</sub>PCH<sub>2</sub>CH<sub>2</sub>PMe<sub>2</sub> (dmpe), the formation of [AlCl<sub>3</sub>]<sub>2</sub>(μ-dmpe) competed with *trans*-[AlCl<sub>2</sub>(dmpe)<sub>2</sub>] containing chelating ligands. All products are extremely moisture sensitive.<sup>983</sup> A series of tetrahedral [InX<sub>3</sub>(PR<sub>3</sub>)] and trigonal bipyramidal *trans*-[InX<sub>3</sub>(PR<sub>3</sub>)<sub>2</sub>] complexes with X = Cl, Br, I; R = Ph or various MeO-substituted phenyl) have been structurally characterized and studied in detail by solid-state <sup>115</sup>In and <sup>31</sup>P NMR spectroscopies.<sup>984</sup> [Ga(PPh<sub>3</sub>)<sub>3</sub>]<sup>+</sup> was the first structurally characterized homoleptic gallium–phosphane complex and has a trigonal pyramidal structure; it was isolated by use of the weakly coordinating [Al(O<sup>t</sup>Bu<sup>F</sup>)<sub>4</sub>]<sup>−</sup> anion (<sup>t</sup>Bu<sup>F</sup> = perfluoro-*tert*-butyl).<sup>985</sup> This work was followed by the isolation of the 2-coordinate [M(P<sup>t</sup>Bu<sub>3</sub>)<sub>2</sub>]<sup>+</sup> (M = Ga, In) and 3-coordinate [In(PPh<sub>3</sub>)<sub>3</sub>]<sup>+</sup>.<sup>986</sup> Phosphane adducts of InH<sub>3</sub> have been prepared by reactions of PR<sub>3</sub> (R = Cy, Ph or cyclopentyl) with [InH<sub>3</sub>(NMe<sub>3</sub>)] in 1:1 or 2:1 M ratios, and the crystal structure of [InH<sub>3</sub>(PCy<sub>3</sub>)<sub>2</sub>] reveals a trigonal bipyramidal structure with a *trans*-arrangement of PCy<sub>3</sub> ligands.<sup>987</sup>

Group 14 M(IV) complexes are illustrated by [SnF<sub>4</sub>(PCy<sub>3</sub>)<sub>2</sub>],<sup>988</sup> *trans*-[SnCl<sub>4</sub>(PMe<sub>3</sub>)<sub>2</sub>],<sup>989</sup> *trans*-[SnCl<sub>3</sub>(PMe<sub>3</sub>)<sub>2</sub>]<sup>+</sup>,<sup>989</sup> and [SnCl<sub>2</sub>(PMe<sub>3</sub>)<sub>2</sub>]<sup>2+</sup> (which has close Sn⋯Cl contacts with [AlCl<sub>4</sub>]<sup>−</sup> counterions),<sup>989</sup> as well as octahedral [SnCl<sub>3</sub>(O<sub>3</sub>SCF<sub>3</sub>)(PMe<sub>3</sub>)<sub>2</sub>] with *trans*-PMe<sub>3</sub> groups, and trigonal bipyramidal [SnCl<sub>2</sub>(PEt<sub>3</sub>)<sub>3</sub>] with equatorial phosphanes. The latter are representative of a series of neutral and cationic phosphane and arsane complexes of tin(IV) halides reported in 2019 by Reid and coworkers.<sup>990</sup> Germanium(II) cations containing neutral, soft-donor ligands are rare, and Reid and coworkers reported [Ge(PMe<sub>3</sub>)<sub>3</sub>][CF<sub>3</sub>SO<sub>3</sub>]<sub>2</sub> in 2021; [Ge(PMe<sub>3</sub>)<sub>3</sub>]<sup>2+</sup> has a trigonal pyramidal structure with a stereochemically active lone pair.<sup>991</sup> Tin(II) is large enough to accommodate four PPh<sub>3</sub> ligands in [Sn(PPh<sub>3</sub>)<sub>4</sub>]<sup>2+</sup>; the space-filling diagram in Fig. 50B shows the extent of intra-cation CH⋯π contacts.<sup>992</sup> Lead(II) complexes are illustrated by the tetrahedral [PbI<sub>2</sub>(PPh<sub>3</sub>)<sub>2</sub>],<sup>993</sup> the structure of which contrasts with that of [PbI<sub>2</sub>(PMe<sub>3</sub>)<sub>2</sub>] in which [Pb<sub>2</sub>I<sub>2</sub>(PMe<sub>3</sub>)<sub>4</sub>(μ-I)]<sup>+</sup> units are connected via short contacts through the I<sup>−</sup> counterion (Pb⋯I = Fig. 50C).<sup>994</sup>

A noteworthy reaction in group 15 coordination chemistry is that of [(η<sup>5</sup>-Cp\*)As(toluene)]<sup>2+</sup> with PMe<sub>3</sub> which yields [As(PMe<sub>3</sub>)<sub>2</sub>]<sup>+</sup> (Fig. 50D) isolated as the [B(C<sub>6</sub>F<sub>5</sub>)<sub>4</sub>]<sup>−</sup> salt.<sup>995</sup> This unusual As(I) species has also been reported by Burford and coworkers, but (as the triflate salt) could not be isolated.<sup>996</sup> The reaction of PMe<sub>3</sub> with SbCl<sub>3</sub> in the presence of Me<sub>3</sub>SiOSO<sub>2</sub>CF<sub>3</sub> leads to the [CF<sub>3</sub>SO<sub>3</sub>]<sup>−</sup> salt of [SbCl<sub>2</sub>(PMe<sub>3</sub>)<sub>2</sub>]<sup>+</sup> with the PMe<sub>3</sub> ligands in the equatorial sites of a distorted see-saw (disphenoidal) structure; comparisons were made with the structures and <sup>31</sup>P NMR spectra for related complexes with chelating bisphosphanes.<sup>997</sup> In a complementary study, SbF<sub>3</sub> was reacted with Me<sub>3</sub>SiOSO<sub>2</sub>CF<sub>3</sub>; phosphane coordination to Sb(III) was expected but redox processes between Sb and P ultimately led to *cyclo*-[Sb<sub>4</sub>(PMe<sub>3</sub>)<sub>4</sub>]<sup>4+</sup>.<sup>998</sup> A series of [SbCl<sub>n</sub>(PR<sub>3</sub>)<sub>m</sub>]<sup>(3-n)+</sup> (R = Me, Ph, Cy; n = 1–4, m = 1, 2) has been reported and the structures analyzed in detail. The group 15 metal center can behave as a Lewis acceptor despite

**Fig. 50** Structures of (A) [BeI<sub>2</sub>(dppm-κ<sup>1</sup>)<sub>2</sub>] (CSD refcode TIVJIU), (B) [Sn(PPh<sub>3</sub>)<sub>4</sub>]<sup>2+</sup> highlighting intra-cation CH⋯π contacts (refcode RELKOJ), (C) [Pb<sub>2</sub>I<sub>2</sub>(PMe<sub>3</sub>)<sub>4</sub>(μ-I)]<sup>+</sup> (refcode ZUBWIF), (D) [As(PMe<sub>3</sub>)<sub>2</sub>]<sup>+</sup> (refcode FONTOU), and (E) (refcode QUCWIW).

the presence of a lone pair, and by considering the substituents and ligands, Burford has defined the relative *trans*-labilizing influence as lone-pair < PPh<sub>3</sub> ≤ Cl<sup>-</sup> < PCy ≈ PMe < Ar<sup>-</sup>.<sup>272</sup> Burford and coworkers have also reported the reaction of Ph<sub>3</sub>P with SbF(O<sub>3</sub>SCF<sub>3</sub>)<sub>2</sub> and the 5-coordinate [SbF(O<sub>3</sub>SCF<sub>3</sub>)<sub>2</sub>(PPh<sub>3</sub>)<sub>2</sub>] was isolated; reductive elimination of [Ph<sub>3</sub>PF]<sup>+</sup> (as the triflate salt) occurs and, after a redox process, the unusual bicyclic [Sb<sub>6</sub>(PPh<sub>3</sub>)<sub>4</sub>]<sup>4+</sup> cation (Fig. 50E) resulted.<sup>999</sup>

### 1.02.3.1.2 R<sub>2</sub>P<sup>-</sup>, RPH<sup>-</sup>, RP<sup>2-</sup>

Upon going from neutral phosphanes to anionic phosphide ligands, we see a significant increase in the number of s-block metal complexes, and sterically demanding substituents such as Dipp are typically employed. We provide selected examples which serve as an entry into this area of coordination chemistry. Mixed donor ligands are not included. Lithium phosphides [LiPR<sub>2</sub>] are precursors to a range of main group metal phosphides as exemplified throughout this section.

The reaction of Dipp<sub>2</sub>PH with <sup>n</sup>BuLi in THF leads to the tetrahedral [Li(THF)<sub>3</sub>{P(Dipp)<sub>2</sub>}], while reactions between Dipp<sub>2</sub>PH and BzNa or BzK in THF result in the formation of [Na<sub>2</sub>(THF)<sub>4</sub>{μ-P(Dipp)<sub>2</sub>}<sub>2</sub>] or [K(THF)<sub>4</sub>{P(Dipp)<sub>2</sub>}], respectively. Under vacuum, loss of THF yields new solvates, including [Li(THF)<sub>2</sub>{P(Dipp)<sub>2</sub>}] which undergoes a dynamic monomer–dimer equilibrium in solution.<sup>1000</sup> An analogous reaction to that above is that of Ph{(Me<sub>3</sub>Si)<sub>2</sub>CH}PH with <sup>n</sup>BuLi which leads to [Li(OEt<sub>2</sub>)<sub>n</sub>{PPh(CH(SiMe<sub>3</sub>)<sub>2</sub>)}] or [Li(THF)<sub>3</sub>{PPh(CH(SiMe<sub>3</sub>)<sub>2</sub>)}]. The etherate can be converted to the Na<sup>+</sup> and K<sup>+</sup> derivatives; [K(OEt<sub>2</sub>)<sub>n</sub>(PPhR)] (R = CH(SiMe<sub>3</sub>)<sub>2</sub>) is a precursor to [Ge<sub>2</sub>(PPhR)<sub>2</sub>(μ-PPhR)<sub>2</sub>], while reaction between [Li(PPhR)] and SnCl<sub>2</sub> followed by crystallization from THF leads to [Li(THF)<sub>4</sub>][Sn(PPhR)<sub>3</sub>] in which Sn(II) is in a trigonal pyramidal environment.<sup>1001</sup> In the sterically crowded [Li(THF)<sub>2</sub>{PPh(2,6-Mes<sub>2</sub>C<sub>6</sub>H<sub>3</sub>)}], the Li<sup>+</sup> is 3-coordinate but with additional Li⋯π contacts to one Mes group; the Li–P distance is relatively short (2.478(4) Å). Treatment of [Li(THF)<sub>2</sub>{PPh(2,6-Mes<sub>2</sub>C<sub>6</sub>H<sub>3</sub>)}] with SnCl<sub>2</sub> yielded [Sn{PPh(2,6-Mes<sub>2</sub>C<sub>6</sub>H<sub>3</sub>)}]<sub>2</sub>.<sup>1002</sup> Lithium complexes derived from (Dipp)PH(CH<sub>2</sub>)<sub>n</sub>PH(Dipp) with n = 1–5 have been reported, and structures are dependent upon n; for n = 1 and 3, discrete monomers with Li<sub>2</sub>P<sub>2</sub> cores were found, whereas for n = 4, the complex [(THF)<sub>3</sub>Li{μ-(Dipp)P(CH<sub>2</sub>)<sub>4</sub>P(Dipp)}Li(THF)<sub>3</sub>] was isolated with each Li<sup>+</sup> being tetrahedrally sited. Detailed NMR spectroscopic studies give insight into the solution behavior of these species.<sup>1003</sup>

Recrystallization of an Et<sub>2</sub>O solution containing 18-crown-6 and KP<sup>t</sup>Bu<sub>2</sub> leads to [K(18-crown-6)(P<sup>t</sup>Bu<sub>2</sub>)] (Fig. 51A); the rather long K–P distance of 3.239(1) Å indicates that the K and P centers possess significant Lewis acidity and basicity, respectively, and indeed, the compound reacts with CO via nucleophilic attack by the basic phosphide.<sup>1004</sup> We have noted earlier (e.g., Figs. 44A, C, 45A) that M<sup>+</sup>⋯π interactions may play an important role in the solid-state structures of complexes of the heavier s-block elements, and this is again observed in [KPPH<sub>2</sub>]. The structure is complicated, and exhibits cyclic K<sub>2</sub>P<sub>2</sub> and K<sub>3</sub>P<sub>3</sub> motifs as well as extensive K<sup>+</sup>⋯π<sub>phenyl</sub> interactions.<sup>1005</sup>

In the group 2 metal complexes [M(18-crown-6)(PPh<sub>2</sub>)<sub>2</sub>] (M = Ca, Ba), the phosphido ligands are axially bound,<sup>1006</sup> and a *trans*-arrangement is also found in [M(THF)<sub>4</sub>(PPh<sub>2</sub>)<sub>2</sub>] (M = Ca, Sr)<sup>1006,1007</sup> and [Ba(THF)<sub>5</sub>(PPh<sub>2</sub>)<sub>2</sub>].<sup>1007</sup> However, *trans*–*cis* isomerism in [Ca(THF)<sub>4</sub>(PPh<sub>2</sub>)<sub>2</sub>] can occur.<sup>939</sup> Note the increase from CN = 6 to 7 on going from Ca<sup>2+</sup> and Sr<sup>2+</sup> to M = Ba<sup>2+</sup>. However, in [Ba(THF)<sub>4</sub>(PMes<sub>2</sub>)<sub>2</sub>] with the bulkier Mes<sub>2</sub>P<sup>-</sup> ligands, a CN = 6 is observed.<sup>1007</sup> Di-, tri- and hexanuclear calcium complexes have been obtained from combinations of PH<sub>2</sub>(Si<sup>t</sup>Bu<sub>3</sub>) and [Ca(THF)<sub>2</sub>]{N(SiMe<sub>3</sub>)<sub>2</sub>}]; in the Ca<sub>2</sub> and Ca<sub>3</sub> species, [PH(Si<sup>t</sup>Bu<sub>3</sub>)]<sup>-</sup> ligands bridge between pairs of Ca<sup>2+</sup> centers, while the hexanuclear cluster is supported by μ-[PH(Si<sup>t</sup>Bu<sub>3</sub>)]<sup>-</sup> and μ<sub>3</sub>-[P(Si<sup>t</sup>Bu<sub>3</sub>)]<sup>2-</sup> ligands.<sup>1008</sup> Westerhausen et al. have also characterized Sr<sub>6</sub>P<sub>8</sub>-clusters which are structurally related to their calcium congeners.<sup>1009</sup> Reaction of SrI<sub>2</sub> with K[PHPh] in THF yields the 1D-coordination polymer [Sr(THF)<sub>2</sub>(μ-PHPh)<sub>2</sub>]<sub>n</sub> with octahedrally sited Sr<sup>2+</sup>; this is one of a series of related group 2 metal assemblies with [PHPh]<sup>-</sup> ligands.<sup>1010</sup>

The Ga(III) complex [Ga(P<sup>t</sup>Bu<sub>2</sub>)<sub>3</sub>] (trigonal planar Ga) results from the reaction of GaCl<sub>3</sub> with 3 or more equivalents of Li [P<sup>t</sup>Bu<sub>2</sub>], while a 1:1 reaction followed by protolysis produced the [P<sup>t</sup>Bu<sub>2</sub>PH<sub>2</sub>]<sup>+</sup> salt of [Li{P<sup>t</sup>Bu<sub>2</sub>P(GaCl<sub>3</sub>)<sub>2</sub>}]<sup>-</sup> in which Li is

**Fig. 51** Structures of (A) [K(18-crown-6)(P<sup>t</sup>Bu<sub>2</sub>)] (CSD refcode TIVLUI), (B) the diradical [Al<sub>2</sub>(P<sup>t</sup>Bu<sub>2</sub>)<sub>4</sub>] (refcode LUNMUD), (C) the diamagnetic [Al<sub>2</sub>(P<sup>t</sup>Bu<sub>2</sub>)<sub>4</sub>] (refcode LUNNAK), (D) [Sn<sub>2</sub>(P(Dipp))<sub>2</sub>] highlighting different P environments (refcode DAGQEK), and (E) [Sn<sub>2</sub>(P(Tripp))<sub>2</sub>] (refcode DAGQOU).

octahedrally sited between two  ${}^t\text{Bu}_2\text{P}(\text{GaCl}_3)_2$  units with Ga–Cl–Li bridges.<sup>1011</sup> An intriguing investigation from Henke et al. starts with the premise that highly energetic  $[\text{Al}(\text{P}^t\text{Bu}_2)_2]$  radicals should dimerize via an intermediate biradical with a long Al $\cdots$ Al distance. The addition of Li $[\text{P}^t\text{Bu}_2]$  to a solution containing the metastable AlCl produced green crystals of  $[\text{Al}_2(\text{P}^t\text{Bu}_2)_4]$  (Fig. 51B) with Al $\cdots$ Al = 3.508 Å. In contrast, replacing AlCl by AlBr resulted in the isolation of yellow crystals of  $[\text{Al}_2(\text{P}^t\text{Bu}_2)_4]$  (Fig. 51C) with Al $\cdots$ Al = 2.587 Å. The structural elucidations were supported by computational investigations, and the differences were explained in terms of the isolation of a high-energy triplet molecule (green compound) in contrast to a stable butterfly structure (yellow crystals).<sup>1012</sup>  $[\text{Ga}_8\text{Cl}_2(\text{P}^i\text{Pr}_2)_2(\mu\text{-P}^i\text{Pr}_2)_6]$  is a representative example of group 13 metal clusters supported by  $\text{R}_2\text{P}^-$  ligands.<sup>1013</sup> Other phosphido  $\text{Al}_n$  and  $\text{Ga}_n$  clusters have also been described.<sup>1014–1021</sup> Treatment of  $[\text{Ge}_9\{\text{Si}(\text{SiMe}_3)_3\}_3]^-$  or  $[\text{Ge}_9\{\text{Si}(\text{SiMe}_3)_3\}_2]^{2-}$  with  $\text{R}_2\text{P}^-$  (R = Cy,  ${}^i\text{Pr}$ ,  ${}^t\text{Bu}$ ) yielded the first Zintl clusters carrying  $\text{R}_2\text{P}$ -substituents; one example is  $[\text{Ge}_9\{\text{Si}(\text{SiMe}_3)_3\}_3(\text{PCy}_2)]$ ,<sup>1022</sup> and related  $\text{Ge}_9$ -clusters have been reported.<sup>1023</sup>

Group 14 M(IV) derivatives with  $\text{R}_2\text{P}^-$  ligands include the tetrahedral  $[\text{GeCl}\{\text{N}(\text{SiMe}_3)_2\}_2(\text{PEt}_2)]$ .<sup>1024</sup> The use of  $[\text{Li}(\text{PPhR})]$  (R = CH(SiMe<sub>3</sub>)<sub>2</sub>) to access  $[\text{Ge}_2(\text{PPhR})_2(\mu\text{-PPhR})_2]$  and  $[\text{Sn}(\text{PPhR})_3]^-$  was detailed earlier in this section,<sup>1001</sup> and we also described the synthesis of  $[\text{Sn}\{\text{PPh}(2,6\text{-Mes}_2\text{C}_6\text{H}_3)\}_2]$ .<sup>1002</sup>  $[\text{Sn}\{\text{P}(\text{Dipp})_2\}_2]$  is noteworthy for being the first example of a compound with a crystallographically confirmed P=Sn bond, arising from a P–Sn  $\pi$ -interaction involving a lone pair on a planar P center (Fig. 51C) and the vacant p-orbital on Sn; the analogous Ge(II) complex has also been fully characterized.<sup>1025,1026</sup> Izod et al. point out that if both P environments were planar, a weaker P–Sn or P–Ge  $\pi$ -interaction would result and this would not compensate for the energy required to rehybridize both P atoms. Significantly, in  $[\text{Sn}\{\text{P}(\text{Tripp})_2\}_2]$ , both P atoms are pyramidal (Fig. 51E), indicating the absence of the Sn–P  $\pi$ -bond.<sup>1026</sup> In the related  $[\text{M}\{\text{P}(\text{Dipp})(\text{Mes})_2\}_2]$  and  $[\text{M}\{\text{P}(\text{Dipp})\{\text{CH}(\text{SiMe}_3)_2\}_2\}_2]$  (M = Ge, Sn) derivatives, Izod et al. have assessed the roles of both P–Ge or P–Sn  $\pi$ -interactions and Ge $\cdots$ arene or Sn $\cdots$ arene interactions.<sup>1027</sup> The first example of an  $[\text{As}(\text{PR}_2)_2]^+$  cation was reported in 2019 in the salt  $[\text{As}\{\text{P}(\text{Dipp})_2\}_2][\text{Al}\{\text{OC}(\text{CF}_3)_3\}_4]$ ; as in the isoelectronic Ge(II) and Sn(II) species above, stabilization of  $[\text{As}\{\text{P}(\text{Dipp})_2\}_2]^+$  is due to a P–As  $\pi$ -interaction.<sup>1028</sup> In addition to the carbene-analogs mentioned above, phosphido complexes of the heavier group 15 elements are exemplified by the trigonal pyramidal  $[\text{AsCl}\{\text{P}(\text{Dipp})_2\}_2]$ .<sup>1028</sup>

In Section 1.02.2.2.3, we discussed main group metal complexes containing  $\beta$ -diketiminato ligands (see Scheme 6 for ligand abbreviations). Complexes which combine  $\beta$ -diketiminato and phosphide ligands include  $[\text{M}(\text{THF})(\text{Nacnac})(\text{PPh}_2)]$  (M = Mg, Ca; Ar = Dipp, see Scheme 6 for definition of Ar),<sup>1029,1030</sup>  $[\text{AlH}(\text{Nacnac})(\text{PPh}_2)]$  (Ar = Dipp),<sup>1031</sup>  $[\text{Ge}(\text{Nacnac})(\text{PPh}_2)]$  (Ar = Dipp),<sup>1032</sup>  $[\text{M}(\text{Nacnac})(\text{PR}_2)]$  (M = Ge, Sn, Pb; Ar = Dipp; R = Ph, Cy),<sup>1033</sup> and the Ge(IV) derivative  $[\text{Ge}(\text{E})(\text{Nacnac})(\text{PCy}_2)]$  (Ar = Dipp; E = S, Se).<sup>1034,1035</sup>

### 1.02.3.1.3 $\text{PCO}^-$ , $\text{PCS}^-$

In Section 1.02.2.1.4, we surveyed main group metal complexes with N-bonded  $\text{NCO}^-$  and  $\text{NCS}^-$  ligands, and we noted terminally N-bonded, bridging N-bonded, and bridging N,X-bound (X = O, S) modes. Now we consider complexes containing P-bonded  $\text{PCO}^-$  and  $\text{PCS}^-$  ligands. These are less common than their nitrogen counterparts. The  $\text{PCO}^-$  and  $\text{PCS}^-$  anions were first reported in 1992 and 1994, respectively, with structurally characterized  $[\text{Li}(\text{dme})_2(\text{PCO-O})]$  and  $[\text{Li}(\text{dme})_3][\text{PCS}]$  (with non-coordinated  $[\text{PCS}]^-$  ion).<sup>1036,1037</sup> Since 2000, the structures of  $\text{Na}(\text{PCO})$  (a 3D-network with P,O-bonded bridging ligands),<sup>1038</sup>  $[\text{Na}_2(\text{dme})_4(\mu\text{-OCP})_2]$  (with Na–O–Na bridges),<sup>1039</sup>  $[\text{Na}(\text{OCP-O})(\text{THF})(\text{Bz}18\text{-crown-6})]$ ,<sup>1040</sup> and the 1D-coordination polymers  $[\text{K}(18\text{-crown-6})(\text{PCO})]_n$ ,<sup>1041</sup>  $[\text{Na}(18\text{-crown-6})(\text{PCS})]_n$ ,<sup>1042</sup> and  $[\text{K}(18\text{-crown-6})(\text{PCS})]_n$  (Fig. 52A),<sup>1042</sup> all with P,X-bonded (X = O, S) bridging ligands have been described. Note the variation in bonding modes across this series of alkali metal compounds, with only the bridging ligands (as in Fig. 52A) being strictly relevant to this section (see Section 1.02.6.1.4 for O-bonded  $\text{PCO}^-$ ).

Group 2 metal complexes with  $[\text{PCO}]^-$  ligands appear to be sparse; one example is *trans*- $[\text{Mg}(\text{PCO})_2(\text{THF})_4]$ , but with O-bonded  $\text{PCO}^-$ .<sup>1040</sup>

The first  $\text{PCO}$ -adducts of Al and Ga were reported in 2019, when Mei et al. demonstrated the use of a sterically hindered salen-type framework to stabilize  $\{\text{Al}^{\text{III}}\text{-OCP}\}$  and  $\{\text{Ga}^{\text{III}}\text{-PCO}\}$  units. Note the change in coordination mode with selective P-coordination to the softer Ga(III) center (angle Ga–P–C = 88.43(11)°, Fig. 52B).<sup>1043</sup> A similar coordination mode is observed in the Ge(II) compound  $[\text{Ge}(\text{Me}_2\text{N-Nacnac})(\text{PCO})]$  in which  $[\text{Me}_2\text{N-Nacnac}]^-$  is an amino-functionalized  $\beta$ -diketiminato ligand (Scheme 6 with Ar = Dipp),<sup>1044</sup> and in  $[\text{Ge}(\text{Nacnac})(\text{PCO})]$  (Ar = 2-Ph<sub>2</sub>PC<sub>6</sub>H<sub>4</sub>).<sup>1045</sup> The Ge–P–C angles in these two complexes are 87.29(16) and 91.7(3)° respectively. The tin(II) analog of the latter has also been characterized,<sup>1045</sup> and a related structure is found in  $[\text{As}(\text{DippNCH}_2\text{CH}_2\text{NDipp})(\text{PCO})]$ .<sup>1046</sup>  $[\text{Sn}(\text{NRR}')(\text{PCO})]$  with R = Si(4- ${}^t\text{Bu}$ C<sub>6</sub>H<sub>4</sub>)<sub>3</sub> and R' = 2,6-

**Fig. 52** (A) Part of the 1D-chain in  $[\text{K}(18\text{-crown-6})(\text{PCS})]_n$  (CSD refcode QUZWOZ; the S and P sites are disordered). (B) An example of a salen-supported  $\{\text{Ga}^{\text{III}}\text{-PCO}\}$  unit (refcode VOBCEX). Structures of (C)  $[\text{Ga}(\text{py})(\text{dpp-bian})(\text{PCO})]$  (refcode SUZJJJ) and (D)  $[\text{Ga}_2(\text{py})_2(\text{dpp-bian})_2(\mu\text{-P}_2)]$  (refcode SUZLIL).

$\{\text{CH}(3,5\text{-}^t\text{Bu}_2\text{C}_6\text{H}_3)_2\}_2\text{-4-MeC}_6\text{H}_2$  is one of a series of Sn(II) and Ge(II) species in which the steric congestion of the amido ligand stabilizes 2-coordinate M(II) in a mononuclear complex.<sup>1047</sup>

One of the interesting aspects of {MPCO}-containing compounds is their potential for the loss of CO and formation of an {M≡P} unit. This has been realized starting from the  $\beta$ -diketiminato complex [Ge(R-Nacnac)(PCO)] (see Scheme 6, Ar = Dipp, R = H) which loses CO upon irradiation and, via an {Ge≡P}-containing intermediate, forms the dimer [Ge<sub>2</sub>(R-Nacnac)<sub>2</sub>( $\mu$ -P)<sub>2</sub>] (Ge–P = 2.2550(6) and 2.2673(6) Å, indicative of some double-bond character).<sup>1048</sup> The work of Goicoechea is prominent in the field of [PCO]<sup>−</sup> complexes. This group has reported the preparation and structure of [Ga(py)(dpp-bian)(PCO)] (Fig. 52C; note the related complex [Ga<sub>2</sub>(dpp-bian)<sub>2</sub>(NCO)<sub>2</sub>], Fig. 27B) and its photolysis with loss of CO to yield [Ga<sub>2</sub>(py)<sub>2</sub>(dpp-bian)<sub>2</sub>( $\mu$ -P<sub>2</sub>)] (Fig. 52D).<sup>1049</sup>

### 1.02.3.2 [P<sub>n</sub>]<sup>x−</sup> ligands derived from P<sub>4</sub>

Chain, ring and cluster species of the group 15 elements P, As, Sb and Bi are covered in a separate section of this reference work.<sup>1050</sup> A themed issue of *Dalton Trans.* ('Phosphorus chemistry: discoveries and advances')<sup>1051</sup> includes a number of papers relevant to the topic. An area of specific interest is the activation of P<sub>4</sub> under mild conditions and a review by Scheer<sup>1052</sup> coupled with papers from Inoue<sup>1053</sup> and Power<sup>1054</sup> give a good entry into this field. In this section we use a few selected examples to illustrate the coordination of small [P<sub>n</sub>]<sup>x−</sup> ligands to main group metals and we focus on activation of P<sub>4</sub>. Many complexes contain M–C bonds, e.g., [Ge(Dipp)<sub>2</sub>(P<sub>4</sub>- $\kappa^2$ )],<sup>1055</sup> and fall outside the scope of this review.

The activation of P<sub>4</sub> by LiSi<sup>t</sup>Bu<sub>3</sub> leads to P<sub>4</sub>(Si<sup>t</sup>Bu<sub>3</sub>)<sub>2</sub>, P<sub>7</sub>(Si<sup>t</sup>Bu<sub>3</sub>)<sub>3</sub>, [Li<sub>3</sub>P(PSi<sup>t</sup>Bu<sub>3</sub>)<sub>3</sub>] and [LiP<sub>5</sub>], while in the presence of LiOSi<sup>t</sup>Bu<sub>3</sub>, the product was [LiP<sub>7</sub>(Si<sup>t</sup>Bu<sub>3</sub>)<sub>2</sub>].<sup>1056</sup> The reaction between P<sub>4</sub> and NaSi<sup>t</sup>Bu<sub>3</sub> produces the dimer [(<sup>t</sup>Bu<sub>3</sub>Si)<sub>3</sub>P<sub>5</sub>Na<sub>2</sub>(THF)]<sub>2</sub> in which the Na atoms have CN = 3 or 4 (Fig. 53A).<sup>1057</sup> A wide range of Ga(III) polyphosphane complexes, the simplest of which is [Ga(Nacnac)(P<sub>4</sub>- $\kappa^2$ )], (Fig. 53B) have been isolated from the reaction of [Ga(Nacnac)] (Ar = Dipp, see Scheme 6) and white phosphorus.<sup>1038</sup> Reactions of [Ga(Nacnac)(P<sub>4</sub>- $\kappa^2$ )] with Cy<sub>2</sub>PCL, Ph<sub>2</sub>PCL, Mes<sub>2</sub>PCL or (C<sub>6</sub>H<sub>5</sub>)<sub>2</sub>PBr have led to compounds containing P<sub>5</sub> units with [GaBr(Nacnac){P<sub>5</sub>(C<sub>6</sub>H<sub>5</sub>)<sub>2</sub>}] as a representative complex (Fig. 53C); kinetics data offer insight into the reaction mechanism.<sup>1058</sup> Power and coworkers have shown that P<sub>4</sub> reacts with Tl<sub>2</sub>(2,6-Dipp<sub>2</sub>C<sub>6</sub>H<sub>3</sub>)<sub>2</sub> with transfer of the aryl groups to phosphorus and formation of [Tl<sub>2</sub>{P<sub>4</sub>(2,6-Dipp<sub>2</sub>C<sub>6</sub>H<sub>3</sub>)<sub>2</sub>}] (Fig. 53D).<sup>1059</sup> Coordination compounds of bismuth with [P<sub>n</sub>]<sup>x−</sup> ligands have proved rather elusive, and innovative work from Coles and coworkers demonstrates the activation of P<sub>4</sub> by an isolated Bi(II) radical (Fig. 53E).<sup>1060</sup>

**Fig. 53** Structures of (A) [(<sup>t</sup>Bu<sub>3</sub>Si)<sub>3</sub>P<sub>5</sub>Na<sub>2</sub>(THF)]<sub>2</sub> (CSD refcode CAQHUY), (B) [Ga(Nacnac)(P<sub>4</sub>- $\kappa^2$ )] (refcode SEGFUI), (C) [GaBr(Nacnac)(P<sub>5</sub>(C<sub>6</sub>H<sub>5</sub>)<sub>2</sub>)] (refcode SAYKAH), and (D) [Tl<sub>2</sub>{P<sub>4</sub>(2,6-Dipp<sub>2</sub>C<sub>6</sub>H<sub>3</sub>)<sub>2</sub>}] (refcode CEDBET). (E) The product of the activation of P<sub>4</sub> by an isolated Bi(II) radical (refcode AYUXEZ).

**Scheme 15** Chelating bisphosphanes included in Section 1.02.3.3.1.

**Fig. 54** Structures of (A)  $[\text{Li}(\text{dmpbz})_3]^+$  (CSD refcode LUDXUF), (B)  $[\text{K}(\text{dppm-H})(\text{diglyme})_2]$  (refcode NISKAD), (C)  $[\text{I}(\text{dppe})\text{BeAl}(\text{Nacac})\text{I}]$  with  $\text{Ar}_{\text{Nacac}} = \text{Dipp}$  (refcode ASIBIQ), and (D)  $[\text{Pb}(\text{dmpe})(\text{O}_2\text{NO-}\kappa^2)_2]$  showing intermolecular  $\text{O}\cdots\text{Pb}$  contacts (refcode MUJMIP).

### 1.02.3.3 Bidentate ligands

#### 1.02.3.3.1 Chelating bisphosphanes

As in Section 1.02.2.2.1 for chelating diamines, we restrict our coverage of main group metal complexes containing chelating bisphosphanes to selected and common ligands (Scheme 15).

Metal complexes from the s-block are relatively sparse. Reid and coworkers have realized the formation of homoleptic  $[\text{Li}(\text{dmpe})_3]^+$ ,  $[\text{Li}(\text{dmpbz})_3]^+$  (Fig. 54A),  $[\text{Na}(\text{dmpe})_3]^+$  and  $[\text{Na}(\text{dmpbz})_3]^+$  cations by using the very weakly coordinating  $[\text{Al}\{\text{OC}(\text{CF}_3)_3\}_4]^-$  and  $[\text{B}\{3,5-(\text{CF}_3)_2\text{-C}_6\text{H}_3\}_4]^-$  anions.<sup>1061</sup> Lithium bis(diphenylphosphanyl)methanide,  $[\text{Li}(\text{dppm-H})]$ , is well established.<sup>1062</sup> In  $[\text{Li}(\text{dppm-H})(\text{tmeda})]$ , the  $\text{Li}^+$  center is tetrahedrally sited with  $\text{Li-P}$  distances of 2.537(4) and 2.568(4) Å,<sup>1063</sup> whereas in  $[\text{Li}(\text{THF})(\text{dppm-H})(\text{tmeda})]$ , the  $\text{Li-P}$  distances of 2.653(4) and 3.018(4) Å indicate preferential coordination of THF and only one principal  $\text{Li-P}$  interaction.<sup>1064</sup> In contrast, in  $[\text{Li}(\text{dppm-H})(\text{dme})_2]$ , both  $\text{Li-P}$  distances are long (2.896(3) Å) suggesting that the species should be considered as a contact ion-pair.<sup>1065</sup> The  $\text{K}^+$  center is 8-coordinate in  $[\text{K}(\text{dppm-H})(\text{dgm})_2]$  (Fig. 54B); this complex can be accessed by treating polymeric  $[\text{K}(\text{dppm-H})(\text{OEt}_2)_{0.5}]_n$  with diglyme.<sup>1066</sup> The conjugate base of dppm also appears in  $[\text{Ca}(\text{THF})_3(\text{dppm-H})_2]$ , which was prepared by treatment of dppm with  $^t\text{BuLi}$ , followed by  $\text{KO}^t\text{Bu}$  and the  $\text{CaI}_2$  in  $\text{Et}_2\text{O}/\text{THF}$ .<sup>1064</sup> A rare example of a Be-Al bonded compound is found in  $[\text{I}(\text{dppe})\text{BeAl}(\text{Nacac})\text{I}]$  with  $\text{Ar} = \text{Dipp}$  (see Scheme 6); the structure (Fig. 54C) features a Be-Al bond distance of 2.368(2) Å.<sup>981</sup>

Octahedral group 13 M(III) coordination environments are found in  $\text{trans-}[\text{AlCl}_2(\text{dmpe})_2]^+$ ,<sup>983</sup>  $\text{trans-}[\text{AlCl}_2(\text{dmpbz})_2]^+$ ,<sup>983</sup>  $\text{trans-}[\text{AlCl}_2(\text{dppbz})_2]^+$ ,<sup>983</sup>  $\text{trans-}[\text{GaX}_2(\text{dmpe})_2]^+$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ),<sup>1067</sup>  $\text{trans-}[\text{GaX}_2(\text{dmpbz})_2]^+$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ),<sup>1068</sup>  $\text{trans-}[\text{InX}_2(\text{dmpbz})_2]^+$  ( $\text{X} = \text{Br}, \text{I}$ ),<sup>1069</sup> and  $[\text{In}_2\text{Cl}_4(\text{dmpbz})_2(\mu\text{-Cl})_2]$ .<sup>1069</sup> Tetrahedral M(III) coordination compounds which have been structurally characterized include  $[\text{GaCl}_2(\text{dppbz})]^+$ ,<sup>1068</sup> and  $[\text{InX}_2(\text{dmpbz})]^+$  ( $\text{X} = \text{Br}, \text{I}$ ).<sup>1069</sup>

The Reid group in particular has been active in the area of group 14 metal bisphosphane complexes. Octahedral group 14 metal(IV) complexes include  $[\text{GeF}_4(\text{dppe})]$ ,<sup>1070</sup>  $[\text{GeF}_4(\text{dmpbz})]$ ,<sup>1070</sup>  $[\text{SnF}_4(\text{depe})]$ ,<sup>988</sup> and  $[\text{SnCl}_4(\text{dppen})]$ .<sup>1071</sup> In group 14, structurally characterized Ge(II) complexes with chelating bisphosphanes are exemplified by  $[\text{GeX}_2(\text{dmpbz})]$  and  $[\text{GeX}_2(\text{dmpe})]$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ; disphenoidal geometries), and  $[\text{GeX}_2(\text{dppbz})]$  ( $\text{X} = \text{Cl}, \text{Br}$ ; with an asymmetrically bound dppbz ligand); other complexes in this series have also been described.<sup>1072</sup> The  $[\text{GeCl}(\text{dppp})]^+$  cation has a trigonal pyramidal structure; its synthesis as  $[\text{GeCl}_3]^-$  and triflate salts, was part of a detailed investigation from Béland et al. focusing on reductive dehalogenation of a zwitterionic Ge(II) species to produce a Ge(I) dimer.<sup>1073</sup> An insightful comparison between complexation of  $\text{SnF}_2$  and  $\text{SnCl}_2$  with bisphosphanes concludes that an underlying problem with  $\text{SnF}_2$  is its insolubility in weak donor solvents and, therefore, the lack of soluble molecular precursors with readily displaced ligands.<sup>1074</sup> Reid and coworkers have reported rare examples of phosphane complexes of lead(II).  $[\text{Pb}(\text{dmpe})(\text{O}_2\text{NO-}\kappa^2)_2]$  is a representative example, and Fig. 54D illustrates that intermolecular  $\text{O}\cdots\text{Pb}$  contacts extend the structure in the solid state; a CN = 8 is achieved by additional contacts not shown in Fig. 54F.<sup>1075</sup>

Phosphane complexes of the heavier group 15 M(III) elements include  $[\text{Sb}(\text{dppm})(\text{O}_3\text{SCF}_3)_3(\text{NCMe})]$  (distorted octahedral) and  $[\text{Bi}(\text{dppm})(\text{O}_3\text{SCF}_3)_3]$ ; in contrast to analogous complexes with monodentate phosphane ligands, the latter (along with related complexes with tridentate triphosphanes) are stable with respect to ligand oxidation.<sup>1076</sup> A coordination number of 3 occurs in  $[\text{SbCl}(\text{dppe})]^{2+}$  and  $[\text{SbCl}(\text{dppm})]^{2+}$ , and 4-coordinate geometries occur in  $[\text{SbCl}_2(\text{dmpe})]^+$  (disphenoidal, axial Cl) and  $[\text{SbCl}_2(\text{dppe})]^+$  (disphenoidal, axial Cl); in  $[\text{SbCl}_2(\text{dppm})]^+$  the dppm ligand is asymmetrically bound with Sb-P distances of 2.6011(4) and 3.0272(4) Å.<sup>997</sup> The Bi(III) compounds  $[\text{BiX}_2(\text{O}_3\text{SCF}_3)(\text{dmpe})]$  ( $\text{X} = \text{Cl}, \text{Br}$ ) and  $[\text{BiCl}(\text{O}_3\text{SCF}_3)_2(\text{dmpe})]$  readily decompose in solution giving elemental Bi; in the solid state, all three complexes are dimers supported either by  $\mu\text{-X}$  or  $\mu\text{-O}_3\text{SCF}_3$  ligands.<sup>1077</sup>

**Scheme 16** Ligand types included in Section 1.02.3.3.2.

**Fig. 55** Structures of (A)  $[K_2\{^tBu_3SiPPPSi^tBu_3\}_2(THF)_4]$  (CSD refcode DAKQOW), (B) part of the 1D-chain in  $[Cs\{^tBu_3SiPPPSi^tBu_3\}_2(THF)]_n$  (refcode BIVZAI), and (C) part of the 1D-chain in  $[Na_2(dme)_{1.5}(tmbp)]_n$  (refcode EFAFIA).

In group 16,  $[Se(dppe)][CF_3SO_3]_2$  and  $[Te(dppe)][CF_3SO_3]_2$  provide rare examples of homoleptic P  $\rightarrow$  chalcogen coordination compounds; in the solid state,  $Se \cdots O$  or  $Te \cdots O$  contacts exist but the interaction is considered to be ionic.<sup>1078</sup>

### 1.02.3.3.2 PXP (X = P, CR) ligands with delocalized backbone

In Section 1.02.2.2.4, we surveyed complexes containing  $[RN_3R']^-$  and  $[RNC(R')NR']^-$  ligands (Scheme 7) and in this section, we look at their P-analogs (Scheme 16) which are rather sparse. Note the distinction between  $[dppm-H]^-$  (discussed in the previous section) and  $[RPC(R')PR']^-$  which possesses a delocalized backbone.

Lerner et al. have investigated the reaction of  $P_4$  with  $^tBu_3SiK$  in detail, and  $K\{^tBu_3SiPPPSi^tBu_3\}$  was among the products reported. The structure of the THF adduct (Fig. 55A) exhibits short P–P bond lengths (2.0721(16) Å) consistent with  $\pi$ -character.<sup>1079</sup> The same group has demonstrated that  $Cs\{^tBu_3SiPPPSi^tBu_3\}$  is more stable than the  $Li^+$ ,  $Na^+$  and  $K^+$  homologs. In the solid state,  $[Cs\{^tBu_3SiPPPSi^tBu_3\}_2(THF)]_n$  possesses a 1D-polymer (Fig. 55B) and P–P bond lengths of 2.090(3) Å.<sup>1080</sup> Although an organometallic compound, we include  $[Al^tBu_2\{ArPCHPAR\}]$  ( $Ar = 2,4,6\text{-}^tBu_3C_6H_2$ )<sup>1081</sup> as a representative of the second ligand type shown in Scheme 16.

### 1.02.3.3.3 Heterocyclics: Reduced 2,2'-biphosphinine

There are no examples of main group metal complexes containing neutral 2,2'-biphosphinine, i.e., the P analog of 2,2'-bipyridine. However, the reduction of 4,4',5,5'-tetramethyl-2,2'-biphosphinine (tmbp) by lithium naphthalene or sodium naphthalene in dme has been investigated, and  $[Na_2(dme)_{1.5}(tmbp)]_n$  was isolated and structurally characterized. A 1D-chain assembles (Fig. 55C) with the  $[tmbp]^{2-}$  ligand chelating to one  $Na^+$  and forming P–Na contacts to two additional  $Na^+$  centers; there are also weak  $Na^+ \cdots \pi$  contacts.<sup>1082</sup>

### 1.02.3.4 Tris(phosphane) ligands: Open-chain and tripodal

Main group metal complexes of tris(phosphane) ligands, both open-chain and tripodal, are limited and Scheme 17 displays the structures of the ligands included in this section. Coordination compounds incorporating the open-chain ligand  $PhP(CH_2CH_2PPh_2)_2$  are illustrated by Sb(III) and Bi(III) complexes. In *fac*- $[Sb\{PhP(CH_2CH_2PPh_2)_2\}(O_3SCF_3)_3]$ , the Sb(III) center is octahedrally sited, although two Sb–O interactions are longer than the third (2.808(3) and 2.746(3) Å vs 2.589(3) Å).<sup>1076</sup>

The reaction between  $TlPF_6$  and  $[Li\{tmeda\}\{PhB(CH_2PPh_2)_3\}]$  leads to  $[Tl\{PhB(CH_2PPh_2)_3\}]$  which, in the solid state is a dimer, but is a monomer in solution.<sup>1083</sup> Significantly, the  $^iPr$  analog  $[Tl\{PhB(CH_2P^iPr_2)_3\}]$  is monomeric in the crystal and this is attributed to the  $^iPr$  substituents forming a protective sheath around the Tl atom.<sup>1084</sup> The compounds  $[Tl\{(3,5-(CF_3)_2C_6H_3)B(CH_2P^iPr_2)_3\}]$  and  $[Tl\{(3,5-Me_2C_6H_3)B(CH_2P^iPr_2)_3\}]$  are distinct in their solid-state structures; in the latter, there are two Tl(I) environments, one engaging in weak intermolecular  $\pi$ -interactions and the other involving a Tl–Tl interaction. In contrast,  $[Tl\{(3,5-(CF_3)_2C_6H_3)B(CH_2P^iPr_2)_3\}]$ <sup>1085</sup> and  $[Tl\{PhB\{CH_2P(4-CF_3C_6H_4)_2\}_3\}]$ <sup>1086</sup> are monomeric in the solid state. The change in the P-substituents on going from  $[Tl\{PhB(CH_2PPh_2)_3\}]$  to  $[Tl\{PhB\{CH_2P(4-CF_3C_6H_4)_2\}_3\}]$  enhances the electrophilic character at the metal center.<sup>1086</sup>

**Scheme 17** Tris(phosphane) ligands; R is an arene, often Ph.

## 1.02.4 Arsenic-donor ligands

### 1.02.4.1 Monodentate ligands

#### 1.02.4.1.1 $R_3As$

Main group metal complexes containing  $R_3As$  ligands are dominated by metals from the p-block. This section covers monodentate  $R_3As$  ligands, as well as  $R_2As(CH_2)_nAsR_2$  ligands bridging two metal centers and tripodal ligands in which each of one or more 'arms' coordinate to a single metal atom.

Tetrahedral group 13 M(III) complexes are illustrated by  $[AlX_3(AsPh_3)]$  ( $X = Cl, I$ ),<sup>1087</sup>  $[GaCl_3(AsPh_3)]$ ,<sup>1087</sup>  $[GaX_3(AsMe_3)]$  ( $X = Cl, Br, I$ ),<sup>1068</sup>  $[GaCl_3(AsEt_3)]$ ,<sup>1088</sup> and  $[InCl_3(AsEt_3)]$ .<sup>1088</sup> The In(III) center can also accommodate two  $AsEt_3$  ligands as in the trigonal bipyramidal *trans*- $[InCl_3(AsEt_3)_2]$ .<sup>1088</sup>  $Ph_3As$  is among the ligands that forms a donor-acceptor adduct with the Lewis superacid  $Al(OR^F)_3$  ( $R^F = C(CF_3)_3$ ).<sup>1089</sup> In  $[Ga_2I_6(\mu-dpae)]$ , each Ga is tetrahedrally sited.<sup>1068</sup> Rather than coordinate to a single Ga(III) center, the tripodal ligand  $MeC(CH_2AsMe_2)_3$  reacts with  $GaX_3$  ( $X = Cl, I$ ) to yield  $[MeC(CH_2AsMe_2)_3]\{GaX_3\}$  when sufficient  $GaX_3$  is available; with a 1:1 M ratio of reactants,  $[MeC(CH_2AsMe_2)_3]\{GaCl_2\}[GaCl_4]$  was isolated.<sup>1090</sup>

Germanium(IV) and tin(IV) complexes incorporating tertiary arsane ligands include *trans*- $[GeCl_4(AsEt_3)_2]$ ,<sup>1070</sup> *trans*- $[SnX_4(AsEt_3)_2]$  ( $X = Cl, Br$ ),<sup>990</sup> *trans*- $[SnCl_3(OS_3CF_3)(AsEt_3)_2]$ ,<sup>990</sup>  $[SnCl_5(AsEt_3)]^-$ ,<sup>990</sup> and *trans*- $[SnCl_4(AsPh_3)_2]$ .<sup>1091</sup> In contrast to the latter octahedral complex, the bromido analog crystallizes as  $[SnBr_4(AsPh_3)] \cdot AsPh_3$  with the non-coordinated arsane molecule showing a close  $As \cdots Br_{axial}$  contact (3.567(3) Å).<sup>1091</sup> Tetrahedral Ge(II) complexes with arsane ligands are exemplified by  $[Ge(AsMe_3)_2(O_3SCF_3)_2]$ . Reid and coworkers were not able to isolate a tris(trimethylarsane) complex from reactions of  $[GeCl_2(diox)]$  with  $Me_3As$  followed by  $CF_3SO_3SiMe_3$  even when using excess  $Me_3As$ ; this behavior differs from that with  $Me_3P$  and was attributed to the weaker  $\sigma$ -donor power of  $Me_3As$  vs  $Me_3P$ .<sup>991</sup>

Compounds containing Sb-As or Bi-As coordinate bonds remain rare.  $[SbCl_3(AsEt_3)]$ ,  $[SbCl_2(AsPh_3)][O_3SCF_3]$  and  $[BiCl_2(AsPh_3)][O_3SCF_3]$  were reported in 2009; in the triflate salts the  $Sb \cdots O$  and  $Bi \cdots O$  distances are 2.965(2) and 2.726(3) Å, respectively, suggesting ion pairs rather than coordinated  $[CF_3SO_3]^-$  ligands.<sup>1092</sup>

#### 1.02.4.1.2 $R_2As^-$

Few non-organometallic complexes involving  $R_2As^-$  ligands have been reported since 2000. The tetrahedral  $[Li(THF)_{2.75}(OEt_2)_{0.25}(AsDipp_2)]$  was used as a precursor to  $[Ge(AsDipp_2)_2]$  and  $[Sn(AsDipp_2)_2]$ . Stabilization by As-Ge/Sn  $\pi$ -interactions is prevented by a high energy barrier to planarization at the As center, and Ge/Sn  $\cdots$ arene interactions are important instead.<sup>1093</sup> The dimer  $[Ge_2Cl_2(AsMes_2)_2(\mu-NPh)_2]$  was observed as one product of the reaction of  $GeCl_2 \cdot diox$  and  $[(Mes_2AsNPh)\{Li(OEt_2)_2\}]$ .<sup>1094</sup>

#### 1.02.4.1.3 $AsCO^-$

In Sections 1.02.2.1.4 and 1.02.3.1.3 we introduced main group metal complexes containing  $NCO^-$  and  $PCO^-$ . The analogous  $AsCO^-$  ligand is little documented. In 2017, Yao et al. published a one-pot synthesis of  $[Na(OCAs)(diox)_x]$ , and used this as a precursor to  $[Ge(AsCO)(Nacnac)]$  ( $Ar = Dipp$ , see Scheme 6 for the  $\beta$ -diketiminate ligand  $[Nacnac]^-$ ). The  $AsCO^-$  ligand coordinates to Ge(II) through As ( $Ge-As = 2.635(1)$  Å,  $Ge-As-C = 84.5^\circ$ ). Loss of CO occurs readily to yield  $[Ge(\equiv As)(Nacnac)]$ .<sup>1095</sup> Results from the Goicoechea group also open up the coordination chemistry of  $AsCO^-$ , e.g., with the organometallic derivative  $[Sn(AsCO)(2,6-Mes_2C_6H_3)_2]^-$ .<sup>1096</sup>

### 1.02.4.2 Bidentate ligands: Chelating $R_2As(X)AsR_2$

Within main group metal coordination chemistry, the most popular chelating  $R_2As(X)AsR_2$  ligand appears to be the preorganized 1,2-bis(dimethylarsino)benzene (dmabz), the arsenic analog of dmpbz, Scheme 15), and complexes from the heavier p-block metals are dominant. Typical examples from group 13 are the tetrahedral  $[GaX_2(dmabz)]^+$  ( $X = Cl, I$ ) and  $[InI_2(dmabz)]^+$ ,<sup>1069</sup> and the dimer  $[In_2Cl_4(dmabz)_2(\mu-Cl)_2]$  (Fig. 56A).<sup>1069</sup> The structure of  $[In_2Cl_2(dmabz)_2(\mu-Cl)_3]^{n+}$  is related to that of  $[In_2Cl_4(dmabz)_2(\mu-Cl)_2]$  but with two terminal In-Cl units converted into In-Cl-In bridges (Fig. 56B).<sup>1069</sup>  $[Bi_2Cl_4(dmabz)_2(\mu-Cl)_2]$ <sup>1097</sup> is structurally related to  $[In_2Cl_4(dmabz)_2(\mu-Cl)_2]$ . Complexes of group 14 M(II) include  $[GeCl(dmabz)]^+$ ,<sup>1072</sup> and

**Fig. 56** Structures of (A)  $[In_2Cl_4(dmabz)_2(\mu-Cl)_2]$  (CSD refcode QOKMIN), (B) part of the 1D-chain in  $[In_2Cl_2(dmabz)_2(\mu-Cl)_3]^{n+}$  in the  $[InCl_4]^-$  salt (refcode QOKMOT), and (C)  $[Ge\{MeC(CH_2AsMe_2)_3\}_2]^{2+}$  (refcode UZEHEP).

$[\text{SnCl}(\text{dmabz})]^+$ ,<sup>1074</sup> which have trigonal pyramidal structures. In  $[\text{Ge}_2(\text{dmabz})]$ , there are significant  $\text{Ge}\cdots\text{I}$  contacts in the solid state which result in a polymeric assembly.<sup>1072</sup>

### 1.02.4.3 Tridentate: Tripod ligands

In Section 1.02.4.1.1, we included  $[\{\text{MeC}(\text{CH}_2\text{AsMe}_2)_3\}(\text{GaX}_3)_3]$  and  $[\{\text{MeC}(\text{CH}_2\text{AsMe}_2)_3\}(\text{GaCl}_2)^+]$  in which the tripodal ligand coordinated to three or one Ga(III) centers, respectively.<sup>1090</sup> Bidentate  $\text{MeC}(\text{CH}_2\text{AsMe}_2)_3$  is also seen in  $[\text{SnBr}_4\{\text{MeC}(\text{CH}_2\text{AsMe}_2)_3-\kappa^2\}]$ .<sup>988</sup> However, in the triflate salt of  $[\text{Ge}\{\text{MeC}(\text{CH}_2\text{AsMe}_2)_3\}]^{2+}$ , the ligand binds a single Ge(II) center (Fig. 56C) in the classical tripodal manner.<sup>991</sup>

## 1.02.5 Antimony-donor ligands

### 1.02.5.1 Monodentate ligands

#### 1.02.5.1.1 $R_3\text{Sb}$

As with main group metal complexes containing  $R_3\text{As}$  ligands, those with monodentate stibanes are relatively few in number if one excludes organometallic species.  $[\text{GaCl}_3(\text{SbPh}_3)]$  has the expected tetrahedral structure ( $\text{Sb}-\text{Ga} = 2.654 \text{ \AA}$ ),<sup>1098</sup> as do  $[\text{GaCl}_3(\text{SbMe}_3)]$ ,<sup>1099</sup>  $[\text{AlI}_3(\text{Sb}^i\text{Pr}_3)]$ ,<sup>1100</sup>  $[\text{GaX}_3(\text{Sb}^i\text{Pr}_3)]$  ( $X = \text{Cl}, \text{I}$ ),<sup>1100</sup>  $[\text{GaBr}_3(\text{SbEt}_3)]$ ,<sup>1100</sup>  $[\text{InX}_3(\text{SbR}_3)]$  ( $X = \text{Cl}, \text{I}$ ;  $R = \text{Et}, ^i\text{Pr}$ ),<sup>1100</sup> and  $[\text{InX}_3(\text{Sb}^n\text{Bu}_3)]$  ( $X = \text{Cl}, \text{Br}$ ).<sup>1088</sup>

#### 1.02.5.1.2 $R_2\text{Sb}^-$

Just as for  $R_2\text{As}^-$  (Section 1.02.4.1.2), non-organometallic main group metal complexes with  $R_2\text{Sb}^-$  ligands are sparse. The reaction of  $[\text{Al}(\text{Nacnac})]$  ( $\text{Ar}$  in  $\text{Nacnac} = \text{Dipp}$ , see Scheme 6) with  $\text{Sb}_2\text{Et}_4$  results in  $\text{Sb}-\text{Sb}$  cleavage and the formation of  $[\text{Al}(\text{SbEt}_2)_2(\text{Nacnac})]$ ; an analogous reaction with  $\text{Bi}_2\text{Et}_4$  follows a similar route,<sup>1101</sup> and related complexes of Ga(III) have also been reported.<sup>1102</sup>

## 1.02.6 Oxygen-donor ligands

### 1.02.6.1 Monodentate ligands: Simple coordination compounds

#### 1.02.6.1.1 $\text{H}_2\text{O}$ (restricted to simple aqua complexes)

Because of the ubiquitous nature of the aqua ligand, we have restricted the discussion to homoleptic aqua complexes of the main group metal ions; additionally, we have included the structures of several hydrated metal halides and perchlorates. Note that for commonly encountered ions such as  $[\text{Li}(\text{OH}_2)_4]^+$ ,  $[\text{Na}(\text{OH}_2)_6]^+$ ,  $[\text{Mg}(\text{OH}_2)_6]^{2+}$ , only selected literature citations are given.

**Fig. 57** Structures of (A)  $[\text{Li}_2(\text{OH}_2)_4(\mu\text{-OH}_2)_2]^{2+}$  (CSD refcode CUSWES01) and (B)  $[\text{Li}_2(\text{OH}_2)_6(\mu\text{-OH}_2)_2]^{2+}$  (refcode SODLEE). Parts of the 1D-chains in (C) *trans*- $[\text{Na}(\text{OH}_2)_2(\mu\text{-OH}_2)_2]_n^{n+}$  (refcode ASABEB), (D)  $[\text{Na}(\text{OH}_2)_2(\mu\text{-OH}_2)_2]_n^{n+}$  with both *trans* and *cis*-arrangements of terminal aqua ligands (refcode OSURUR02), (E) *cis*- $[\text{Na}(\text{OH}_2)_2(\mu\text{-OH}_2)_2]_n^{n+}$  (refcode DARNIU), (F) *trans*- $[\text{Na}(\text{OH}_2)_4(\mu\text{-OH}_2)]_n^{n+}$  (refcode CUPQIO), (G) *cis*- $[\text{Na}(\text{OH}_2)_4(\mu\text{-OH}_2)]_n^{n+}$  (refcode PEPNUU), and (H)  $[\text{Na}_2(\text{OH}_2)_2(\mu\text{-OH}_2)_5]_n^{2n+}$  (refcode LULSAN).

For the group 1  $M^+$  ions, we expect the coordination number to typically increase as the group is descended. However, although CN = 4 is most typical for  $Li^+$ , tetrahedral  $[Li(OH_2)_4]^+$ ,<sup>1103–1111</sup> square-based pyramidal or trigonal bipyramidal  $[Li(OH_2)_5]^+$ ,<sup>1112,1113</sup> and octahedral  $[Li(OH_2)_6]^+$ ,<sup>1114</sup> have all been structurally characterized. Dinuclear aqua complexes of lithium are represented by  $[Li_2(OH_2)_4(\mu-OH_2)_2]^{2+}$  (Fig. 57A),<sup>1115,1116</sup> and  $[Li_2(OH_2)_6(\mu-OH_2)]^{2+}$  (Fig. 57B).<sup>1117,1118</sup>

For  $Na^+$ , the octahedral hexaqua ion is common,<sup>1119–1127</sup> with octahedral coordination also seen in  $[Na_2(OH_2)_8(\mu-OH_2)_2]^{2+}$ ,<sup>1128–1134</sup> and  $[Na_4(OH_2)_{12}(\mu-OH_2)_6]^{4+}$ .<sup>1131</sup> The variety of 1D-polymeric assemblies based upon interconnected  $\{Na(OH_2)_6\}$  units is fascinating and these include  $[Na(\mu-OH_2)_3]_n^{n+}$  (face-sharing octahedra),<sup>370</sup>  $[Na(OH_2)_2(\mu-OH_2)_2]_n^{n+}$  with *trans*-terminal aqua ligands (Fig. 57C),<sup>1135–1143</sup>  $[Na(OH_2)_2(\mu-OH_2)_2]_n^{n+}$  with  $Na^+$  centers along the 1D-chain having alternating *cis*- and *trans*-terminal aqua ligands (Fig. 57D),<sup>1144–1146</sup>  $[Na(OH_2)_2(\mu-OH_2)_2]_n^{n+}$  with *cis*-terminal aqua ligands (Fig. 57E),<sup>1147–1149</sup>  $[Na(OH_2)_4(\mu-OH_2)]_n^{n+}$  with a *trans*-arrangement of  $\mu-OH_2$  (Fig. 57F),<sup>1150</sup>  $[Na(OH_2)_4(\mu-OH_2)]_n^{n+}$  with a *cis*-arrangement of  $\mu-OH_2$  (Fig. 57G),<sup>1151</sup> and  $[Na_2(OH_2)_2(\mu-OH_2)_5]_n^{2n+}$  (Fig. 57H).<sup>1152</sup> Such 1D-polymeric assemblies, especially isomers of  $[Na(OH_2)_2(\mu-OH_2)_2]_n^{n+}$ , are well established, but there is also the possibility of extension into a 2D-network as observed in, for example, a layered structure which contains  $[Na_4(OH_2)_{14}]_n^{4n+}$  sheets (Fig. 58A) alternating with layers of Lindqvist heteropolyanions,<sup>1153</sup> the hydrate of sodium (*E*)-2-(2-fluorobenzylidene) butanoate in which  $[Na_2(OH_2)_7]_n^{2n+}$  2D-sheets feature octahedral  $\{Na(OH_2)_6\}$  units connected as shown in Fig. 58B,<sup>1154</sup> and in  $[Na(OH_2)_3]_n^{n+}$  in which all the aqua ligands are in a bridging mode and each  $Na^+$  center is in a distorted trigonal pyramidal rather than octahedral environment.<sup>1155</sup> A departure from CN = 6 is found in  $[Na_2(OH_2)_{12}(\mu-OH_2)]^{2+}$  in which each  $Na^+$  is bound to six terminal and one bridging aqua ligand,<sup>1156</sup> and in the 1D-polymeric  $[Na_4(OH_2)_{14}]_n^{4n+}$  in which both 5- and 6-coordinate  $Na^+$  are observed.<sup>1157</sup> Higher CN values are typical for the heavier group 1 metals, for example,  $[K(OH_2)_7]^+$ ,<sup>1158</sup>  $[K(OH_2)_8]^+$ ,<sup>1159</sup>  $[Rb(OH_2)_9]^+$ ,<sup>1112</sup> and  $[Cs(OH_2)_{10}]^+$ .<sup>1112</sup> However, the diversity of extended chains and networks found for  $Na^+$  (Figs. 57 and 58) is not reproduced for the later alkali metals.

In group 2, the same general trend as in group 1 is observed with a CN = 4 in  $[Be(OH_2)_4]^{2+}$ ,<sup>265,1160,1161</sup> and CN = 6 in the ubiquitous  $[Mg(OH_2)_6]^{2+}$  (only a few examples of *ca.* 430 structures in the CSD between 2000 and 2022 are given).<sup>1140,1162–1175</sup> Calcium shows a wider range of CNs than  $Mg^{2+}$ , starting with CN = 6 in  $[Ca(OH_2)_6]^{2+}$ ,<sup>1140,1176</sup> CN = 7 in  $[Ca(OH_2)_7]^{2+}$ ,<sup>1150,1177–1179</sup> and CN = 8 in  $[Ca(OH_2)_8]^{2+}$ .<sup>1175</sup> A CN of 6 is seen in the 1D-polymer  $[Ca(OH_2)_4(\mu-OH_2)_2]_n^{2n+}$ .<sup>1180</sup> In  $[Ca_2(OH_2)_8(\mu-OH_2)_3]^{4+}$ , each  $Ca^{2+}$  is 7-coordinate,<sup>1181</sup> while a CN of 8 is found in  $[Ca_2(OH_2)_{12}(\mu-OH_2)_2]^{4+}$ .<sup>1167,1182</sup> Crystalline  $CaBr_2 \cdot 9H_2O$ ,  $CaI_2 \cdot 8H_2O$ ,  $CaI_2 \cdot 7H_2O$  and  $CaI_2 \cdot 6.5H_2O$  contain the  $[Ca(OH_2)_8]^{2+}$ ,  $[Ca_2(OH_2)_{12}(\mu-OH_2)_2]^{4+}$ ,  $[Ca_2(OH_2)_{12}(\mu-OH_2)_2]^{4+}$ , and  $[Ca_2(OH_2)_{10}(\mu-OH_2)_3]^{4+}$  cations, respectively, each with CN = 8 (distorted antiprism).<sup>1183</sup> Hennings et al. have also reported the structures of  $Ca(ClO_4)_2 \cdot 4H_2O$  and  $Ca(ClO_4)_2 \cdot 6H_2O$ ; these contain the neutral polymer  $[Ca(OH_2)_4(\mu-ClO_4-1\kappa O^1:2\kappa O^2)]_n$  and discrete  $[Ca(OH_2)_6(ClO_4-\kappa^1)]^+$  cations, respectively.<sup>1184</sup>

For the heaviest group 2 metals, values of CN  $\geq 8$  are common, for example, in  $[Sr(OH_2)_8]^{2+}$  (CN = 8),<sup>1175,1179</sup>  $[Sr_2(OH_2)_{10}(\mu-OH_2)_4]^{4+}$  (CN = 9),<sup>1185</sup>  $[Ba_2(OH_2)_{14}(\mu-OH_2)_2]^{4+}$  (CN = 9),<sup>1186</sup>  $[Ba_2(OH_2)_{10}(\mu-OH_2)_4]^{4+}$  (CN = 9),<sup>1185</sup>  $[Ba(OH_2)_3(\mu-OH_2)_3]_n^{2n+}$  (CN = 9, Fig. 59A),<sup>1187</sup>  $[Ba_2(OH_2)_{10}(\mu-OH_2)_4]_n^{4n+}$  (CN = 10),<sup>1188</sup> and  $[Ba_2(OH_2)_8(\mu-OH_2)_6]_n^{4n+}$  (CN = 10, Fig. 59B).<sup>1189</sup> It is also worth noting that the structures of  $Sr(ClO_4)_2 \cdot 3H_2O$ ,  $Sr(ClO_4)_2 \cdot 4H_2O$  and  $Sr(ClO_4)_2 \cdot 9H_2O$  have been studied by Hennings et al., complementing the investigations of the calcium halides and perchlorates described above.  $Sr(ClO_4)_2 \cdot 3H_2O$  and  $Sr(ClO_4)_2 \cdot 4H_2O$  assemble into 3D-networks with aqua ligands in both terminal and bridging modes, and

**Fig. 58** (A) Part of an  $[Na_4(OH_2)_{14}]_n^{4n+}$  2D-net in a layered structure which also contains Lindqvist heteropolyanions (CSD refcode LAYCAQ), and (B) part of the  $[Na_2(OH_2)_7]_n^{2n+}$  sheet in the hydrate of sodium (*E*)-2-(2-fluorobenzylidene) butanoate (refcode PEHSEC). (C) Part of the  $[Na(OH_2)_3]_n^{n+}$  2D-net with all bridging aqua ligands (refcode SOQZAA).

**Fig. 59** Parts of the 1D-chains in (A)  $[Ba(OH_2)_3(\mu-OH_2)_3]_n^{2n+}$  (CSD refcode LINYEB), and (B)  $[Ba_2(OH_2)_8(\mu-OH_2)_6]_n^{4n+}$  (refcode TEDWAC).

perchlorate ions in  $\mu\text{-ClO}_4\text{-}1\kappa\text{O}^1\text{:}2\kappa\text{O}^2$  bonding modes. In contrast,  $\text{Sr}(\text{ClO}_4)_2\cdot 9\text{H}_2\text{O}$  crystallizes with discrete  $[\text{Sr}(\text{OH}_2)_7(\text{ClO}_4\text{-}\kappa^1)_2]$  complexes and  $\text{H}_2\text{O}$  solvate molecules.<sup>1190</sup>

The octahedral  $[\text{Al}(\text{OH}_2)_6]^{3+}$  ion is found in the solid-state structures of, for example,  $[\text{Al}(\text{OH}_2)_6]_2[\text{C}_6(\text{CO}_2)_6]\cdot 4\text{H}_2\text{O}$ ,<sup>1191</sup>  $[\text{Al}(\text{OH}_2)_6][\text{MeSO}_3]_3$ ,<sup>1192</sup>  $[4\text{-H}_2\text{NpyH}][\text{Al}(\text{OH}_2)_6][\text{SO}_4]_2\cdot 4\text{H}_2\text{O}$ ,<sup>1171</sup> and  $[2\text{-H}_2\text{NpyH}][\text{Al}(\text{OH}_2)_6][\text{SO}_4]_2\cdot 4\text{H}_2\text{O}$ ,<sup>1193</sup>  $[\text{pipzH}_2]_{0.5}[\text{Al}(\text{OH}_2)_6][\text{SO}_4]_2\cdot 4\text{H}_2\text{O}$ ,<sup>1194</sup>  $[\text{Al}(\text{OH}_2)_6][\text{NO}_3]_3\cdot (15\text{-crown-}5)\cdot 4\text{H}_2\text{O}$ ,<sup>1195</sup> and  $[\text{H}_2\text{im}][\text{Al}(\text{OH}_2)_6][\text{SO}_4]_2$ .<sup>1196</sup> Octahedral hexaqua ions of Ga(III) and In(III) have also been structurally characterized in the solid state,<sup>1197–1199</sup> and  $[\text{Me}_4\text{N}]_6[\text{In}(\text{OH}_2)_6][\text{InF}_6]_3\cdot 18\text{H}_2\text{O}$  contains octahedral  $[\text{In}(\text{OH}_2)_6]^{3+}$  cations which form strong  $\text{O}\cdots\text{H}\cdots\text{F}$  hydrogen bonds with the  $[\text{InF}_6]^{3-}$  anions ( $\text{O}\cdots\text{F} = 2.472(1)\text{ \AA}$ ).<sup>1200</sup>

The crystal structure of  $[\text{Bi}(\text{H}_2\text{O})_9][\text{CF}_3\text{SO}_3]_3$  was reported in 2000 (a redetermination); the conversion of the hydrated Bi(III) ion to  $[\text{Bi}_6\text{O}_4(\text{OH})_4]^{6+}$  was prevented by using solutions containing a large excess of  $\text{HClO}_4$  or  $\text{CF}_3\text{SO}_3\text{H}$  (1.0–2.0 mol  $\text{dm}^{-3}$ ). The  $[\text{Bi}(\text{H}_2\text{O})_9]^{3+}$  ion has a tricapped trigonal prismatic structure.<sup>1201</sup>

### 1.02.6.1.2 ROH, R<sub>2</sub>O

The use of coordinating alcohols and ethers as solvents in reactions results in their pervasive incorporation into coordination compounds, either to occupy otherwise vacant coordination sites or preferential coordination in place of other ligands present in a reaction mixture. As in many sections in this review, we have therefore had to be selective in the examples included in this discussion. We have chosen to focus on homoleptic complexes in which ROH or R<sub>2</sub>O is the ligand of focus rather than a secondary ligand, and in this section we deal only with monodentate ligands. As we saw with aqua ligands, the hard O-donor in alcohols and ethers is most compatible with hard metal ions, either s-block or M<sup>3+</sup> from the p-block.

Tetrahedral coordination for Li<sup>+</sup> is seen in  $[\text{Li}(\text{HOME})_4]^+$ ,<sup>1202–1207</sup>  $[\text{Li}(\text{HO}^i\text{Pr})_4]^+$  (in  $[\text{LiO}^i\text{Pr}]\cdot 5i\text{PrOH}$  with a hydrogen-bonded chain structure),<sup>1208</sup> and  $[\text{Li}_2(\text{HOME})_4(\mu\text{-HOME})_2]^{2+}$ .<sup>1209</sup> Two series of <sup>t</sup>BuOH solvates of LiX (X = Cl, Br, I) have been reported with LiX:<sup>t</sup>BuOH ratios of 1:4 and 1:6; in both, Li<sup>+</sup> is 4-coordinate and structurally characterized complexes are  $[\text{Li}(\text{HO}^t\text{Bu})_4]\text{X}$  (X = Cl, I) and  $[\text{Li}(\text{HO}^t\text{Bu})_4]\text{X}\cdot 2^t\text{BuOH}$  (X = Cl, Br, I).<sup>1210</sup> The  $[\text{Na}(\text{HOME})_5]^+$  ion in  $[\text{Na}(\text{HOME})_5]_2[\text{Mo}_6(\mu_3\text{-Br})_8(\text{OME})_6]$  has a square-based pyramidal structure.<sup>1211</sup> The  $[\text{K}(\text{HOME})_4]^+$  ion has been described, with the four O-donors in a plane and the K<sup>+</sup> center disordered above and below this plane.<sup>1212</sup>

Homoleptic group 2 metal complexes with alcohol ligands include  $[\text{Mg}(\text{HOME})_6]^{2+}$ ,<sup>1213–1216</sup>  $[\text{Mg}(\text{HOEt})_6]^{2+}$ ,<sup>1213,1217</sup> and  $[\text{Ca}(\text{HOME})_6]^{2+}$ .<sup>1218</sup> Additionally, there is a range of complexes with alcohols and simple anionic ligands. These are represented by *trans*- $[\text{MgCl}_2(\text{HOEt})_4]$  and  $[\text{Mg}_2\text{Cl}_2(\text{HOEt})_6(\mu\text{-Cl})_2]$  (compounds of interest as precursors for Ziegler-Natta polymerization catalysts),<sup>1219</sup> *trans*- $[\text{Mg}(\text{OH}_2)_2(\text{HOEt})_4]^{2+}$ ,<sup>1220</sup> *trans*- $[\text{Mg}(4\text{-O}_2\text{Cpy})_2(\text{HOME})_4]$ ,<sup>1221</sup> *cis*- $[\text{Ca}(\text{OH}_2)_2(\text{HOME})_4]^{2+}$ ,<sup>1222</sup> and *trans*- $[\text{Ca}(\text{O}_3\text{SCF}_3\text{-}\kappa^1)_2(\text{HOME})_4]$ .<sup>1223</sup>

The cyclic aluminophosphonate  $[\text{Al}_2(\text{HO}^n\text{Bu})_8(\mu\text{-PhHPO}_2\text{-}1\kappa\text{O}^1\text{:}2\kappa\text{O}^2)]^{4+}$  has been isolated and structurally characterized as a chloride salt; a detailed solid-state NMR spectroscopic study was carried out.<sup>1224</sup>

We move now to main group metal complexes containing ether ligands, focusing again only on homoleptic complexes and other simple species. Low CNs for Li<sup>+</sup> are seen in  $[\text{Li}(\text{OEt}_2)_2]^+$  (angle O–Li–O = 113.4(4)°,<sup>672</sup> trigonal planar  $[\text{Li}(\text{OEt}_2)_3]^+$ ,<sup>1225</sup> tetrahedral  $[\text{Li}(\text{OH}_2)_2(\text{THF})_2]^+$ ,<sup>1226</sup> tetrahedral  $[\text{Li}(\text{OEt}_2)_4]^+$ ,<sup>1227–1230</sup> and tetrahedral  $[\text{Li}(\text{OEt}_2)(\text{THF})_3]^+$ .<sup>1231–1236</sup> Cubanes containing  $\{\text{Li}(\text{OEt}_2)\}$  units are illustrated by  $[\text{Li}_4(\text{OEt}_2)_4(\mu_3\text{-Br})_4]$ .<sup>1237</sup>

In line with the structures of a number of Na<sup>+</sup> complexes described earlier in this review, a square-planar geometry is found in *trans*- $[\text{Na}(\text{OEt}_2)_2(\text{NCMe})_2]^+$ .<sup>256</sup> This contrasts with the tetrahedral or distorted tetrahedral structures reported for  $[\text{Na}(\text{OEt}_2)_4]^+$  combined with various complex anions.<sup>177,1238,1239</sup> Na<sup>+</sup> also forms the 5-coordinate cation  $[\text{Na}(\text{OEt}_2)(\text{THF})_4]^+$ .<sup>1240</sup> Four-coordinate K<sup>+</sup> is observed in  $[\text{K}(\text{OEt}_2)_4]^+$ ,<sup>1241–1243</sup> but higher CNs are also observed, for example, in  $[\text{K}(\text{OEt}_2)(\text{THF})_5]^+$ .<sup>1244</sup> Simple complexes containing monodentate ether ligands are not prevalent for Rb<sup>+</sup> and Cs<sup>+</sup>. Examples of structurally simple group 2 metal complexes containing monodentate ether ligands are tetrahedral  $[\text{Be}(\text{O}^n\text{Bu}_2)_2(\text{O}_3\text{SCF}_3\text{-}\kappa^1)_2]$ ,<sup>1245</sup>  $[\text{Be}_2(\text{OEt}_2)_2\text{Cl}_2(\mu\text{-Cl})_2]$ ,<sup>1246</sup> *trans*- $[\text{Mg}(\text{OEt}_2)_4(\text{GaH}_4\text{-}\kappa^1)_2]$ ,<sup>1247</sup> *trans*- $[\text{Ca}_2(\text{OEt}_2)_4]$ ,<sup>671</sup> and  $[\text{Mg}_3(\text{OEt}_2)_6(\mu\text{-Cl})_3(\mu_3\text{-Cl})_2]$ .<sup>1248</sup> As in group 1, complexes containing only monodentate ether ligands are not well represented for the heaviest metals in group 2.

Within the p-block, structurally characterized simple complexes containing monodentate ether ligands include  $[\text{AlCl}_3(\text{OEt}_2)]$ .<sup>1249</sup> Mitzel et al. reported the isolation and structure of *trans*- $[\text{GeF}_4(\text{OEt}_2)_2]$ ,<sup>1250</sup> and the tin(IV) complex *trans*- $[\text{Sn}(\text{O}_2\text{CCF}_3\text{-}\kappa^1)_4(\text{OEt}_2)_2]$  was described as part of a detailed investigation of tin trifluoroacetates as vapor phase single-source precursors for F-doped SnO<sub>2</sub>.<sup>1251</sup>

### 1.02.6.1.3 RO<sup>−</sup>

The field of main group metal compounds containing alkoxide or aryloxide ligands is large, and is often motivated by the search for precursors to metal oxide films and materials or the development of catalysts, e.g., for polymerization. Because of the extent of the literature, we have decided to confine this section to citations of the most pertinent reviews which have appeared within the past 20 years. The following topics (organized according to periodic group) should provide entries into the area:

- lithium double metal alkoxides<sup>1252</sup>;
- Mg(II) alkoxides and aryloxides as promoters of chemical transformations of lactic acid<sup>1253</sup>;
- dinuclear catalysts for the ring opening polymerization of lactide<sup>1254</sup>;
- relevant to Mg(II): precursors of polymerization catalysts and new materials<sup>1255</sup>;
- main group metal complexes as catalysts or initiators for polymerization of lactides<sup>1256</sup>;

- heterometallic alkoxides (includes both main group and transition metals)<sup>1257</sup>;
- Ga(III) and In(III) alkoxides and aryloxides<sup>37</sup>;
- molecular precursors for gallium and indium oxide thin films<sup>38</sup>;
- precursors for semiconducting materials (includes Sn and Sb alkoxides)<sup>40</sup>;
- precursors to bismuth oxide-based materials.<sup>1258</sup>

#### 1.02.6.1.4 NCO<sup>-</sup> and PCO<sup>-</sup>

Main group metal complexes with N-bonded NCO<sup>-</sup> ligands were described in Section 1.02.2.1.4, and this also covered bridging N,O-bound ligands, examples of which will not be repeated here. Examples of main group metal complexes containing terminal O-bonded NCO<sup>-</sup> appear to be sparse, and are represented by [K(18-crown-6)(OPPh<sub>3</sub>)(OCN)],<sup>296</sup> and [Sn(tpp)(OH)(OCN)] (which shows a substitutional disorder of the axial OH<sup>-</sup> and OCN<sup>-</sup> ligands).<sup>1259</sup> Group 1 metal complexes containing O-bound or P,O-bridging PCO<sup>-</sup> were included in Section 1.02.3.1.3.<sup>1036,1038–1042</sup> We also described the use of a sterically demanding salen-type framework to stabilize {Al<sup>III</sup>-OCP}; in contrast, the Ga(III) analog exhibits a P-bound PCO<sup>-</sup> ligand (Fig. 52B).<sup>1043</sup>

#### 1.02.6.1.5 R<sub>3</sub>PO

Phosphane oxide ligands are popular, with their metal complexes sometimes being the result of adventitious oxidation of the corresponding phosphane. The large numbers of main group metal complexes incorporating R<sub>3</sub>PO ligands means that in this section, we focus only on selected coordination compounds. Of the 324 hits in the CSD between 2000 and 2022 for terminal R<sub>3</sub>PO–M units (M = group 1 (Li–Cs), 2 (Be–Ba), group 13 (Al–Tl), group 14 (Ge–Pb), 15 (As–Bi)), the distribution of M–O–P angles is shown in Fig. 60; the search was made using Conquest v. 2022.1.0.<sup>88</sup>

Homoleptic complexes of the group 1 metals include tetrahedral [Li(OPPh<sub>3</sub>)<sub>4</sub>]<sup>+</sup>,<sup>1260–1263</sup> and [Na(OPPh<sub>3</sub>)<sub>4</sub>]<sup>+</sup> (in the PF<sub>6</sub><sup>-</sup> salt),<sup>1264</sup> and related structures are found in [Na(OPPh<sub>3</sub>)<sub>3</sub>(THF)]<sup>+</sup>,<sup>1265</sup> and [Na(OPPh<sub>3</sub>)<sub>3</sub>(O<sub>3</sub>SCF<sub>3</sub>-κ<sup>2</sup>)].<sup>1266</sup> [KI(OPPh<sub>3</sub>)(18-crown-6)] crystallizes in the trigonal space group R3c and the K–O–P bond angle is 180°<sup>1267</sup>; this is one of several examples of linear M–O–P units (Fig. 60) found in [KX(OPPh<sub>3</sub>)(18-crown-6)] complexes, in which crystallographic symmetry is associated with the M–O–P linearity.<sup>296,1268–1271</sup> Reaction of LiBr and dppeO<sub>2</sub> in THF led to the assembly of [Li<sub>2</sub>(dppeO<sub>2</sub>)<sub>3</sub>Br<sub>2</sub>]<sub>n</sub> which has a 2D-network with (6,3) topology; each Li<sup>+</sup> is tetrahedrally sited and is bound to one Br<sup>-</sup> and three O atoms of three different dppeO<sub>2</sub> ligands making the Li a 3-connecting node (Fig. 61A).<sup>1272</sup> An extended assembly is also observed in [Li(dppeO<sub>2</sub>)<sub>2</sub>]<sub>n</sub><sup>+</sup> (isolated as the [CuClBr]<sup>-</sup> salt) in which tetrahedral Li<sup>+</sup> centers are linked by pairs of bridging dppeO<sub>2</sub> ligands into a 1D-coordination polymer

Fig. 60 Distribution of M–O–P angles for terminal R<sub>3</sub>PO–M units (see text for search details).

Fig. 61 Structures of (A) part of one (6,3) net in [Li<sub>2</sub>(dppeO<sub>2</sub>)<sub>3</sub>Br<sub>2</sub>]<sub>n</sub> (CSD refcode LAPGIT), (B) [Li<sub>3</sub>Cl<sub>3</sub>(μ-OPEt<sub>3</sub>)<sub>3</sub>(μ<sub>3</sub>-OPEt<sub>3</sub>)] (refcode MISGIF), (C) [BeCl<sub>3</sub>(OPPh<sub>2</sub>CH<sub>2</sub>PPh<sub>3</sub>)] (refcode CAGXEP), and (D) part of the 3D-network in [Pb(dppeO<sub>2</sub>)<sub>2</sub>(NO<sub>3</sub>-κ<sup>2</sup>)<sub>2</sub>]<sub>n</sub> showing only the 4-connecting Pb(II) nodes (refcode MUJNEM).

with a double-loop-like structure.<sup>1273</sup> A few multinuclear lithium clusters provide examples of R<sub>3</sub>PO ligands in  $\mu$ - and  $\mu_3$ -bonding modes, and these are illustrated by [Li<sub>3</sub>Cl<sub>3</sub>( $\mu$ -OPET<sub>3</sub>)<sub>3</sub>( $\mu_3$ -OPET<sub>3</sub>)] (Fig. 61B).<sup>1274</sup>

The zwitterion [BeCl<sub>3</sub>(OPPh<sub>2</sub>CH<sub>2</sub>PPh<sub>3</sub>)] (Fig. 61C) contains an interesting example of a monodentate phosphane oxide formally related to dppm,<sup>1275</sup> and [AlBr<sub>3</sub>(OPPh<sub>2</sub>CH<sub>2</sub>PPh<sub>3</sub>)] adopts an analogous structure.<sup>1276</sup> It is relevant, therefore, to comment that the doubly oxidized form of dppm forms a trigonal prismatic complex with Na<sup>+</sup> in [Na(dppmO<sub>2</sub>- $\kappa^2$ )<sub>3</sub>]Cl.<sup>1277</sup> Note that the corresponding [Mg(dppmO<sub>2</sub>- $\kappa^2$ )<sub>3</sub>]<sup>2+</sup> complex is octahedral.<sup>1278</sup> Octahedral coordination is also seen in [Mg(OPPh<sub>3</sub>)<sub>2</sub>(NO<sub>3</sub>- $\kappa^2$ )<sub>2</sub>].<sup>1279</sup> Ph<sub>3</sub>PO binds as an axial ligand to [Mg(pc)].<sup>1261</sup> Combinations of MCl<sub>2</sub> (M = Mg, Ca, Sr, Ba), Ph<sub>3</sub>PO and SbCl<sub>5</sub> in solution conditions led to [SbCl<sub>6</sub>]<sup>-</sup> salts of distorted tetrahedral [M(OPPh<sub>3</sub>)<sub>4</sub>]<sup>2+</sup> for M = Mg, Ca, Sr, and to [Ba(OPPh<sub>3</sub>)<sub>5</sub>]<sup>2+</sup>; this investigation also included reactions with chelating bis(phosphane) dioxides.<sup>1280</sup> Tetrahedral [MgCl<sub>2</sub>(OPPh<sub>3</sub>)<sub>2</sub>] has also been reported.<sup>1281,1282</sup> Although only 2 equivalents of Ph<sub>3</sub>PO were used in the reaction of CaI<sub>2</sub> in THF, the product was *mer*-[CaI<sub>2</sub>(OPPh<sub>3</sub>)<sub>3</sub>(THF)], while the use of 4 equivalents gave *trans*-[CaI<sub>2</sub>(OPPh<sub>3</sub>)<sub>4</sub>]. Salts of the octahedral [Ca(OP<sup>n</sup>Pr<sub>3</sub>)<sub>5</sub>]<sup>+</sup> and [Ba(OPPh<sub>3</sub>)<sub>5</sub>]<sup>+</sup> were also isolated.<sup>1283</sup> The crystal structure of *trans*-[CaCl<sub>2</sub>(OPPh<sub>3</sub>)<sub>4</sub>] has been reported,<sup>1284</sup> as have the structures of octahedral *cis*-[Ca(OH)<sub>2</sub>(OPPh<sub>3</sub>)<sub>4</sub>]<sup>2+</sup>,<sup>1285</sup> and *fac*-[Ca(OH)<sub>3</sub>(OPPh<sub>3</sub>)<sub>3</sub>]<sup>2+</sup> (as the [AuCl<sub>4</sub>]<sup>-</sup> salt).<sup>1286</sup> [Ca(OPPh<sub>3</sub>)<sub>2</sub>{N(SiMe<sub>3</sub>)<sub>2</sub>}]<sub>2</sub> has a distorted tetrahedral structure with angles O–Ca–O = 95.74(4)° and N–Ca–N = 129.44(5)°; the structure was compared with those of several related compounds.<sup>1287</sup> As part of an investigation of cationic Lewis base-free  $\beta$ -diketimate complexes of Mg<sup>2+</sup> and Ca<sup>2+</sup> (isolated as their [B(C<sub>6</sub>F<sub>5</sub>)<sub>4</sub>]<sup>-</sup> salts), the tetrahedral complexes [Mg(Nacnac)(OPET<sub>3</sub>)<sub>2</sub>]<sup>+</sup> and [Mg(Nacnac)(OPET<sub>3</sub>)(FC<sub>6</sub>H<sub>5</sub>)]<sup>+</sup> (Ar = Dipp in [Nacnac]<sup>-</sup>, see Scheme 6) have been described.<sup>1288</sup> The centrosymmetric strontium complex [Sr<sub>2</sub>(OPPh<sub>3</sub>)<sub>2</sub>( $\mu$ -OH)<sub>2</sub>(Nacnac)<sub>2</sub>] (Ar = Dipp, see Scheme 6) contains 5-coordinate Sr, and is prepared by Ph<sub>3</sub>PO-for-THF ligand substitution from a related dimer.<sup>1289</sup>

Moving on to group 13 metals, and the tetrahedral compound [Al(OPET<sub>3</sub>)(OR)<sub>3</sub>] (R = C(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>) is an adduct of the thermally stable Lewis superacid Al{OC(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>}.<sup>1290</sup> The Al(I) compound [Al(Nacnac)] (Ar = Dipp, see Scheme 6) reacts with Ph<sub>3</sub>PO or Et<sub>3</sub>PO with cleavage of the P=O bond and formation of hydroxyl species, along with deprotonation of one Me group in [Nacnac]<sup>-</sup> to yield [Al(Nacnac–H)(OH)(OPR<sub>3</sub>)]; the reaction is proposed to proceed through an intermediate {R<sub>3</sub>PO → Al(Nacnac)} species.<sup>1291</sup> Gallium(III) complexes are illustrated with tetrahedral [GaCl<sub>3</sub>(OPMe<sub>3</sub>)], [GaI<sub>2</sub>(OPMe<sub>3</sub>)<sub>2</sub>]<sup>+</sup> and [(GaBr<sub>3</sub>)<sub>2</sub>{ $\mu$ -1,2-(OPPh<sub>2</sub>CH<sub>2</sub>)<sub>2</sub>C<sub>6</sub>H<sub>4</sub>}] in which the bisphosphane dioxide is monodentate to two GaBr<sub>3</sub> units.<sup>1292</sup> The In(III) complexes *trans*-[InX<sub>2</sub>(OPPh<sub>3</sub>)<sub>4</sub>]<sup>+</sup> (X = Cl, Br) were prepared by halide transfer reactions involving Te(IV) compounds and were isolated as the [PhTeX<sub>4</sub>]<sup>-</sup> salts,<sup>1293</sup> and the structure of *fac*-[InCl<sub>3</sub>(OH)<sub>2</sub>(OPMe<sub>3</sub>)<sub>2</sub>] has also been reported.<sup>1294</sup> In the 5-coordinate [InI<sub>3</sub>{OP(4-MeOC<sub>6</sub>H<sub>4</sub>)<sub>3</sub>}]<sub>2</sub>, the phosphane oxide ligands are mutually *trans*; this is one of a series of complexes studied by solid-state <sup>115</sup>In NMR spectroscopy.<sup>1295</sup> Thallium(I) forms a trigonal pyramidal complex [Tl(OPPh<sub>3</sub>)<sub>3</sub>]<sup>+</sup>.<sup>1268</sup>

Complexes of Ge(IV) and Sn(IV) include octahedral *trans*-[GeF<sub>4</sub>(OPR<sub>3</sub>)<sub>2</sub>] (R = Me, Et, Ph),<sup>1296</sup> *trans*-[SnF<sub>4</sub>(OPMe<sub>3</sub>)<sub>2</sub>] and related complexes with chelating bis(phosphane) dioxides,<sup>1297</sup> *trans*-[SnF<sub>4</sub>(OPPh<sub>3</sub>)<sub>2</sub>],<sup>988</sup> *trans*-[SnI<sub>4</sub>{OP(4-MeC<sub>6</sub>H<sub>4</sub>)<sub>3</sub>}]<sub>2</sub>,<sup>1298</sup> *cis*-[SnCl<sub>4</sub>(OPPh<sub>3</sub>)<sub>2</sub>],<sup>1299</sup> *cis*-[SnI<sub>4</sub>(OPPh<sub>3</sub>)<sub>2</sub>],<sup>1300</sup> *fac*-[GeCl<sub>3</sub>(OPMe<sub>3</sub>)<sub>3</sub>]<sup>+</sup>,<sup>1296</sup> *cis*-[GeX<sub>2</sub>(OPMe<sub>3</sub>)<sub>4</sub>]<sup>2+</sup> (X = Cl, Br),<sup>1296</sup> and the zwitterions [SnF<sub>5</sub>(OPR<sub>2</sub>CH<sub>2</sub>PHR<sub>2</sub>)] (R = Ph, Cy).<sup>1301</sup> In the anionic complex [(SnCl<sub>5</sub>)<sub>2</sub>( $\mu$ -dppeeO<sub>2</sub>)]<sup>2-</sup>, each Sn(IV) center is octahedrally sited.<sup>1302</sup> Moving on to group 14 M(II) compounds takes us to the ylide-containing complex [SnCl<sub>2</sub>(OPPh<sub>2</sub>CHPPH<sub>3</sub>)] in which the Sn(II) center is in a trigonal pyramidal environment,<sup>1303</sup> and to 4-coordinate [SnCl<sub>2</sub>(OPMe<sub>3</sub>)<sub>2</sub>] which possesses a disphenoidal structure with one axial Me<sub>3</sub>PO and one equatorial Me<sub>3</sub>PO.<sup>1074</sup> Under solvothermal conditions (MeCN/EtOH), PbI<sub>2</sub>, KI, I<sub>2</sub> and dppe react to give the 3D-network [Pb<sub>3</sub>( $\mu$ -I)<sub>6</sub>( $\mu$ -dppeeO<sub>2</sub>)<sub>3</sub>]<sub>n</sub>·nEtOH, and in the presence of H<sub>2</sub>O<sub>2</sub>, the product was [Pb<sub>2</sub>( $\mu$ -I)<sub>2</sub>( $\mu_3$ -I)<sub>2</sub>( $\mu$ -dppeeO<sub>2</sub>)<sub>n</sub>]; the former compound contains discrete {Pb<sub>3</sub>( $\mu$ -I)<sub>6</sub>} units connected by bridging dppeeO<sub>2</sub> ligands, while the latter contains [Pb<sub>2</sub>( $\mu$ -I)<sub>2</sub>( $\mu_3$ -I)<sub>2</sub>]<sub>n</sub> 1D-chains interconnected by dppeeO<sub>2</sub> ligands.<sup>1304</sup> Levason and coworkers investigated reactions of Pb(NO<sub>3</sub>)<sub>2</sub> with various bisphosphanes, and the presence of adventitious O<sub>2</sub> resulted in the formation of [Pb( $\mu$ -depeO<sub>2</sub>)<sub>2</sub>(NO<sub>3</sub>- $\kappa^2$ )<sub>2</sub>]<sub>n</sub> in which each Pb(II) has CN = 8 but acts as a 4-connecting node as shown in Fig. 61D.<sup>1075</sup>

Within the group 15 metals, a series of Sb(III) complexes has been described by Bamford et al.: [SbX<sub>3</sub>(OPCy<sub>3</sub>)] (X = F, Cl) with disphenoidal geometry, and [SbCl<sub>3</sub>(OPCy<sub>3</sub>)<sub>2</sub>] with a square-based pyramidal structure.<sup>1305</sup> Octahedral coordination is found in [Bi<sub>2</sub>I<sub>4</sub>( $\mu$ -I)<sub>2</sub>(OPPh<sub>3</sub>)<sub>4</sub>] (Fig. 62A) and this compound is one of a series representing a new class of semiconducting materials.<sup>1306</sup>

Fig. 62 The structures of (A) [Bi<sub>2</sub>I<sub>4</sub>( $\mu$ -I)<sub>2</sub>(OPPh<sub>3</sub>)<sub>4</sub>] (CSD refcode TPOBII11), and (B) [TeBr<sub>4</sub>(OPPh<sub>3</sub>)<sub>2</sub>] (refcode QUHKOU).

Examples of phosphane oxide coordination to Te(IV) include  $[\text{TeF}_4(\text{OPPh}_3)]$ ,<sup>1307</sup>  $[\text{TeF}_4(\text{OPMe}_3)]$ ,<sup>1307</sup> and *cis*- $[\text{TeBr}_4(\text{OPPh}_3)_2]$  (Fig. 62B).<sup>1308</sup>

### 1.02.6.1.6 Monodentate heterocyclic ligands

There is a wealth of main group complexes incorporating monodentate heterocyclic ligands and THF is ubiquitous, undoubtedly because of its use as a solvent. Many examples have been included in previous sections in this review and here, we focus only on homoleptic complexes containing THF, furan and 1,4-dioxane and on simple halido and aqua derivatives which also contain these heterocyclic ligands. Note that, in many cases and especially for the s-block metals, the complexes detailed below are not the main focus of the original literature work and their structures have often received scant discussion.

Tetrahedral  $[\text{Li}(\text{THF})_4]^+$  is extremely well documented and a few of the very many examples are given in the following references.<sup>1233,1309–1323</sup> Despite the ubiquitous nature of  $[\text{Li}(\text{THF})_4]^+$ , it is noteworthy that trigonal bipyramidal  $[\text{Li}(\text{THF})_5]^+$ ,<sup>1324</sup> and octahedral  $[\text{Li}(\text{THF})_6]^+$  with long Li–O bond lengths (2.16–2.17 Å)<sup>1325,1326</sup> have also been reported. Complexes of  $\text{Li}^+$  containing THF and halido ligands are illustrated by  $[\text{LiBr}(\text{THF})_3]$  and  $[\text{Li}_2(\text{THF})_4(\mu\text{-Br})_2]$ ,<sup>1327</sup> and  $[\text{Li}_2(\text{THF})_6(\mu\text{-Cl})]^+$  which is interesting in that the dimer is supported by a single bridging chlorido ligand (Fig. 63A, angle Li–Cl–Li ranging from 124–174° in different salts)<sup>1328–1331</sup>; the bromido and iodido analogs of the latter are also known (angle Li–Br–Li = 159–168° in different salts, Li–I–Li = 155.9° or 180° which is symmetry-imposed, CSD refcode ZEKCOK).<sup>1016,1332–1334</sup> Other intriguing species include  $[\text{Li}_3(\text{THF})_9(\mu_3\text{-Cl})]^{2+}$  (Fig. 63B)<sup>1335</sup>  $[\text{Li}_4(\text{THF})_{10}(\mu_3\text{-Cl})_2]^{2+}$ ,<sup>1336</sup> and  $[\text{Li}_4(\text{THF})_{10}(\mu_3\text{-Br})_2]^{2+}$ .<sup>1337</sup>

Although both tetrahedral and square-planar  $[\text{Na}(\text{THF})_4]^+$  ions have been structurally characterized,<sup>1338,1339</sup> the CN typically increases on descending group 1. Both trigonal bipyramidal and square-based pyramidal  $[\text{Na}(\text{THF})_5]^+$  have been observed<sup>208,863,1340–1348</sup> with octahedral  $[\text{Na}(\text{THF})_6]^+$  being more typical as illustrated by selected examples.<sup>1349–1364</sup>

Potassium commonly forms the octahedral  $[\text{K}(\text{THF})_6]^+$ ,<sup>503,1240,1309,1365–1372</sup> but in addition  $[\text{K}(\text{THF})_4]^+$ ,<sup>1373</sup>  $[\text{K}(\text{THF})_5]^+$ ,<sup>1374–1376</sup> and  $[\text{K}(\text{THF})_7]^+$ ,<sup>503,1377</sup> have been observed. Cesium exhibits a 7-coordinate complex in  $[\text{Cs}(\text{THF})_7][\text{B}\{3,5\text{-}(\text{CF}_3)_2\text{C}_6\text{H}_3\}_4]^-$ .<sup>1111</sup>

Square-planar  $[\text{Mg}(\text{THF})_4]^{2+}$  in the  $[\text{Ph}\{\text{CH}(\text{SiMe}_3)_2\}\text{P}(\text{BH}_3)_2]^-$  salt adds to the examples of this coordination environment (see earlier) in complexes where the geometry is not imposed by, for example, a porphyrinato ligand. However in this complex, there are close  $\text{Mg}\cdots\text{H}\text{-B}$  contacts, and a similar situation arises in the  $\text{Ca}^{2+}$  and  $\text{Sr}^{2+}$  analogs.<sup>1378</sup> The trigonal bipyramidal  $[\text{Mg}(\text{THF})_5]^{2+}$  ion has been structurally characterized.<sup>1379</sup> Octahedral  $[\text{Mg}(\text{THF})_6]^{2+}$  is well established,<sup>1315,1378,1380–1388</sup> and a CN of 6 is also found in *trans*- $[\text{Mg}(\text{OH}_2)_2(\text{THF})_4]^{2+}$ ,<sup>1389</sup>  $[\text{MgCl}(\text{THF})_5]^+$ ,<sup>683,1390</sup>  $[\text{MgBr}(\text{THF})_5]^+$ ,<sup>1385,1391–1393</sup> *trans*- $[\text{MgCl}_2(\text{THF})_4]$ ,<sup>1394,1395</sup> *trans*- $[\text{MgBrCl}(\text{THF})_4]$ ,<sup>1396</sup> *trans*- $[\text{MgBr}_2(\text{THF})_4]$ ,<sup>1396–1398</sup>  $[\text{Mg}_2(\text{THF})_6(\mu\text{-Cl})_3]^+$  (Fig. 63C, relevant to electrolyte solutions used in rechargeable Mg-containing batteries)<sup>682,1390,1399–1407</sup> and  $[\text{Mg}_2(\text{THF})_6(\mu\text{-Br})_3]^+$ .<sup>1408,1409</sup>

Calcium forms the  $[\text{Ca}(\text{THF})_6]^{2+}$  ion,<sup>1380,1410–1417</sup> and octahedral coordination is also observed in *trans*- $[\text{Ca}(\text{OH}_2)_2(\text{THF})_4]^{2+}$ ,<sup>1418</sup> *trans*- $[\text{CaBr}_2(\text{THF})_4]$ ,<sup>671,1419,1420</sup>  $[\text{CaI}(\text{THF})_5]^+$ ,<sup>1416,1417,1421</sup> *trans*- $[\text{CaI}_2(\text{THF})_4]$ ,<sup>1422</sup>  $[\text{Ca}_2(\text{THF})_8(\mu\text{-Br})_2]^{2+}$ ,<sup>1380</sup> The octahedral  $[\text{Sr}(\text{THF})_6]^{2+}$  ion has been observed in  $[\text{Sr}(\text{THF})_6][\text{VMes}_4]_2$ ,<sup>1417</sup> but a CN of seven is consistent with the increased size of the ion compared to the lighter group 2 metal ions and is found in  $[\text{Sr}(\text{THF})_7]^{2+}$ ,<sup>1417</sup> and *trans*- $[\text{SrI}_2(\text{THF})_5]$  (a pentagonal bipyramidal structure, Fig. 63D).<sup>1423</sup> For  $\text{Ba}^{2+}$ , a CN = 8 is exemplified in  $[\text{Ba}(\text{THF})_8]^{2+}$ .<sup>1424</sup> As part of their investigation of heterobimetallic compounds with complex cations of the group 2 metals coupled with organic anions of M(III) (M = B, Al, Ga, and V), Langer et al. have demonstrated the increased CN with size of metal ion in  $[\text{M}(\text{THF})_n]^{2+}$  (M = Ca, Sr, Ba) with a series of related salts.<sup>1417</sup>

Examples of simple complexes (homoleptic, THF/halido, THF/aqua being the criteria for ‘simple’) of the p-block metals with THF ligands are sparse compared to those of the s-block metals. For aluminum, examples include *trans*- $[\text{AlCl}_2(\text{THF})_4]^+$ ,<sup>1425–1428</sup> and *trans*- $[\text{AlBr}_2(\text{THF})_4]^+$ .<sup>1429</sup> For the group 16 metals, a representative complex is  $[\text{TeCl}_5(\text{THF})]^-$ .<sup>1426</sup>

Moving from THF to furan has a dramatic effect on the number of structurally characterized main group metal complexes. Excluding metallated compounds leaves  $[\text{Bi}_2(\text{furan})_2\text{I}_6(\mu\text{-I})_2]^{2-}$  (Fig. 64A)<sup>1430,1431</sup> as an example of a complex containing non-substituted furan ligands.

The disposition of the O-donors in 1,4-dioxane leads to its role as a bridging ligand, although it can also be found terminally bound to main group metal atoms. Examples of discrete molecular complexes containing monodentate diox include the tetrahedral  $[\text{Li}(\text{diox})_4]^+$ ,<sup>1432,1433</sup>  $[\text{Na}(\text{diox})_4(\text{SiPh}_2\text{SiHPh}_2)]$  (square-based pyramidal),<sup>1434</sup>  $[\text{Na}(\text{diox})_2(\text{dme})(\text{THF})]^+$  (CN = 5),<sup>1435</sup>

**Fig. 63** Structures of (A)  $[\text{Li}_2(\text{THF})_6(\mu\text{-Cl})]^+$  (CSD refcode AXATOI), (B)  $[\text{Li}_3(\text{THF})_9(\mu_3\text{-Cl})]^{2+}$  (refcode MEFKUD), (C)  $[\text{Mg}_2(\text{THF})_6(\mu\text{-Cl})_3]^+$  (refcode AVIXAF), (D) *trans*- $[\text{SrI}_2(\text{THF})_5]$  (refcode IJAVAR).

**Fig. 64** Structures of (A)  $[\text{Bi}_2(\text{furan})_2]_6(\mu\text{-l})_2]^{2-}$  (CSD refcode AZORUE), and (B)  $[\text{Ga}_2\text{Cl}_4(\text{diox})_2]$  (refcode DOXGAC01). (C) Part of the 3D-net in  $[\text{Na}(\mu\text{-diox})_3]_n^{n+}$  (refcode JIGQOI). (D) Structure of the  $[\text{K}_2(18\text{-crown-6})_2(\mu\text{-diox})]^{2+}$  unit found in the  $[(\text{C}_{13}\text{H}_8)\text{CPh}_2(\text{C}_5\text{H}_4)\text{Nd}(\text{BH}_4)_2]^-$  salt (refcode UBUZIA).

octahedral *trans*- $[\text{Na}(\text{OH}_2)_2(\text{diox})_4]^+$  (not discussed in the original work, CSD refcode UKEJEB),<sup>1436</sup> *trans*- $[\text{K}(18\text{-crown-6})(\text{diox})_2]^+$ ,<sup>1437,1438</sup> the 7-coordinate  $[\text{Ca}(\text{diox})_3(\text{NCMe})_4]^{2+}$  and  $[\text{Ca}(\text{diox})_2(\text{NCMe})_3(\text{OH}_2)_2]^{2+}$ .<sup>1410</sup> The cation  $[\text{Li}_2(\text{diox})_6(\mu\text{-diox})]^{2+}$  features both monodentate and bridging diox ligands with each  $\text{Li}^+$  tetrahedrally sited.<sup>1439</sup>  $[\text{Na}_2(\text{MeOC}_6\text{H}_5)_6(\mu\text{-diox})]^{2+}$  is another example of a discrete species with a bridging diox ligand.<sup>1440</sup>

A new polymorph of  $[\text{Ga}_2\text{Cl}_4(\text{diox})_2]$  was reported in 2017; the vacant coordination site in the pseudo-trigonal bipyramidal coordination sphere of Ga (Fig. 64B) is occupied by a long-distance contact to a diox ligand in an adjacent molecule in the lattice.<sup>1441</sup>

Polymeric assemblies supported by bridging diox ligands are illustrated by the following examples from group 1. A redetermination of the structure of  $[\text{Li}(\mu\text{-Cl})(\mu\text{-diox})]_n$  is consistent with a diamondoid network with 4-connecting  $\{\text{LiO}_2\text{Cl}_2\}$ -nodes,<sup>1442</sup> and this has also been described by Jin et al.<sup>1443</sup> In contrast, in  $[\text{Li}_2(\mu\text{-Cl})(\mu\text{-diox})_3]_n^{2n+}$  (isolated as the  $[\text{TaCl}_6]^{2-}$  salt), the 3D-assembly is a puckered hexagonal net with 4-connecting  $\{\text{LiO}_3\text{Cl}\}$ -nodes (distorted tetrahedral, Li–O in the range 1.888(12) to 1.960(10) Å and O–Li–O angles of 101.3(5) to 115.0(6)°).<sup>1444</sup> In  $[\text{Li}_2(\text{O}_3\text{S}^n\text{C}_4\text{F}_9)_2(\mu\text{-diox})]_n$ , each tetrahedrally sited  $\text{Li}^+$  is coordinated by O-donors of three different  $[\text{C}_4\text{F}_9\text{SO}_3]^-$  and one diox; the latter bridge between pairs of  $\text{Li}^+$  and a 2D-sheet assemblies, decorated on the outer surfaces with  ${}^n\text{C}_4\text{F}_9$  chains in extended conformations.<sup>1445</sup> In  $[\text{Na}(\text{H}_3\text{BNHETtBH}_3)(\mu\text{-diox})]_n$ , an intricate network assembles by virtue of a combination of bridging diox ligands and Na–H–B bridges.<sup>1446</sup>  $[\text{Na}(18\text{-crown-6})(\mu\text{-diox})]_n^{n+}$  forms a 1D-coordination polymer,<sup>447,1447</sup> while  $[\text{Na}(\mu\text{-diox})_3]_n^{n+}$  assembles into a 3D-network (Fig. 64C) with diox ligands connecting octahedrally sited  $\text{Na}^+$  ions.<sup>447</sup> The 3D  $[\text{Na}(\mu\text{-diox})_3]_n^{n+}$  network is also found in the  $[\text{PCO}]^-$  salt.<sup>1038</sup> In  $[\text{Na}(\text{diox})_{1.5}][\text{BARF}_4]$ , the  $\text{Na}^+$  ions are octahedrally sited, bound by *trans*-monodentate diox, *trans*-bridging diox (to give an infinite  $\{\text{Na}(\mu\text{-diox})\}_n$  chain) and *trans*- $\text{F}^{\text{BARF}_4}$  contacts; the  $[\text{BARF}_4]^-$  anions act as bridging ligands between the 1D-chains.<sup>1448</sup>

The  $[\text{K}_2(18\text{-crown-6})_2(\mu\text{-diox})]^{2+}$  motif shown in Fig. 64D is observed in the  $[(\text{C}_{13}\text{H}_8)\text{CPh}_2(\text{C}_5\text{H}_4)\text{Nd}(\text{BH}_4)_2]^-$  salt; the vacant coordination site on each  $\text{K}^+$  ion is occupied by a weak  $\eta^2$ -interaction with the fluorene unit in the complex anion.<sup>1449</sup> In the 1D-polymer  $[\text{K}(\text{OH}_2)_4(\mu\text{-diox})]_n^{n+}$ , the bridging diox ligands are mutually *trans* within an octahedral  $\text{K}^+$  coordination sphere.<sup>1450</sup> The reaction of  $(\text{Me}_3\text{Si})_3\text{P}$ , CsF and  $\text{Mes}^*\text{COCl}$  ( $\text{Mes}^* = 2,4,6\text{-}t\text{-Bu}_3\text{C}_6\text{H}_2$ ) in 1,4-dioxane led to a series of products including tri- and tetraphosphides; in the diox adduct of  $[\text{Cs}\{\text{P}(\text{SiMe}_3)\}]$ , a 2D-network supported by  $\{\text{Cs}(\mu\text{-diox})\text{Cs}\}$  units assembles.<sup>1451</sup>

Many examples of Mg(II) complexes containing diox ligands are organometallic, and diox is often used to precipitate magnesium halides from Grignard solutions. An investigation of structure–solubility relationships in these systems also includes the characterization of  $[\text{MgX}_2(\mu\text{-diox})_2]_n$  ( $X = \text{Cl}, \text{Br}$ ) which form (4,4) nets with 4-connecting *trans*- $\{\text{MgX}_2\text{O}_4\}$  units.<sup>1452</sup> The  $\text{AlH}_3$  adduct  $[\text{AlH}_3(\mu\text{-diox})]_n$  contains trigonal bipyramidal Al(III) centers with axial diox ligands and the structure propagates into a 1D-polymer,<sup>1453</sup> and  $[\text{GaCl}_3(\mu\text{-diox})]_n$  is structurally similar.<sup>1454</sup> In group 14, the 1D-coordination polymer  $[\text{SnBr}_4(\mu\text{-diox})]_n$ , each Sn(IV) has a *cis*-arrangement of diox ligands (Fig. 65A).<sup>1455</sup>

Extended assemblies of the heavier group 15 elements are represented by  $[\text{Sb}_2\text{Cl}_6(\mu\text{-diox})_3]_n$  which forms an interpenetrating 3D-network with each Sb(III) center acting as a 3-connecting node; part of one network is shown in Fig. 65B.<sup>1456</sup> A diox adduct of  $\text{SeO}_3$  has been reported, although reactions of  $\text{SeO}_3$  with 1,4-dioxane were fraught with risk of explosion. Nonetheless,  $[\text{SeO}_3(\text{-diox})]_n$  was isolated and structurally characterized; the diox ligands connect planar  $\{\text{SeO}_3\}$  units into 1D-chains but interestingly, there are two crystallographically independent chains, one with symmetrically bound axial diox ligands ( $\text{Se}-\text{O}_{\text{diox}} = 2.314$  Å) and one with  $\text{Se}-\text{O}_{\text{diox}}$  bond lengths of 2.189 and 2.460 Å.<sup>1457</sup> Fig. 65C shows part of the 1D-polymer found in  $[\text{TeF}_4(\mu\text{-diox})]_n$  ( $\text{Te}-\text{O} = 2.686$  Å); this structural study is part of a wider investigation of the gas phase structures of  $\text{TeF}_4$  and  $\text{TeCl}_4$ , and of the solid-state structures of a series of their adducts.<sup>294</sup>

**Fig. 65** (A) Part of a 1D-chain in  $[\text{SnBr}_4(\mu\text{-diox})]_n$  (CSD refcode XUMQEB). (B) Part of the 3D-net in  $[\text{Sb}_2\text{Cl}_6(\mu\text{-diox})_3]$ ; the overall structure is an interpenetrating network (refcode BEKHUV01). (C) Part of a 1D-chain in  $[\text{TeF}_4(\mu\text{-diox})]_n$  (refcode HUQNUD).

### 1.02.6.1.7 Monodentate acetato ligands

We discuss the different modes of bonding of acetato ligands in detail in Section 1.02.6.2.4. In the present section, we provide selected examples of complexes (excluding those with M–C bonds) containing monodentate acetato ligands in which the second O-donor is clearly remote from the metal center.

In the 1D-coordination polymer  $[\text{Na}_2(\mu\text{-OH}_2)_4(\text{OAc})_2(\text{OH}_2)_2]_n$ , the chain is supported by bridging aqua ligands and each  $\text{Na}^+$  is octahedrally sited. The structure is related to that of  $[\text{Na}(\text{OH}_2)_2(\mu\text{-OH}_2)_2]_n^{n+}$  shown in Fig. 57E; in  $[\text{Na}_2(\mu\text{-OH}_2)_4(\text{OAc})_2(\text{OH}_2)_2]_n$ , each  $\text{Na}^+$  carries terminal aqua and acetato ligands in a *cis*-arrangement.<sup>1458</sup> In the octahedral *trans*- $[\text{Mg}(\text{OAc})_2(\text{OH}_2)_4]$ , the acetato ligands are monodentate with Mg–O and Mg $\cdots$ O distances of 2.0811 and 3.3261 Å; this is a redetermination of the structure.<sup>1459</sup> Scheurell et al. have described a family of magnesium acetate solvates and their hydrates and these include  $[\text{Mg}(\text{OAc})_2(\text{OH}_2)_3(\text{EtOH})]$  (with *cis*-AcO<sup>−</sup> ligands) and  $[\text{Mg}(\text{OAc})_2(\text{HOAc})_2(\text{OH}_2)_2]$  (with *trans*-AcO<sup>−</sup> ligands); the second O atom of each monodentate AcO<sup>−</sup> is involved in intermolecular hydrogen bonding.<sup>1460</sup> An investigation of the structural nature of calcium magnesium acetate (CMA) road deicers includes a redetermination of the structure of  $[\text{Ca}(\text{OAc})_2(\text{OH}_2)] \cdot n\text{AcOH}$  which is better written as  $[\text{Ca}_2(\mu\text{-OAc})_3(\text{OAc})(\text{HOAc})(\text{OH}_2)_2]_n \cdot n\text{AcOH}$  and incorporates both monodentate and bridging acetato ligands.<sup>1459</sup>

Within the p-block,  $[\text{Ge}(\text{OAc})_3]^-$  is an example of a homoleptic complex with monodentate acetato ligands; it possesses a trigonal pyramidal structure and was isolated as the thermally stable  $[\text{Ph}_3\text{PrP}]^+$  salt.<sup>1461</sup> The Pb(II) containing salt  $[\text{emim}]_2[\text{Pb}(\text{OAc})_4]$  was isolated during the course of the preparation of the ionic liquid 1-ethyl-3-methylimidazolium acetate. The  $[\text{Pb}(\text{OAc})_4]^{2-}$  ion contains one chelating and three monodentate ligands and was the first example of a homoleptic 5-coordinate Pb(II) carboxylate complex with a stereochemically active lone pair.<sup>1462</sup> In  $[\text{Sb}(\mu\text{-O}_2\text{C}_2\text{H}_4)(\text{OAc})]_n$ , a 1D-polymer assembles by virtue of the ethane-1,2-diolato ligands. Each chelates to one Sb(III) center and each O atom of the ethane-1,2-diolato then bridges between two metal atoms; a CN = 5 for the Sb atom is completed by a monodentate acetato ligand.<sup>1463</sup>  $[\text{SeO}_2(\text{OAc})_2]$  was the first example of a selenonyl carboxylate; the Se(VI) center is in a distorted tetrahedral environment, with Se–O<sub>AcO</sub> bond lengths of 1.770(1) and 1.751(1) Å, and an O<sub>AcO</sub>–Se–O<sub>AcO</sub> = 96.5(1)°; the monodentate bonding mode of the AcO<sup>−</sup> ligands is defined by the long contacts to the second O atoms (Se $\cdots$ O<sub>AcO</sub> = 2.933(1) and 2.787(1) Å).<sup>1464</sup>

## 1.02.6.2 Bidentate ligands

### 1.02.6.2.1 1,2-Dimethoxyethane

A variety of coordination compounds incorporating dme are described in other sections in this review. Here, we focus only on homoleptic complexes. For the group 1 metals, such complexes are typically counterions and receive only passing mention in published work. Despite the ubiquitous nature of ions such as  $[\text{Li}(\text{THF})_4]^+$ , the tetrahedral  $[\text{Li}(\text{dme})_2]^+$  ion<sup>1465–1468</sup> is less common than the 6-coordinate  $[\text{Li}(\text{dme})_3]^+$ , and this is presumably a consequence of the presence of chelating rather than monodentate ligands. In some cases, short contacts between the  $\{\text{Li}(\text{dme})_2\}^+$  moiety and, for example, N,<sup>1469</sup> Se,<sup>1470</sup> or Cl<sup>1471–1474</sup> atoms in the complex anion lead to an expansion of the coordination sphere.  $[\text{Li}(\text{dme})_3][\text{PCS}]$  with discrete ions was mentioned earlier in the review,<sup>1036,1037</sup> and the octahedral  $[\text{Li}(\text{dme})_3]^+$  cation is well established, with 217 hits since 2000 in the CSD. Selected examples are found in the following references.<sup>704,1475–1481</sup> Octahedral  $[\text{Na}(\text{dme})_3]^+$  is also ubiquitous, with 82 structurally characterized examples reported since 2000; selected references are given.<sup>1482–1489</sup> For K<sup>+</sup>, the larger size of the metal ion leads to CN ≥ 6, with octahedral  $[\text{K}(\text{dme})_3]^+$ ,<sup>1490</sup>  $[\text{K}(\text{dme})_3]^+$  with close contacts to the complex anion increasing the coordination sphere,<sup>1491</sup>

**Fig. 66** (A) Structure of  $[\text{Nb}(\text{pc})\text{K}_2(\text{dme})_4(\mu\text{-dme})(\mu_3\text{-O})]$  (CSD refcode XAHZIR). (B) Linear arrangement of  $[\text{Cs}(\text{dme})_3]^+$  and  $[\text{CB}_{11}\text{H}_{12}]^-$  ions in  $[\text{Cs}(\text{dme})_3][\text{CB}_{11}\text{H}_{12}]$ ; H atoms are omitted for clarity (refcode WIBKUQ).

$[\text{K}(\text{dme})_4]^+$  (CN = 7 with one monodentate dme)<sup>1491</sup> and  $[\text{K}(\text{dme})_4]^+$  (CN = 8)<sup>1492–1500</sup> being reported. The compound  $[\text{Nb}(\text{pc})\text{K}_2(\text{dme})_4(\mu\text{-dme})(\mu_3\text{-O})]$  deserves inclusion because of the  $\{\text{K}_2(\text{dme})_4(\mu\text{-dme})\}$  unit shown in Fig. 66A.<sup>1501</sup> In  $[\text{Cs}(\text{dme})_3][\text{CB}_{11}\text{H}_{12}]$ , the cations and anions are arranged in alternate positions along the crystallographic *c*-axis (Fig. 66B) and the CN of  $\text{Cs}^+$  is expanded by short interaction between  $\text{Cs}^+$  and BH or CH units (the carborane cages are disordered).<sup>1502</sup>

Homoleptic and other simple complexes of the group 2 metals with dme ligands are relatively well exemplified. Octahedral coordination is observed in  $[\text{Mg}(\text{dme})_3]^{2+}$ ,<sup>1503–1505</sup> *cis*- $[\text{Mg}(\text{dme})_2(\text{O}_3\text{SCF}_3\text{-}\kappa^1)_2]$ ,<sup>1506</sup> and  $[\text{Mg}_2(\text{dme})_4(\mu\text{-Cl})_2]$ .<sup>1405,1507</sup> As with  $[\text{Mg}_2(\text{THF})_6(\mu\text{-Cl})_3]$  (Fig. 63C), these compounds are of interest in studies of electrolytes in rechargeable Mg-containing batteries. The octahedral *cis*- $[\text{MgBr}_2(\text{dme})_2]$  is of relevance to the preparation of chiral Grignard reagents.<sup>670</sup> The variability of CN for the heavier metal ions in group 2 is illustrated by the following: octahedral *cis*- $[\text{Ca}(\text{dme})_2(\text{NPh}_2)_2]$ ,<sup>1508</sup> octahedral *cis*- $[\text{Sr}(\text{dme})_2(\text{N}^i\text{PrPh})_2]$ ,<sup>667</sup>  $[\text{Ca}(\text{OH}_2)_3(\text{dme})_2]^{2+}$  and  $[\text{Ca}(\text{OH}_2)_4(\text{dme})_2]^{2+}$  (CNs = 7 and 8, respectively),<sup>1509</sup>  $[\text{CaBr}(\text{OH}_2)_2(\text{dme})_2]^+$  (CN = 7),<sup>1510</sup> coordination numbers of 7 and 8 in  $[\text{Ca}(\text{OH}_2)_2(\text{dme})_2(\text{NCS})_2]$  and  $[\text{Ca}(\text{dme})_3(\text{NCS})_2]$ , respectively,<sup>274</sup>  $[\text{Ca}(\text{dme})_4]^{2+}$  (CN = 8),<sup>1417,1511</sup>  $[\text{SrI}_2(\text{THF})(\text{dme})_2]$  (CN = 7),<sup>1512</sup>  $[\text{SrI}_2(\text{dme})_3]$  (CN = 8),<sup>1513</sup>  $[\text{SrI}_2(\text{THF})_2(\text{dme})_2]$  (CN = 8),<sup>1423</sup> and  $[\text{BaI}_2(\text{THF})_2(\text{dme})_2]$  and  $[\text{BaI}_2(\text{dme})_3]$  (CN = 8).<sup>1512</sup>

The octahedral *cis*- $[\text{AlCl}_2(\text{dme})_2]^+$  is one of the few examples of simple dme coordination compounds of the p-block metals.

### 1.02.6.2.2 Diol and diolato ligands

Examples in this section are restricted to ethane-1,2-diol, ethane-1,2-diolate and related ligands. Ethane-1,2-diol (ethylene glycol) is often a non-innocent solvent, forming a range of s-block metal complexes. These include octahedral  $[\text{Li}(\text{HOCH}_2\text{CH}_2\text{OH})_3]^+$  and  $[\text{Na}(\text{HOCH}_2\text{CH}_2\text{OH})_3]^+$ ,<sup>1514</sup> and the 8-coordinate  $[\text{Ba}(\text{HOCH}_2\text{CH}_2\text{OH})_4]^{2+}$ .<sup>1515</sup> Tonouchi et al. have studied a series of alkali metal fluoride-diol complexes. While  $[\text{CsF}(\text{HOCH}_2\text{CH}_2\text{OH})]_n$  has a 2D-sheet structure,  $[(\text{MF})_5(\text{HOCH}_2\text{CH}_2\text{OH})_4]_n$  (M = K, Rb) form columnar structures; the effects of increasing the  $C_n$  chain within the diol were also investigated.<sup>1516</sup>

Diolato ligands feature in the cluster complex  $[\text{Al}_{10}(\mu\text{-OAc})_{20}(\mu\text{-O}_2\text{C}_2\text{H}_4)_4(\mu\text{-F})_2]$  described in Section 1.02.6.2.4, and in propane-1,2-diolato and butane-1,2-diolato analogs.<sup>1517</sup> Although the 'brown-ring' test has been an analytical tool for over 100 years, full characterization of the  $[\text{Fe}(\text{OH}_2)_5(\text{NO})]^{2+}$  cation has remained elusive. In 2019, the crystal structures of hydrates of  $[\text{Fe}(\text{OH}_2)_5(\text{NO})][\text{M}(\text{pin}^F)_2(\text{OH}_2)_2]$  (M = Ga<sup>III</sup>, Fe<sup>III</sup>) were reported, and the square-based pyramidal  $[\text{Ga}(\text{pin}^F)_2(\text{OH}_2)]^-$  ion is relevant to this review.<sup>1518</sup>

In 2007, Klüfers et al. commented that only *ca.* 24 germanium complexes containing 1,2-diolate ligands had been structurally characterized, and that spiro-germanes of the type  $[\text{Ge}(\text{diolato})_2]$  were surprisingly absent. A detailed investigation of reactions of  $\text{GeCl}_4$  or  $\text{Ge}(\text{OMe})_4$  with different diols revealed that tetrahedrally sited Ge(IV) in crystalline  $[\text{Ge}(\text{diolato})_2]$  compounds was limited to sterically demanding substituents as exemplified in Fig. 67A. With ethane-1,2-diol, for example, the 6-coordinate

**Fig. 67** Structures of (A) bis(1,1'-bicyclohexyl-1,1'-diolato)germanium(IV) (CSD refcode GICLUA) and (B) *trans*- $[\text{Ge}(\text{O}_2\text{C}_2\text{H}_4)_2(\text{HOCH}_2\text{CH}_2\text{OH})_2]$  (refcode GICMIP, only the OH H atoms are shown). (C) Part of a 2D-sheet in  $\beta\text{-Sn}(\text{O}_2\text{C}_2\text{H}_4)$  (refcode BIVHET01). (D) Structure of the see-saw shaped  $[\text{Se}(\text{O}_2\text{C}_2\text{H}_4)_2]$  (Se–O distances = 1.874(2), 1.780(2), 1.863(2), 1.791(2) Å; refcode HOCBAD).

*trans*-[Ge(O<sub>2</sub>C<sub>2</sub>H<sub>4</sub>)<sub>2</sub>(HOC<sub>2</sub>H<sub>4</sub>OH)<sub>2</sub>] (Fig. 67B) forms.<sup>1519</sup> In [Ge<sub>2</sub>(O<sub>2</sub>C<sub>2</sub>H<sub>4</sub>)<sub>2</sub>(μ-O<sub>2</sub>C<sub>2</sub>H<sub>4</sub>)<sub>2</sub>], each Ge(IV) is 5-coordinate, with one O donor of two diolate ligands in bridging mode.<sup>1520</sup>

1,2-Ethanediolate complexes of Sn(II) and Pb(II) exhibit polymorphism; α- and β-Sn(O<sub>2</sub>C<sub>2</sub>H<sub>4</sub>) can be selectively prepared by controlling the reaction times when tin(II) oxalate reacts with 1,2-ethanediol, while α- and β-Pb(O<sub>2</sub>C<sub>2</sub>H<sub>4</sub>) were obtained by controlling the quantities of NaOH and/or water used in the preparations. In β-Sn(O<sub>2</sub>C<sub>2</sub>H<sub>4</sub>), each Sn(II) center is in a disphenoidal (see-saw) environment and the structure extends into a 2D-sheet (Fig. 67C). Thermal decomposition of both α- and β-Sn(O<sub>2</sub>C<sub>2</sub>H<sub>4</sub>) yields nanocrystalline SnO<sub>2</sub>.<sup>1521</sup> The reaction of Sn(O<sup>t</sup>Bu)<sub>4</sub> with H<sub>2</sub>pin<sup>F</sup> results in the formation of [Sn(pin<sup>F</sup>)<sub>3</sub>]<sup>2-</sup> (isolated as the Et<sub>3</sub>NH<sup>+</sup> salt) which possesses a distorted trigonal prismatic structure; the Sn(II) complex [Sn(pin<sup>F</sup>)<sub>2</sub>]<sup>2-</sup> was also reported.<sup>1522</sup> The Pb(II) coordination network [Pb<sub>4</sub>I<sub>4</sub>(μ<sub>4</sub>-O<sub>2</sub>C<sub>2</sub>H<sub>4</sub>)<sub>2</sub>]<sub>n</sub> is a rare example of a 3D-oxyiodoplumbate assembled from neutral 2D-[Pb<sub>2</sub>I<sub>4</sub>]<sub>n</sub> sheets.<sup>1523</sup>

Fig. 67D shows the structure of [Se(O<sub>2</sub>C<sub>2</sub>H<sub>4</sub>)<sub>2</sub>]; an NBO analysis revealed that the Se–O bonds possess heteropolar character and the Se lone pair exhibits predominantly *s*-character.<sup>1524</sup>

### 1.02.6.2.3 β-Diketonates

The number of main group metal coordination compounds containing β-diketonate ligands is vast, and once again, we have had to define strict criteria for the selection of complexes for coverage. We focus mainly on homoleptic compounds, and those with halido, pseudo-halido or other simple co-ligands.

Mononuclear group 1 metal complexes are illustrated by tetrahedral [Li(OH<sub>2</sub>)<sub>2</sub>(Rtfacac)] (R = 4-BrC<sub>6</sub>H<sub>4</sub>),<sup>1525</sup> and 6-coordinate [Na(hfacac)<sub>3</sub>]<sup>2-</sup> (which was included in a study of hydrophobic ionic liquids with strongly coordinating anions).<sup>1526</sup> [Li(<sup>t</sup>Butfacac)]<sub>n</sub> and [K(18-crown-6)(hfacac)]<sub>n</sub> illustrate different ways in which CF<sub>3</sub>-derivatives of [acac]<sup>-</sup> can produce polymeric structures with group 1 metals. In [Li(<sup>t</sup>Butfacac)]<sub>n</sub>, each O-donor of a [<sup>t</sup>Butfacac] ligand bridges between a pair of Li<sup>+</sup> ions resulting in a 1D-coordination polymer.<sup>1527</sup> In [K(18-crown-6)(hfacac)], the [hfacac]<sup>-</sup> ligand acts as a chelate to one K<sup>+</sup> center and then connects [K(18-crown-6)(hfacac)] units into a 1D-chain through K–F interactions (K–F = 3.081(6) Å for one of two disordered positions).<sup>1528</sup> [Na<sub>3</sub>(μ-acac)<sub>3</sub>(μ-<sup>i</sup>PrOH)]<sub>n</sub> and [Na<sub>3</sub>(μ-acac)<sub>3</sub>(py)]<sub>n</sub> also form 1D-coordination polymers.<sup>1529,1530</sup> [Rb<sub>2</sub>(Rtfacac)<sub>2</sub>(OH<sub>2</sub>)<sub>2</sub>]<sub>n</sub> (R = Ph) assembles into a 2D-sheet with the [Phtfacac]<sup>-</sup> ligand acting both as O,O'-chelate and as an F-donor.<sup>1531</sup> [Cs(μ-<sup>t</sup>BuO<sub>2</sub>acac)]<sub>n</sub> possesses a 2D-network with octahedrally sited Cs<sup>+</sup> ions (Fig. 68A); the ligand coordinates through both the β-diketonate unit and the <sup>t</sup>BuO units. The structure is not discussed in detail in the original work which is focused upon a synergistic ion-binding strategy for asymmetric catalysis of anionic sigmatropic rearrangements.<sup>1532</sup>

Group 2 metal complexes include the tetrahedral [Be(Ph<sub>2</sub>acac)<sub>2</sub>],<sup>1533</sup> octahedral [Mg(hfacac)<sub>3</sub>]<sup>-</sup> (which may be prepared using hydrophobic [hfacac]<sup>-</sup>-containing ionic liquids),<sup>1534–1536</sup> *trans*-[Mg(acac)<sub>2</sub>(3,5-Me<sub>2</sub>py)<sub>2</sub>],<sup>1537</sup> [Mg(<sup>t</sup>Bu<sub>2</sub>acac)<sub>2</sub>(tmeda)],<sup>1538</sup> *trans*-[Mg(tfacac)<sub>2</sub>(OH<sub>2</sub>)<sub>2</sub>],<sup>1539</sup> and *trans*-[Mg(hfacac)<sub>2</sub>(OH<sub>2</sub>)<sub>2</sub>].<sup>1540</sup> The bis(2-methoxyethyl) ether adduct of [Mg(hfacac)<sub>2</sub>(OH<sub>2</sub>)<sub>2</sub>] has been used as an MOCVD precursor to thin films of MgF<sub>2</sub>.<sup>1540</sup> β-Diketonates can act as axial ligands in [M(18-crown-6)(β-diketonate)<sub>2</sub>] (M = Sr, Ba) complexes; related [M(18-crown-6)(β-diketonate)<sub>2</sub>] (*cis* relationship between the β-diketonates), [M(18-crown-6)(OH<sub>2</sub>)(β-diketonate)]<sup>+</sup> and [M(15-crown-5)(β-diketonate)<sub>2</sub>] species have also been reported.<sup>1541–1546</sup> Davies et al. have described the tetramer [Mg(<sup>t</sup>Bu<sub>2</sub>acac)(μ<sub>3</sub>-OMe)(MeOH)]<sub>4</sub> which possesses a cubane structure with each Mg<sup>2+</sup> center coordinated by a chelating β-diketonate, a terminal MeOH, and three μ<sub>3</sub>-methoxy ligands; using THF solutions of the complex, liquid-injection MOCVD has been applied to deposit thin films of MgO.<sup>1547</sup> [Mg(acac)(μ<sub>3</sub>-OMe)(MeOH)]<sub>4</sub> is closely related to [Mg(<sup>t</sup>Bu<sub>2</sub>acac)(μ<sub>3</sub>-OMe)(MeOH)]<sub>4</sub>.<sup>1548</sup> Calcium is 6-coordinate in *trans*-[Ca(Ph<sub>2</sub>acac)<sub>2</sub>(THF)<sub>2</sub>], but exhibits a CN of 7 in [Ca(Ph<sub>2</sub>acac)<sub>2</sub>(tgm)].<sup>1549</sup> The larger Sr<sup>2+</sup> can accommodate four chelating β-diketonates as exemplified by [Sr(Rtfacac)<sub>4</sub>]<sup>2-</sup> (R = Ph), while in [Sr(<sup>t</sup>Bu<sub>2</sub>acac)<sub>2</sub>(OH<sub>2</sub>)<sub>2</sub>(EtOH)], a CN = 7 is observed.<sup>1550</sup> A CN of 8 is observed in [Sr(<sup>t</sup>Bu<sub>2</sub>acac)<sub>2</sub>(<sup>t</sup>PrOH)<sub>4</sub>].<sup>1551</sup>

Fig. 68 Structures of (A) part of one 2D-sheet in [Cs(μ-<sup>t</sup>BuO<sub>2</sub>acac)]<sub>n</sub> (CSD refcode FAQQEW), (B) [Al(acac)<sub>2</sub>]<sub>2</sub>[Mg(μ-<sup>i</sup>Pr)<sub>4</sub>] (refcode GUVHEK), (C) [Sn(acac)(OAc)] (refcode BIDWIV), (D) [Sn(tfacac)<sub>2</sub>] (refcode BAMWOE), and (E) [Sn(acac)(μ-O<sub>3</sub>SCF<sub>3</sub>-1κO<sup>1</sup>:2κO<sup>2</sup>)]<sub>n</sub> (refcode BULBIU).

The trinuclear species  $[\{Al(acac)_2\}_2\{Mg(\mu-O^iPr)_4\}]$  (Fig. 68B) makes an appropriate transition in our discussion from group 2 to group 13 metal complexes.<sup>1552</sup> Group 13 metal(III) complexes include tetrahedral  $[Ga(acac)Cl_2]$  and  $[Ga(^tBu_2acac)Cl_2]$ ,<sup>1553</sup> and the octahedral  $[Al(acac)_3]$ ,<sup>1554,1555</sup>  $[Al(^tBuOacac)_3]$ ,<sup>1556</sup>  $[Al(MeO_2acac)_3]$ ,<sup>1557</sup>  $[Al(^tBuO_2acac)_3]$ ,<sup>1557</sup>  $[Al(Rtfacac)_3]$  (R = MeO),<sup>1558</sup>  $[Al(hfacac)_3]$ ,<sup>1559</sup>  $[Al(^tBu_2acac)_3]$ ,<sup>1560,1561</sup>  $[Ga(acac)_3]$ ,<sup>1562</sup>  $[Ga(acac)_2(Hacac)]^+$ ,<sup>1562</sup>  $[Ga(^tBu_2acac)_3]$ ,<sup>1560</sup>  $[Ga(Ph_2acac)_3]$ ,<sup>1563</sup> *trans*- $[Ga(acac)_2(THF)_2]^+$ ,<sup>1553</sup>  $[In(acac)_3]$ ,<sup>1564</sup>  $[In(^tBu_2acac)_3]$ ,<sup>1560,1565</sup> and  $[In(acac)Br_2(THF)_2]$  (with *trans*-THF).<sup>1566</sup>  $[Ga(acac)_3]$  has been introduced into perovskite precursor solutions to create a core-shell structure to protect perovskite crystallites.<sup>1562</sup> Dinuclear group 13 metal species are illustrated by  $[Al_2(hfacac)_4(\mu-OH)_2]$  and  $[Al_2(hfacac)_4(\mu-O^iPr)_2]$  (CN = 6),<sup>1559</sup>  $[Al_2(^tBu_2acac)_2(O^t-Bu)_2(\mu-O^tBu)_2]$  (CN = 5),<sup>1567</sup>  $[Ga_2(Ph_2acac)_4(\mu-OMe)_2]$  (CN = 6),<sup>1568</sup> and  $[In_2(Ph_2acac)_4(\mu-OO^tBu)_2]$  (CN = 6).<sup>1569</sup> The dimers  $[Ga_2Cl_2(acac)_2]$  and  $[Ga_2Cl_2(^tBu_2acac)_2]$  are supported by direct Ga–Ga bonds (2.396(3) and 2.391(2) Å, respectively).<sup>1570</sup> The crystal structure of  $[Tl(acac)]$  reveals that units interact through weak Tl...Tl contacts, the distance of 3.8553(5) Å being approximately twice the van der Waals radius of Tl, leading to an infinite assembly.<sup>1571</sup> A change to  $[Ph_2acac]^-$  results in the formation of dimeric  $[Tl_2(Ph_2acac)_2]$  in the solid state, and close contacts occur between these units.<sup>1572</sup>

Group 14 metal(IV) derivatives are represented by  $[Ge(acac)_3]^+$ ,<sup>1573</sup> *cis*- $[Ge(N_3)_2(acac)_2]$ ,<sup>1574</sup> *cis*- $[SnCl_2(acac)_2]$ ,<sup>1575</sup> *cis*- $[SnCl_2(Ph_2acac)_2]$ ,<sup>1576</sup> *fac*- $[SnCl_3(acac)(OH_2)]$ ,<sup>1577</sup> and *cis*- $[Sn(OEt)_2(acac)_2]$ .<sup>1578</sup> In the trimer  $[Sn_3(acac)_6(\mu-O)_3]$ , the three Sn(IV) centers are in a triangular array and each metal is 6-coordinate, being bound by two chelating  $[acac]^-$  and two bridging oxido ligands.<sup>1579</sup> Mono  $[acac]^-$  derivatives of tin(II) are uncommon. In  $[Sn(acac)(O_2Ac)]$  (in which one Sn–O<sub>acetato</sub> bond is noticeably long, 2.607(5) Å), the coordination geometry (Fig. 68C) reflects the role of the stereochemically active lone pair on Sn(II).<sup>1580</sup> A similar coordination geometry is found in the CVD precursor  $[Sn(hfacac)_2]$ ,<sup>1581</sup> in  $[Sn(^tBu_2acac)_2]$ ,<sup>1582</sup> and in  $[Sn(tfacac)_2]$  (Fig. 68D), although here, the molecules are organized into chains with Sn...Sn distances of 4.290 and 4.299 Å; this compound was used as a precursor to SnO<sub>2</sub> thin films.<sup>1583</sup>  $[Pb(acac)_2]$  is monomeric in the solid state and adopts a structure consistent with the presence of a stereochemically active lone pair; however, in addition to the four Pb–O bonds (range 2.32–2.37 Å), each Pb(II) center exhibits four short Pb...O contacts (3.01–3.26 Å).<sup>1584</sup> In bis(1,1,1-trifluoro-5-methoxy-5-methyl-hexane-2,4-dionato)lead(II), molecules associate into dimers through a Pb...Pb interaction (4.112 Å) and dimers are maintained in the vapor phase.<sup>1585</sup>  $[Sn(acac)(\mu-O_3SCF_3-1\kappa O^1:2\kappa O^2)]_n$  is a second example of a mono  $[acac]^-$  derivative of Sn(II) and assembles as a 1D-coordination polymer (Fig. 68E); adjacent chains exhibit Sn...Sn contacts (4.282 Å).<sup>1586</sup> In  $[Pb(hfacac)_2(18-crown-6)]$ , the Pb(II) center is 8-coordinate with a chelating  $[hfacac]^-$  ligand sited above and below the macrocyclic ligand.<sup>1587,1588</sup>

For the heavier elements in group 15, examples of  $\beta$ -diketonate complexes include  $[Sb(^tBu_2acac)_3]$  which exhibits a distorted 6-coordinate structure with three chelating ligands and a stereochemically active lone pair.<sup>1589,1590</sup>  $[Sb(^tBu_2acac)_2(OEt)]$  is square-based pyramidal with the ethoxy ligand in the axial site.<sup>1589</sup>  $[Bi(acac)_3]$  is atypical of Bi(III)  $\beta$ -diketonate complexes in that it is polymeric in the solid state, with 7-coordinate Bi(III) coordinated by one chelating/bridging and two chelating  $[acac]^-$  ligands.<sup>1591</sup> In  $[Bi_2(hfacac)_6]$ <sup>1592</sup> and  $[Bi_2(Ph_2acac)_6]$ ,<sup>1593</sup> each Bi(III) is bound by three chelating ligands, and two O-donors of two of the ligands also bridge between the metal atoms; the latter complex has been used as a precursor for Pt–Bi<sub>2</sub>O<sub>3</sub> thin films.

#### 1.02.6.2.4 Carboxylates: Bidentate and bridging

Carboxylates are ubiquitous ligands for s- and p-block metal ions, and thus, we can only include highly selected examples of carboxylate complexes. Oxalato complexes are covered separately in Section 1.02.6.2.5. Many coordination networks are directed by multifunctional ligands bearing two, three or more  $-CO_2^-$  donor groups. This area of coordination chemistry is too extensive to be covered here, and the reader is directed to pertinent reviews.<sup>3,51,61,1594,1595</sup> In this section, we have chosen to limit the discussion to complexes containing acetato ligands in order to give a broad picture of the different possible bonding modes. Rather than use strict IUPAC nomenclature to describe the bonding modes, we refer to them by the notation in Scheme 18. Complexes containing well-defined monodentate acetato ligands (mode I, Scheme 18) were described in Section 1.02.6.1.7. Modes I–III in Scheme 18 make the transition from monodentate to chelating ligands bound to a single metal center, while modes IV–XIV illustrate different bridging modes, examples of which are given below. Note that modes V and VII are the same in terms of connectivity but we make a distinction based upon the spatial positions of the metal atoms; mode V is best known in  $\{M_2(\mu-O_2CR)_4\}$ -paddle-wheel motifs.

For the group 1 metals, increased CN is observed, as expected, on descending the group. In  $[Li(\mu-OAc)(\mu-OH_2)]_n$ , Li<sup>+</sup> is tetrahedrally sited and 1D-chains assemble from alternating  $\{Li_2(\mu-OAc)_2\}$  and  $\{Li_2(\mu-OH_2)_2\}$  motifs; the OAc<sup>−</sup> ligand adopts mode V (Scheme 18). This investigation deals more widely with polymorphs of anhydrous LiOAc and its hydrate.<sup>1596</sup>  $[Li_9(\mu-OAc)_9(\mu-OH_2)]_n \cdot nTHF$  also contains 4-coordinate Li<sup>+</sup> and the complicated 3D-network combines different modes of acetato bonding including V, IX, and XI.<sup>1597</sup> Different polymorphs of NaOAc are known and the structures of two new polymorphs have been determined by Ditttrich et al.<sup>1598</sup> The structure of  $[Na_4(\mu-OAc)_3(\mu_4-ClO_4)]_n$  is described by Hannon and coworkers as comprising 'sodium acetate planes linked together by sodium perchlorate cylinders'; each AcO<sup>−</sup> ligand is in bonding mode XIII (Scheme 18), and the crystal lattice contains MeOH-filled channels running along the *c*-axis.<sup>1599</sup>  $[K(\mu-OAc)(\mu-AcOH)]_n$  assembles into a 2D-sheet, with the acetato ligands adopting bridging mode XII (Scheme 18); hydrogen-bonded interactions link the coordinated AcOH and AcO<sup>−</sup> ligands.<sup>1600</sup> In both  $[K(18-crown-6)(OAc)] \cdot 2H_2O$  and  $[K(18-crown-6)(OAc)(OH_2)] \cdot HOAc$ , the AcO<sup>−</sup> ion is in a chelating mode. In the former, K<sup>+</sup> is 8-coordinate and AcO<sup>−</sup> adopts bonding mode III (Scheme 18) with K–O = 2.6992(11) and 2.8861(11) Å; a mode closer to II is found in  $[K(18-crown-6)(OAc)(OH_2)] \cdot HOAc$ , but the increase in the CN to 9 causes elongation of the K–O bonds to 2.9562(16) and 3.0303(19) Å.<sup>1601</sup>

The mixed halido species  $[Cs_3Br_2Pb_2(\mu-OAc)_2(\mu_4-Br)(\mu_3-I)]_n$  is of interest for its NLO properties; part of the 3D-structure is shown in Fig. 69A and the acetato ligands chelate to Pb(II) and bridge between Cs<sup>+</sup> centers (mode VIII in Scheme 18).<sup>1602</sup> The

**Fig. 69** (A) Part of the 3D-network (viewed down the  $c$ -axis) in  $[\text{Cs}_3\text{Br}_2\text{Pb}_2(\mu\text{-OAc})_2(\mu_4\text{-Br})(\mu_3\text{-I})]_n$  (CSD refcode PARNEF). (B) Part of the 3D-net in  $[\text{Mg}_3(\mu\text{-OAc})_6(\mu\text{-MeOH})_6]_n$ , showing only the 4-connecting Mg(II) nodes (refcode BELYIC). (C) Part of the 1D-chain in  $\{[\text{Ca}(\text{OH})_2(\mu\text{-OAc})]\text{Cl}\}_n \cdot n\text{H}_2\text{O}$  (refcode CALCLA02). (D)  $\text{F}^-$  and  $\text{AcO}^-$  bridging modes in  $[\text{BaF}(\text{OAc})]_n$  (refcode IQICOD). (E) Structure of  $[\text{Ga}_{10}(\mu\text{-OAc})_{10}(\mu\text{-OMe})_{20}]$  (refcode CESGAJ).

related NLO compounds  $[\text{Cs}_3\text{Pb}_2(\text{OAc})_2\text{I}_5]$  and  $[\text{Rb}_3\text{Pb}_2(\text{OAc})_2\text{X}_5]$  with  $\text{X} = \text{Br}, \text{Cl}$  have similar structures to that shown in Fig. 69A.<sup>1603,1604</sup>

The group 2 metals, in particular  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$ , offer a wealth of carboxylate complexes. The dimer  $[\text{Mg}_2(\text{OH})_6(\mu\text{-OAc})_3]^+$  (6-coordinate Mg) offers an example of bridging mode V (Scheme 18),<sup>1605</sup> and this mode, combined with mode X bridging ligands, is also seen in  $[\text{Mg}_3(\text{OH})_2(\text{AcOH})_2(\mu\text{-OAc})_6]$  which has a linear  $\text{Mg}_3$ -core.<sup>1460,1606</sup> The work of Miller et al. on the structural

**Scheme 18** Different modes of coordination of  $\text{MeCO}_2^-$  to main group metal centers. Formal C–O bond orders are not specified. The dotted line in mode V signifies that the M atoms are close but does not imply M–M bonding.

properties of CMA road deicers is an instructive entry into the area.<sup>1459</sup> In Section 1.02.6.1.7, we illustrated examples of Mg(II) complexes containing monodentate  $\text{AcO}^-$  as part of a wider study of magnesium acetate solvates and their hydrates. In  $[\text{Mg}_3(\mu\text{-OAc})_6(\mu\text{-MeOH})_6]_n$ , a 3D-network is formed with 6-coordinate  $\text{Mg}^{2+}$  (CN includes two terminal MeOH) linked by bridging (mode VII) acetato ligands. Each Mg(II) acts as a 4-connecting node and Fig. 69B shows part of the 3D-net. In  $[\text{Mg}(\text{OAc})_2(\text{HOAc})]_n \cdot 1.8n\text{AcOH}$ , the coordinated AcOH molecules are terminally bonded, while the  $\text{AcO}^-$  ligands adopt two different modes (IV or IX, Scheme 18), leading to 1D-chains.<sup>1460</sup> Scheurell et al. have also reported that the dehydration of  $\text{Mg}(\text{OAc})_2 \cdot 4\text{H}_2\text{O}$  produces basic magnesium acetate which has a porous network; the structures of  $[\text{Mg}_5(\mu_3\text{-OH})_2(\text{OAc})_8] \cdot 2\text{EtOH}$  and  $[\text{Mg}_5(\mu_3\text{-OH})_2(\text{OAc})_8] \cdot 1.19\text{H}_2\text{O}$  were also determined. Within this series of structures,  $\text{AcO}^-$  ligands are found in bonding modes V, VII, IX, and XI.<sup>1607</sup> Thermal dehydration of  $\text{Ca}(\text{OAc})_2 \cdot \text{H}_2\text{O}$  at 300 °C yields anhydrous  $\alpha\text{-Ca}(\text{OAc})_2$  which exhibits low- and high-temperature forms; during the phase transition, the coordination mode of an  $\text{AcO}^-$  ligand switches from monodentate to bidentate.<sup>1608</sup>  $\{[\text{Ca}(\text{OH}_2)_4(\mu\text{-OAc})\text{Cl}]_n \cdot n\text{H}_2\text{O}\}$  possesses a 1D-polymeric structure with the bridging  $\text{AcO}^-$  is mode VIII (Fig. 69C) and a CN = 8 for  $\text{Ca}^{2+}$ .<sup>1609</sup> As part of a study of the ternary system  $\text{Ca}(\text{OAc})_2\text{-Ca}(\text{O}_2\text{CH})_2\text{-H}_2\text{O}$ , Bette et al. reported the structures of  $[\text{Ca}_3(\mu\text{-OAc})_4(\text{O}_2\text{CH})_2(\text{OH}_2)_4]_n$  (which contains terminal formate ligands and  $\text{AcO}^-$  in bonding mode VIII, Scheme 18) and  $[\text{Ca}(\mu\text{-OAc})(\mu\text{-O}_2\text{CH})(\text{OH}_2)]_n$  (containing bridging formates and  $\text{AcO}^-$  in mode X).<sup>1610</sup>

The Sr(II) complex  $[\text{Sr}(\text{OAc})_3]^-$  has been isolated as the [emim]<sup>+</sup> salt as part of an investigation of dialkylimidazolium acetate ionic liquids with relevance to nuclear fuel recycling. The 1D-polymer  $[\text{Sr}(\mu\text{-OAc})_3]_n^{n-}$  contains 9-coordinate Sr(II) in a severely distorted tricapped trigonal prismatic geometry; the bridging  $\text{AcO}^-$  ligands that support the chain adopt bonding mode X (Scheme 18).<sup>1611</sup>  $[\text{Ba}(\text{OAc})(\mu\text{-OAc})(\text{OH}_2)_3]_n$  is a 1D-polymer with CN = 9 for  $\text{Ba}^{2+}$ ; three aqua and one chelating  $\text{AcO}^-$  occupy five coordination sites, and  $\text{Ba}^{2+}$  ions are linked into a chain by mode VIII (Scheme 18) bridging  $\text{AcO}^-$  ligands, similar to the arrangement shown in Fig. 69C.<sup>1612</sup> The compounds  $[\text{MF}(\text{OAc})]_n$  (M = Sr, Ba) assemble into 2D-networks, details of which were elucidated from powder X-ray diffraction data. Each M(II) is in a *cis*- $\{\text{MF}_2\text{O}_4\}$  environment (Fig. 69D), with the  $\text{AcO}^-$  ligands in bridging mode XI (Ba–O = 2.61(7)–2.92(4) Å, Sr–O = 2.54(2)–2.8(2) Å), and each F in a  $\mu_4$ -mode (Ba–F = 2.65(5), 2.71(5) Å, Sr–F = 2.4(2), 2.6(2) Å).<sup>1613</sup>  $[\text{Ba}_9(\text{OAc})_{14}(\text{ClO}_4)_4]_n$  forms an unusual 3D-network in which the building block is a  $\text{Ba}_9$ -cluster with a 'body-centered cubic' (bcc) geometry. Each face of the cube is bridged by  $\text{AcO}^-$  in mode XIII (i.e., also bound to the central Ba of the bcc unit) and  $\text{Ba}_9$  units are then linked by a combination of bridging  $\text{OAc}^-$  and  $\text{ClO}_4^-$  ions. The structure is best appreciated by viewing in 3D (CSD refcode LUHZUI).<sup>1614</sup>

Moving to group 13, and examples of 1D-coordination polymers include  $[\text{M}(\mu\text{-OAc})_2(\mu\text{-OH})]_n$  with M = Ga or In in which the metal is 6-coordinate and pairs of M(III) centers are bridged by two  $\text{AcO}^-$  (bridging mode V) and a hydroxido ligand,<sup>1615,1616</sup> and  $[\text{In}(\mu\text{-OAc})_3]_n$ , the first example of a group 13  $\text{M}(\text{OAc})_3$  compound with an infinite chain in the solid state.<sup>1617</sup> Within group 13, there are a number of examples of discrete high nuclearity species exhibiting mode V (Scheme 18) bridging acetates. These are represented by the cyclic  $[\text{Al}_{10}(\mu\text{-OAc})_{10}(\mu\text{-OEt})_{20}]$ ,  $[\text{Al}_{10}(\mu\text{-OAc})_{10}(\mu\text{-OMe})_{20}]$ , and  $[\text{Al}_{10}(\mu\text{-OAc})_{20}(\mu\text{-O}_2\text{C}_2\text{H}_4)_4(\mu\text{-F})_2]$ ,<sup>1517</sup> and  $[\text{Ga}_{10}(\mu\text{-OAc})_{10}(\mu\text{-OMe})_{20}]$  (described as a 'gallic wheel,' Fig. 69E).<sup>1618</sup>

In the solid state, tin(II) acetate assembles into 1D-chains in groups of four chains, with the Sn(II) centers within the group facing one another (Sn...Sn = 4.171 and 4.189 Å) to generate columns which follow the *c*-axis. Along each 1D-chain, the bonding mode of the  $\text{AcO}^-$  ligand resembles mode X (Scheme 18), although the Sn–O distances in the chelate rings are 2.170(6) and 2.293(7) Å, and 2.207(6) and 2.372(8) Å, making a description of between modes V and X more realistic.<sup>1619</sup>  $[\text{Sn}(\text{acac})(\text{OAc})]_n$  (Fig. 68C), the acetato ligand adopts mode II (Scheme 18) with Sn– $\text{O}_{\text{AcO}}$  distances of 2.165(4) and 2.607(5) Å.<sup>1580</sup> In 2016, the structures of two enantiotropic polymorphs of anhydrous  $\text{Pb}(\text{OAc})_2$  were determined for the first time. In both the  $\alpha$ - and  $\beta$ -forms, the extended arrays are supported by bridging ligands which adopt modes VIII and X (Scheme 18). This work also includes a series of lead(II) acetate derivatives which illustrate a variety of bonding  $\text{AcO}^-$  modes in 1D- and 2D-assemblies.<sup>1620</sup> A related infinite assembly  $[\text{Pb}_2(\mu\text{-OAc})_4(\mu\text{-2,5-dimethylbenzene-1,4-diol})]_n$  has also been described.<sup>1621</sup> Reactions of carboxylic acids with Pb are relevant to the corrosion of lead and lead-tin alloys. One of the corrosion products is  $[\text{Pb}_6(\mu_4\text{-O})_4(\mu\text{-OAc})_2(\text{OAc})_2]_n \cdot n\text{H}_2\text{O}$ , and the solid-state structure consists of interconnected double chains; half of the  $\text{AcO}^-$  ligands adopt mode VI (Scheme 18) within a chain, while the other  $\text{AcO}^-$  groups are in bridging mode VII (Scheme 18) and link adjacent chains, leading to 2D-sheets.<sup>1622</sup>  $[\text{Pb}(\text{OAc})(\mu\text{-OAc})(\text{thiourea})]_n$  is a 1D-coordination polymer in which each Pb(II) center is bound by two  $\text{AcO}^-$  ligands in modes III and X, respectively. However, the Pb–O bond lengths for the chelating units (2.489(3), 2.483(3), 2.520(2) and 2.990(2) Å) indicate that one interaction is weak; the thiourea S-atoms are also involved in Pb...S interactions.<sup>1623</sup> Fig. 69D illustrated part of the 2D-sheet in  $[\text{BaF}(\text{OAc})]_n$ , highlighting the bridging modes of the ligands; analogous coordination modes are observed in  $[\text{PbF}(\text{OAc})]_n$ .<sup>1613</sup>

The Bi(III) complex  $[\text{Bi}(\text{OAc})_2(\text{THF})_4]^+$  was characterized in the salt  $[\text{Bi}(\text{OAc})_2(\text{THF})_4]_3[\text{Bi}_7\text{I}_{24}]$ , and contains 8-coordinate Bi.<sup>1624</sup>

### 1.02.6.2.5 Oxalate

The oxalate dianion is widely used as a bridging motif in coordination assemblies and is a building block in numerous coordination networks. However, it also appears as a bidentate, chelating ligand in, for example, the octahedral  $[\text{Al}(\text{ox})_3]^{3-}$ .<sup>1625</sup> As in previous sections, we limit the discussion to homoleptic complexes and those with simple co-ligands. We refer to the different bridging modes of  $\text{ox}^{2-}$  using the notation in Scheme 19, rather than applying strict IUPAC nomenclature.

In compounds such as sodium oxalate, the cation–anion interactions are essentially electrostatic,<sup>1626</sup> and we choose not to consider the structures in terms of oxalate bonding modes. However, it is pertinent to include reference to an investigation of the influence of hydrostatic pressure on the crystal structure of  $\text{Na}_2[\text{ox}]$ .<sup>1626</sup> Group 2 metal oxalates are well represented. In

**Scheme 19** Different bridging modes of the  $\text{ox}^{2-}$  anion. The same notations are used for  $\text{H}_2\text{ox}$  and  $\text{Hox}^-$  ligands.

$[\text{Mg}(\text{OH}_2)_2(\mu\text{-ox})]_n$ ,  $\text{Mg}^{2+}$  is in a  $\{\text{trans-Mg}(\text{OH}_2)(\text{ox})_2\}$  environment with the  $\text{ox}^{2-}$  ligands in mode I (Scheme 19), connecting the units into 1D-chains; in 2008, this represented a new polymorph of  $\text{Mg}(\text{ox}) \cdot 2\text{H}_2\text{O}$ .<sup>1627</sup> In  $[\text{H}_2\text{dab}][\text{Mg}_2(\text{ox})_3]$ ,  $[\text{Mg}_2(\mu\text{-ox})_3]_n^{2n-}$  sheets consist of octahedrally sited  $\text{Mg}^{2+}$  connected by bridging  $\text{ox}^{2-}$  ligands in mode I (Scheme 19); this gives rise to a honeycomb-like layered structure.<sup>1628</sup> A similar local  $\{\text{Mg}(\text{ox})_3\}$  coordination environment is also observed in the salt  $[\text{H}_2\text{dabco}][\text{Mg}(\text{ox})_2] \cdot 3\text{H}_2\text{O}$ ; however, only two of the three ligands per  $\text{Mg}^{2+}$  are in bridging modes, leading to the assembly of 1D-chains. This latter compound is one of a series investigated for their structural phase transitions between 203 and 217 K.<sup>1629</sup> Pastoro et al. reported a method of trapping  $\text{CO}_2$  which involved reduction (using vitamin C as a sacrificial reductant) and precipitation as crystalline  $\text{Ca}(\text{ox}) \cdot 2\text{H}_2\text{O}$  (the mineral weddellite) with the  $\text{ox}^{2-}$  ligand adopting mode II (Scheme 19).<sup>1630</sup> The phase transitions between the calcium oxalates whewellite ( $\text{Ca}(\text{ox}) \cdot \text{H}_2\text{O}$ ), weddellite and caoxite ( $\text{Ca}(\text{ox}) \cdot 3\text{H}_2\text{O}$ ) have been studied by Izatulina et al. and bonding modes I, II, III and IV (Scheme 19) are all represented.<sup>1631</sup> The  $\text{ox}^{2-}$  ligand is found in mode IV (Scheme 19) in  $[\text{Ca}_2(\mu\text{-ox})(\mu\text{-Cl})_2(\mu\text{-OH}_2)_2]_n$  (synthetic novgorodovaite) in which 2D-sheets are linked by bridging aqua ligands. On going from the dihydrate to the heptahydrate, coordinated chlorido ligands are replaced by aqua ligands with an associated change to a 2D-sheet structure with hydrogen-bonded  $\text{Cl}^-$  ions and  $\text{H}_2\text{O}$  molecules between the sheets.<sup>1632</sup>

'Acid strontium oxalate',  $\text{Sr}_2(\text{Hox})_2(\text{ox}) \cdot 2\text{H}_2\text{O}$ , possesses a 3D-assembly with the  $\text{Hox}^-$  and  $\text{H}_2\text{O}$  ligands bridging between different pairs of  $\text{Sr}^{2+}$  centers, and the  $\text{ox}^{2-}$  ligand adopting mode III (Scheme 19).<sup>1633</sup> Barium oxalates offer a wide range of structural motifs. The discrete molecular ion  $[\text{Ba}(\text{OH}_2)_2(\text{Hox})_4]^{2-}$  (CN = 10) contains chelating  $\text{Hox}^-$  ligands and a *trans*-arrangement of aqua ligands.<sup>1634</sup>  $[\text{Ba}_2(\text{ox})_2(\text{OH}_2)]_n$  precipitated from aqueous solutions of  $\text{BaCl}_2$  and  $(\text{NH}_4)_2\text{ox}$  possesses a 3D-network with 9-coordinate  $\text{Ba}^{2+}$ , terminal aqua ligand and  $\text{ox}^{2-}$  ligands in bonding mode IV (Scheme 19).<sup>96</sup> Borel et al. described the 3D-networks in  $[\text{Ba}(\text{ox})(\text{OH}_2)(\mu\text{-OH}_2)_2]_n$ ,  $[\text{Ba}(\text{ox})(\text{H}_2\text{ox})(\text{OH}_2)_2]_n$  and  $[\text{Ba}_2(\text{ox})(\text{Hox})_2(\text{OH}_2)_2]_n$ . The repeat unit in  $[\text{Ba}(\text{ox})(\text{OH}_2)(\mu\text{-OH}_2)_2]_n$  is

**Fig. 70** The repeat units in (A)  $[\text{Ba}(\text{ox})(\text{OH}_2)(\mu\text{-OH}_2)_2]_n$  (CSD refcode BAOXAL03), (B)  $[\text{Ba}(\text{ox})(\text{H}_2\text{ox})(\text{OH}_2)_2]_n$  (refcode BAHOXH13). (C) Part of one sheet in  $[\text{In}_2(\text{ox})_3(\text{OH}_2)_3]_n \cdot 7n\text{H}_2\text{O}$  with solvent in the channels omitted (refcode BAPMIP). (D) The structure of the dinuclear complex  $[\text{Sn}_2(\text{ox})_3]^{2-}$  (refcode CIXSIM). (E) Part of one  $[\text{Sn}_2(\text{ox})_3]_n^{2n-}$  sheet in  $\text{Sn}_2(\text{NH}_4)_2(\text{ox})_3 \cdot 3\text{H}_2\text{O}$  (refcode BAHRAE).

shown in Fig. 70A with the  $\text{ox}^{2-}$  ligand adopting mode V (Scheme 19). In contrast, in  $[\text{Ba}(\text{ox})(\text{H}_2\text{ox})(\text{OH}_2)_2]_n$  (Fig. 70B), bridging mode I is found for both  $\text{ox}^{2-}$  and  $\text{H}_2\text{ox}$ , while in  $[\text{Ba}_2(\text{ox})(\text{Hox})_2(\text{OH}_2)_2]_n$  (CN = 9),  $\text{ox}^{2-}$  and  $\text{Hox}^-$  adopt modes III and I, respectively.<sup>1635</sup> In the 2,4,6-trinitrophenolate salt of  $[\text{Ba}_2(\text{ox})(\text{OH}_2)_4(\mu\text{-OH}_2)_4]^{2+}$ , 2D-sheets are present with the  $\text{ox}^{2-}$  ligand adopting mode III (Scheme 19) and  $\text{Ba}^{2+}$  having a CN = 9.<sup>1636,1637</sup>

Group 13 metal oxalato complexes in which  $\text{ox}^{2-}$  ligands are bidentate include  $[\text{Al}(\text{ox})_3]^{3-}$ ,<sup>1625,1638,1639</sup> and  $[\text{Ga}(\text{ox})_3]^{3-}$ ,<sup>1640-1642</sup> Dinuclear complexes are represented by  $[\text{Ga}_2(\text{ox})_4(\mu\text{-ox})]^{4-}$  (bridging mode I).<sup>1643,1644</sup> In the 1D-polymer  $[\text{Ga}(\mu\text{-F})(\text{ox})_2]_n^{2n-}$  (isolated as the  $[\text{H}_2(4,4'\text{-bpy})]^{2+}$  salt), the oxalates are in a chelating mode and each Ga(III) is octahedrally sited with  $\{\text{trans-GaF}_2(\text{ox})_2\}$  units.<sup>1645</sup> Feng, Bu and coworkers have demonstrated the use of linear ligands ( $\text{ox}^{2-}$  in mode I, Scheme 19) for the preparation of zeolite type-structures with RHO, GIS, and ABW (defined in reference 1646) topologies.<sup>1647</sup> In  $\{[\text{H}_2\text{en}][\text{In}_2(\text{ox})_4]\}_n \cdot 4n\text{H}_2\text{O}$ , each In(III) has CN = 8 and is bound by four  $\text{ox}^{2-}$  ligands (mode I, Scheme 19) to assemble a porous 3D-network.<sup>1648</sup> Further examples of extended indium oxalate structures include  $[\text{In}_2(\text{ox})_3(\text{OH}_2)_3]_n \cdot 7n\text{H}_2\text{O}$  which possesses a layer structure with mode I  $\text{ox}^{2-}$  ligands and both 7- and 8-coordinate In(III) (Fig. 70C); thermal decomposition of this material yielded nanocrystalline  $\text{In}_2\text{O}_3$ .<sup>1649</sup> The 2D-layer structure of  $[\text{In}_2(\mu\text{-ox})_3(\text{OH}_2)_4]_n \cdot 2n\text{H}_2\text{O}$  contains 7-coordinate In(III) connected by bridging  $\text{ox}^{2-}$  ligands which adopt either mode I or VI (Scheme 19); the pentagonal bipyramidal coordination sphere also contains axial aqua ligands.<sup>1650</sup> A CN of 7 is also found in the 1D-polymer  $[\text{In}(\mu\text{-ox})(\text{OH}_2)_3]^+$  in which the oxalate ligand adopts mode I (Scheme 19).<sup>1651</sup> The hydrothermal reaction of  $\text{In}_2\text{O}_3$  and oxalic acid in the presence of boric acid produces  $[\text{In}_3(\mu\text{-OH})_3(\mu\text{-ox})_3(\text{OH}_2)_3]_n \cdot n\text{H}_2\text{O}$  which has an open, 3D-network; the  $\text{ox}^{2-}$  ligands adopt mode I (Scheme 19) and links In(III) centers into chains which are interconnected by bridging hydroxido ligands.<sup>1652</sup> Audebrand et al. have reported a series of mixed metal oxalates which includes  $[\text{InK}(\text{ox})_2(\text{OH}_2)_4]_n$  with a 3D-network in which each In(III) is 8-coordinate bound by four chelating  $\text{ox}^{2-}$ ; taking the  $\text{O}\cdots\text{K}$  contacts into account, each  $\text{ox}^{2-}$  adopts mode III, binding two In(III) and two  $\text{K}^+$  (CN = 8).<sup>1644</sup>

Mononuclear complexes of the group 14 M(IV) metals are illustrated by the octahedral  $[\text{Ge}(\text{ox})_3]^{2-}$ ,<sup>1653-1656</sup> *cis*- $[\text{Ge}(\text{O}-\text{H})_2(\text{ox})_2]^{2-}$ ,<sup>1657</sup>  $[\text{SnCl}_4(\text{ox})]^{2-}$ ,<sup>1658,1659</sup> *fac*- $[\text{SnCl}_3(\text{OH}_2)(\text{ox})]^-$ ,<sup>1660,1661</sup> *cis*- $[\text{SnCl}_2(\text{ox})_2]^{2-}$ ,<sup>1662</sup> and *cis*- $[\text{SnI}_2(\text{ox})_2]^{2-}$ .<sup>1663</sup> A CN = 8 is found for Sn(IV) in  $[\text{PrNH}_2]_4[\text{Sn}(\text{ox})_4]$ .<sup>1664</sup> Mononuclear oxalato complexes containing a group 14 M(II) metal center are represented by the 4-coordinate  $[\text{Sn}(\text{ox})_2]^{2-}$  which exhibits two bidentate ligands and a stereochemically active lone pair.<sup>1665,1666</sup> A similar coordination environment is found in  $[\text{Sn}_2(\text{ox})_3]^{2-}$  (Fig. 70D).<sup>1665-1667</sup> In  $[\text{NH}_4]_2[\text{Sn}_2(\text{ox})_3] \cdot 3\text{H}_2\text{O}$ , there is a 2D-network of formula  $[\text{Sn}_2(\text{ox})_3]_n^{2n-}$  in which ligands adopt mode I (Scheme 19); Fig. 70E illustrates the corrugated nature of the sheet and the role of the stereochemically active lone pair at each Sn(II) center.<sup>1668</sup>  $[\text{NH}_4][\text{SnF}(\text{ox})]$  is one of a series of low dimensional tin(II)-containing materials reported by Oliver and coworkers; it contains  $[\text{SnF}(\text{ox})]_n^{n-}$  chains with the  $\text{ox}^{2-}$  ligand coordinated to three Sn(II) centers (mode VIII, Scheme 19).<sup>1669</sup> In the dihydrate of the  $[\text{H}_2\text{en}]^{2+}$  salt,  $[\text{SnF}(\text{ox})]_n^{n-}$  1D-chains are again present, but the  $\text{ox}^{2-}$  ligand adopts mode VI (Scheme 19), leaving one O-donor uncoordinated.<sup>1667</sup> An example of a Pb(II) species is the 1D-polymer  $[\text{Pb}(\text{phen})_2(\mu\text{-ox})]_n \cdot 5n\text{H}_2\text{O}$  (CN = 8,  $\text{ox}^{2-}$  bonding mode I).<sup>1670</sup>

Oxalato complexes of the heavier group 15 elements include  $[\text{Sb}(\mu\text{-OH})(\mu\text{-ox})]_n$  for which powder diffraction data and refinement by the Rietveld method have been reported. The  $\text{ox}^{2-}$  ligands adopt mode I (Scheme 19) and each Sb(III) center is in a pentagonal pyramidal environment (plus a stereochemically active lone pair), being coordinated by two bridging  $\text{ox}^{2-}$  and two bridging hydroxido ligands to produce a 3D-network.<sup>1671</sup> The birefringent material  $[\text{Hamgu}]_2[\text{Sb}_2(\text{ox})\text{F}_4] \cdot \text{H}_2\text{O}$  contains 1D-coordination polymer chains  $[\text{Sb}_2(\mu\text{-ox})\text{F}_4]_n^{2n-}$  supported by bridging  $\text{ox}^{2-}$  ligands in mode I (Scheme 19); the 6-coordinate Sb(III) center carries a stereochemically active lone pair.<sup>1672</sup> Bismuth oxalates include  $[\text{Bi}_2(\text{ox})_3] \cdot 6\text{H}_2\text{O}$  and  $[\text{Bi}_2(\text{ox})_3] \cdot 8\text{H}_2\text{O}$  which exhibit similar 3D-networks with Bi(III) centers connected by bridging  $\text{ox}^{2-}$  in modes I and VII (Scheme 19); each Bi(III) additionally binds two  $\text{H}_2\text{O}$  ligands leading to a CN of 9, with the lone pair on Bi(III) being stereochemically inactive.<sup>1673</sup> The 3D-network in  $[\text{NH}_4][\text{Bi}(\text{ox})_2] \cdot 3.72\text{H}_2\text{O}$  comprises 8-coordinate Bi(III) coordinated by four  $\text{ox}^{2-}$  ligands in mode I (Scheme 19).<sup>1674</sup> A hydrothermal synthesis was used to form  $\{[\text{Hpy}]_2[\text{Bi}_2(\text{OH}_2)_2(\text{ox})_4]\}_n \cdot 2n\text{H}_2\text{O}$  and  $\{[\text{NH}_4][\text{Bi}(\text{ox})_2]\}_n \cdot 3n\text{H}_2\text{O}$ , in which the Bi(III) centers have CN = 9 and 8, respectively, the difference being a coordinated aqua ligand in the former compound. The  $\text{ox}^{2-}$  ligands adopt mode I (Scheme 19) to connect the Bi atoms into 3D-networks which are thermally stable up to 200 °C.<sup>1675</sup> The structure of  $[\text{Bi}(\mu\text{-ox})(\mu\text{-OH})]_n$  comprises a 3D-network, in which 1D- $\{\text{Bi}(\mu\text{-ox})\}_n$  chains with the  $\text{ox}^{2-}$  ligand in mode I are interconnected by bridging hydroxido ligands.<sup>1676</sup>

### 1.02.6.2.6 *N,N'*-Dioxides of 2,2'-bpy (bpy) and 4,4'-bpy

In this section, we use the abbreviation bpy to refer to 2,2'-bipyridine, while its isomer 4,4'-bipyridine is abbreviated to 4,4'-bpy; their *N,N'*-dioxides are bpydo and 4,4'-bpydo, respectively. The coordination of bpydo in a chelating mode leads to a noticeably twisted bpy unit, as illustrated below. Like 4,4'-bpy, 4,4'-bpydo is a common building block in coordination polymers and networks, and a range of examples is included in this section. We focus only on compounds in which the *N,N'*-dioxides are the main feature of interest.

For the group 1 metals, structural characterization of salts of  $[\text{K}(4,4'\text{-bpydo})_2]_n^{n+}$ ,  $[\text{Rb}(4,4'\text{-bpydo})_2]_n^{n+}$  and  $[\text{Cs}(4,4'\text{-bpydo})_2]_n^{n+}$  reveal similar 3D-networks in the space group  $P4/ncc$  in which anions occupy channels which follow the *c*-axis.<sup>1677-1680</sup> With the aim of designing porous coordination networks with cheap and non-toxic metals, and which show selective or high adsorption capacity, Noro et al. have focused on combinations of  $\text{Mg}^{2+}$  or  $\text{Ca}^{2+}$  with 4,4'-bpydo. Reaction of  $\text{Mg}(\text{OAc})_2 \cdot 4\text{H}_2\text{O}$  with 4,4'-bpydo gave  $[\text{Mg}_2(\mu\text{-OAc})_4(\mu_4\text{-}4,4'\text{-bpydo})]_n$  which has the 2D-network shown in Fig. 71A; each 4,4'-bpydo ligand binds four  $\text{Mg}^{2+}$  centers. 3D-Architectures are accessed by employing 1,4-benzenedicarboxylic acid as a co-ligand.<sup>1681</sup> A 3D-network is exhibited by  $[\text{Ca}_2(\text{OH}_2)_2(\mu\text{-}4,4'\text{-bpydo})_6]_n^{4n+}$ , isolated as the  $[\text{Bi}_2\text{I}_8]^{2-}$  salt; there are two

**Fig. 71** (A) Part of one 2D-sheet in  $[\text{Mg}_2(\mu\text{-OAc})_4(\mu_4\text{-}4,4'\text{-bpydo})]_n$  (CSD refcode MOTRAQ). (B) Part of the 1D-polymer in  $[\text{Tl}_2(\text{NO}_3)_6(\mu\text{-}4,4'\text{-bpydo})_3]_n \cdot 2n\text{CH}_2\text{Cl}_2$  (refcode DEFYUJ). (C) Pb(II) coordination environment in the 2D-sheets in  $[\text{Pb}(\text{NO}_3)_2(\mu\text{-}4,4'\text{-bpdo})(\text{OH}_2)]_n$  (refcode WARFIF). Part of one 2D-sheet in (D)  $[\text{Pb}(\mu\text{-Cl})_2(\mu\text{-}4,4'\text{-bpdo})]_n$  (refcode DEYYEM) and (E)  $[\text{Pb}_2(\mu\text{-Cl})_2(\mu_3\text{-Cl})_2(\mu\text{-}4,4'\text{-bpdo})]_n$  (refcode MIZKUC). The structures of (F)  $[\text{BiCl}_4(\text{bpydo})]^-$  (refcode AKAFOK), (G)  $[\text{Bi}_2\text{Br}_4(\mu\text{-Br})_2(\text{bpydo})_2]$  in the MeCN solvate (refcode ISOYEX), and (H) part of a 1D-chain in  $[\text{Bi}_2\text{Br}_6(4,4'\text{-bpydo})_3]_n$  (refcode GAFKIL).

crystallographically independent  $\text{Ca}^{2+}$  centers, one with a *trans*-arrangement of aqua ligands (a 4-connecting node) and one bound by six different bridging 4,4'-bpydo ligands.<sup>1682</sup>

Moving to the p-block, and the reaction between  $\text{Tl}(\text{NO}_3)_3$  and 4,4'-bpydo yielded a ladder-type coordination polymer in which the Tl(III) center has CN = 9; the 4,4'-bpydo ligands form both the 'rungs' and 'rails' of the ladder (Fig. 71B).<sup>1683</sup> A combination of  $\text{Pb}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$  and 4,4'-bpdo produces  $[\text{Pb}(\text{NO}_3)_2(\mu\text{-}4,4'\text{-bpdo})(\text{OH}_2)]_n$  which has a 2D-network in which each Pb(II) center is bound by three 4,4'-bpdo, two chelating  $\text{NO}_3^-$  and one aqua ligand. As Fig. 71C shows, one O-donor of each 4,4'-bpydo ligand coordinates to two Pb(II) centers resulting in  $\{\text{Pb}_2\text{O}_2\}$  units within the network.<sup>1684</sup> In  $[\text{Pb}(\mu\text{-Cl})_2(\text{bpdo})]_n$ , 1D- $\{\text{Pb}(\mu\text{-Cl})_2\}_n$  chains are decorated by chelating bpydo ligands, the latter having the typical twisted conformation; each Pb(II) center is 6-coordinate.<sup>1685</sup> Crystallization of  $\text{PbX}_2$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ) with 4,4'-bpdo led to the assembly of isostructural 2D-networks in which 4,4'-bpdo ligands connect infinite  $\{\text{PbX}_2\}_n$  chains; Fig. 71D illustrates part of one sheet in  $[\text{Pb}(\mu\text{-Cl})_2(\mu\text{-}4,4'\text{-bpdo})]_n$ .<sup>1686</sup> A related assembly is found in  $[\text{Pb}_2(\mu\text{-Cl})_2(\mu_3\text{-Cl})_2(\mu\text{-}4,4'\text{-bpdo})]_n$  (Fig. 71E).<sup>1685</sup>

Interest in several bismuth(III) complexes with bpydo or 4,4'-bpydo is, in part, motivated by their photophysical properties. Fig. 71F shows the structure of  $[\text{BiCl}_4(\text{bpydo})]^-$ , highlighting the twisted bpy unit,<sup>1687</sup> which is again seen in the dimer  $[\text{Bi}_2\text{Br}_4(\mu\text{-Br})_2(\text{bpydo})_2]$ . Interestingly, on going to the solvated compound  $[\text{Bi}_2\text{Br}_4(\mu\text{-Br})_2(\text{bpydo})_2] \cdot 0.5\text{MeCN}$ , a second isomer of  $[\text{Bi}_2\text{Br}_5(\mu\text{-Br})(\text{bpydo})_2]$  is observed with the bpydo ligands adopting the unusual bridging mode shown in Fig. 71G.<sup>1688</sup> The 1D-coordination polymer  $[\text{Bi}_2\text{Br}_6(\mu\text{-}4,4'\text{-bpydo})_3]_n$  contains octahedrally sited Bi(III) with a *fac*-arrangement of bromido ligands and O-donors; Fig. 71H illustrates the bridging roles of 4,4'-bpydo ligands.<sup>1689</sup>

### 1.02.6.3 Tridentate (open-chain)

To illustrate open-chain, tridentate  $O, O', O''$ -ligands in main group metal complexes, we have restricted the discussion to bis(2-methoxyethyl) ether (dgm, the abbreviation stemming from the non-IUPAC name diglyme). The bis(chelating) mode is ubiquitous. Both  $[\text{Li}(\text{dgm})_2]^+$  and  $[\text{Na}(\text{dgm})_2]^+$  (CN = 6) are well established, and only selected references are given.<sup>1479,1480,1690,1691</sup> Other examples for the s-block metals include  $[\text{Li}_2(\text{dgm})_2(\mu\text{-O}_3\text{SCF}_3 \cdot 1\kappa\text{O}^1:2\kappa\text{O}^2)_2]$  (CN = 5),<sup>1692</sup>  $[\text{K}(\text{dgm})_3]^+$  (CN = 9),<sup>1693</sup>  $[\text{K}(\text{dppm-H})(\text{dgm})_2]$  (CN = 8, Fig. 54B),<sup>1066</sup>  $[\text{Cs}(\text{dgm})_3]^+$  (CN = 9),<sup>1693</sup>  $[\text{Mg}(\text{dgm})_2]^{2+}$  (CN = 6),<sup>1694</sup>  $[\text{Mg}_2\text{Cl}_2(\mu\text{-Cl})_2(\text{dgm})_2]$  (CN = 6),<sup>1402</sup>  $[\text{CaI}(\text{dgm})_2]^+$  (CN = 7),<sup>1695</sup>  $[\text{Ca}(\text{dgm})_2(\text{OH}_2)_2]^{2+}$  (CN = 8),<sup>1696</sup>  $[\text{Ba}(\text{dgm})_2(\text{OH}_2)_3]^{2+}$  (CN = 9),<sup>1696</sup> and *trans*- $[\text{BaI}_2(\text{dgm})_2]$  (CN = 8).<sup>1512</sup> Simple complexes incorporating p-block metals are poorly represented and are illustrated by  $[\text{SnCl}(\text{dgm})]^+$  (CN = 4 with a stereochemically active lone pair).<sup>1697</sup>

**Scheme 20** Open-chain ligands discussed in Section 1.02.6.4.

**Fig. 72** Structures of (A)  $[\text{Li}_2(\text{undecaglyme})]^+$  (CSD refcode GOFMAQ), (B)  $[\text{Li}(\text{pentagm})]^+$  (refcode LUQHAL), (C)  $[\text{Mg}(\text{OH}_2)_2(\text{teg})]^{2+}$  (refcode BAHTEL), (D)  $[\text{Ba}(\text{teg})_2]^{2+}$  (refcode DACRIM), and (e)  $[\text{GeBr}(\text{tgm})]^+$  (refcode IDUCIW).

### 1.02.6.4 Polydentate (open-chain)

The coverage of coordination compounds containing polydentate open-chain ligands is restricted to the ligands shown in Scheme 20; the abbreviations tgm, tetragm, pentagm and teg originate from the non-IUPAC names triglyme, tetraglyme, pentaglyme and tetraethyleneglycol, respectively. As expected, complexes of the s-block metals dominate over those of the p-block, and coordination of the ligands to produce multiple chelate rings is the norm. For small ions such as  $\text{Li}^+$ , this typically leads to the formation of polynuclear species as shown in Fig. 72A. Group 1 metal complexes containing PEG (polyethylene glycol) or long-chain polyglyme ligands (e.g.,  $[\text{Li}_2(\text{undecaglyme})]^+$ , Fig. 72A) are of interest as polymer electrolytes.<sup>1698–1700</sup>

Group 1 metal complexes are exemplified by  $[\text{Li}(\text{pentagm})]^+$  (CN = 6, Fig. 72B),<sup>1701</sup>  $[\text{Na}(\text{tgm})_2]^+$  (CN = 8),<sup>1702,1703</sup> the 1D-polymer  $[\text{Na}(\text{tetragm})_2(\mu\text{-O}_3\text{SCF}_3\text{-}1\kappa\text{O}^1\text{:}2\kappa\text{O}^2)]_n$  (CN = 7),<sup>1704</sup>  $[\text{Na}(\text{tetragm})(\text{ClO}_4\text{-}\kappa^2)]$  (CN = 7),<sup>1705</sup>  $[\text{Na}(\text{pentagm})(\text{OClO}_3)]$  (CN = 7 although three independent molecules in the asymmetric unit show subtly different bonding modes for the perchlorate ion),<sup>1705</sup>  $[\text{Na}(\text{pentagm})(\text{PF}_6)]$  (CN = 7),<sup>1705</sup>  $[\text{K}(\text{tgm})_2]^+$  (CN = 8),<sup>1706</sup> the 1D-coordination polymer  $[\text{K}(\text{pentagm})(\mu\text{-PF}_6)]_n$  (CN = 8),<sup>1701</sup>  $[\text{K}(\text{pentagm})(\text{O}_3\text{SCF}_3\text{-}\kappa^2)]$ ,<sup>1707</sup> (CN = 8),  $[\text{K}(\text{hexagm})(\text{PF}_6\text{-}\kappa^2)]$  (CN = 9),<sup>1701</sup> and  $[\text{Cs}(\text{tetragm})_2]^+$  (CN = 10).<sup>1708</sup> As expected, these complexes illustrate an increase in the CN as the group is descended.

Group 2 metal complexes are well represented. Octahedral coordination is observed in *cis*- $[\text{MgBr}_2(\text{tgm})]$  and  $[\text{Mg}_2(\text{tgm})_2(\mu\text{-Br})_2]^{2+}$  which feature in an investigation of chiral Grignard reagents.<sup>670</sup> A pentagonal bipyramidal coordination sphere is found in  $[\text{Mg}(\text{OH}_2)_2(\text{teg})]^{2+}$  (Fig. 72C),<sup>1709</sup>  $[\text{MgBr}_2(\text{tetragm})]^{2+}$ ,<sup>1710</sup> and  $[\text{Mg}(\text{MeHim})_2(\text{tetragm})]^{2+}$ ,<sup>1711</sup> while the larger  $\text{Ca}^{2+}$  ion can accommodate a CN of 7 and 8 in  $[\text{Ca}(\text{OH}_2)_2(\text{teg})]^{2+}$  (CN = 7),<sup>1709</sup>  $[\text{Ca}(\text{OH}_2)_3(\text{teg})]^{2+}$  (CN = 8),<sup>1709</sup>  $[\text{Ca}(\text{OH}_2)_4(\text{tgm})]^{2+}$  (CN = 8),<sup>1509,1696</sup> and  $[\text{Ca}(\text{tgm})(\text{hfacac})_2]$  (CN = 8).<sup>1712</sup> Strontium(II) complexes are exemplified by  $[\text{Sr}(\text{tgm})_2]^{2+}$  (CN = 8),<sup>1713</sup>  $[\text{Sr}(\text{tgm})(\text{hfacac})_2]$  (CN = 8),<sup>1712</sup> and  $[\text{Sr}(\text{OH}_2)_4(\text{teg})]^{2+}$  (CN = 9).<sup>1709</sup> The complex  $[\text{Ba}_2(\text{dme})(\text{tgm})]$  has a CN = 8 and a *trans*-arrangement of iodido ligands, while in the 9-coordinate  $[\text{Ba}_2(\text{dme})(\text{tetragm})]$ , the  $\text{I}^-$  ligands are mutually *cis*.<sup>1714</sup> A CN of 9 is observed in  $[\text{Sr}(\text{tgm})_2]^+$ ,<sup>1512</sup> and  $[\text{Ba}(\text{tgm})_2(\text{THF})]^{2+}$ .<sup>1715</sup> 10-Coordinate metal centers are observed in  $[\text{Sr}(\text{teg})_2]^{2+}$ ,<sup>1709</sup>  $[\text{Ba}(\text{teg})_2]^{2+}$  (Fig. 72D),<sup>1709,1716,1717</sup>  $[\text{Sr}(\text{tetragm})_2]^{2+}$ ,<sup>1718</sup>  $[\text{Ba}(\text{tetragm})_2]^{2+}$ ,<sup>1714,1719</sup>  $[\text{Ba}(\text{tgm})_2(\text{OCMe}_2)_2]^{2+}$ ,<sup>1719</sup> and  $[\text{Ba}(\text{OH}_2)(\text{tgm})_2]^+$ .<sup>1696</sup>

Within group 14,  $[\text{GeBr}(\text{tgm})]^+$  (Fig. 71E),  $[\text{SnBr}(\text{tgm})]^+$ ,  $[\text{GeBr}(\text{tetragm})]^+$  and  $[\text{SnBr}(\text{tetragm})]^+$  have similar structures with a stereochemically active lone pair.<sup>1720</sup> Macdonald et al. reported a series of tin(II) triflate and chloride salts incorporating open-

chain and macrocyclic polyether ligands; these include  $[\text{Sn}(\text{tgm})(\text{O}_3\text{SCF}_3)_2]$  (CN = 6) and  $[\text{Sn}(\text{tetragm})(\text{O}_3\text{SCF}_3)_2]$  (CN = 7).<sup>1721</sup> Coordination compounds of the group 15 metals are limited in number, and a representative example is the 8-coordinate  $[\text{BiCl}_3(\text{tetragm})]$ .<sup>1722</sup>

### 1.02.6.5 Macrocyclic ligands

The field of crown ether ligands is vast, and we are not able to overview it here in depth. Many examples have been given in earlier sections, e.g., Sections 1.02.2.1.1, 1.02.2.1.3, 1.02.2.1.4, 1.02.2.1.5.1, 1.02.3.1.2, 1.02.3.1.3, 1.02.6.1.4 and 1.02.6.2.3, and Figs. 4, 18, 19, 22–24, 26, 28, 51, 52 and 64. Pertinent reviews cover alkali metals,<sup>1723</sup> lithium (with a focus on optical lithium sensors),<sup>1724</sup> thallium,<sup>46</sup> and group 13 and 14 metal ions.<sup>34</sup>

## 1.02.7 Sulfur-donor ligands

### 1.02.7.1 Monodentate ligands

#### 1.02.7.1.1 $R_2S$

Main group metal complexes containing simple thioethers are restricted in number. Dimethyl sulfide appears in the tetrahedral  $[\text{BeX}_2(\text{SMe}_2)_2]$  ( $X = \text{Cl}, \text{Br}, \text{I}$ ) and the dimers  $[\text{Be}_2\text{X}_2(\text{SMe}_2)_2(\mu\text{-X})_2]$  ( $X = \text{Cl}, \text{Br}, \text{I}$ )<sup>1725</sup>; the authors note that the Be–S bond is relatively weak which makes thioether adducts suitable precursors to, for example, beryllium alkyl species. The versatility of  $[\text{BeBr}_2(\text{SMe}_2)_2]$  as a precursor has also been reported by Krossing.<sup>1726</sup> Within the p-block,  $\text{Me}_2\text{S}$  derivatives are illustrated by *trans*- $[\text{SnCl}_4(\text{SMe}_2)_2]$ ,<sup>1727</sup> and  $[\text{SbCl}_3(\text{SMe}_2)]$  (disphenoidal geometry).<sup>1728</sup> In  $[\text{BiBr}_3\{\mu\text{-MeS}(\text{CH}_2)_3\text{SMe}\}]_n$ ,  $\text{MeS}(\text{CH}_2)_3\text{SMe}$  ligands coordinate to Bi(III) in a monodentate and bridging fashion, linking  $\{\text{Bi}_2\text{Br}_4(\mu\text{-Br})_2\}$ -units into a 2D-sheet. In contrast,  $[\text{Bi}_2\text{Br}_6\{\text{PhS}(\text{CH}_2)_2\text{SPh}\}]_n$  contains infinite  $\{\text{Bi}_2\text{Br}_6\}_n$  chains interconnected by thioether ligands (Fig. 73A).<sup>1729</sup> Both  $[(\text{GaCl}_3)_2\{\mu\text{-MeS}(\text{CH}_2)_2\text{SMe}\}]$  and  $[(\text{GaCl}_3)_2\{\mu\text{-PhS}(\text{CH}_2)_2\text{SPh}\}]$  possess discrete molecular structures.<sup>1730</sup>

1,2-Bis(methylsulfanyl)benzene ( $1,2\text{-(MeS)}_2\text{C}_6\text{H}_4$ ) reacts with  $\text{BiCl}_3$  to produce the 1D-polymer  $[\text{BiCl}_3\{1,2\text{-(MeS)}_2\text{C}_6\text{H}_4\}]_n$  with chelating thioether ligands (Fig. 73B). In contrast,  $[\text{Sb}_2\text{Cl}_6\{1,2\text{-(MeS)}_2\text{C}_6\text{H}_4\}_2]_n$  contains dimeric units (Fig. 73C) which are then connected via Sb–Cl–Sb bridges into chains; the bonding mode of the  $1,2\text{-(MeS)}_2\text{C}_6\text{H}_4$  ligand is unusual and features long Sb⋯S contacts. This study extends to a wider range of Sb(III) and Bi(III) complexes containing arene-centered thioether ligands. On going from  $1,2\text{-(MeS)}_2\text{C}_6\text{H}_4$  to  $1,2\text{-(MeSCH}_2)_2\text{C}_6\text{H}_4$ , the tendency for chelation is reduced, leading to bridging modes.<sup>1731</sup> This is also seen in the discrete gallium(III) compound  $[(\text{GaCl}_3)_2\{\mu\text{-}(1,2\text{-(MeSCH}_2)_2\text{C}_6\text{H}_4)\}]$ ,<sup>1730</sup> and an analogous structure is observed for  $[(\text{AlCl}_3)_2\{\mu\text{-}(1,2\text{-(EtSCH}_2)_2\text{C}_6\text{H}_4)\}]$ .<sup>1732</sup>

#### 1.02.7.1.2 $S_n^{2-}$ (bridging modes)

In this section, we first consider coordination compounds containing  $S_2^{2-}$  ligands, followed by those with longer polysulfide anions. The section is organized by bonding mode rather than by periodic group. Modes of bonding of  $S_2^{2-}$  are summarized in Scheme 21, and examples of homometallic main group metal compounds are sparse. Bonding mode I of the  $S_2^{2-}$  ligand is exemplified in the structure of  $[\text{MeNH}_3]_2[\text{Sb}_8\text{S}_{14}]$  which contains pairs of chains supported by sulfide bridges linked by bridging  $S_2^{2-}$  ligands to produce double chains (Fig. 74A); further association occurs through longer Sb⋯S contacts.<sup>1733</sup> The network is retained

**Fig. 73** (A) Part of the 2D-sheet in  $[\text{Bi}_2\text{Br}_6\{\text{PhS}(\text{CH}_2)_2\text{SPh}\}]_n$  (CSD refcode KIGFAH). (B) Part of the 1D-chain in  $[\text{BiCl}_3\{1,2\text{-(MeS)}_2\text{C}_6\text{H}_4\}]_n$  (refcode WALZUG). (C) A  $[\text{Sb}_2\text{Cl}_6\{1,2\text{-(MeS)}_2\text{C}_6\text{H}_4\}_2]_n$  unit in the 1D-polymer  $[\text{Sb}_2\text{Cl}_6\{1,2\text{-(MeS)}_2\text{C}_6\text{H}_4\}_2]_n$  (refcode WAMBAP).

**Scheme 21** Modes of bonding of the  $S_2^{2-}$  ligand.

**Fig. 74** (A) Part of a double chain in  $[\text{Sb}_8\text{S}_{14}]_n^{2n-}$  (CSD refcode DAYBUB). Structures of (B)  $[\text{Al}_2(\text{Nacnac})_2(\mu\text{-S}_3)_2]$  (refcode FAQCUW) and (C)  $[\text{Al}_2(\text{Nacnac})_2(\mu\text{-O})(\mu\text{-S}_4)]$  (refcode CEYSEG) (both with  $\text{R} = \text{Dipp}$  in  $[\text{Nacnac}]^-$ , see **Scheme 6**). (D) Structure of  $[\{\text{K}(18\text{-crown-6})\}_2(\eta_4\text{-S}_4)]$  (refcode QOXJOE). (E) Part of the 1D-chain in  $[\{\text{Rb}(18\text{-crown-6})\}_2(\text{NH}_3)_2(\mu\text{-NH}_3)(\mu_3\text{-S}_4)]_n$  (refcode QOZLAT). Bonding modes of (F) the  $\text{S}_6^{2-}$  ligand in  $[\text{K}_2(\mu_6\text{-S}_6)(\text{THF})_2]_n$  (refcode JEXCEV) and (G) the  $\text{S}_9^{2-}$  ligand in  $[\text{K}_2(\mu_7\text{-S}_9)(\text{THF})]_n$  (refcode JEXCIZ).

upon going to the  $[\text{H}_3\text{N}(\text{CH}_2)_3\text{NH}_3]^{2+}$  salt.<sup>1734</sup> Bonding mode II occurs in  $[\text{Mg}_2(\text{THF})_2(\text{Nacnac})_2(\mu\text{-S}_2)]$  ( $\text{R} = \text{Dipp}$  in  $[\text{Nacnac}]^-$ , see **Scheme 6**).<sup>1735</sup>

The  $\text{S}_3^{2-}$  ligand occurs in a bridging mode in  $[\text{Al}_2(\text{Nacnac})_2(\mu\text{-S}_3)_2]$  ( $\text{R} = \text{Dipp}$  in  $[\text{Nacnac}]^-$ , see **Scheme 6**) in which each Al(III) is tetrahedrally sited (**Fig. 74B**); the  $\text{Al}_2\text{S}_6$  ring has a crown conformation analogous to that in  $\text{S}_8$ .<sup>1736</sup> A bridging  $\text{S}_3^{2-}$  ligand also occurs as one of the products obtained when  $\text{S}_8$  reacts with reduced Bi(II) species.<sup>1737</sup> (Note, however, that the most important finding of this communication is the structural characterization of a dimeric Bi complex of the tetrasulfide radical anion  $\text{S}_4^-$ ; this was the first report of the structure of a complex (main group or transition metal) of a polysulfido radical anion.) With an increase in the chain length to  $\text{S}_4^{2-}$ , the formation of a favorable 5-membered chelate ring becomes viable, as is observed in  $[\text{Al}(\text{Nacnac})(\text{S}_4)]$  ( $\text{R} = \text{Dipp}$  in  $[\text{Nacnac}]^-$ , see **Scheme 6**) which is a rare example of an aluminum polysulfide; the related  $[\text{Al}(\text{Nacnac})(\text{S}_6)]$  with chelating  $\text{S}_6^{2-}$  was also isolated.<sup>1738</sup> The Sn(IV) compounds  $[\text{Sn}\{\text{Me}_2\text{NC}(\text{NCy})_2\}_2(\text{S}_4)]$  and  $[\text{Sn}\{\text{Me}_2\text{NC}(\text{NCy})_2\}_2(\text{S}_6)]$  exhibit chelating  $\text{S}_n^{2-}$  ligands and are members of a series of guanidinato complexes that have been assessed for use as single-source precursors for Sn and SnS thin films.<sup>758</sup> A related derivative is  $[\text{Sn}\{\text{Et}_2\text{NC}(\text{NCy})_2\}\{\text{N}(\text{SiMe}_3)_2\}(\text{S}_4)]$ .<sup>765</sup> The  $\text{S}_4^{2-}$  ligand can adopt varying bridging modes. In  $[\text{Al}_2(\text{Nacnac})_2(\mu\text{-O})(\mu\text{-S}_4)]$  ( $\text{R} = \text{Dipp}$  in  $[\text{Nacnac}]^-$ , see **Scheme 6**), the sulfide is monodentate with respect to each Al(III) center (**Fig. 74C**).<sup>1739</sup> **Fig. 74D** and **E** illustrate additional bridging modes in alkali metal derivatives. Reaction of  $\text{S}_8$  and 18-crown-6- with  $\text{KC}_8$  produced  $[\{\text{K}(18\text{-crown-6})\}_2(\eta_4\text{-S}_4)]$  (**Fig. 74D**) in which all S atoms are within a similar distance of the two  $\text{K}^+$  centers; the range of K–S distances is 3.191(8)–3.334(9) Å.<sup>1740</sup>  $[\{\text{Rb}(18\text{-crown-6})\}_2(\text{NH}_3)_2(\mu\text{-NH}_3)(\mu_3\text{-S}_4)]_n$  was a by-product in the reaction of Rb metal,  $\text{Si}_2$  and 18-crown-6 in liquid  $\text{NH}_3$ , and assembles into a 1D-coordination polymer; the  $\text{S}_4^{2-}$  ligands supports the polymer backbone and also binds the peripheral  $\{\text{Rb}(18\text{-crown-6})(\text{NH}_3)\}$  units (**Fig. 74E**).<sup>1741</sup> The  $\text{S}_6^{2-}$  ligand interacts with six  $\text{K}^+$  centers in  $[\text{K}_2(\mu_6\text{-S}_6)(\text{THF})_2]_n$  which forms a 2D-network; the bonding mode is highlighted in **Fig. 74F**. Increasing the polysulfide chain length to  $\text{S}_9^{2-}$  leads to the formation of the 2D-network  $[\text{K}_2(\mu_7\text{-S}_9)(\text{THF})]_n$ , and **Fig. 74G** displays the bonding mode of the ligand.<sup>1742</sup>

### 1.02.7.1.3 S-Bonded $\text{NCS}^-$

In **Section 1.02.2.1.4**, we surveyed main group metal complexes containing N-bonded  $\text{NCS}^-$  ligands. This ambidentate ligand also offers a range of compounds in which it is coordinated through the S atom, although s- and p-block metal coordination compounds in which the  $\text{SCN}^-$  ligand is terminally bound appear to be rare. A related complex is  $[\text{GaCl}_3(\text{SCNSiMe}_3)]$ .<sup>1743</sup> We have already described  $[\text{K}(18\text{-crown-6})(\mu\text{-SCN})\text{In}(\text{NCS})_5]^{2-}$  which contains an  $\text{NCS}^-$  ligand which is S-bound to  $\text{K}^+$  and N-bound to In(III) (**Fig. 28F**).<sup>443</sup> This kind of bridging mode is relatively well represented (the  $\text{NCS}^-$  bridge often suffering from crystallographic disorder), and other examples are  $[\text{Li}(\mu\text{-SCN})(\mu\text{-hmpa})]_n$  (a 1D-polymer with alternate pairs of  $\text{Li}^+$  centers bridged by two  $\text{SCN}^-$  or two hmpa ligands),<sup>1744</sup>  $[\text{K}(18\text{-crown-6})(\mu\text{-SCN})]_n$  (**Fig. 75A**),<sup>1745</sup>  $[\text{Mg}(\mu\text{-SCN})_2(\text{THF})_2]_n$  (a 1D-chain with octahedral  $\text{Mg}^{2+}$  centers bearing *trans*-THF ligands and connected by pairs of bridging  $\text{NCS}^-$  ligands),<sup>1746</sup>  $[\text{Ca}(\mu\text{-OH}_2)_2(\mu\text{-SCN})_2]_n$  (a 2D-

**Fig. 75** Part of the 1D-chains in (A)  $[K(18\text{-crown-6})(\mu\text{-SCN})]_n$  (CSD refcode KTHOXD05), (B)  $[Ba(OH_2)(NCS)(18\text{-crown-6})(\mu\text{-SCN})]_n$  (refcode GOKKUO, only aqua H atoms are shown), (C)  $[Ba\{HO(CH_2O)_3H\}(\mu\text{-SCN})_2]_n$  (refcode TADQEY), and (D)  $[Sn(NCS)(\mu\text{-SCN})]_n$  (refcode WIXLEX).

**Scheme 22** Structures of the heterocyclic ligands tetrahydrothiophene (tht), thiophene (thp), 1,4-dithiane (dith) and thianthrene (tth).

network with  $\{Ca(\mu\text{-OH}_2)_2\}_n$  chains interconnected by bridging  $SNC^-$  ligands,<sup>1747</sup>  $[Ba(OH_2)(NCS)(18\text{-crown-6})(\mu\text{-SCN})]_n$  (Fig. 75B,  $Ba-S = 3.335(1) \text{ \AA}$ ),<sup>1748</sup> and  $[Ba(NCS)\{HO(CH_2O)_3H\}(\mu\text{-SCN})]_n$  (with a structure related to that in Fig. 75C,  $Ba-S = 3.3307(6) \text{ \AA}$ ).<sup>1749</sup> In  $[Ba\{HO(CH_2O)_3H\}(\mu\text{-SCN})_2]_n$  (Fig. 75C),  $NCS^-$  ligands adopt two different bridging modes, one through the N-donor and one through both N- and S-donors.<sup>1750</sup>

Structurally simple complexes of the p-block metals include  $[Sn(NCS)(\mu\text{-SCN})]_n$  (a 1D-chain supported by bridging  $SCN^-$  ligands, Fig. 75D),<sup>1751</sup> and  $[Bi(THF)(\mu\text{-SCN})_3]_n$  (which forms a 2D-network with adjacent Bi(III) centers bridged by two  $NCS^-$  ligands).<sup>441</sup>

#### 1.02.7.1.4 Heterocyclic ligands

Main group metal coordination compounds with monodentate S-heterocyclic ligands are not extensive and we have restricted the coverage to the ligands shown in Scheme 22, and the soft nature of sulfur naturally leads to a dominance of heavier p-block metals. Complexes containing tht are limited to a few p-block metal species, illustrated by the square-planar *trans*- $[SeCl_2(tht)_2]$  and *trans*- $[TeCl_2(tht)_2]$ ,<sup>1752</sup> octahedral *trans*- $[TeX_4(tht)_2]$  ( $X = Cl, Br$ ),<sup>1307</sup> and the dimer  $[Te_2Br_6(tht)_2(\mu\text{-Br})_2]$ .<sup>1307</sup> In reactions of  $[AuCl(tht)]$  with  $Sn\{N(SiMe_3)_2\}_2$ , the tht ligand is transferred from gold to tin resulting in the formation of  $[Au\{SnCl(NR_2)_2\}\{Sn(tht)(NR_2)_2\}]$  and  $[Au\{Sn(NR_2)_3\}\{Sn(tht)(NR_2)\}]$  ( $R = SiMe_3$ ).<sup>1753</sup> Searches of the CSD for complexes of the main group metals (post 2000) that incorporate non-functionalized thiophene ligands generated no hits, but there are a few examples in which a thiophen-2-yl unit is present.  $[Na(3\text{-}(thiophen\text{-}2\text{-}yl)phen)(BF_4)]$  forms dimeric units by virtue of bridging  $BF_4^-$  ligands, and these further associate through weak  $Na \cdots S$  interactions ( $Na-S = 3.383(5) \text{ \AA}$ ).<sup>1754</sup> Reactions between tris(thiophen-2-yl)methanol (HL) and NaH or KH in THF produced cubanes  $[M_4L_4(THF)_2]$  ( $M = Na, K$ ) in which each  $L^-$  ligand coordinates through the O- and three S-donors.<sup>1755</sup>

The few examples of p-block metal complexes containing 1,4-dithiane ligands illustrate different bonding modes. The ligand is ideally suited as a linker in coordination polymers, and this is exemplified in  $[SnBr_4(\mu\text{-dith})]_n$  which contains *trans*- $\{SnBr_4S_2\}$  coordination spheres ( $Sn-S = 2.6546(6) \text{ \AA}$ ).<sup>1756</sup> 1,4-Dithiane binds to Sb(III) in  $[SbCl_2(dith-\kappa^2)]^+$ ; the dith ligand adopts a boat conformation and coordinates through both S-donors but in an asymmetric manner ( $Sb-S = 2.694(1)$  and  $3.003(2) \text{ \AA}$ ); additional 1,4-dithiane molecules link the  $[SbCl_2(dith-\kappa^2)]^+$  units into 1D-chains although the interactions are rather weak ( $Sb-S = 3.023(2) \text{ \AA}$ ).<sup>1757</sup>

The reaction of tth with  $\text{AlCl}_3$  in a melt yields tetrahedral  $[\text{AlCl}_3(\text{tth})]$  with one non-coordinated S-donor. Note that oxidation of tth is a competitive process and a by-product was  $[\text{tth}_3][\text{Al}_2\text{Cl}_7]_2$  containing  $[\text{tth}_3]^{2+}$  cations.<sup>1758</sup>

### 1.02.7.2 Bidentate: $[\text{S}(\text{CH}_2)_2\text{S}]^{2-}$ and $\text{RS}(\text{X})\text{SR}$

In Section 1.02.7.1.1, we included the coordination of  $\text{RS}(\text{CH}_2)_n\text{SR}$  and 1,2-(MeS) $_2\text{C}_6\text{H}_4$ , 1,2-(MeSCH $_2$ ) $_2\text{C}_6\text{H}_4$  and 1,2-(EtSCH $_2$ ) $_2\text{C}_6\text{H}_4$ . Although the emphasis was on bridging modes (i.e., monodentate to a given metal center), chelation was also illustrated (e.g., see Fig. 73B). We now consider bidentate ligands which show a preference for chelating modes.

Coordination to a single metal center by  $[\text{S}(\text{CH}_2)_2\text{S}]^{2-}$  or  $\text{RS}(\text{CH}_2)_2\text{SR}$  ligands leads to a favorable 5-membered chelate ring. Structurally simple complexes containing the ethane-1,2-dithiolato ligand,  $\text{edt}^{2-}$ , are exemplified by  $[\text{GaCl}_2(\text{edt})]^-$  (tetrahedral),<sup>1759</sup>  $[\text{Ga}(\text{edt})_2]^-$  (tetrahedral),<sup>1759</sup>  $[\text{Ge}(\text{edt})_2]$  (tetrahedral),<sup>1760</sup>  $[\text{AsX}(\text{edt})]$  (X = Cl, I; trigonal pyramidal),<sup>1761</sup>  $[\text{As}_2(\text{edt})_2(\mu\text{-edt})]$  (trigonal pyramidal),<sup>1761</sup> and  $[\text{SbCl}(\text{edt})]$  (trigonal pyramidal).<sup>1762</sup> Complexes containing neutral, chelating  $\text{RS}(\text{CH}_2)_2\text{SR}$  ligands include *cis*- $[\text{AlI}_2\{\text{MeS}(\text{CH}_2)_2\text{SMe}\}_2]^+$  (octahedral),<sup>1732</sup> *trans*- $[\text{AlCl}_2\{\text{MeS}(\text{CH}_2)_2\text{SMe}\}_2]^+$  (octahedral),<sup>1732</sup> *trans*- $[\text{InX}_2\{\text{PrS}(\text{CH}_2)_2\text{S}^i\text{Pr}\}_2]^+$  (X = Cl, Br; octahedral),<sup>1763</sup>  $[\text{GeF}_4\{\text{RS}(\text{CH}_2)_2\text{SR}\}]$  (R = Me, Et; octahedral),<sup>1764</sup>  $[\text{SnF}_4\{\text{RS}(\text{CH}_2)_2\text{SR}\}]$  (R = Et, <sup>i</sup>Pr; octahedral),<sup>1764</sup>  $[\text{As}_2\text{I}_4\{\text{MeS}(\text{CH}_2)_2\text{SMe}\}_2(\mu\text{-I})_2]$  (octahedral As),<sup>1765</sup>  $[\text{BiBr}_3\{\text{MeS}(\text{CH}_2)_2\text{SMe}\}_2]$  (CN = 7),<sup>1729</sup>  $[\text{TeX}_4\{\text{MeS}(\text{CH}_2)_2\text{SMe}\}]$  (X = Cl, Br; octahedral Te(IV)),<sup>1766</sup> and  $[\text{TeCl}\{\text{PrS}(\text{CH}_2)_2\text{S}^i\text{Pr}\}]^+$  (*ca.* planar Te(II) with a weak Te...Cl contact to the  $[\text{Te}_2\text{Cl}_9]^-$  anion).<sup>1766</sup> Six-membered chelate rings are observed in the octahedral  $[\text{SnCl}_4\{\text{PhS}(\text{CH}_2)_3\text{SPh}\}]$ ,<sup>1767</sup> and  $[\text{TeCl}_4\{\text{MeS}(\text{CH}_2)_3\text{SMe}\}_2]$ .<sup>1307</sup>

### 1.02.7.3 Tridentate

Main group metal coordination compounds incorporating simple tridentate S,S',S''-ligands are not so well represented, and we focus on the few complexes of the p-block metals containing the conjugate base of 2,2'-thiobis(ethane-1-thiol).  $[\text{Sn}(\text{edt})\{\text{S}(\text{CH}_2\text{CH}_2\text{S})_2\}]$  has a trigonal bipyramidal structure with the  $\{\text{S}(\text{CH}_2\text{CH}_2\text{S})_2\}$  facially-bound.<sup>1768</sup> The Sb(II) center in  $[\text{SbI}\{\text{S}(\text{CH}_2\text{CH}_2\text{S})_2\}]$  exhibits a disphenoidal (see-saw) coordination environment with the I<sup>-</sup> ligand in an axial site.<sup>1769</sup> In  $[\text{Ge}\{\text{S}(\text{CH}_2\text{CH}_2\text{S})_2\}(1\text{-HN-2-SC}_6\text{H}_4)]$ , the Ge(IV) center can be described as 5-coordinate, although it exhibits one long Ge-S contact to the central S of the tridentate ligand (3.055(1) Å vs 2.214(1) and 2.2154(9) Å).<sup>1770</sup>

### 1.02.7.4 Macrocyclic ligands (S only donors)

The sulfur-containing macrocyclic ligands incorporated into coordination compounds of the main group metals and reported since 2000 are shown in Scheme 23. The section is organized by ring size, starting with 1,4,7-trithiacyclononane (9S3) for which tridentate (to one metal center) and bridging modes are illustrated.  $\text{Na}[\text{BAr}^{\text{F}}_4]$  was used as a source of 'naked'  $\text{Na}^+$  to prepare  $[\text{Na}(9\text{S3})(\text{THF})_2][\text{BAr}^{\text{F}}_4]$  and  $[\text{Na}(24\text{S8})][\text{BAr}^{\text{F}}_4]$  (see below); severe crystallographic disorder in the  $[\text{Na}(9\text{S3})(\text{THF})_2]^+$  ion militates against discussion of the bond parameters.<sup>1771</sup> In *fac*- $[\text{AsCl}_3(9\text{S3})]$ , the As(III) center is octahedrally sited.<sup>1765</sup> In 2008, Levason, Reid and coworkers reported the first validated chalcogenoether complexes of Ge(II) and these included  $[\text{GeCl}_2(\mu\text{-}9\text{S3})]_n$  (Fig. 76A); the Ge-S bonds are relatively long (range 2.697(3) to 2.782(3) Å for three independent Ge(II) centers in the crystal structure).<sup>1772</sup> Like 9S3, 10S3 may coordinate in a tridentate mode to a single metal center. This is observed in  $[\text{Pb}(10\text{S3})(\text{OClO}_3\text{-}\kappa^2)_2(\text{OH}_2)]$  which exhibits a stereochemically active lone pair; however, the perchlorate ions are only weakly bound to Pb(II).<sup>1773</sup>

**Scheme 23** Structures and acronyms of the sulfur-containing macrocyclic ligands discussed in Section 1.02.8.3. Note that another common method of abbreviation used in the literature is of the form, e.g., [9]aneS3, [10]aneS3, and so on.

**Fig. 76** Part of the 1D-chains in (A)  $[\text{GeCl}_2(9\text{S}3)]_n$  (CSD refcode QOMBAW), (B)  $[\text{SnBr}_4(\mu\text{-}12\text{S}4)]_n$  (refcode AQARAL), (C)  $[\text{SnBr}_4(\mu\text{-}16\text{S}4)]_n$  (refcode AQARIT). (D) The structure of  $\text{trans-}[\text{GaCl}_2(16\text{S}4)]^+$  (refcode CAXJOC). (E) Coordination of 14S4 in  $[\text{Sb}_2\text{Br}_4(\mu\text{-}Br)_2(\mu\text{-}14\text{S}4)]_n$  which extend into a 3D-network (refcode QOFLUS). (F) Structure of the  $[\text{Na}(24\text{S}8)]^+$  ion (refcode JUCGOF).

The 12S4 ligand occurs in a bridging mode in  $[\text{SnBr}_4(\mu\text{-}12\text{S}4)]_n$  (Fig. 76B) and this is one of a series of related Sn(IV) complexes reported by Levason et al. The compounds  $[\text{SnBr}_4(\mu\text{-}14\text{S}4)]_n$  and  $[\text{SnBr}_4(\mu\text{-}16\text{S}4)]_n$  (Fig. 76C) are also 1D-polymers, but with a *trans*-arrangement of S-donors.<sup>1774</sup> For group 13 metal complexes of stoichiometry  $\text{MCl}_3(14\text{S}4)$ , a structural change is observed on going from Al to Ga.  $[\text{AlCl}_2(14\text{S}4)][\text{AlCl}_4]$  contains  $[\text{AlCl}_2(14\text{S}4)]^+$  cations with a tridentate ligand,<sup>1732</sup> whereas  $[\text{GaCl}_3(\mu\text{-}14\text{S}4)]_n$  is a 1D-coordination polymer with trigonal bipyramidal Ga(III) with S-donors in the axial sites.<sup>1775</sup> In contrast,  $\text{trans-}[\text{GaCl}_2(16\text{S}4)]$  is a discrete molecular complex (Fig. 76D).<sup>1775</sup> Earlier, we described the 1D-coordination polymer  $[\text{GeCl}_2(\mu\text{-}9\text{S}3)]_n$ . With 14S4, a 2D-sheet assembles with each 14S4 ligand binding four Ge(II) centers in  $[\text{Ge}_2\text{Cl}_4(\mu\text{-}14\text{S}4)]_n$ . In contrast,  $[\text{GeBr}_2(\mu\text{-}14\text{S}4)]_n$  is a 1D-polymer with only two S-donors per macrocycle involved in coordination; chains are interconnected through weak  $\text{Ge}\cdots\text{Br}$  contacts. A similar structure is found for  $[\text{GeBr}_2(\mu\text{-}16\text{S}4)]_n$ .<sup>1772</sup> As opposed to the discrete molecular *fac*- $[\text{AsCl}_3(9\text{S}3)]$  (see above), 14S4 combines with  $\text{AsCl}_3$  to give  $[\text{AsCl}_2(\mu\text{-}Cl)(\mu\text{-}14\text{S}4)]_n$ ; this is a 2D-network containing octahedrally sited As(III).<sup>1765</sup> Note that while  $\text{AsCl}_3$  and 14S4 give a 1:1 adduct even in the presence of an excess of  $\text{AsCl}_3$ ,  $\text{SbX}_3$  and 14S4 combine to give a 2:1 species exclusively. In  $[\text{Sb}_2\text{Br}_4(\mu\text{-}Br)_2(\mu\text{-}14\text{S}4)]_n$ , the macrocyclic ligand coordinates through all four S-donors (Fig. 76E) and a 3D-network results; however, note that one Sb–Br contact is weak (3.497(2) Å compared to 2.535(2), 2.548(2) and 2.609(2) Å).<sup>1776</sup> In Section 1.02.7.1.4, we described the structure of  $[\text{TeX}_4(\text{tht})_2]$  (X = Cl, Br). Hector et al. also investigated reactions of  $\text{TeX}_4$  with [14]aneS4. Although this typically yielded mixed products as insoluble solids, it was possible to isolate the 1D-polymer  $[\text{TeCl}_4(\mu\text{-}14\text{S}4)]_n$  which exhibits octahedral Te(IV) with a *cis*-arrangement of S-donors.<sup>1307</sup>

The macrocycle 18S6 is the S-analog of 18-crown-6, the coordination chemistry of which was described in numerous sections in this review (see Section 1.02.6.5). Germanium(II) forms the complex  $[\text{GeCl}(18\text{-crown-}6)]^+$  in which the  $\text{GeCl}^+$  unit is bound by four of the six S-donors.<sup>1777</sup> Reid and coworkers have investigated the effects of replacing some or all of the O- by S-donors.<sup>1778</sup> Relevant to this section is the reaction of  $[\text{GeCl}_2(\text{diox})]$  with 18S6 which yields the 1D-polymer  $[\text{GeCl}_2(\mu\text{-}18\text{S}6)]_n$  with a structure similar to that of  $[\text{GeCl}_2(\mu\text{-}9\text{S}3)]$  (Fig. 76A).<sup>1778</sup>

The preparation of  $[\text{Na}(24\text{S}8)][\text{BAR}^F_4]$  was mentioned above; the conformational flexibility of the ligand allows it to encapsulate the  $\text{Na}^+$  ion as shown in Fig. 76F with Na–S bond distances in the range 2.9561(15)–3.0524(15) Å.<sup>1771</sup>

## 1.02.8 Selenium-donor ligands

### 1.02.8.1 Monodentate and bidentate ligands

#### 1.02.8.1.1 $R_2\text{Se}$

On going from S- to Se-donor ligands, the number of structurally characterized main group metal complexes is significantly reduced. In keeping with hard–soft metal–ligand principles, complexes of the heavier p-block elements are dominant.

Mishra et al. investigated  $\text{Me}_2\text{Se}$  coordination compounds of gallium and indium halides as potential precursors for Se-containing semiconducting materials. As part of this study, tetrahedral  $[\text{GaI}_3(\text{SeMe}_2)]$ , trigonal bipyramidal  $[\text{InI}_3(\text{SeMe}_2)_2]$ , *fac*- $[\text{InCl}_3(\text{OH}_2)_2(\text{SeMe}_2)]$ ,  $[\text{In}_2\text{Cl}_4(\text{SeMe}_2)_4(\mu\text{-}Cl)_2]$  (Fig. 77A) were isolated and structurally characterized.<sup>1779</sup> Related compounds are tetrahedral  $[\text{AlCl}_3(\text{SeMe}_2)]$ ,<sup>1732</sup>  $[\text{GaCl}_3(\text{SeMe}_2)]$  (Fig. 77B),<sup>1730</sup> and  $[\text{InBr}_3(\text{SeMe}_2)]$ .<sup>1763</sup> *trans*- $[\text{SnCl}_4(\text{SeEt}_2)_2]$  is representative of complexes of the group 14 metals.<sup>1780</sup> Coordination of  $R_2\text{Se}$  to the heavier group 16 congener Te is illustrated by *trans*- $[\text{TeCl}_4(\text{-} \text{SeMe}_2)_2]$  and *trans*- $[\text{TeBr}_4(\text{SeMe}_2)_2]$ .<sup>1307</sup>

As we saw for  $\text{RS(X)SR}$  ligands, a number of  $\text{RSe(X)SeR}$  ligands are found in bridging modes and are monodentate with respect to a single metal center. This bonding mode is illustrated in the solid-state structure of the Ga(III) complex  $[(\text{GaCl}_3)_2\{\mu\text{-}^t\text{BuSe}(\text{CH}_2)_2\text{Se}^t\text{Bu}\}]$ ,<sup>1730</sup> and in the Tl(I) compound  $[\text{Tl}\{\mu\text{-}Me\text{Se}(\text{CH}_2)_3\text{SeMe}\}][\text{PF}_6]$  which contains 1D- $[\text{Tl}\{\mu\text{-}$

**Fig. 77** Structures of (A)  $[\text{In}_2\text{Cl}_4(\text{SeMe}_2)_4(\mu\text{-Cl})_2]$  (CSD refcode BUPTM), and (B)  $[\text{GaCl}_3(\text{SeMe}_2)]$  (refcode XOHNUH). (C) The  $[\text{Bi}_4(\text{Cl}_6)(\mu\text{-Cl}_6)(\mu\text{-1,2-(MeSe)}_2\text{C}_6\text{H}_4)_3]$  molecule is one motif found in  $[(\text{BiCl}_3)_4\{1,2\text{-(MeSe)}_2\text{C}_6\text{H}_4\}_3]$  (refcode WAMCAQ). (D) Structure of  $[\text{Sb}_2\text{Cl}_4(\mu\text{-Cl})_2(8\text{Se}_2)_2]$  (refcode EWIWAI). (E) Part of the 1D-polymer  $[\text{As}_2\text{Cl}_4(\mu\text{-Cl})_2(8\text{Se}_2)_2]_n$  (refcode EWIVUB). (F) Structure of the  $[\text{Al}(\text{seth})_3]^{3+}$  cation (refcode NEFREX).

$\text{MeSe}(\text{CH}_2)_3\text{SeMe}]_n^{n+}$  chains. Shortening the spacer in this last ligand results in a switch to a 3D-network, with each Tl(I) center bound by four Se atoms from different  $\text{MeSe}(\text{CH}_2)_2\text{SeMe}$  ligands; the coordination geometry is distorted tetrahedral with Tl–Se bond lengths in the range 3.2769(8)–3.5058(8) Å. These two compounds represented the first thallium(I) selenoether complexes.<sup>1781</sup>

$[(\text{SbCl}_3)_2\{\mu\text{-MeSe}(\text{CH}_2)_3\text{SeMe}\}_2]$  contains dimeric units which associate into 1D-chains through weak  $\text{Sb}\cdots\text{Cl}$  interactions ( $\text{Sb}\text{---}\text{Cl} = 3.236(3)$  Å). In the bromido-analog, the  $\text{MeSe}(\text{CH}_2)_3\text{SeMe}$  ligands are again in a bridging mode but a 2D-sheet assembles with each  $\{\text{SbBr}_3\text{Se}_3\}$  having a *fac*-arrangement of ligands.<sup>1782</sup> Moving down the group to Bi(III) leads to the formation of  $[\text{BiCl}_3\{\mu\text{-MeSe}(\text{CH}_2)_3\text{SeMe}\}]_n$  with a 2D-network based on  $\{\text{Bi}_2\text{Cl}_4(\mu\text{-Cl})_2\}$  subunits linked by bridging  $\text{MeSe}(\text{CH}_2)_3\text{SeMe}$  ligands, and  $[\text{BiBr}_3\{\mu\text{-MeSe}(\text{CH}_2)_3\text{SeMe}\}]_n$  has a similar solid-state structure.<sup>1729</sup> Levason et al. also reported a compound of stoichiometry  $[(\text{BiCl}_3)_4\{1,2\text{-(MeSe)}_2\text{C}_6\text{H}_4\}_3]$ , the solid-state structure of which contains two tetrabismuth(III) units in the asymmetric unit. One consists of the molecular  $[\text{Bi}_4(\text{Cl}_6)(\mu\text{-Cl}_6)\{\mu\text{-1,2-(MeSe)}_2\text{C}_6\text{H}_4\}_3]$  motif shown in Fig. 77C, while the second can be considered in terms of these same units linked by  $\text{Bi}\cdots\text{Cl}$  interactions into an infinite polymer.<sup>1731</sup>

### 1.02.8.1.2 Heterocyclics

1,5-Diselenacyclooctane (8Se2) and selenanthrene (seth, the Se-analog of tth, Scheme 22) act as monodentate, bridging, and bidentate ligands in the following examples. The first examples of Ge(II) complexes of selenoether ligands were reported in 2011 by Levason, Reid and coworkers. These included  $[\text{GeCl}_2(\mu\text{-}8\text{Se}_2)]_n$  which has a 1D-polymeric structure with bridging 8Se2 ligands, each in a boat-conformation; each Ge(II) center is in a disphenoidal (see-saw) environment with S-donors in the axial sites.<sup>1778</sup> Whereas  $[\text{Sb}_2\text{Cl}_4(\mu\text{-Cl})_2(8\text{Se}_2)_2]$  is a discrete dimer in the solid state with monodentate 8Se2 ligands (Fig. 77D), an As(III) complex with the same stoichiometry forms a 1D ladder-like coordination polymer supported by bridging 8Se2 ligands (Fig. 77E). The molecules of  $[\text{Sb}_2\text{Cl}_4(\mu\text{-Cl})_2(8\text{Se}_2)_2]$  associate through weak  $\text{Se}\cdots\text{Sb}$  contacts into infinite chains. In both compounds, 8Se2 adopts a boat conformation.<sup>1783</sup> On going to Bi(III), the ladder polymer is again observed in  $[\text{Bi}_2\text{Cl}_4(\mu\text{-Cl})_2(8\text{Se}_2)_2]_n$ .<sup>1784</sup>

The reaction of selenanthrene with neat  $\text{AlCl}_3$  in 3:7 molar ratio yielded  $[\text{Al}(\text{seth})_3][\text{Al}_2\text{Cl}_7]_3$  which contains the octahedral  $[\text{Al}(\text{seth})_3]^{3+}$  cation (Fig. 77F) with chelating ligands (Al–Se bond lengths are in the range 2.588(2)–2.598(2) Å).<sup>1758</sup>

### 1.02.8.1.3 RSe(X)SeR

In Section 1.02.8.1.1, we considered compounds in which  $\text{RSe}(\text{X})\text{SeR}$  ligands were in bridging modes, acting as monodentate ligands to each metal center. Now we examine  $\text{RSe}(\text{X})\text{SeR}$  ligands in chelating modes. As part of a wider investigation of chalcogeno ether complexes of Al(III) halides, George et al. reported *trans*- $[\text{AlCl}_2\{\text{MeSe}(\text{CH}_2)_2\text{SeMe}\}_2]$  (Al–Se = 2.5950(13), and 2.6232(13) Å).<sup>1732</sup>  $[\text{SnCl}_4(\text{BuSe}(\text{CH}_2)_2\text{Se}^n\text{Bu})]$  has a discrete molecular structure containing octahedral tin(IV), and was used as a precursor for CVD deposition of  $\text{SnSe}_2$  thin films.<sup>1785</sup> Complexes of the soft, heavy group 15 metals are represented by the dimer  $[\text{In}_2\text{Cl}_4(\mu\text{-Cl})_2\{\text{MeSe}(\text{CH}_2)_2\text{SeMe}\}_2]$  and the octahedral complex *trans*- $[\text{InBr}_2\{\text{MeSe}(\text{CH}_2)_2\text{SeMe}\}_2]$ .<sup>1763</sup> In  $[\text{BiCl}_3\{1,2\text{-(MeSe)}_2\text{C}_6\text{H}_4\}]$ , Bi(III) is in a square-based pyramidal environment and the chelating 1,2-( $\text{MeSe}$ )<sub>2</sub>C<sub>6</sub>H<sub>4</sub> ligand occupies basal sites. However, the Bi–Se bonds are long (3.1376(13) Å) and are described as being weak interactions; weak  $\text{Bi}\cdots\text{Cl}$  contacts link the molecules into chains.<sup>1731</sup>

**Fig. 78** Inset: The structure of the tripodal ligand tripodSe<sub>3</sub>. (A) Part of the 1D-chain in [SbBr<sub>3</sub>(μ-tripodSe<sub>3</sub>)]<sub>n</sub> (refcode QOFLQM). (B) Structure of [Bi<sub>2</sub>I<sub>4</sub>(μ-I)<sub>2</sub>(tripodSe<sub>3</sub>-κ<sup>2</sup>)<sub>2</sub>] (CSD refcode KIGGUC). (C) Part of the 2D-network in [BiCl<sub>2</sub>(μ-Cl)(μ-tripodSe<sub>3</sub>)]<sub>n</sub> (refcode KIGGIQ).

### 1.02.8.2 Tridentate ligands

There are a few examples of group 15 metal complexes containing 1,1,1-tris(methylselenomethyl)ethane (tripodSe<sub>3</sub>, Fig. 78). A combination of tripodSe<sub>3</sub> and SbBr<sub>3</sub> leads to a 1D-coordination polymer; Sb(III) is in an octahedral site and each tripodSe<sub>3</sub> ligand is in a bridging mode as shown in Fig. 78A.<sup>1776</sup> Reactions of BiX<sub>3</sub> (X = Cl or I) with tripod Se<sub>3</sub> give rise to products which, in the solid state, are not isostructural. [Bi<sub>2</sub>I<sub>4</sub>(μ-I)<sub>2</sub>(tripodSe<sub>3</sub>-κ<sup>2</sup>)<sub>2</sub>] is a discrete dimer (Fig. 78B) with one Se-atom non-coordinated; the chelate ring exhibits Bi–Se bond lengths of 2.96(1) and 3.19(1) Å. In contrast, the chlorido analog contains 7-coordinate Bi(III) and the tripodal ligand chelates to one Bi(III) and is monodentate to an adjacent Bi(III). The structure propagates into a 2D-sheet, part of which is shown in Fig. 78C.<sup>1729</sup> It is interesting to note that although there are examples of tripodSe<sub>3</sub> acting as a typical tripodal ligand to several d-block metal ions (e.g., in [Ru(tripodSe<sub>3</sub>)<sub>2</sub>]<sup>2+</sup>),<sup>1786</sup> there are no such examples featuring main group metals in the CSD.

### 1.02.8.3 Macrocyclic ligands (Se only donors)

In comparison to the sulfur-containing macrocyclic ligands shown in Scheme 23, those containing selenium and found in structurally characterized p-block metal coordination compounds reported since 2000 are restricted to 16Se4 and 24Se6 (Scheme 24). The smaller 8Se2 was included in Section 1.02.8.1.2 as a heterocyclic ligand.

**Scheme 24** Selenium-macrocyclic ligands.

**Fig. 79** (A) Part of the 2D-sheet in [(GeCl<sub>2</sub>)<sub>2</sub>(16Se<sub>4</sub>)]<sub>n</sub> (CSD refcode ILIHUH). (B) Part of the 1D-chain in [GeBr<sub>2</sub>(16Se<sub>4</sub>)]<sub>n</sub> (refcode ILIJAP). (C) The molecular structure of [(AsCl<sub>3</sub>)<sub>4</sub>(24Se<sub>6</sub>)]<sub>n</sub> (refcode QUTLIA). (D) Building block in the 3D-network of [(AsBr<sub>3</sub>)<sub>2</sub>(μ<sub>4</sub>-16Se<sub>4</sub>)]<sub>n</sub> (refcode MIYZAV). (E) Part of the 1D-ladder in [Bi<sub>2</sub>Br<sub>4</sub>(μ-Cl)<sub>2</sub>(16Se<sub>4</sub>)<sub>2</sub>]<sub>n</sub> (refcode MEMSIG).

The reactions of GaCl<sub>3</sub> or InCl<sub>3</sub> with 16Se<sub>4</sub> yield [MCl<sub>2</sub>(16Se<sub>4</sub>)] [MCl<sub>4</sub>] (M = Ga, In) in which the cations display *trans*-octahedral coordination spheres.<sup>1775</sup> In contrast to Ga(III), Ge(II) shows a preference for *exocyclic*-coordination with the formation of [(GeCl<sub>2</sub>)<sub>2</sub>(16Se<sub>4</sub>)]<sub>n</sub>, [GeBr<sub>2</sub>(16Se<sub>4</sub>)]<sub>n</sub> and [(GeI<sub>2</sub>)<sub>2</sub>(16Se<sub>4</sub>)]<sub>n</sub>. While the chlorido and iodo derivatives have similar 2D-networks (Fig. 79A), the bromido complex assembles into a 1D-chain (Fig. 79B). Note that [(GeI<sub>2</sub>)<sub>2</sub>(16Se<sub>4</sub>)]<sub>n</sub> co-crystallizes with GeI<sub>4</sub> and is only a minor product of the reaction of GeI<sub>2</sub> with 16Se<sub>4</sub> in anhydrous MeCN.<sup>1778</sup>

The first macrocyclic selenoether complex of As(III), [(AsCl<sub>3</sub>)<sub>4</sub>(24Se<sub>6</sub>)], was described in 2001 by Barton et al. The complex has a discrete molecular structure featuring both *endo*- and *exocyclic* bonding modes (Fig. 79C).<sup>1787</sup> The structures of [(AsCl<sub>3</sub>)<sub>2</sub>(μ<sub>4</sub>-16Se<sub>4</sub>)]<sub>n</sub> and [(AsBr<sub>3</sub>)<sub>2</sub>(μ<sub>4</sub>-16Se<sub>4</sub>)]<sub>n</sub> comprise similar 3D-networks based on weakly associated {As<sub>2</sub>X<sub>4</sub>(μ-X)<sub>2</sub>} dimers which are interconnected by 16Se<sub>4</sub> molecules. Fig. 79D depicts the building block in [(AsBr<sub>3</sub>)<sub>2</sub>(μ<sub>4</sub>-16Se<sub>4</sub>)]<sub>n</sub> focusing on the coordination environment of the macrocycle.<sup>1765</sup> Fig. 77D illustrated the ladder-like structure of [As<sub>2</sub>Cl<sub>4</sub>(μ-Cl)<sub>2</sub>(8Se<sub>2</sub>)<sub>2</sub>]<sub>n</sub>. A similar structure is observed for [Bi<sub>2</sub>Br<sub>4</sub>(μ-Br)<sub>2</sub>(16Se<sub>4</sub>)<sub>2</sub>]<sub>n</sub> (Fig. 79E), and attempts to utilize the non-coordinated Se donors by treatment with BiBr<sub>3</sub> in MeCN solution were unsuccessful.<sup>1784</sup> Reid and coworkers have reported [BiX<sub>3</sub>(24Se<sub>6</sub>)], but no structural data appear to be available.<sup>1784</sup>

### Abstract

Multiple bond compounds between heavier main group elements should be of great interest, especially due to their unique structures arising from their weak  $\pi$  bonds and the resulting reactivity towards small organic compounds. In order to accommodate the weak  $\pi$ -bond energies of these multiple bonds of heavier main group elements, the bonding situation should be substantially perturbed, i.e., the second order Jahn-Teller effect, which results in unique physical and chemical properties. This update describes the recent outcomes on the synthesis of multiple bond compounds between heavier main group elements published between 2013 and 2021. Those before 2013 have been published in the previous contributions in *Comprehensive Inorganic Chemistry II*, Ed. Jan Reedijk and Kenneth Poepelmeier, Elsevier B.V., 2013 (ISBN: 978-0-08-096529-1).

### 1.03.1 Introduction

Since silicon represents the next homologue to carbon in the periodic table, the question about the analogy between carbon and silicon has been thought for a long time. Many chemists have studied the chemical similarities and differences between them, because “carbon” is a central element in organic chemistry, and “silicon” is a representative main group element in inorganic chemistry. Low-coordinate species of the second-row main group elements, such as olefins ( $>C=C<$ ), carbonyl compounds ( $>C=O$ ), imines ( $>C=N-$ ), aromatic compounds (e.g., benzene, naphthalene), azo compounds ( $-N=N-$ ), carbenes ( $>C:$ ), etc. play very important roles in organic chemistry. Conversely, the chemistry of heavier elements homologues of these low-coordinate species has been undeveloped so far most probably due to their extremely high reactivity and inherent instability under ambient conditions, while these unsaturated compounds have been postulated in many reactions as reactive intermediates. Prior to the 1970s, all attempts at synthesizing the low-coordinate species of elements of the third period and downward (namely, heavier main group elements) proved unsuccessful, leading to the formation of cyclic oligomers or polymers containing only single covalent bonds even under the conditions without any oxygen and water.<sup>1</sup> Therefore, it became believed that “elements having a principal quantum

**Chart 1** The first double-bond compounds of heavier main group elements.

number greater than two should not be able to form a  $\pi$ -bond, i.e., so called “double bond rule”.<sup>2</sup> It should be most likely interpreted in terms of the poor overlap of  $p$  orbitals, due to either large distance between the two bonding atoms or poor size match (e.g., Si–C bond), precluding favorable bonding interactions. However, this rule came to be doubted during the 1970s with the reports on the preparations of such low-coordinate compounds of heavier main group elements in the gas phase and the trapping reactions of them at low temperature. Then, the first distannene (Sn=Sn, 1976),<sup>3</sup> phosphaalkene (P=C, 1978),<sup>4</sup> diphosphene (P=P, 1981),<sup>5</sup> silene (Si=C, 1981),<sup>6</sup> and disilene (Si=Si, 1981)<sup>7</sup> were successfully synthesized as stable compounds by utilizing sterically demanding substituents, disproving the “double bond rule” (Chart 1). These compounds are significant landmarks in the chemistry of kinetically stabilized low-coordinate compounds of heavier main group elements. Since then, several numbers of isolable low-coordinate compounds of heavier main group elements have been reported and their chemical and physical properties have been investigated in detail.<sup>8</sup>

For the stabilization of highly reactive compounds such as low-coordinate compounds of heavier main group elements, two established methodologies are well known, i.e., thermodynamic and kinetic stabilization. The former is defined as stabilization of the ground state by the resonance effect of neighboring heteroatoms, that is, introduction of an electron-donating or -withdrawing substituents, and/or intermolecular complexation with donor molecules and/or Lewis acids such as transition metals. The latter is stabilization resulting from raising the transition state by taking advantage of steric protection using bulky groups, which suppress self-oligomerization and side-reactions with other molecules. Kinetic stabilization is superior to thermodynamic stabilization from viewpoint of investigation into the intrinsic bonding nature, since the thermodynamic stabilization perturbs the intrinsic nature of the species to a greater extent than the kinetic stabilization. Since several review articles are now available on the chemistry of low-coordinate heavier main group elements, which are kinetically and thermodynamically stabilized,<sup>8–10</sup> the contents in this section will be restricted to deal with the synthesis and properties of multiple-bond compounds of heavier group 14, 15 and 16 elements, i.e., unsaturated compounds such as cationic species (R<sub>3</sub>Si<sup>+</sup>, R<sub>2</sub>P<sup>+</sup>, etc.), tetrylene (>Si: etc.), pnictinidene (–P: etc.), and those thermodynamically stabilized with intra- and inter donor coordination are not included. In addition, this update describes only the recent outcomes on the synthesis of multiple bond compounds between heavier main group elements published between 2013 and 2021, because those before 2013 have been published in the previous contributions in *Comprehensive Inorganic Chemistry II*, Ed. Jan Reedijk and Kenneth Poepelmeier, Elsevier B.V., 2013 (ISBN: 978-0-08-096529-1).

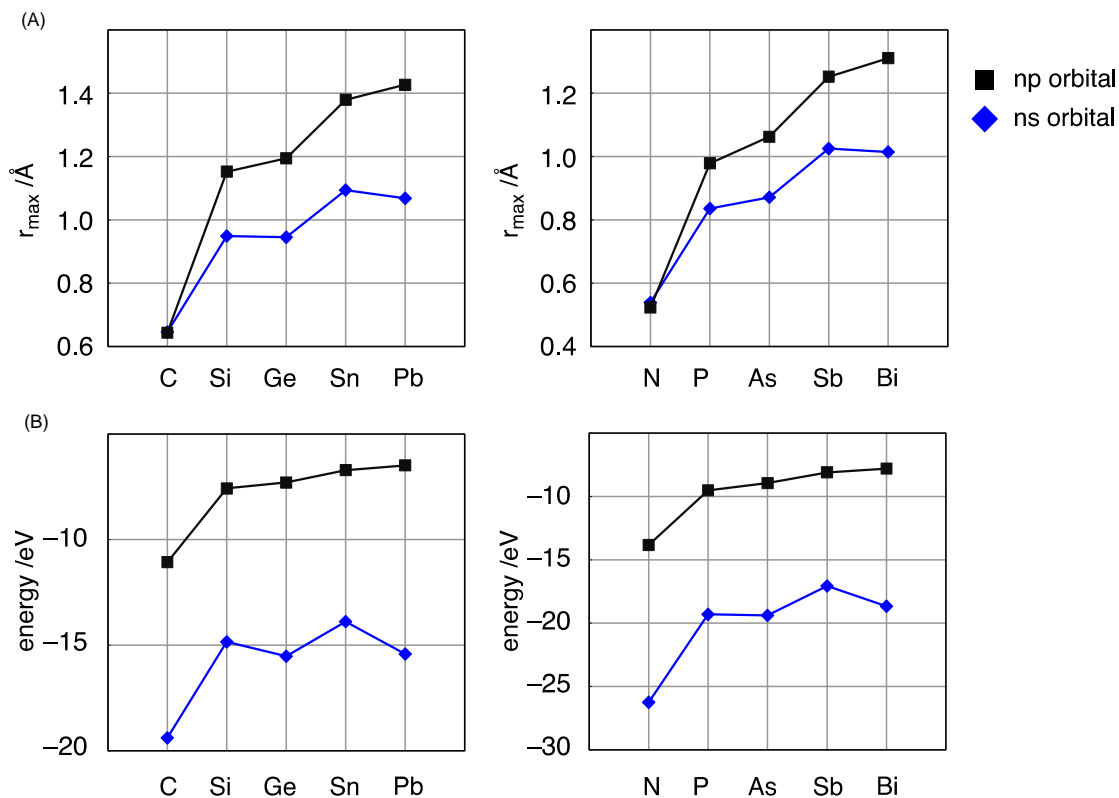

### 1.03.2 Theoretical aspects

Since several  $\pi$ -bonding systems of heavier main group elements have been created by utilizing kinetic stabilization, their structural characters have been thoroughly investigated based on the experimental and theoretical insights.<sup>8–10</sup> For example, although H<sub>2</sub>C=CH<sub>2</sub> is known to exhibit a planar structure around the C=C  $\pi$ -bonding (D<sub>2h</sub>), the planar structures of the heavier analogues, H<sub>2</sub>E = EH<sub>2</sub> (E=Si, Ge, Sn, Pb), are unexpectedly not an energy minimum but a transition state in contrast to the carbon case. The minimum structures of H<sub>2</sub>E = EH<sub>2</sub> were computed as *trans*-bent structure (C<sub>2h</sub>) (Fig. 1).<sup>11</sup> Actually, most of the isolated double bond compounds between heavier group 14 elements, R<sub>2</sub>E = ER<sub>2</sub> (diterpenes), were found to exhibit *trans*-pyramidalized (*trans*-bent) structures as well as the first isolated disilene, Mes<sub>2</sub>Si=SiMes<sub>2</sub>.<sup>7</sup> The intrinsic nature of a diterpene having a *trans*-bent structure can be interpreted in either (i) double donor-acceptor bonds based on the valence bond theory, or (ii) a pseudo (2nd-order) Jahn-Teller effect with mixing of  $\sigma^*$  orbital with the  $\pi$  orbital.<sup>11,12</sup>

In Fig. 2 are shown the radii of the valence atomic orbitals (maximal electron-density) and the corresponding orbital levels, which are calculated for group 14 and 15 elements.<sup>13</sup> It should be noted that the valence  $ns$  and  $np$  atomic orbitals show great difference in their sizes for the heavier atoms (Si, Ge, Sn, Pb), though the size of the  $2s$  atomic orbital of carbon is almost equal to that of the  $2p$  atomic orbitals due to the absence of inner-shell  $p$  electrons. The tendency of the size of  $ns$  and  $np$  orbitals can be applied not only to group 14 elements but also to other groups. The size-difference between the  $ns$  and  $np$  orbitals increases on going down the row in the periodic table. Thus, the heavier atoms have a lower tendency to form  $s$ - $p$  hybrid orbitals with high  $p$  character and they prefer to preserve the valence  $s$  electrons as core-like electrons with keeping their original  $ns$ - $np$  valence electronic configuration, on the contrary to the case of 2nd row elements. The core-like characters of the valence  $s$  electrons cause the inert lone pair in heavier elements. Conversely, the second-row elements such as carbon prefer to promote one of two valence  $2s$  electrons into the vacant  $2p$  orbital to form  $s$ - $p$  hybrid orbitals. The mixing of the  $2s$  and  $2p$  orbitals, which exhibit almost the same size, can yield the  $s$ - $p$  hybrid orbital as spreading in the direction of bonding (Fig. 3). Thus, the orbital overlapping should be greater in the use of the hybridized

**Fig. 1** Heavier analogues of an alkene.

**Fig. 2** (A) Sizes and (B) energy levels of valence ns and np orbitals for group 14 and 15 elements.

**Fig. 3** Mixing of s and p orbitals.

orbitals to form strong bonds. Accordingly, the resulting gain of the bonding energy can sufficiently compensate the loss of energy for the electron promotion from 2s orbital to 2p orbital.

For the bonding situation of the  $\pi$  bond in heavier diterpenes ( $\text{H}_2\text{E}=\text{EH}_2$ , Si, Ge, Sn, Pb), the orbital interactions between the  $\text{H}_2\text{E}$  units should be considered on the basis of the valence bond theory.<sup>8</sup> Because the heavier group 14 elements prefer to retain their  $ns^2np^2$  valence electronic configuration as described above, the ground state of the tetrylene unit ( $\text{H}_2\text{E}$ ) should be singlet with the s-character lone pair, in contrast to a carbene ( $\text{H}_2\text{C}$ ), which exhibits triplet ground state. Indeed, the singlet-triplet energy difference ( $\Delta E_{\text{ST}}$ ) of the tetrylene ( $\text{H}_2\text{E}$ ) increases  $\Delta E_{\text{ST}} = 16.7$  ( $\text{H}_2\text{Si}$ ), 21.8 ( $\text{H}_2\text{Ge}$ ), 24.8 ( $\text{H}_2\text{Sn}$ ), and 34.8 ( $\text{H}_2\text{Pb}$ ) kcal/mol, though that of  $\text{H}_2\text{C}$  is estimated as  $-14.0$  kcal/mol.<sup>14</sup> Because of the intrinsic nature of tetrylenes, the relative stability of the singlet species of  $\text{R}_2\text{E}$  ( $\text{E}=\text{C}, \text{Si}, \text{Ge}, \text{Sn}, \text{Pb}$ ;  $\text{R} = \text{alkyl or aryl}$ ) as compared with the corresponding dimer,  $\text{R}_2\text{E}=\text{ER}_2$ , are estimated to increase as the element row descends,  $\text{C} < \text{Si} < \text{Ge} < \text{Sn} < \text{Pb}$ . Accordingly, one can expect that a divalent organolead compound (plumbylene) may be isolable as a stable compound. Because there have been huge numbers of stable stannylenes and plumbylene with heteroatom substituents, tetrylenes and those thermodynamically stabilized with intra- and inter donor coordination are not included in this review in the following sections.<sup>10</sup> However, tetrylenes without any electronic and steric stabilization effect were known to be thermally unstable to undergo facile disproportionation. Thus, it should be difficult to isolate tetrylenes as stable compounds under ambient conditions, since tetrylenes generally exhibit extremely high reactivity due to their considerable electrophilicity. Tetrylenes have the singlet ground state with a vacant p-orbital and an s-character lone pair as valence orbitals. The extremely high reactivity of tetrylenes should be due to their vacant p-orbitals, since their 6 valence electrons are less than 8 electrons from the viewpoint of octet rule and the lone pair of the tetrylenes should be inert due to its high s-character. In order to stabilize such tetrylenes enough to be isolated as stable compounds, thermodynamic and/or kinetic stabilization should be afforded towards the reactive vacant p-orbital. Thus, several numbers of “isolable” tetrylenes have been synthesized by using the thermodynamic stabilization of heteroatoms such as N, O, and P, etc., and/or the kinetic stabilization utilizing bulky substituents (Fig. 4).<sup>10</sup> Thus, the number of the valence electrons should be very important to know the property of the low-coordinate species of main group elements.

Carbon substituents on a tetrylene should affect less electronic perturbation as compared with the heteroatom substituents such as N, O, and P, which can stabilize the vacant p-orbital of a tetrylene (Fig. 4). The intrinsic nature of tetrylenes should be obscured in the cases of heteroatom-substituted tetrylenes due to the electronic effects of the heteroatom substituents, i.e., intramolecular coordination of the heteroatom, and hapticity of the ligands. Thus, sterically demanding carbon-substituents on a tetrylene should be effective to suppress the electronic perturbation towards its vacant p-orbital from intra- and intermolecular coordination. That is the reason why some carbon substituted tetrylenes have been isolated with sterically demanding substituents, and they exhibit high reactivity due to their vacant p orbitals even though they would be kinetically stabilized. When the steric hindrance of the carbon-substituted tetrylene is insufficient, the tetrylene ( $\text{R}_2\text{E}$ ) would undergo self-dimerization or oligomerization leading to the formation of the corresponding dimer, i.e., double-bond compounds ( $\text{R}_2\text{E}=\text{ER}_2$ ), oligomer, or polymer. Thus, the bonding situation of a double-bond between heavier group 14 elements can be interpreted in terms of a dimer of a tetrylenes.<sup>8,9</sup>

It can be concluded that, in the case of heavier group 14 elements, a tetrylene exhibits singlet ground state with  $ns^2np^2$  configuration, and has a vacant p-orbital and s-character lone pair. Because a tetrylene is highly reactive towards self-oligomerization and/or electrophilic reactions due to its vacant p-orbital, it can be isolated as a monomeric form only when sterically demanding or heteroatom substituent would be introduced on the tetrylene center. When it has only small substituents, it should undergo facile oligomerization giving the corresponding oligomer/polymer. On the other hand, a tetrylene with “moderately” bulky substituent, which would sufficiently suppress the facile oligomerization, but insufficient to keep its monomeric form, should undergo dimerization to give the corresponding double bond compound, a diterpene, as a dimer of tetrylenes (Fig. 5).

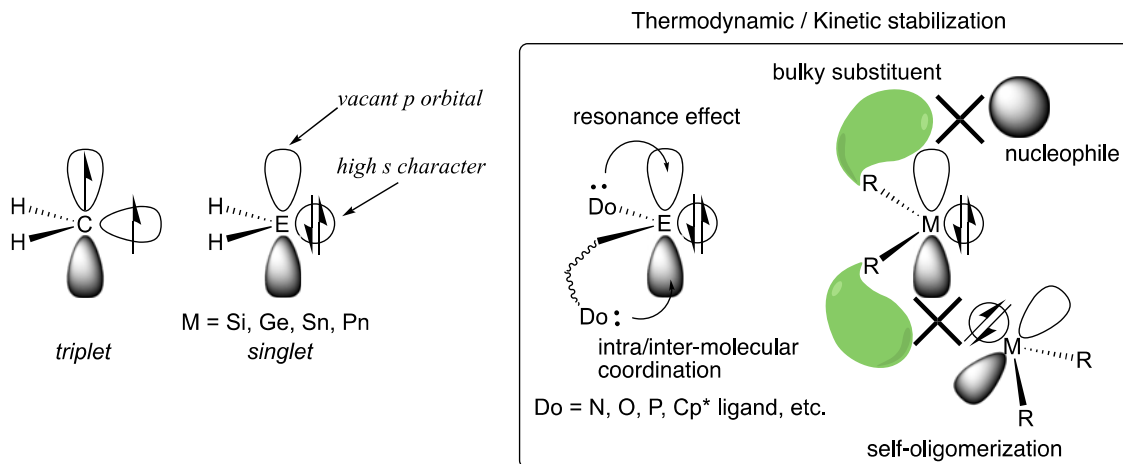

Fig. 4 Thermodynamic and kinetic stabilization for tetrylenes ( $\text{R}_2\text{E}$ ;  $\text{E}=\text{Si}, \text{Ge}, \text{Sn}, \text{Pb}$ ).

**Fig. 5** Fate of a tetrylene ( $R_2E$ ,  $E=Si, Ge, Sn, Pb$ ) depending on the substituents.

On the consideration of above-mentioned feature of a tetrylene, one can see severe repulsion between the closed-shell orbitals of two  $H_2E$  units would prevent dimerization leading to the formation of a dimer,  $H_2E=EH_2$ , in the planar form as shown in Fig. 6. Accordingly, two  $H_2E$  units can form a double bond not only elongated to avoid the repulsion but also in *trans*-pyramidalized configuration, where each  $H_2E$  unit donates a lone pair of electrons to an empty  $p$  orbital of the other to form double donor-acceptor bonds as shown in Fig. 6.

In addition, much heavier elements of Sn and Pb atoms are very reluctant to form a distinct double-bond,  $H_2Sn=SnH_2$  and  $H_2Pb=PbH_2$ , and the bridged dimer of  $H_2E$  and 1,2-H-shifted isomer,  $HE-EH_3$ , are the more stable isomers (Fig. 7),<sup>14</sup> since at least one atom in these isomers can maintain  $ns^2np^2$  valence electronic configuration as divalent species without hybridization of orbitals leading to the formation of tetravalent species. Thus, two tetrylenes ( $H_2E$ ) can form a double bond as a *trans*-pyramidalized geometry based on (i) valence bond theory. According to the bending from the planar geometry ( $D_{2h}$ ) to the *trans*-pyramidalized geometry ( $C_{2h}$ ), the occupied  $\pi$  ( $b_u$ ) orbital is mixing with the vacant  $\sigma^*$  ( $b_u$ ) to form stabilized slipped- $\pi$  orbital ( $b_u$ ) from the viewpoint of (ii) a pseudo Jahn-Teller effect (Fig. 8).<sup>12</sup>

As in the case of double-bond compounds of heavier group 14 elements, a triple-bond compound of heavier group 14 elements, a ditetryne ( $HE\equiv EH$ ), exhibits the *trans*-bent structure ( $D_{2h}$ ) in contrast to an alkyne, which has an undistorted linear geometry ( $D_{\infty h}$ ).<sup>9,15</sup> Their *trans*-bent structures can be explained by consideration of the bonding interaction between the HE components as well. In all cases of group 14 elements (C, Si, Ge, Sn, Pb), HC and HE exhibit doublet ground states, and their lowest excited states should be quartet.<sup>16</sup> However, those of the heavier element cases, HE ( $E=Si, Ge, Sn, Pb$ ), are much larger than that of HC. Thus, CH can exhibit its excited quartet state with small promotion energy to form one  $s$ -bond and two  $\pi$  bonds between the two HC units in linear geometry of  $HC\equiv CH$  (Fig. 6B), where the gain of triple-bond energies can compensate sufficiently the loss of promotion energy.<sup>15,16</sup> Conversely, two HE units prefer to retain their original electron configurations as doublet states as forming a triple bond, since the large promotion energies cannot be compensated by forming weak ( $\sigma + 2\pi$ ) bonds. Thus, the coupling of doublet HE units could occur as shown in Fig. 4B to form the  $HE\equiv EH$  triple bond with two donor-acceptor bonds and one  $\pi$  bond. From viewpoint of a pseudo Jahn-Teller effect, the *trans*-bent structure can also be explained by  $\pi$ - $\sigma^*$  mixing as in the case of diterpenes (Fig. 9).<sup>15</sup> The linear structure of  $HE\equiv EH$  has occupied valence orbitals of one  $\sigma$  ( $\sigma_g$ ) and two  $\pi$  orbitals ( $\pi_u$ ). According to the *trans*-bending of  $HE\equiv EH$ , one of the  $\pi$  orbitals, in-plane  $\pi_{in}$  orbital, can be mixing with the low-lying  $\sigma^*$  ( $\sigma_u$ ) orbital due to the same symmetry to form slipped  $\pi_{in} + \sigma^*$  orbital ( $b_u$ ). The orbital stabilization due to the mixing of  $\pi$  and

**Fig. 6** Interaction between (A)  $H_2E$  moieties in  $H_2E=EH_2$  and (B) HE moieties in  $HE\equiv EH$ .

M	energy of isomers
C	(a)
Si, Ge	(b) < (c) < (d)
Sn, Pb	(d) < (c) < (b)

**Fig. 7** Isomers of  $\text{H}_2\text{E}=\text{EH}_2$  (E = group 14 elements).

**Fig. 8** Pseudo (2nd-order) Jahn-Teller effect with mixing of  $\sigma^*$  orbital with the  $\pi$  orbital of  $\text{H}_2\text{E}=\text{EH}_2$  upon *trans*-pyramidalization.

$\sigma^*$  orbitals via the *trans*-bending in  $\text{HE}\equiv\text{EH}$  should be much effective relative to those in  $\text{H}_2\text{E}=\text{EH}_2$ , because the  $\pi_{\text{in}}-\sigma^*$  energy difference in  $\text{HE}\equiv\text{EH}$  should be much smaller than that in  $\text{H}_2\text{E}=\text{EH}_2$ .

The  $\pi$ -bonding situation in heavier group 15 elements is very different from that in heavier group 14 elements.<sup>8,9b,d</sup> When thinking about the bonding situation, it is important to consider the number of valence p electrons. Pnictogen atoms (group 15 elements) have the  $ns^2np^3$  electron configuration, i.e., have one more valence p electron than group 14 atoms ( $ns^2np^2$  electron configuration). On the consideration of the  $ns^2np^3$  electron configuration of pnictogens, the monovalent heavier group 15 element species, a pnictinidene ( $-\text{P}$ : etc.), should have a triplet ground state (Fig. 10). Accordingly, one can understand that it is very difficult to isolate monovalent species of group 15 elements, pnictidenes, as stable compounds because of their triplet ground states with very reactive half-occupied p-orbitals, as compared with the cases of divalent species of heavier group 14 elements, tetrylenes. Instead of the high reactivity/instability of the monovalent species, a dimer of a pnictinidene, a dipnictene, can form a clear double bond without s-p orbital hybridization with the orthogonal np atomic orbitals as shown in Fig. 10. Indeed, it was found that the  $\text{R}-\text{Pn}=\text{Pn}$  angles should be approaching 90 degrees upon descending the elemental row from N to Bi, because the heavier elements reluctant to form s-p hybrid orbitals as described above.<sup>8,9b,d,13</sup>

As well, chalcogen atoms with  $ns^2np^4$  electron configuration can also form a clear double bond with group 14 elements as heavier elements analogues of carbonyl compounds ( $>\text{E}=\text{Ch}$ ),<sup>9c</sup> because chalcogens can form two chemical bonds with the orthogonal np atomic orbitals  $ns^2np^4$  electron configuration. Difficulty in the isolation of such heavier analogues of carbonyl

**Fig. 9** Pseudo (2nd-order) Jahn-Teller effect with mixing of  $\sigma^*$  orbital with the  $\pi$  orbital of  $\text{HE}\equiv\text{EH}$  upon *trans*-bending.

**Fig. 10** Electronic structure of a dipnictene ( $\text{HE}=\text{EH}$ ,  $\text{E}=\text{P, As, Sb, Bi}$ ).

compounds should be the thermal stability. That is, since no further substituent can be introduced on the doubly bonded chalcogen atom, the heavier analogues of a carbonyl compound would undergo facile oligomerization due to the lack of kinetic stability. Conversely, chalcogen cation ( $\text{Ch}^+$ ) can form a double bond bearing substituents,  $\text{RCh}^+=\text{Ch}^+\text{R}$  as well as a dipnictene despite the cationic charge repulsion, because its electron configuration is same as a pnictogen,  $ns^2np^3$ .

Thus, it can be concluded that, when the bonding situation of heavier main group elements would be considered, it should be very important to understand two key points: (i) heavier elements are reluctant to form s-p hybrid orbital, and the large promotion

energy should be required on forming an s-p hybrid orbital, and (ii) the bond formation situation should depend on the number of valence p electrons.

### 1.03.3 Low-coordinate compounds of heavier group 14 elements

#### 1.03.3.1 Introduction

The field of low-coordinate derivatives is one of the mainstreams of the contemporary chemistry of heavy tetrels (tetrel = element of the group 14). Likewise, within the realm of the low-coordinate compounds of the heavy group 14 elements, the field of the multiply bonded derivatives is arguably among the most popular topics of interest. Accordingly, the literature covering this field is vast with an uncountable number of examples of such unsaturated compounds reported to date. However, since the last edition of the *Comprehensive Inorganic Chemistry*, which included our contribution on the multiply bonded derivatives of the group 14 elements, was published in 2013,<sup>17</sup> in this chapter the literature coverage will start from 2013. We will limit our discussion to the range of compounds featuring double and triple bonds involving the heavy group 14 elements, whereas aromatic derivatives representing special and independent class of the unsaturated organometallics will be outside the framework of this chapter.

Moreover, numerous compounds in which the low-coordinate tetrel centers are intramolecularly (by *n*-donor substituents, most frequently, by N-groups) or intermolecularly (by the external donor ligands, typically, by NHC) coordinated and supported, were reported. However, in such compounds electronic support and accordingly thermodynamic stabilization occurs at the expense of the intrinsic nature of unsaturation, often to such a great extent that the electronic perturbation caused by the electron donation almost completely nullify the low-coordinate nature of the compounds in question. It is very problematic and highly risky to classify such compounds as truly low-coordinate species, although some authors still claim them as “doubly bonded”, “triply bonded”, etc., even though in many cases they are best described as the “singly bonded” species. In our chapter, such intramolecularly coordinated derivatives, in which the very presence of the multiple bond is somewhat doubtful, will be excluded from our consideration. As the only exception, intermolecularly coordinated (typically, by NHC) compounds, which cannot be otherwise stabilized to be isolated, will be discussed in our chapter. They include vinylidene derivatives  $>E=E(NHC)$ : and compounds of the type:  $E^0(NHC)=E^0(NHC)$ : ( $E=Si, Ge, Sn$ ), both classes being ultimately stabilized by the strong NHC-coordination. Considering each class of unsaturated compounds, we will start discussion with the brief mentioning of the historically important first stable representatives and will then consider other examples published since 2013. For more comprehensive reading on the multiple bonds to the heavy group 14 elements, we address readers to one of our previous overviews.<sup>18</sup>

#### 1.03.3.2 Doubly bonded derivatives

##### 1.03.3.2.1 Alkene analogues

###### 1.03.3.2.1.1 Homonuclear derivatives, $E=E$ ( $E=Si, Ge, Sn, Pb$ )

###### 1.03.3.2.1.1.1 Disilenes $>Si=Si<$

Although disilenes were not the first reported stable heavy group 14 element alkene analogues (the first were distannenes, *vide infra*), they are undoubtedly most popular, and accordingly the number of publications on isolable disilenes is by far exceeding those of any other class of alkene analogues of the heavy tetrels. The very first, historically most important, isolable disilene  $Mes_2Si=SiMes_2$  ( $Mes=2,4,6-Me_3-C_6H_2$ ), was reported by West and coworkers in 1981.<sup>7</sup> Since then, an overwhelming number of other stable disilenes was reported in the literature, however as mentioned in the Introduction, in this overview we will briefly discuss only papers published in or after 2013. Disilenes, as well as other heavy tetrel analogues, are characterized by the following most important spectral and structural parameters: (a)  $^{29}Si$  NMR chemical shift of the doubly bonded Si atoms,  $\delta(^{29}Si)$  (in ppm) (typically, low-field shifted), (b) length of the Si=Si bond,  $r_{SiSi}$  (in Å) (typically, short), (c) geometry of the substituents at the Si=Si bond defined by either bent angle  $\theta$  (in °) or by the sum of the bond angles around the  $sp^2$ -Si atoms,  $\Sigma$  (in °); (d) twisting of the Si=Si bond,  $\tau$  (in °) (typically, Si=Si bond is planar (non-twisted)) (Chart 2). Accordingly, below for the disilenes in question we will discuss their structures based on these parameters.

Although many groups are actively involved in disilene chemistry, one of the major players in the field is the research group of Iwamoto who made an important contribution within the last decade. Thus, a range of disilenes was synthesized by the functionalization disilene potassium derivatives with organic or heteroatom halides. In such way, “push-pull” disilene  $N-Si=Si-B$  featuring both donating (amino) and accepting (boryl) groups was prepared exhibiting the characteristics typical for disilenes: (1)  $\delta(^{29}Si) = 142.4$  (N- $sp^2$ -Si) and  $-33.0$  (B- $sp^2$ -Si) ppm; (2)  $r_{Si=Si} = 2.2146(6)$  Å; (3)  $\Sigma = 358.1/359.7^\circ$  (planar geometry around

Chart 2 Bent angles of a disilene.

the  $sp^2$ -Si atoms).<sup>19</sup> The structural and computational studies revealed an important contribution of the  $N^+ = Si-Si=B^-$  resonance form caused by the electronic directions of substituents. A series of heteroaryl(thienyl)- and aryl(anthracenyl, acridinyl)-disilenes was also prepared from the potassium disilenide.<sup>20</sup> All of them uniformly displayed deshielded Si nuclei [ $\delta = 44.2$ – $141.5$  ppm], short Si=Si bonds [ $r_{Si=Si} = 2.1669(5)$ – $2.1846(5)$  Å], and *trans*-bent geometry [ $\theta = 11.9$ – $26.0^\circ$ ]. Interestingly, such disilenes showed absorption bands with contribution of intramolecular charge transfer (ICT),  $p(Si=Si) - p^*(aryl)$ . Applying this synthetic approach, Iwamoto and coworkers synthesized disilenes featuring endocyclic Si=Si bonds functionalized at the  $sp^2$ -Si atoms by aryl and silyl substituents.<sup>21</sup> Spectral and structural features of these disilenes were similar to those of acyclic disilenes: low-field shifted resonances of the  $sp^2$ -Si nuclei [ $\delta = 74.9$ – $134.2$  ppm], short Si=Si bonds [ $r_{Si=Si} = 2.1525(7)$ – $2.1915(5)$  Å], and unremarkable *trans*-bent geometry [ $\theta = 0.1$ – $22.5^\circ$ ]. Mono- and bis-borylated cyclic disilenes were also readily available by the above-mentioned synthetic route, showing typical characteristics: highly deshielded  $sp^2$ -Si nuclei [ $\delta = 128.7$ – $187.2$  ppm], relatively short Si=Si bonds [ $r_{Si=Si} = 2.1990(8)$ – $2.2114(5)$  Å], small *trans*-bending [ $\theta = 4.4$ – $9.8^\circ$ ] and twisting [ $\tau = 16.7$ – $19.3^\circ$ ] of the Si=Si bond.<sup>22</sup> The remarkable red-shift on going from mono- to bis-boryl disilene testifies for the effective conjugation between the Si=Si bond and the vacant  $2p$ -orbital of the B atom.

Another approach to disilenes adopted by Iwamoto group was based on the reductive dehalogenation of 1,2-dihalodisilanes  $>SiX-SiX<$  with potassium graphite. Using this method, they recently prepared disilenes which silyl substituents were unexpectedly joined into the polycyclic scaffolds.<sup>23</sup> Unusual polycyclic structures, however, did not greatly affect the structural features of these disilenes, which were characterized by the low-field resonances of the doubly bonded Si atoms [ $\delta = 133.4$ – $146.7$  ppm], short Si=Si bonds [ $r_{Si=Si} = 2.1665(14)$ – $2.2020(6)$  Å], and *trans*-bending of the Si=Si bonds [ $\theta = 5.5$ – $38.2^\circ$ ].

Silicon cluster containing two exocyclic Si=Si bonds at the edges of the tricyclo[2.2.0.0<sup>2,5</sup>]hexasilane framework was unexpectedly isolated from the mixture of several products formed upon the thermolysis of Si<sub>8</sub>-siliconoid cluster.<sup>24</sup> Both Si=Si bonds in this compound are rather short:  $r = 2.1570(12)$  and  $2.1641(12)$  Å.

The most spectacular achievement of Iwamoto group was definitely isolation of the tricyclic compound **1** as the silicon analogue of the smallest bridgehead alkene that was stabilized by the 4-(*N,N*-dimethylamino)pyridine (DMAP) base.<sup>25</sup> **1** was selectively formed upon the thermolysis of tricyclo[2.1.0.0<sup>1,3</sup>]pentasilane in the presence of excess DMAP (Scheme 1). Although the resonance of the naked  $sp^2$ -Si atom was not observed (signal of the DMAP-coordinated  $sp^2$ -Si atom was found at +84.5 ppm), structure of **1** was unequivocally established by its X-ray diffraction. The central Si<sub>4</sub>-bicyclo[1.1.0]butane fragment is expectedly folded ( $127.04(2)^\circ$ ), and the bridgehead Si–Si bond is very long (2.6215(6) Å). The endocyclic Si=Si bond of 2.2906(6) Å is quite long for the standard double bond, and DMAP-coordinated  $sp^2$ -Si atom is remarkably pyramidalized. Based on the crystallographic data and computational studies, the real structure of **1** is best described as a zwitterion **1'** containing a (tetrasil)homocyclopropenylum ion and a silyl anion, rather than a bicyclic structure with a localized Si=Si double bond (Scheme 1).

Interestingly, when treated with BPh<sub>3</sub>, **1** underwent elimination of the DMAP-BPh<sub>3</sub> complex and formation of the disilene **2** as a dimer of the hypothetical silylene **3**, which is an isomer of **1** (Scheme 1). The exocyclic Si=Si bond in **2** is relatively long (2.248(2) Å) and expectedly *trans*-bent ( $54^\circ$ ).

Another very interesting disilene, bicyclo[1.1.0]tetrasil-1(3)-ene **4** (as a silicon analogue of non-existing bicyclo[1.1.0]but-1(3)-ene) containing a formal double bond between the bridgehead silicones in an inverted tetrahedral configuration, was recently

Scheme 1

Scheme 2

reported by Iwamoto and coworkers.<sup>26</sup> This compound was prepared by the reductive dechlorination of the  $>\text{Si}(\text{Cl})\text{SiCl}_3$ -precursor with  $\text{KC}_8$  (Scheme 2). The doubly bonded Si nuclei resonated at +217.0 ppm, which value is substantially low-field shifted compared to other known acyclic and cyclic silyl-substituted disilenes. Such exceptional deshielding of the  $\text{sp}^2$ -Si atoms suggests, that in contrast to other disilenes, **4** contains a higher-lying  $s$ -orbital and lower-lying  $\pi^*$ -orbital between the bridgehead Si atoms. The central  $\text{Si}=\text{Si}$  bond in **4** is exceptionally long, 2.4716(11) Å, being much longer than the typical  $\text{Si}=\text{Si}$  bond and even longer than the standard  $\text{Si}-\text{Si}$  single bonds, testifying for a rather unusual nature of this bond. Based on the results of DFT calculations, the authors concluded that this bridgehead  $\text{Si}=\text{Si}$  bond consists of a  $\sigma$ -bond with an inverted tetrahedral geometry and a  $\pi$ -bond.

Schschkewitz group reacted their disilyllithium derivative  $\text{Tip}_2\text{Si}=\text{Si}(\text{Tip})\text{Li}$  (Tip = 2,4,6- $\text{Pr}_3\text{-C}_6\text{H}_2$ ) with aryl halides and dihalides to prepare a range of novel (tetraaryl)disilenes  $\text{Tip}_2\text{Si}=\text{Si}(\text{Tip})\text{Ar}$  (Ar = 2,4,6-(MeO)<sub>3</sub>-C<sub>6</sub>H<sub>2</sub>; 2,4,6-Me<sub>3</sub>-C<sub>6</sub>H<sub>2</sub>; 2,3,5,6-Me<sub>4</sub>-C<sub>6</sub>H<sub>2</sub>; naphthalen-2-yl; anthracen-9-yl) and conjugated bisdisilenes  $\text{Tip}_2\text{Si}=\text{Si}(\text{Tip})\text{-[LU]-Si}(\text{Tip})=\text{SiTip}_2$  [LU (linking unit) = -C<sub>6</sub>H<sub>4</sub>-C<sub>6</sub>H<sub>4</sub>-; -C<sub>6</sub>H<sub>4</sub>-C≡C-C<sub>6</sub>H<sub>4</sub>-; 2,6-naphthalene; 9,10-anthracene].<sup>27</sup> As is characteristic for aryl disilenes, all these compounds exhibited moderately deshielded silicon nuclei [ $\delta = 52.7\text{--}71.5$  ppm], short  $\text{Si}=\text{Si}$  bonds [ $r_{\text{Si}=\text{Si}} = 2.1424(7)\text{--}2.1622(6)$  Å], nearly planar geometry around the  $\text{sp}^2$ -Si atoms [ $\Sigma = 357.4\text{--}360.0^\circ$ ], and unremarkable *trans*-bending [ $\theta = 0.0\text{--}15.3^\circ$ ] and twisting [ $\tau = 0.5\text{--}11.4^\circ$ ] along the  $\text{Si}=\text{Si}$  bond. The photophysical and computational data provide evidence for the extended  $p$ -conjugation through the entire backbone of these disilenes. Accordingly, tetrasiladienes  $\text{Tip}_2\text{Si}=\text{Si}(\text{Tip})\text{-[LU]-Si}(\text{Tip})=\text{SiTip}_2$  exhibited room temperature-fluorescence in the solid state and in a hexane solution. Moreover, anthryl-bridged tetrasiladiene represents a first example of a room temperature near infrared-emissive  $\text{Si}=\text{Si}$  derivatives.

Tamao and Matsuo group synthesized a series of disilenes  $\text{EindSi}(\text{Ar})=\text{Si}(\text{Ar})\text{Eind}$  (Ar = 1-naphthyl, phenyl, 1-pyrenyl, thiofen-2-yl, 2,2'-bithiophene-5-yl) stabilized by the very bulky (Eind)-group (Eind = 1,1,3,3,5,5,7,7-octaethyl-*s*-hydrindacen-4-yl) and prepared by a standard reductive dehalogenation of the dibromide precursors  $\text{Eind}(\text{Ar})\text{SiBr}_2$  with lithium naphthalenide.<sup>28</sup> All disilenes uniformly exhibited *trans*-configuration of substituents, with the only exception of 1-pyrenyl-substituted disilene, in which an attractive  $p$ - $p$  interaction between the pyrenyl groups was considered as the factor determining the stereochemistry of the reaction. Novel disilenes were characterized by unremarkably deshielded silicon atoms [ $\delta = 51.5\text{--}63.4$  ppm], short  $\text{Si}=\text{Si}$  bonds [ $r_{\text{Si}=\text{Si}} = 2.1584(9)\text{--}2.1718(6)$  Å], essentially planar geometry of the  $\text{Si}=\text{Si}$  bond with some *trans*-bending [ $\theta = 0.6\text{--}19.1^\circ$ ] and quite negligible twisting [ $\tau = 0.0\text{--}2.8^\circ$ ]. Most of these disilenes exhibited room-temperature intramolecular charge-transfer (ICT) fluorescence, both in the solid state and in solution, caused by the extended  $p$ -conjugation between the  $\text{Si}=\text{Si}$  bonds and aromatic  $\pi$ -electron systems.

An interesting tetraphospha-substituted disilene  $(\text{Mes}_2\text{P})_2\text{Si}=\text{Si}(\text{PMes}_2)_2$  was recently synthesized by Izod and coworkers by the reaction of  $\text{SiBr}_4$  with 4 eqv. of  $\text{Mes}_2\text{PLi}$ .<sup>29</sup> The <sup>29</sup>Si NMR (CP MAS) chemical shift was observed at +111.7 ppm, that is in the typical range for disilenes. The  $\text{Si}=\text{Si}$  bond of 2.1901(12) Å is also normal for disilenes, although *trans*-bending was unusually high for disilenes ( $\theta = 40.6^\circ$ ).

Other examples of the recently reported disilenes include those in which  $\text{Si}=\text{Si}$  bond is incorporated into the cyclic or polycyclic framework.<sup>30</sup> Thus, in **5** the skeletal  $\text{Si}=\text{Si}$  bond is a part of the cyclopentasilane-fused hexasilabenzvalene, the central core of which represents a valence isomer of elusive hexasilabenzene (Scheme 3). The  $\text{sp}^2$ -Si atoms in **5** are strongly deshielded ( $\delta = 187.3$  ppm), the length of the  $\text{Si}=\text{Si}$  bond is normal for the double bond ( $r_{\text{Si}=\text{Si}} = 2.212(2)$  Å). Because of its highly rigid fused cyclic skeleton, **5** exhibited strongly *trans*-bent and highly twisted  $\text{Si}=\text{Si}$  bond:  $\theta = 36.5/42.5^\circ$  and  $\tau = 16.2^\circ$ , respectively.<sup>30a</sup>

Scheme 3

In  $^1\Delta$ -1,2,3,4-trisilagermetene **6**, prepared by the ring expansion reaction of 1-disilagermirene with  $\text{Cl}_2\text{Si-IPr}$  complex (IPr = 1,3-bis(2,6-diisopropylphenyl)-2*H*-imidazol-2-ylidene), both doubly bonded Si atoms were found in the region typical for the four-membered ring cyclic disilenes, +168.0 and +176.9 ppm (Scheme 4).<sup>30b</sup> The  $\text{GeSi}_3$ -ring in **6** is folded ( $24.2^\circ$ ), and the  $\text{Si}=\text{Si}$  bond of 2.199(9) Å conforms to the standards for the double bonds.

Scheme 4

The tetralkyldisilene **7** with exceptionally bulky triptycenylyl substituents was also recently reported (Scheme 5).<sup>30c</sup> Reflecting extraordinary high steric hindrances around the double bond, **7** exhibited a (*Z*)-configuration, elongated  $\text{Si}=\text{Si}$  bond [ $r_{\text{Si}=\text{Si}} = 2.223(1)$  Å], pyramidalization at  $\text{sp}^2$ -Si atoms ( $\Sigma = 351^\circ$ ), and rather important twisting about the  $\text{Si}=\text{Si}$  bond ( $\tau = 34^\circ$ ). The doubly bonded Si atoms resonated in low-field at +115.6 ppm.

Some disilenes, although isolated and spectroscopically characterized, were lacking X-ray structural determination. They include cyclopentasilene,<sup>31</sup> tetrasilyldisilene  $(\text{Me}_3\text{Si})_2\text{Si}=\text{Si}(\text{SiMe}_3)\text{Si}^t\text{Bu}_3$  existing in equilibrium with the isomeric bis(silyl)silylene

Scheme 5

$(\text{Me}_3\text{Si})_3(^t\text{Bu}_3\text{Si})\text{Si}$ <sup>32</sup>; bis(boryl)disilene (boryl)PhSi=SiPh(boryl) (boryl = *cyclo*[−BN(Ar)CH=CHN(Ar)−]).<sup>33</sup>

In recently reported diimino(disilyl)disilene  $[(\text{Me}_3\text{Si})_3\text{Si}(\text{NHI})\text{Si}=\text{Si}(\text{NHI})[\text{Si}(\text{SiMe}_3)_3]$  (NHI = *N*-heterocyclic imine)<sup>34</sup> and diamino(diaryl)disilene featuring intramolecular coordination of imino-groups on  $\text{sp}^2$ -Si atoms,<sup>35</sup> the silicon-silicon interatomic distances are very long (2.3124(7) Å)<sup>34</sup> or exceptionally long (2.623(1) Å).<sup>35</sup> Accordingly, classification of such compounds as disilenes is somewhat debatable, as they can be alternatively (and even better) viewed as very weak donor-acceptor adducts of two silylenes (rather than the true disilenes).

#### 1.03.3.2.1.1.2 Digermenes >Ge=Ge<

The first stable digermenes [tetra(alkyl)digermenes] were prepared and structurally characterized by Lappert and coworkers in 1976.<sup>36</sup> Since 2013, several remarkable examples of isolable digermenes were synthesized by different synthetic approaches. Thus, Scheschkewitz group prepared their digermene **8** by dimerization of the cyclic germylene generated from its NHC complex (Scheme 6).<sup>37</sup> The  $\text{Ge}=\text{Ge}$  bond in **8** of 2.2944(4) Å is typical for such double bonds, and as is expected for the heavy Group 14 element derivatives, both Ge atoms are strongly pyramidalized ( $\Sigma = 334.5^\circ$ ) and substituents are *trans*-bent ( $\theta = 37.7^\circ$ ). In solution,  $\text{Ge}=\text{Ge}$  double bond retained its structural integrity.

Scheme 6

In 2018, the same group reported an interesting example of the first isolable digermene  $\text{Tip}_2\text{Ge}=\text{Ge}(\text{Tip})\text{Li}$  prepared by the simple reduction of  $\text{Tip}_2\text{GeCl}_2$  precursor with metallic lithium.<sup>38a</sup> The Ge=Ge bond is typical for digermenes [ $r_{\text{Ge}=\text{Ge}} = 2.284(6)$  Å], being also unremarkably *trans*-bent ( $\theta = 7.1/12.8^\circ$ ) and twisted ( $\tau = 19.9^\circ$ ). This digermene is synthetically useful and can be functionalized at the anionic Ge center, thus giving access to novel digermenes  $\text{Tip}_2\text{Ge}=\text{Ge}(\text{Tip})\text{R}$  (R=SiMe<sub>3</sub>, SiPhMe<sub>2</sub>, SiPh<sub>3</sub>, SiMe<sub>2</sub>Cl, SiMePhCl, SiPh<sub>2</sub>Cl), and even the first persistent acyldigermenes  $\text{Tip}_2\text{Ge}=\text{Ge}(\text{Tip})[\text{C}(\text{O})\text{R}]$  (R = <sup>t</sup>Bu, 2-methylbutan-2-yl, 1-adamantyl) are accessible via this synthetic route.<sup>38</sup>

Utilizing highly effective (Eind)-substituent, the groups of Matsuo and Sasamori prepared 1,2-dihalodigermenes  $\text{Eind}(\text{X})\text{Ge}=\text{Ge}(\text{X})\text{Eind}$  (X=Cl, Br) by the reaction of germylene  $\text{Eind}_2\text{Ge}$ : with  $\text{GeX}_2$ -dioxane complex.<sup>39</sup> As is typical for digermenes featuring electronegative substituents, dihalodigermenes exhibited strongly *trans*-bent ( $\theta = 43.3$  and  $44.3^\circ$ ) and pyramidal configuration ( $\Sigma = 337.1$  and  $335.9^\circ$ ) at the  $\text{sp}^2$ -Ge atoms. The Ge=Ge bonds are rather long [ $r_{\text{Ge}=\text{Ge}} = 2.4145(3)$  and  $2.4119(5)$  Å] indicative of the weak bonding between the Ge atoms, which was further substantiated by the observation of ready dissociation of the Ge=Ge bond. Thus, in solution dihalodigermenes  $\text{Eind}(\text{X})\text{Ge}=\text{Ge}(\text{X})\text{Eind}$  exist as halogermynes  $\text{Eind}(\text{X})\text{Ge}$ .

Another approach to stable digermenes was demonstrated by Sasamori, Tokitoh and coworkers, who reacted their stable digermene  $\text{BbtGe}\equiv\text{GeBbt}$  (Bbt = 2,6-[(Me<sub>3</sub>Si)<sub>2</sub>CH]<sub>2</sub>-4-[(Me<sub>3</sub>Si)<sub>3</sub>C]-C<sub>6</sub>H<sub>2</sub>) (see Section 1.03.3.1) with ethylene.<sup>40</sup> The corresponding [2 + 2] cycloadduct, 1,2-digermacyclobutene featuring endocyclic Ge=Ge double bond stabilized by the bulky Bbt substituents, revealed folded four-membered ring, *trans*-bent geometry of substituents at the Ge=Ge bond ( $\theta = 39.5$  and  $39.7^\circ$ ), and notably long Ge=Ge bond [ $r_{\text{Ge}=\text{Ge}} = 2.4132(5)$  Å], similar to the one described in the above paragraph. Stretching and weakness of the Ge=Ge bond was attributed to the ring strain and *trans*-bending effects.

Unusual digermenes in which endocyclic Ge=Ge units bridge polycyclic scaffolds were reported by Marschner group.<sup>41</sup> Thus, reaction of 1,3-dipotassiotsilane with  $\text{GeBr}_2$ -dioxane and  $\text{PEt}_3$  unexpectedly produced bicyclic digermene **9**, whereas analogous reaction of 1,4-dipotassiocyclohexasilane with  $\text{GeBr}_2$ -dioxane and  $\text{PEt}_3$  gave tetracyclic digermene **10** (Scheme 7). Both digermenes

**Scheme 7**

**9** and **10** showed similar structural characteristics typical for the cyclic digermenes, namely, shortened Ge=Ge bonds ( $r_{\text{Ge}=\text{Ge}} = 2.2663(9)$  and  $2.2896(6)$  Å), negligible *trans*-bending ( $\theta = 2.5$  and  $2.1/8.3^\circ$ ), and small twisting ( $\tau = 16.2$  and  $5.2^\circ$ ). According to CV measurements, digermene **9** revealed two reversible reduction waves corresponding to formation of anion-radical and dianion, respectively, whereas cation-radical formed upon one-electron oxidation of **9** was unstable.

By contrast, both oxidation and reduction of the (tetrasilyl)digermene (<sup>t</sup>Bu<sub>2</sub>MeSi)<sub>2</sub>Ge=Ge(SiMe<sup>t</sup>Bu<sub>2</sub>)<sub>2</sub> were fully reversible in *o*-dichlorobenzene with the potentials  $E_{1/2}(\text{ox}) = 0.38$  V and  $E_{1/2}(\text{red}) = -1.5$  V, respectively.<sup>42</sup> This digermene was prepared by Lee, Sekiguchi and coworkers by the reduction of the (<sup>t</sup>Bu<sub>2</sub>MeSi)<sub>2</sub>GeCl<sub>2</sub> precursor with potassium graphite.<sup>42</sup> The length of the Ge=Ge bond is normal for digermenes [ $r_{\text{Ge}=\text{Ge}} = 2.346(2)$  Å] and both Ge centers are essentially planar ( $\Sigma = 358.8$  and  $359.2^\circ$ ). Although this digermene does not dissociate into germynes in solution, which was supported by UV measurements, it exhibited extraordinarily long wavelength UV absorption at 618 nm [ $\pi$  (HOMO)- $\pi^*$  (LUMO) transition]. This fact, along with

the exceptionally great twisting about the Ge=Ge double bond ( $\tau = 52.8^\circ$ ), provides experimental evidence for the remarkably reduced  $4p_\pi(\text{Ge})-4p_\pi(\text{Ge})$  orbital overlap resulting in the partial breaking of the Ge–Ge  $\pi$ -bond, and accordingly causing very important contribution of biradical character to the Ge=Ge bond.

Reacting their NHC-coordinated chlorogermylene with either  $\text{Na}\{\text{B}[3,5-(\text{CF}_3)_2-\text{C}_6\text{H}_3]_4\}$  or  $\text{Li}\{\text{Al}[\text{OC}(\text{CF}_3)_3]_4\}$ , Aldridge and coworkers prepared dicationic species **11**, which can be viewed as a digermene featuring cationic imidazolium substituents (Scheme 8).<sup>43</sup> The length of the Ge=Ge bond in **11** is consistent with its formulation as a double bond [ $r_{\text{Ge}=\text{Ge}} = 2.300(2) \text{ \AA}$ ], and Ge atoms are only insignificantly pyramidalized ( $\Sigma = 353.1$  and  $353.6^\circ$ ). Replacing NHC-substituents on Ge atoms in **11** with  $\text{Me}_4\text{-NHC}$ , and

Scheme 8

boryl substituents with  $[2,6\text{-Mes}_2\text{-C}_6\text{H}_3]$  ( $\text{Mes} = 2,4,6\text{-Me}_3\text{-C}_6\text{H}_2$ ), the same authors synthesized another dicationic digermene featuring slightly longer Ge=Ge distance of  $2.380(1) \text{ \AA}$ .<sup>44</sup>

The exciting possibility of the digermene metathesis, as the germanium version of alkene metathesis, was very recently demonstrated by Scheschkewitz group.<sup>45</sup> They heated unsymmetrically substituted digermene  $\text{Tip}_2\text{Ge}=\text{Ge}(\text{Tip})[\text{SiR}_2\text{Dma}]$  ( $\text{R} = \text{Me}, \text{Ph}$ ;  $\text{Dma} = 2\text{-}N,N\text{-dimethylanilino}$  group) to afford a mixture of  $\text{Tip}_2\text{Ge}=\text{GeTip}_2$  and *trans*- $[\text{DmaR}_2\text{Si}](\text{Tip})\text{Ge}=\text{Ge}(\text{Tip})[\text{SiR}_2\text{Dma}]$  ( $\text{Ge}=\text{Ge}$  for  $\text{R} = \text{Me}$ :  $r_{\text{Ge}=\text{Ge}} = 2.2576(5) \text{ \AA}$ ,  $\theta = 21.5^\circ$ ,  $\tau = 0^\circ$ ). Most importantly, this approach was successfully applied towards the development of ADMET (Acyclic Diene METathesis) of digermenes. Thus, thermolysis (benzene,  $60^\circ\text{C}$ , 48 h) of a diene featuring terminal digermene units connected by a *p*-phenylene bridge,  $\text{Tip}_2\text{Ge}=\text{Ge}(\text{Tip})\text{-SiMe}_2\text{-1,4-[2,5-(Me}_2\text{N)}_2\text{-C}_6\text{H}_2]\text{-SiMe}_2\text{-Ge}(\text{Tip})=\text{GeTip}_2$  ( $\text{Ge}=\text{Ge}$ :  $r_{\text{Ge}=\text{Ge}} = 2.3038(4) \text{ \AA}$ ,  $\theta = 24.9/31.9^\circ$ ,  $\tau = 18.0^\circ$ ), yielded the corresponding ADMET-polyene  $\text{Tip}_2\text{Ge}=\{\text{Ge}(\text{Tip})\text{-SiMe}_2\text{-1,4-[2,5-(Me}_2\text{N)}_2\text{-C}_6\text{H}_2]\text{-SiMe}_2\text{-Ge}(\text{Tip})=\}_n\text{-GeTip}_2$  with the number-average degree of polymerization = 23, mass-average degree of polymerization = 45, and dispersity index = 1.95.

### 1.03.3.2.1.1.3 Distannenes $>\text{Sn}=\text{Sn}<$

The first stable distannenes [tetra(alkyl)distannenes] were synthesized and structurally characterized by Lappert group in the same year 1976, as isostructural digermenes.<sup>3,36b</sup> After 2013, several interesting distannenes were synthesized and structurally characterized. Thus, Wesemann reported a range of distannenes **12–14** in which the  $\text{Sn}=\text{Sn}$  double bond is incorporated into the polycyclic aromatic skeleton.<sup>46</sup> They were uniformly prepared by a straightforward procedure, namely, reaction of bulky aryl(chloro)stannylenes  $\text{Ar}(\text{Cl})\text{Sn}$ : ( $\text{Ar} = 2,6\text{-Mes}_2\text{-C}_6\text{H}_3$ ) and  $\text{Ar}'(\text{Cl})\text{Sn}$ : ( $\text{Ar}' = 2,6\text{-Tip}_2\text{-C}_6\text{H}_3$ ) with dilithium arene-diides (Scheme 9). Spectral and structural features of distannenes **12** and **13/14** are distinctly different,  $\text{Sn}=\text{Sn}$ :  $\delta(^{119}\text{Sn}) = 862$  and  $396/412$  ppm,  $r_{\text{Sn}=\text{Sn}} = 3.0009(7)$  and  $2.7299(3)/2.7688(2) \text{ \AA}$ ,  $\theta = 45/59$  and  $55/(46/49)^\circ$ , respectively. However, the longest UV-absorptions (HOMO-LUMO transition) were very similar for all distannenes **12–14**, appearing near 600 nm. Applying this synthetic route,

Scheme 9

Scheme 10

the same authors prepared also distannene, in which the Sn=Sn bond is bridged by an acenaphthene unit and the substituents at the Sn atoms are 2,6-Mes<sub>2</sub>-C<sub>6</sub>H<sub>3</sub> groups.<sup>47</sup> Similar to distannenes 13 and 14, the new compound featured the following characteristics for its Sn=Sn double bond:  $\delta(^{119}\text{Sn}) = 375$  ppm,  $r_{\text{Sn}=\text{Sn}} = 2.7838(2)$  Å,  $\theta = 43/65^\circ$ , and  $\tau = 65^\circ$ .

A very interesting example of the distannene-stannylene equilibrium was recently reported by Wesemann and coworkers.<sup>48</sup> They simply reacted 1,1'-dilithioferrocene with either Ar(Cl)Sn: (Ar = 2,6-Mes<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>) or Ar'(Cl)Sn: (Ar' = 2,6-Tip<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>) (Scheme 10). Despite the similarity of the starting stannylenes, the outcome of the reaction strongly depends on the steric bulk of aryl substituent at tin. Thus, with bulkier Ar' group, there was an equilibrium between the bis(stannylene) 15A and distannene 15B structures, with the former being favored in the solid state and in solution at high temperatures and the latter being favored in solution at low temperatures ( $-80^\circ\text{C}$ ) (Scheme 10). By contrast, when smaller aryl group Ar was applied, the corresponding distannene derivative 16B was by far predominant structure both in the solid state and in solution, and its chemical shift  $d(^{119}\text{Sn})$  of 449 ppm did not change significantly in the temperature range from  $-80^\circ\text{C}$  [ $\delta(^{119}\text{Sn}) = 437$  ppm] to  $100^\circ\text{C}$  [ $\delta(^{119}\text{Sn}) = 468$  ppm] which implies retaining of the structural integrity of the Sn=Sn bond in solution at these temperatures (Scheme 8). Accordingly, no evidences for the existence of the monomeric stannylenes 16A were found in both solution and in the solid. The reduced bulkiness of the aryl group (Ar vs. Ar') in 16 was attributed to the higher stability of the Sn=Sn bond in 16B (in contrast to 15B).

A bicyclic distannene, as a tin analogue of the above-described bicyclic digermene 9 (see Scheme 7),<sup>41</sup> was prepared by Marschner and coworkers by the reaction of 1,3-dipotassiotrisilane with SnCl<sub>2</sub> in the presence of appropriate Lewis base (PMe<sub>3</sub>, PEt<sub>3</sub>, Me<sub>4</sub>-NHC).<sup>49</sup> This distannene revealed <sup>119</sup>Sn NMR chemical shift of 730.7 ppm that was low-field shifted compared with other silylated distannenes, although its longest UV-absorption of 558 nm was blue-shifted compared to the silylated distannenes. The Sn=Sn double bond is short, measuring only 2.6162(11) Å, being also *trans*-bent ( $\theta = 36.0^\circ$ ) and twisted ( $\tau = 22.6^\circ$ ). Likewise, reacting dipotassium salt of oligosilylanylene-1,5-diide with SnCl<sub>2</sub>·dioxane Marschner group isolated another bicyclic distannene 17 featuring two seven-membered rings fused by the bridging Sn=Sn unit (Scheme 11).<sup>50</sup> 17 showed typical for distannenes <sup>119</sup>Sn NMR chemical shift of 636.9 ppm, and rather long Sn=Sn double bond of 2.7409(9) Å which has a *trans*-bent ( $\theta = 31.1^\circ$ ) and twisted ( $\tau = 17.0/81.6^\circ$ , for two seven-membered rings which have very different conformations) geometry.

Scheme 11

Several stable distannenes were reported by Power and coworkers. Thus, reaction of the Sn(II) hydrides  $[\text{Ar}^{i\text{Pr}_6}\text{Sn}(m\text{-H})]_2$  and  $[\text{Ar}^{i\text{Pr}_4}\text{Sn}(m\text{-H})]_2$  [ $\text{Ar}^{i\text{Pr}_6} = 2,6\text{-}(2,4,6\text{-}^i\text{Pr}_3\text{-C}_6\text{H}_2)\text{-C}_6\text{H}_3$ ,  $\text{Ar}^{i\text{Pr}_4} = 2,6\text{-}(2,6\text{-}^i\text{Pr}_2\text{-C}_6\text{H}_3)\text{-C}_6\text{H}_3$ ] with ethylene and (*tert*-butyl)ethylene afforded distannenes  $\text{Ar}^{i\text{Pr}_6}(\text{CH}_3\text{CH}_2)\text{Sn}=\text{Sn}(\text{CH}_2\text{CH}_3)\text{Ar}^{i\text{Pr}_6}$  18 and  $\text{Ar}^{i\text{Pr}_4}(\text{tBuCH}_2\text{CH}_2)\text{Sn}=\text{Sn}(\text{CH}_2\text{CH}_2\text{tBu})\text{Ar}^{i\text{Pr}_4}$  19.<sup>51</sup> In solution, distannene 18 dissociates into monomeric stannylenes as was evidenced by the low-field <sup>119</sup>Sn NMR resonance observed at 1908 ppm (at 330 K), whereas on cooling down to 250 K two signals were found at 289 and 2915 ppm indicating existence of both distannene and stannylene species in solution. Likewise, distannene 19 also is in solution equilibrium with the corresponding stannylstannylenes: <sup>119</sup>Sn NMR resonances observed at 320 and 1875 ppm. Both 18 and 19 displayed similar structural characteristics:  $r_{\text{Sn}=\text{Sn}} = 2.732(5)$  and  $2.714(2)$  Å,  $\theta = 57.4$  and  $55.5^\circ$ , and  $\Sigma = 335.2$  and  $339.3^\circ$ . Reaction of diarylstannylene  $(\text{Ar}^{i\text{Pr}_4})_2\text{Sn}$ : [ $\text{Ar}^{i\text{Pr}_4} = 2,6\text{-}(2,6\text{-}^i\text{Pr}_2\text{-C}_6\text{H}_3)\text{-C}_6\text{H}_3$ ] with toluene, *m*-xylene and mesitylene at  $80^\circ\text{C}$  provided distannenes  $\text{Ar}^{i\text{Pr}_4}(\text{ArCH}_2)\text{Sn}=\text{Sn}(\text{CH}_2\text{Ar})\text{Ar}^{i\text{Pr}_4}$  (Ar = C<sub>6</sub>H<sub>5</sub>, 3-Me-C<sub>6</sub>H<sub>4</sub>, 3,5-Me<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>) as C–H metathesis products.<sup>52</sup> All of them dissociated in solution into the monomeric aryl(alkyl)stannylenes  $\text{Ar}^{i\text{Pr}_4}(\text{ArCH}_2)\text{Sn}$ ; which was evidenced by their low-field <sup>119</sup>Sn NMR resonances found at 1660–1671 ppm (typical for stannylenes). In the solid-state, however, these compounds exist as the dimeric

distannenes, as can be clearly seen from their crystallographic data:  $r_{\text{Sn}=\text{Sn}} = 2.782(3)$  and  $2.787(1)$  Å,  $\theta = 41.2$  and  $43.0^\circ$ , and  $\Sigma = 330.7$  and  $338.3^\circ$ .

#### 1.03.3.2.1.1.4 Diplumbenes $>\text{Pb}=\text{Pb}<$

The first stable diplumbene  $\text{Tip}_2\text{Pb}=\text{PbTip}_2$ , that exists in an equilibrium with the corresponding plumbylene  $\text{Tip}_2\text{Pb}$ ·, was reported much later than its lighter analogues (disilene, digermene, and distannene), in 1999, by Weidenbruch and coworkers.<sup>53</sup> Since 2013, little progress has been made into the field of stable diplumbenes with only one report from Power group.<sup>54</sup> They reacted diarylplumbylene  $(\text{Ar}^{\text{Me6}})_2\text{Pb}$ :  $[\text{Ar}^{\text{Me6}} = 2,6-(2,4,6-\text{Me}_3-\text{C}_6\text{H}_2)-\text{C}_6\text{H}_3]$  with  $\text{Me}_3\text{M}$  ( $\text{M}=\text{Al}, \text{Ga}$ ) to afford aryl(methyl) diplumbene  $\text{Ar}^{\text{Me6}}(\text{Me})\text{Pb}=\text{Pb}(\text{Me})\text{Ar}^{\text{Me6}}$  as the result of substituents scrambling reaction, and thus representing a new synthetic route to diplumbenes. Given its remarkably low-field shifted  $^{207}\text{Pb}$  NMR resonance of 8248 ppm, the solution structure of this compound was attributed to that of the monomeric plumbylene  $\text{Ar}^{\text{Me6}}(\text{Me})\text{Pb}$ ·. The  $\text{Pb}=\text{Pb}$  double bond is rather long [ $3.2866(5)$  Å] and Pb centers are notably pyramidalized [ $\Sigma = 325.3^\circ$ ].

#### 1.03.3.2.1.2 Heteronuclear derivatives, $\text{E}=\text{E}'$ ( $\text{E}=\text{Si}, \text{Ge}, \text{Sn}, \text{Pb}$ )

##### 1.03.3.2.1.2.1 $>\text{E}=\text{E}'$ ( $\text{E} = \text{Group 14 element}, \text{E}' = \text{Group 13 element}$ )

The transient sila- and germaborenes  $[(^t\text{Bu}_2\text{MeSi})_2\text{E}=\text{B}-\text{Mes}]$  ( $\text{E}=\text{Si}, \text{Ge}$ ) were reported in 2005 by Sekiguchi and coworkers,<sup>55a</sup> and the first stable silaborene  $[(^t\text{Bu}_2\text{MeSi})_2\text{E}=\text{B}-\text{R}]$  ( $\text{R} = 2,2,6,6\text{-tetramethylpiperidino}$ ) was prepared in 2006 by the same group.<sup>55a</sup>

As the latest advances in the field, one can mention a new silaborene-chloride adduct **20** reported by Iwamoto and coworkers,<sup>56</sup> and the first germaborenes independently prepared and very recently reported by Kinjo (germaborene **21** with an exocyclic  $\text{Ge}=\text{B}$  bond)<sup>57</sup> and Wesemann (germaborene **22** with an endocyclic  $\text{Ge}=\text{B}$  bond) research groups<sup>58</sup> (Scheme 12). In all cases, formation of the  $>\text{E}=\text{B}-$  ( $\text{E}=\text{Si}, \text{Ge}$ ) bond was uniformly accomplished by the reduction of the corresponding dihalo-precursors  $>\text{E}(\text{X})-\text{B}(\text{X})-\text{X}$  ( $\text{X}=\text{Cl}, \text{Br}$ ) with either potassium graphite or magnesium.

Scheme 12

The silaborene-chloride adduct **20** (Scheme 12) features the following spectral and structural parameters of the  $\text{Si}=\text{B}$  fragment:  $r = 1.859(2)$  Å (short bond),  $\Sigma = 359.3(\text{Si})$  and  $360.0(\text{B})^\circ$  (planar geometry around these atoms),  $\delta[^{29}\text{Si}(\text{sp}^2)] = 56.8$  and  $\delta[^{11}\text{B}(\text{sp}^2)] = 38.0$  ppm. Experimental and computational data strongly suggest that **20** is best represented as an anionic silaborene [ $>\text{Si}=\text{B}^-<$ ] rather than (boryl)silyl anion resonance form [ $>\text{Si}^--\text{B}<$ ].

The first two stable germaborenes were published face-to-face in the same issue of *Angew. Chem. Int. Ed.* in 2020. Kinjo germaborene **21** exhibits low-field  $^{11}\text{B}$  NMR chemical shift of the doubly bonded B atom at 94.5 ppm, rather short  $\text{Ge}=\text{B}$  bond ( $r = 1.911(7)$  Å), pyramidal geometry at the Ge center ( $340^\circ$ ), and remarkably bent  $\text{Ge}-\text{B}-\text{N}$  fragment (bond angle =  $158.6^\circ$ ) (Scheme 12).<sup>57</sup> The  $\text{Ge}=\text{B}$  double bond character in **21** was further supported by computations,  $\text{WBI}_{\text{Ge}=\text{B}} = 1.67$ . Likewise, Wesemann germaborenes **22a** ( $\text{X}=\text{Cl}$ ) and **22b** ( $\text{X}=\text{Br}$ ) were characterized by even shorter  $\text{Ge}=\text{B}$  bonds [ $r = 1.886(2)$  Å (for **22a**) and  $1.895(3)$  Å (for **22b**)], trigonal-planar geometry around the  $\text{sp}^2$ -atoms [ $\Sigma = 359.6/359.6^\circ$  (Ge, for **22a/22b**) and  $359.8/360.0^\circ$  (B, for **22a/22b**)], chemical shifts  $\delta(^{11}\text{B})$  as a doublet at 17.3 ppm ( $^1J_{\text{P,B}} = 132$  Hz) (for **22a**) and 10.3 ppm ( $^1J_{\text{P,B}} = 134$  Hz) (for **22b**) (Scheme 12).<sup>58a</sup> The NBO calculations revealed 1.94e-occupancy for the  $\text{Ge}-\text{B}$  s-bond and 1.67e-occupancy for the  $\text{Ge}-\text{B}$  p-bond, which leads to the  $\text{WBI}_{\text{Ge}=\text{B}}$  of 1.51. According to the Natural Resonance Theory (NRT) calculations, the dominating Lewis structure (NRT weights = 29.0% for **22a** and 28.7% for **22b**) is the one with the  $\text{Ge}=\text{B}$  double bond, thus implying formulation of **22a,b** as the germaborenes. Applying the same synthetic strategy, Wesemann group prepared also Ph-substituted germaborene **22c** ( $\text{X}=\text{Ph}$ ) (Scheme 12).<sup>58b</sup> The spectral and structural features of the novel germaborene **22c** are similar to those of the previously reported **22a,b**, namely:  $\delta(^{11}\text{B}) = 16.2$  ppm,  $r_{\text{Ge}=\text{B}} = 1.899(3)$  Å.

As for the doubly bonded “group 13” = “group 14” combinations, including group 13 elements heavier than boron, we can mention only 1,3-disila-2-gallata- and -indataallenic anionic derivatives  $[(^t\text{Bu}_2\text{MeSi})_2\text{Si}-\text{E}-\text{Si}(\text{SiMe}^t\text{Bu}_2)_2]^- [\text{Li}(\text{thf})_4]^+$  (E=Ga, In), featuring the first structurally authenticated Si=Ga and Si=In double bonds, respectively, and reported by Sekiguchi and coworkers in 2004.<sup>59a</sup> This was then followed by the synthesis of the 1,3-digerma-2-gallata- and -indataallenic anionic derivatives  $[(^t\text{Bu}_2\text{MeSi})_2\text{Ge}-\text{E}-\text{Ge}(\text{SiMe}^t\text{Bu}_2)_2]^- [\text{Li}(\text{thf})_4]^+$  (E=Ga, In) as the first compounds with Ge=Ga and Ge=In double bonds, synthesized by the same authors.<sup>59b</sup> Since then, no progress has been made to this field.

### 1.03.3.2.1.2.2 $>\text{E}=\text{E}'<$ (E, E' = Group 14 element)

The stable silenes (or silaethenes)  $>\text{Si}=\text{C}<$  are the first isolable doubly bonded derivatives involving Si atoms. The very first stable silene was prepared by Brook<sup>6</sup> and coworkers and reported in the same year 1981 when West reported his disilene  $>\text{Si}=\text{Si}<$ .<sup>7</sup>

Since 2013, several remarkable isolable silenes were reported in the literature, and their structures and peculiar features are discussed below (Scheme 13). Thus, Scheschkewitz and coworkers synthesized a series of silenes with both *endo*- and *exocyclic* Si=C bonds. They include tricyclic Brook-type bis(silene) **23** [ $r_{\text{Si}=\text{C}} = 1.771(4) \text{ \AA}$ ],<sup>60</sup> Brook-type four-membered ring cyclic silenes **24a-c** [ $r_{\text{Si}=\text{C}} = 1.761(3) \text{ \AA}$  (for **24a**) and  $r_{\text{Si}=\text{C}} = 1.7638(16) \text{ \AA}$  (for **24c**)],<sup>60</sup> silaaziridines **25a-c** with exocyclic Si=C double bonds [ $r_{\text{Si}=\text{C}} = 1.735(2) \text{ \AA}$  (for **25a**)],<sup>61</sup> and *para*-phenylene bridged bis(silaaziridine) **26** [ $r_{\text{Si}=\text{C}} = 1.726(4)/1.743(4) \text{ \AA}$ ].<sup>61</sup> Apeloig recently reported reversible (*Z* → *E/E* → *Z*)-isomerization of his silene **27**, originally obtained as a 95:5 (*E/Z*)-mixture, which in the absence of crystallographic data was characterized by the low-field resonances of the doubly bonded Si and C atoms at 72.3 ppm and 181.1 ppm, respectively. Activation barrier for the (*Z* → *E*)-isomerization was determined from kinetic measurements as  $24.4 \pm 1.2 \text{ kcal/mol}$ , and that for the reverse (*E* → *Z*)-isomerization as  $24.3 \pm 1.2 \text{ kcal/mol}$ .<sup>62</sup> Iwamoto and coworkers also synthesized silaaziridine derivative **28** with an exocyclic Si=C double bond [ $r_{\text{Si}=\text{C}} = 1.730(5) \text{ \AA}$ ].<sup>63</sup> Reacting their iminosilylsilanone with Wittig reagents, Inoue and coworkers succeeded in the olefination of the former to produce a series of (*Z*)- or (*E*)-silenes **29** as the products of sila-Wittig reaction.<sup>64</sup> Kato, Bacciredo and their coworkers prepared a tricyclic silene **30** with an exocyclic Si=C double bond, featuring rather peculiar substitution pattern at the doubly bonded Si center which leads to a partial delocalization of the double bond [ $r_{\text{Si}=\text{C}} = 1.725(2) \text{ \AA}$ ].<sup>65</sup> Haas, Stueger and coworkers reported Brook-type silenes **31** and **32** featuring *endocyclic* and *exocyclic* Si=C double bonds, respectively [ $r_{\text{Si}=\text{C}} = 1.786(2) \text{ \AA}$  (for **31**) and  $r_{\text{Si}=\text{C}} = 1.767(2) \text{ \AA}$  (for **32**)].<sup>66</sup>

Scheme 13

The first stable germenes were independently reported in 1987 by the research groups of Berndt<sup>67</sup> and Escudié.<sup>68</sup> Since 2013, only one novel example was reported, namely, the first isolable Brook-type germene **33** with an exocyclic Ge=C double bond, synthesized by Haas and coworkers.<sup>69</sup> This *O*-silylated germene **33** was readily available by the reaction of the stable germenolate (almost exclusively exhibiting the character of acyl germyl anion with a negatively charged Ge atom, a Ge–C single bond, and a C=O double bond) with Me<sub>3</sub>SiCl (Scheme 14). Germene **33** shows a characteristic low-field signal for its doubly bonded C atom at 210.0 ppm, and a Ge=C distance of 1.835(2) Å that is typical for germenes. Nevertheless, the Ge=C double bond in **33** is notably

Scheme 14

distorted, as was evidenced by its twisting and pyramidalization at the Ge center ( $\Sigma = 351.7^\circ$ ).

As for the doubly bonded derivatives  $>E = E' <$  consisting of the different heavier group 14 elements, several combinations are possible. Of them, the lightest one is silagermene  $>Si = Ge <$ . The first metastable silagermene Me<sub>2</sub>Si=GeMe<sub>2</sub> was reported by Baines and coworkers in 1992, however this compound was stable only at low temperatures (below  $-70^\circ\text{C}$ ) isomerizing at higher temperatures into the mesityl(silyl)germylene Mes(Mes<sub>3</sub>Si)Ge<sup>70</sup>. The first room temperature-stable silagermene, 2-disilagermirene with an endocyclic Si=Ge double bond, was synthesized and isolated by Lee, Sekiguchi and coworkers in 2000.<sup>71</sup> This was followed by the subsequent report from the same authors on the first structurally authenticated silagermene, namely, 1,2-disila-3-germacyclopenta-2,4-diene with an endocyclic Si=Ge–C=C diene fragment.<sup>72</sup>

Since 2013, only one remarkable example of isolable silagermenes, potassium silagermenide **34** as a Si=Ge analogue of a vinyl anion, was reported by Scheschkewitz and coworkers and prepared by the reduction of the germylene precursor with KC<sub>8</sub> (Scheme 15).<sup>73</sup> The resonance of the doubly bonded Si atom in **34** was found in the characteristic low-field at 142.9 ppm (in C<sub>6</sub>D<sub>6</sub>) and 138.5 ppm (in THF-*d*<sub>8</sub>). In **34**, the Si=Ge double bond length of 2.2590(3) Å well agrees with those earlier reported for other silagermenes, and the GeSi<sub>2</sub>C-four-membered ring is nearly planar with a folding of  $1.9^\circ$ . Based on its X-ray and UV data, a significant extent of  $\pi$ -conjugation between the Si=Ge and C=N double bonds in **34** was assumed, and accordingly the  $\pi_{Si=Ge}\pi^*_{C=N}$  interaction energy was calculated as 23.6 kcal/mol. Silagermenide **34** can be functionalized at the anionic Ge atom to form neutral Ge-substituted silagermenes **35a,b** (Scheme 15). Both (silyl)silagermene **35a** (R=SiPh<sub>3</sub>) and (phosphanyl)silagermene **35b** [R=P(N<sup>*i*</sup>Pr<sub>2</sub>)<sub>2</sub>] revealed low-field shifted <sup>29</sup>Si NMR resonances [singlet at 136.6 ppm and doublet at 104.5 ppm ( $^2J_{Si-P} = 9.8$  Hz), respectively], and short Si=Ge double bonds [2.2020(2) and 2.2252(4) Å, respectively]. In addition, in **35a**, the GeSi<sub>2</sub>C-four-membered ring is almost planar with a quite negligible folding of  $0.2^\circ$ , and the Ge atom is slightly pyramidalized ( $\Sigma = 357.3^\circ$ ).

Among the hybrid  $>Sn = E <$  systems comprising sp<sup>2</sup>-Sn atom, the stanene  $>Sn = C <$  was prepared and structurally characterized for the first time by Berndt and coworkers in 1987.<sup>74</sup> The first, and still the only known, silastannene, namely (tBu<sub>2</sub>MeSi)<sub>2</sub>Si=SnTip<sub>2</sub>, was synthesized in 2002 by Sekiguchi and coworkers.<sup>75</sup> The first germastannenes Tip<sub>2</sub>Ge=SnTip<sub>2</sub> and (tBu<sub>2</sub>MeSi)<sub>2</sub>Ge=SnTip<sub>2</sub>/[(*E*)-(tBu<sub>2</sub>MeSi)(Tip)Ge=Sn(Tip)(SiMe'Bu<sub>2</sub>)] were independently reported in 2003 by the research groups of Weidenbruch<sup>76</sup> and Sekiguchi,<sup>77</sup> respectively. The only known cyclic germastannene, disilagermastannetene, incorporating an endocyclic Ge=Sn double bond into the four-membered ring skeleton, was reported by Lee, Sekiguchi and coworkers in 2004.<sup>78</sup> Since then,

Scheme 15

Scheme 16

there were no new entries to the field of  $>Sn=E<$  type compounds. Heteronuclear derivatives containing Pb atoms,  $>Pb=E<$  ( $E=C-Sn$ ), still remain unknown.

### 1.03.3.2.1.2.3 $>E=E'-$ ( $E = \text{group 14 element}$ , $E' = \text{group 15 element}$ )

The very first silaimines, that is compounds featuring  $Si=N$  double bond, were independently reported by Klingebiel ( ${}^i\text{Pr}_2\text{Si}=\text{N}-\text{Mes}^*$ ,  $\text{Mes}^* = 2,4,6\text{-}^t\text{Bu}_3\text{-C}_6\text{H}_2$ )<sup>79</sup> and Wiberg ( ${}^t\text{Bu}_2\text{Si}=\text{N}-\text{Si}^t\text{Bu}_3$ )<sup>80</sup> groups in 1986. Since 2013, three stable silaimines **36–38** were synthesized by the research groups of Lips,<sup>81</sup> Jones,<sup>82</sup> and Inoue<sup>83</sup> (Scheme 16). Lips silaimine **36** features rather peculiar  $Si_4$ -ring structure with an exocyclic  $Si=N$  double bond [ $\delta(^{29}\text{Si}) = -65.7$  ppm,  $r_{\text{SiN}} = 1.625(2)$  Å], Jones silaimine **37** manifests a  $Si=N$  double bond where Si is a part of the *N*-heterocyclic silylene unit and N has an *N*-heterocyclic boryl substituent [ $\delta(^{29}\text{Si}) = -48.0$  ppm,  $r_{\text{SiN}} = 1.502(2)$  Å], and Inoue silaimine **38** features *N*-heterocyclic imino (NHI) and silyloxy-substituents at Si and silyl substituent at N [ $\delta(^{29}\text{Si}) = -50.1$  ppm,  $r_{\text{SiN}} = 1.573(2)$  Å].

Phosphasilenes  $>Si=P-$  are known since 1987 when Bickelhaupt and coworkers reported synthesis of the first room temperature stable phosphasilenes,<sup>84</sup> followed by the first crystallographic authentication of the  $Si=P$  bond by Niecke in 1993.<sup>85</sup> Since 2013, two stable phosphasilenes **39–40** were reported by Scheschkewitz and coworkers.<sup>86</sup> Phosphasilene  $\text{Tip}_2(\text{Me}_2\text{N})\text{Si}-(\text{Tip})\text{Si}=\text{P}-\text{NMe}_2$  **39** was isolated as *E/Z*-isomeric mixture (*E/Z* = 95/5) upon the reaction of disilenide  $\text{Tip}_2\text{Si}=\text{Si}(\text{Tip})\text{Li}$  with  $\text{ClP}(\text{NMe}_2)_2$  followed by the isomerization of the initially formed  $\text{Tip}_2\text{Si}=\text{Si}(\text{Tip})[\text{P}(\text{NMe}_2)_2]$  to **39**.<sup>86a</sup> Phosphasilene **39** revealed characteristic low-field resonances for both P and Si atoms [for *E*-isomer:  $\delta(^{31}\text{P}) = 344.8$  ppm ( ${}^1J_{\text{P-Si}} = 186.5$  Hz) and  $\delta(^{29}\text{Si}) = 103.5$  ppm ( ${}^1J_{\text{SiP}} = 186.5$  Hz)] and typical for phosphasilenes short  $Si=P$  double bond [ $r_{\text{SiP}} = 2.1187(7)$  Å]. Calculation of the Mulliken charges in the model **39** clearly shows “inverse” polarization of the  $Si^{\delta-}=\text{P}^{\delta+}$  bond:  $-0.095$  (Si) and  $+0.169$  (P). Reacting **39** with  $\text{MesLi}$ , Scheschkewitz and coworkers prepared *P*-mesityl-phosphasilene  $\text{Tip}_2(\text{Me}_2\text{N})\text{Si}-(\text{Tip})\text{Si}=\text{P}-\text{Mes}$  **40** isolated as *E/Z*-mixture (*E/Z* = 84/16).<sup>86b</sup> **40** exhibited the following spectral and structural features (for *E*-isomer):  $\delta(^{31}\text{P}) = 234.4$  ppm ( ${}^1J_{\text{P-Si}} = 193.9$  Hz) and  $\delta(^{29}\text{Si}) = 193.9$  ppm,  $r_{\text{SiP}} = 2.0923(6)$  Å.

Arsasilenes  $>Si=As-$  were first synthesized<sup>87a</sup> and subsequently structurally characterized<sup>87b</sup> by Driess and coworkers in 1992 and 1995, respectively. Driess recently additionally contributed to the field by the synthesis of arsinidene-silylene complex **42** which alternatively can be viewed as arsilene (Scheme 17).<sup>88</sup> **42** showed the following physico-chemical characteristics:  $\delta(^{29}\text{Si}) = 65.9$  ppm,  $r_{\text{Si-As}} = 2.1661(6)$  Å, and its  $Si=As$  bond order was calculated as 1.72 (Wiberg bond index, WBI) and 1.66 (Mayer bond order, MBO).

Scheme 17

Scheme 18

Lee, Sekiguchi and coworkers applied a different synthetic approach towards stable  $>\text{Si}=\text{E}-$  (E = heavy group 15 element) derivatives, namely, by the reaction of their isolable 1,1-dilithiosilane derivative (<sup>t</sup>Bu<sub>2</sub>MeSi)<sub>2</sub>SiLi<sub>2</sub> with the group 15 halides Mes\*EX<sub>2</sub> (E=P, As, Sb) (Scheme 18).<sup>89</sup> In such way, a series of isostructural phosphasilene (<sup>t</sup>Bu<sub>2</sub>MeSi)<sub>2</sub>Si=P–Mes\* **43**, arsilene (<sup>t</sup>Bu<sub>2</sub>MeSi)<sub>2</sub>Si=As–Mes\* **44**, and stibasilene (<sup>t</sup>Bu<sub>2</sub>MeSi)<sub>2</sub>Si=Sb–Mes\* **45** were prepared and fully characterized, with the latter being the first compound featuring a Si=Sb bond and as such representing the “heaviest” double bond between the silicon and pnictogen element. All these compounds feature particular *push-pull* substitution pattern (electron donors on silicon and electron acceptor on pnictogen), resulting in the relaxation of the natural polarity (and thus high reactivity) of the Si<sup>δ+</sup>=E<sup>δ-</sup> (E=P–Sb) bond, caused by the differing electronegativity of silicon and pnictogen atoms. All these compounds uniformly displayed low-field shifted resonances of the doubly bonded Si atoms:  $\delta(^{29}\text{Si}) = 201.2$  ppm (for **43**, doublet with  $^1J_{\text{Si-P}} = 171.3$  Hz;  $\delta(^{31}\text{P}) = 389.3$  ppm), 214.1 ppm (for **44**), and 215.2 ppm (for **45**). In all **43–45**, the Si=E (E=P–Sb) bond is: (a) remarkably shortened [ $r_{\text{Si-P}} = 2.1114(7)$  Å (**43**),  $r_{\text{Si-As}} = 2.2164(14)$  Å (**44**),  $r_{\text{Si-Sb}} = 2.4146(7)$  Å (**45**)]; (b) practically undistorted [**43–45**:  $\Sigma_{\text{Si}} = 360.0^\circ$  and  $\tau = 0.6\text{--}2.3^\circ$ ]. The Si=E **43–45** is best described as covalent (rather than ionic or donor-acceptor) interactions, given notably low values for the natural ionicity of their double bonds  $I_{\text{Si}=\text{E}}$ : 0.14 ( $\sigma$ -bond) and 0.18 ( $\pi$ -bond) (for phosphasilene **43**), 0.11 ( $\sigma$ -bond) and 0.14 ( $\pi$ -bond) (for arsilene **44**), 0.07 ( $\sigma$ -bond) and 0.06 ( $\pi$ -bond) (for stibasilene **45**). The frontier molecular orbitals of **43–45** are uniformly represented by the Si=E  $\pi$ -orbital (HOMO) and  $\pi^*$ -orbital (LUMO), respectively, whereas HOMO-1 is represented by the pnictogen lone pair  $n$ -orbital.

Among the germanium derivatives of the type  $>\text{Ge}=\text{E}-$  (E = group 15 element), the first reported were germainines  $>\text{Ge}=\text{N}-$ , synthesized and structurally characterized in 1991 by Meller and coworkers.<sup>90</sup> Their heavier congeners, phosphagermenes  $>\text{Ge}=\text{P}-$ , were prepared for the first time<sup>91a</sup> and crystallographically identified<sup>91b</sup> by Escudié and coworkers. No other representatives of the stable germainines and phosphagermenes were reported within the last decade.

The “heaviest” currently known doubly bonded combination between the germanium and group 15 element is arsagermene  $>\text{Ge}=\text{As}-$ . The first (and still the only) example of such compounds, arsagermene (<sup>t</sup>Bu<sub>2</sub>MeSi)<sub>2</sub>Ge=As–Mes\* **46** was recently synthesized by Lee, Sekiguchi and coworkers.<sup>92</sup> **46** was readily available by the simple coupling of 1,1-dilithiogermane derivative (<sup>t</sup>Bu<sub>2</sub>MeSi)<sub>2</sub>GeLi<sub>2</sub> and Mes\*AsF<sub>2</sub>. The Ge=As double bond in **46** is quite short [ $r_{\text{Ge=As}} = 2.2727(8)$  Å] and practically planar, like the C=C bond in alkenes ( $\Sigma_{\text{Ge}} = 360.0^\circ$  and  $\tau_{\text{Ge=As}} = 0.1^\circ$ ). The calculated Ge=As bond order is 1.79 (WBI) and 1.93 [Natural Resonance Theory (NRT) bond order, with 92% NRT covalent character]. The Natural Population Analysis (NPA) charges for the Ge and As atoms are rather similar (+0.08 and +0.14, respectively), indicative of the very small polarization of the double bond in accord with the relaxation of the natural polarity of the Ge<sup>δ+</sup>=As<sup>δ-</sup> bond caused by the peculiar *push-pull* substitution pattern in **46**. As is typical for such compounds, the HOMO and LUMO are represented by the bonding ( $\pi$ ) and antibonding ( $\pi^*$ ) orbitals of the Ge=As double bond, whereas HOMO-1 is the lone pair orbital at the As atom.

For the doubly bonded combinations of tin of the type  $>\text{Sn}=\text{E}-$  (E = group 15 element), only stannaimines  $>\text{Sn}=\text{N}-$  and phosphastannenes  $>\text{Sn}=\text{P}-$  are synthesized, with no examples of the isolable arsastannenes  $>\text{Sn}=\text{As}-$  and stibastannenes  $>\text{Sn}=\text{Sb}-$  known to date. The first stannaimine [(Me<sub>3</sub>Si)<sub>2</sub>N]<sub>2</sub>Sn=N–Ar (Ar = 2,6-<sup>i</sup>Pr<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>) was prepared by Meller group,<sup>93</sup> whereas the first phosphastannene [(Me<sub>3</sub>Si)<sub>2</sub>CH]<sub>2</sub>Sn=P–Mes\* (Mes\* = 2,4,6-<sup>t</sup>Bu<sub>3</sub>-C<sub>6</sub>H<sub>2</sub>) was synthesized by Escudié and coworkers.<sup>94</sup> The latest report on the isolable phosphastannene **47**, with rather unusual substituents at both Sn and P atoms, came from Inoue group.<sup>95</sup> **47** was prepared by the reaction of the precursor (stannylene-phosphinidene NHC complex) with B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> in the attempted removal of NHC ligand from P atom (Scheme 19). Due to its specific zwitterionic *push-pull* structure, **47** displayed significantly shielded P and Sn nuclei:  $\delta(^{31}\text{P}) = -93.1$  ppm [ $^1J(^{31}\text{P}-^{117/119}\text{Sn}) = 2919/3046$  Hz] and  $\delta(^{119}\text{Sn}) =$

Scheme 19

152.2 ppm [ $^1J(^{119}\text{Sn}-^{31}\text{P}) = 3069$  Hz]. The Sn=P double bond in **47** is planar ( $\Sigma_{\text{Sn}} = 359.9^\circ$ ) and very short [2.3450(10) Å], being the shortest tin-phosphorus interatomic distance reported to date.

#### 1.03.3.2.1.2.4 $>E=E'$ ( $E = \text{group 14 element}$ , $E' = \text{group 16 element}$ )

Among all the title compounds, with no doubts, by far most difficult-to-realize and accordingly most synthetically challenging are silanones  $>\text{Si}=\text{O}$ , which are sometimes coined as “Kipping’s dream”. Before 2013, there were several reports from Driess group on the isolable organosilicon compounds featuring Si–O bond possessing some extent of the doubly bonded character, including silanoic ester<sup>96a</sup> and NHC-supported silanone.<sup>96b</sup>

Since 2013, several research groups closely approached the “silanone problem,” uniformly applying the reaction of the corresponding stable silylenes with  $\text{N}_2\text{O}$  as the synthetic method of choice. In 2015, Iwamoto group reported persistent cyclic dialkylsilanone **48** [ $\delta(^{29}\text{Si}_{\text{Si}=\text{O}}) = 128.7$  ppm] that was stable in toluene solution below  $-80^\circ\text{C}$  rapidly isomerizing at higher temperatures (by the 1,3-migration of  $\text{Me}_3\text{Si}$ -group from C to O) to the corresponding siloxysilene (Scheme 20).<sup>97</sup>

In 2017, Kato and coworkers described several compounds which were classified as cyclic silanones, namely, (amino)(phosphonium bora-ylide)silanone **49**<sup>98a</sup> and its carbon analogue, (amino)(phosphonium-ylide)silanone **50**<sup>98b</sup> (the latter is stable below  $-50^\circ\text{C}$ ) (Scheme 20). However, based on their peculiar spectral and structural features [ $\delta(^{29}\text{Si}) = 71.3/38.4$  ppm and  $r_{\text{Si}-\text{O}} = 1.5432(12)/1.533(1)$  Å, for **49/50**, respectively], and also on the computational data, the electronic situation in these compounds is best described by the canonical structures **49A** and **50A** (but not by the silanone resonance form),<sup>98</sup> manifesting Si=B or Si=C double bonds and bora-ylide or phosphonium-ylide moiety, respectively (Scheme 20). Later, the same authors reported also a room temperature stable *N*-hetero-Rh<sup>1</sup>-metallic silanone **51**, featuring their traditional tricyclic framework incorporating Rh atom [ $\delta(^{29}\text{Si}) = 81.5$  ppm and  $r_{\text{Si}-\text{O}} = 1.540(3)$  Å] (Scheme 20).<sup>99</sup>

Filippou and coworkers also contributed to the stable silanone field by preparation of acyclic ionic metallasilanone **52** featuring  $\text{Cr}(\text{Cp}^*)(\text{CO})_3$ -fragment ( $\text{Cp}^* = \text{C}_5\text{Me}_5$ ) as a rather unusual substituent at the  $\text{sp}^2$ -Si atom [ $\delta(^{29}\text{Si}) = 169.6$  ppm,  $r_{\text{Si}-\text{O}} = 1.526(3)$  Å,  $\Sigma_{\text{Si}} = 359.9^\circ$ ] (Scheme 20).<sup>100</sup> According to DFT calculations, the Si–O bond in **52** is expectedly strongly polarized towards oxygen [85% NBO density on O atom; NPA charges: +1.77 (Si) and –1.21 (O); ionic contribution (1.30) is remarkably greater than the covalent contribution (0.56)], thus indicating a crucial contribution of the zwitterionic resonance structure  $\text{Si}^+-\text{O}^-$ .

Inoue and his group made a step closer to the authentic silanone by synthesis of their stable neutral acyclic silanone **53**, featuring  $p$ -donating *N*-heterocyclic imino (NHI) and  $s$ -donating silyl group as substituents at the  $\text{sp}^2$ -Si atom [for  $\text{R}=\text{tBu}$ :  $\delta(^{29}\text{Si}) = 28.8$  ppm,  $r_{\text{Si}-\text{O}} = 1.537(3)$  Å,  $\Sigma_{\text{Si}} = 360.0^\circ$ ] (Scheme 20).<sup>101</sup> Computational analysis of **53** clearly indicated the critical

Scheme 20

importance of the  $p$ -donation from the NHI ligand to electron-deficient Si atom (seen in HOMO-10) and also  $\sigma$ -donation from the silyl substituent to the  $sp^2$ -Si ( $\sigma_{\text{Si-C}} \rightarrow \pi^*_{\text{Si=O}}$ , seen in LUMO+4) for the overall stabilization of otherwise highly reactive Si=O bond. On the other hand, such stabilization occurs at the expense of diminishing Si=O double bond character, as an alternative zwitterionic resonance form (with the Si=N double bond, positive charge on N and negative charge on O atom) begins to operate and contribute to the overall structure of 53.

The long-term quest for the stable silanones was finally culminated in the recent publication from Iwamoto group on the synthesis of their neutral cyclic dialkylsilanone 54 containing electronically unperturbed Si=O double bond (Scheme 20).<sup>102</sup> 54 does not feature coordination of any internal or external Lewis base or Lewis acid to its Si=O double bond, thus lacking any electronically perturbing  $\sigma$ - and  $\pi$ -conjugation stabilizing effects and therefore representing the first example of a genuine silanone. For its Si=O double bond, silanone 54 exhibited low-field <sup>29</sup>Si NMR chemical shift of 90.0 ppm, planar geometry around the  $sp^2$ -Si atom ( $\Sigma_{\text{Si}} = 360.0^\circ$ ), and exceptionally short Si=O bond distance of 1.518(2) Å, the shortest one among all  $>\text{Si=O}$  derivatives reported to date. DFT calculations of 54 revealed the HOMO-13, LUMO, and HOMO-8 as  $\pi_{\text{Si=O}}$ ,  $\pi^*_{\text{Si=O}}$ , and the lone pair orbital of the  $\text{O}_{\text{Si=O}}$  atom. NPA analysis clearly disclosed the presence of a highly polar  $\text{Si}^{\delta+}=\text{O}^{\delta-}$  double bond in 54: +2.08 (Si) and -1.10 (O), that implies intrinsically high electrophilicity of the silicon center and high nucleophilicity of the O center of the genuine Si=O double bond.

The synthesis of the heavier analogues of silanones, that is (diaryl)silanethiones  $>\text{Si=S}$ , (diaryl)silaneselones  $>\text{Si=Se}$ , and (diaryl)silanetellones  $>\text{Si=Te}$ , was pioneered by Tokitoh group.<sup>103</sup> These achievements were followed by the report from Iwamoto, Kira and coworkers on the synthesis of the stable dialkylsilane-thione, -selone, and -tellone.<sup>104</sup> No further progress has been made to this field since 2013.

The first generation of the stabilized germanone  $>\text{Ge=O}$  complexes, [NHC  $\rightarrow$  germanone]<sup>105a</sup> and [DMAP  $\rightarrow$  germanone]<sup>105b</sup> (DMAP = 4-dimethylaminopyridine), was reported by Driess and coworkers. The major breakthrough to the field of stable germanones was achieved when Matsuo, Tamao and coworkers published their seminal paper on the isolable dirarylgermanone (Eind)<sub>2</sub>Ge=O (Eind = 1,1,3,3,5,5,7,7-octaethyl-*s*-hydrindacen-4-yl) 55 (Scheme 21).<sup>106</sup>

Germanone 55 is stabilized only kinetically by means of its exceptionally bulky Eind substituents, lacking highly perturbing thermodynamic stabilization effects (both inductive and resonance) and thus representing a closest approach towards the genuine germanone. In 55, the Ge=O double bond features a trigonal-planar  $sp^2$ -Ge atom ( $\Sigma_{\text{Ge}} = 359.8^\circ$ ) and a very short Ge=O bond [ $r_{\text{Ge=O}} = 1.6468(5)$  Å]. As is typical for heavy ketones, the Ge=O bond in 55 is highly polarized [NPA charges: +1.798 (Ge) and -1.046 (O); WBI = 1.252], thus being better represented by a charge-separated, *germylene oxide*, resonance form (Eind)<sub>2</sub>Ge<sup>+</sup>-O<sup>-</sup> 55A, rather than the charge-free, *germanone*, resonance extreme (Eind)<sub>2</sub>Ge=O 55.

The first representatives of the heavier analogues of germanones, namely, germanethiones  $>\text{Ge=S}$ , germaneselones  $>\text{Ge=Se}$ , and germanetellones  $>\text{Ge=Te}$ , were all prepared by Tokitoh and coworkers: (Tbt(*Tip*))Ge=S (Tbt = 2,4,6-[(Me<sub>3</sub>Si)<sub>2</sub>CH]<sub>3</sub>-C<sub>6</sub>H<sub>2</sub>), Tbt(*Tip*))Ge=Se, and Tbt(*Tip*))Ge=Te/Tbt(*Dis*))Ge=Te [Dis=CH(SiMe<sub>3</sub>)<sub>2</sub>].<sup>107</sup> Since 2013, there is only one new report on the stable germanethione, namely, (Eind)<sub>2</sub>Ge=S 56, synthesized by Matsuo and coworkers by the reaction of stable germylene (Eind)<sub>2</sub>Ge: with elemental sulfur S<sub>8</sub>, similar to the above case of germanone 55 (see Scheme 21).<sup>108</sup> Although germanethione 56 revealed structural features similar to those of the previously reported germanone 55<sup>106</sup> [trigonal-planar Ge ( $\Sigma_{\text{Ge}} = 360.0^\circ$ ) and short Ge=S bond ( $r_{\text{Ge=S}} = 2.0569(9)$  Å)], its Ge<sup>δ+</sup>=S<sup>δ-</sup> bond is remarkably less polarized compared to the Ge<sup>+</sup>-O<sup>-</sup> bond in germanone 55. This was evidenced by the accompanying computations on the Ge=S bond in 56, NPA charges: +1.336 (Ge) and -0.613 (S) [*vs.* +1.821 (Ge) and -1.039 (O), in 55], WBI = 1.635 [*vs.* 1.263, in 55].

As for the tin containing derivatives of the type  $>\text{Sn=E}$  (E=O-Te), the lightest and most challenging stannanones  $>\text{Sn=O}$  are still unknown. The first stannanthione Tbt(*Tip*))Sn=S,<sup>109a</sup> stannaneselone Tbt(*Ar*))Sn=Se [Ar = 2,6-(2-<sup>i</sup>Pr-C<sub>6</sub>H<sub>4</sub>)<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>],<sup>109b,c</sup> and stannanetellone Bbt(*Ar'*))Sn=Te [Bbt = 2,6-[(Me<sub>3</sub>Si)<sub>2</sub>CH]<sub>2</sub>-4-[(Me<sub>3</sub>Si)<sub>3</sub>C]-C<sub>6</sub>H<sub>2</sub>, Ar' = 2,6-(2,4-<sup>i</sup>Pr<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>)<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>],<sup>109d</sup> were all prepared and characterized by Tokitoh and coworkers. No new compounds of the type  $>\text{Sn=E}$  (E=S-Te) were reported since 2013.

Scheme 21

### 1.03.3.2.2 1,3-Diene analogues

#### 1.03.3.2.2.1 Homonuclear derivatives $>E=E-E=E<$ ( $E=Si, Ge$ )

The very first isolable tetrasilabuta-1,3-diene  $Tip_2Si=(Tip)Si-Si(Tip)=SiTip_2$ <sup>110a</sup> and tetragermabuta-1,3-diene  $Tip_2Ge=(Tip)Ge-Ge(Tip)=GeTip_2$ <sup>110b</sup> were reported by Weidenbruch in 1997 and 2000, respectively, uniformly prepared by the metalation of the disilene  $Tip_2Si=SiTip_2$  or digermene  $Tip_2Ge=GeTip_2$  with metallic lithium followed by the reaction of intermediate vinyl-lithium derivative  $[Tip_2E=E(Tip)Li]$  ( $E=Si, Ge$ ) with MesBr.

Since 2013, a couple of other 1,3-diene derivatives were reported. The first one, tetragermacyclobutadiene  $Ge_4[EMind]_4$  ( $EMind = 1,1,7,7$ -tetraethyl-3,3,5,5-tetramethyl-*s*-hydrindacen-4-yl) **57** (as the germanium version of the previously reported remarkable tetrasilacyclobutadiene), was synthesized by Matsuo and coworkers.<sup>111</sup> **57** was prepared by the reduction of dichloro-digermene  $[EMind](Cl)Ge=Ge(Cl)[EMind]$  with lithium naphthalenide (Scheme 22). In contrast to its silicon congener, **57** was quite thermally stable, and exhibited UV-absorptions at 458 ( $\epsilon = 15000$ ), 510 ( $\epsilon = 7400$ ), and 836 nm ( $\epsilon = 150$ ). The  $Ge_4$ -ring has a planar (sum of the internal bond angles =  $360^\circ$ ) rhombic shape with  $Ge-Ge$  bonds = 2.430 Å (av.). Two germanium atoms exhibit  $sp^2$ -like trigonal-planar geometry ( $\Sigma = 360.0^\circ$ ), whereas the other two feature  $sp^3$ -like pyramidal configuration ( $\Sigma = 334.0$  and  $327.7^\circ$ , respectively) with the *trans*-bending of substituents at these germanium atoms ( $\theta = 37.9$  and  $40.6^\circ$ , respectively). Computational studies disclosed the  $Ge-Ge$  bond orders in **57** to be 1.08–1.09 (Wiberg bond indices, WBI). The natural population analysis (NPA) clearly showed charge separation within the  $Ge_4$ -ring: two Ge atoms are only slightly positively charged (+0.146 and +0.151), whereas the other two Ge atoms are strongly positively charged (+0.602 and +0.573). All these data suggest the important contribution of the alternately charge-separated resonance form  $cyclo-[Ge^+-Ge^--Ge^+-Ge^-]$ , as was also the case of the previously reported tetrasilacyclobutadiene. Overall, the polar Jahn-Teller distortion causes relaxation of the intrinsic  $4p$ -electron antiaromaticity of the tetragermacyclobutadiene **57** to form a planar rhombic-shaped charge-separated singlet structure, which has nonaromatic character (according to NICS calculations).

The second example, tetrasilabuta-1,3-diene **58**, was reported by Iwamoto group, being prepared starting from  $Me_3Si(Tip)Si=Si(Tip)SiMe_3$  by its reduction with <sup>t</sup>BuOK generating potassium disilene  $[Me_3Si(Tip)Si=Si(Tip)-K]$ , which was subsequently oxidized with 1,2-dibromoethane to form finally **58**,  $Me_3Si(Tip)Si=Si(Tip)-Si(Tip)=Si(Tip)SiMe_3$ .<sup>112</sup> Both *antiperiplanar* (**58<sub>ap</sub>**) and *synclinal* (**58<sub>sc</sub>**) conformations of **58** were separately crystallized as the purple and red crystals, respectively. The  $Si=Si$  bonds in **58<sub>ap</sub>** (2.1599(12)–2.1755(12) Å, for three independent molecules) are marginally longer than those of **58<sub>sc</sub>** (2.1592(7)/2.1617(7) Å), all being within the range of the typical  $Si=Si$  double bonds. The central  $Si-Si$  bond between the two  $Si=Si$  double bonds is notably shorter in **58<sub>ap</sub>** compared to that of **58<sub>sc</sub>**: 2.2801(12)–2.2862(11) Å and 2.2902(2) Å. These structural features provide evidence for the better *p*-conjugation between the two  $Si=Si$  double bonds in **58<sub>ap</sub>**. Such conclusion was further supported by the observation of the longest wavelength absorption of **58** (537 nm) that was remarkably red-shifted compared to that of the starting disilene  $Me_3Si(Tip)Si=Si(Tip)SiMe_3$  (394 nm). Interestingly, **58** can be functionalized at its terminal Si atoms by the metalation with <sup>t</sup>BuOK to generate intermediate tetrasilabutadienyl anion salt  $[Me_3Si(Tip)Si=Si(Tip)-Si(Tip)=Si(Tip)-K]$  (stable below  $-50^\circ C$ ), which readily reacts with  $Et_3SiCl$  at  $-50^\circ C$  forming novel unsymmetrically substituted tetrasiladiene  $Me_3Si(Tip)Si=Si(Tip)-Si(Tip)=Si(Tip)-SiEt_3$ .

#### 1.03.3.2.2.2 Heteronuclear derivatives $>E=E'-E''=E'''<$ ( $E, E', E'', E''' = \text{group 14 element}$ )

The compounds of this type, featuring formally conjugated 1,3-diene moieties  $>E=E'-C=C<$  ( $E, E'=Si, Ge$ ), were first reported by Lee and Sekiguchi in 2000,<sup>113</sup> followed by the report from Power group in 2004.<sup>114</sup> In the first case,<sup>113</sup> the  $>Si=Ge-C=C<$  fragment was incorporated into the cyclopentadiene skeleton in which no noticeable conjugation between the  $Si=Ge$  and  $C=C$  bonds was found, whereas in the second one<sup>114</sup> the  $>Ge=Ge-C=C<$  unit constituted a  $Ge_2C_2$ -cyclobutadiene scaffold.

The structural analogue of the above-described Power digermacyclobutadiene,<sup>114</sup> namely, 1,2-Tbb-3,4-diphenyl-1,2-digermacyclobutadiene ( $Tbb = 4$ -<sup>t</sup>Bu-2,6-[( $Me_3Si$ )<sub>2</sub>CH]<sub>2</sub>-C<sub>6</sub>H<sub>2</sub>) **59**, was recently reported by Sasamori and coworkers, prepared by the [2 + 2] cycloaddition of isolable digermene  $TbbGe=GeTbb$  and diphenylacetylene.<sup>115</sup> **59** featured nearly planar  $Ge_2C_2$ -ring with the endocyclic  $Ge=Ge$  and  $C=C$  double bonds of 2.4160(5) and 1.362(5) Å, respectively [ $Ge-C$  bond length: 2.022(2) Å].

Scheme 22

Two other recently reported examples of the title compounds were of the  $>C=Si-Si=C<$  types. The first one,  $cAAC=Si(Cl)-Si(Cl)=cAAC$  ( $cAAC$ : cyclic alkyl(amino) carbene,  $cyclo-[C-CMe_2-CH_2-CMe_2-N(2,6-^iPr_2-C_6H_3)]$ ) **60**, was synthesized by Roesky and coworkers by the reduction of ( $cAAC$ :  $\rightarrow SiCl_4$ ) complex with  $KC_8$ .<sup>116</sup> The doubly bonded Si atoms in **60** resonated at 25.6 ppm, and both of them featured pyramidal configuration ( $\Sigma = 325.3$  and  $328.0^\circ$ ). The Si=C and Si-Si bond lengths were measured as 1.823(3)/1.826(3) Å and 2.3058(13) Å, the former being elongated compared with the standard Si=C double bonds whereas the latter being shortened compared with the typical Si-Si single bonds. Although such structural peculiarities might be explained by the partial conjugation within the C=Si-Si=C diene system, the authors stated that the conjugation is not effective because C-Si-Si-C unit is not planar but twisted (due to the steric hindrances) which results in the elongation of the C=Si bonds.

By contrast, 2,3-disilabuta-1,3-diene  $Ad=Si(SiMe_2^tBu)-Si(SiMe_2^tBu)=Ad$  ( $Ad = 2$ -adamantylidene) **61**, prepared by Iwamoto and coworkers by the reaction of 1,2-dilithiodisilane ( $^tBuMe_2Si$ )<sub>2</sub>Si(Li)-Si(Li)(SiMe<sub>2</sub><sup>t</sup>Bu)<sub>2</sub> with 2-adamantanone, exhibited significant interaction between the two Si=C units in solution.<sup>117</sup> This was evidenced by the important red-shift of the longest wavelength UV-absorption in **61** of 371 nm, compared with other structurally similar silenes. Likewise, the <sup>29</sup>Si and <sup>13</sup>C NMR resonances of the Si=C unit were found in the region typical for the structurally similar silenes: 41.2 and 197.3 ppm, respectively. The C=Si-Si=C unit adopts a synclinal conformation with the dihedral angle of 76.8°, and the geometries around the doubly bonded Si and C atoms were essentially planar:  $\Sigma = 359.8$  and  $360.0^\circ$ , respectively. The Si=C bond of 1.748(2) Å in **61** is notably shorter than that in Roesky 1,3-diene **60**, whereas the central Si-Si bond of 2.3149(13) Å in **61** is marginally longer than that in **60**.

The reaction of the above-described 1,2-digermacyclobutadiene **59**<sup>115</sup> with  $(Me_2N)_3P=Se$  afforded 2,5-digermaselenophene **62** via the intermediate formation of the "houseen"-type selenadigermirane followed by its valence isomerization to **62**, as reported by Sasamori and coworkers (Scheme 23).<sup>118</sup> Based on the structural data of its cyclic skeleton [ $r_{C-C} = 1.921(3)/1.922(3)$  Å,

Scheme 23

$r_{C-C} = 1.375(4)$  Å,  $\theta_{Tbb} = 7.8^\circ$  (*trans*), nonplanar SeGe<sub>2</sub>C<sub>2</sub> five-membered ring] and computational studies, the structure of **62** is best described as a singlet (digerma)biradicaloid resonance form **62B** whereas classical Lewis structure **62A** is of a minor importance (Scheme 23). Nevertheless, **62** showed some appreciable extent of aromaticity, as its NICS(1) was notably negative ( $-8.0$ ), comparable to that of the parent organic selenophene. The <sup>77</sup>Se NMR resonance of **62** was found in the low-field at 481.8 ppm, thus suggesting that **62** retains its *trans*-pyramidalized structure in solution as well.

### 1.03.3.2.3 Allene analogues

#### 1.03.3.2.3.1 Group 14 element derivatives $>E=E'=E<$ ( $E, E'=C, Si, Ge, Sn$ )

The first compound of this type, namely, tristannaallene ( $^tBu_3Si$ )<sub>2</sub>Sn=Sn=Sn( $Si^tBu_3$ )<sub>2</sub>, was reported by Wiberg and coworkers in 1999.<sup>119</sup> Several years later (in 2003), a milestone trisilaallene  $R_2Si=Si=SiR_2$  was prepared by Kira's group,<sup>120a</sup> followed by the synthesis of its heavier homologues, trigermaallene  $R_2Ge=Ge=GeR_2$  and 1,3-digerma-2-silaallene  $R_2Ge=Si=GeR_2$ , and 2-germa-1,3-disilaallene  $R_2Si=Ge=SiR_2$  (everywhere,  $R_2 = [cyclo-(Si-C(SiMe_3)_2-CH_2-CH_2-C(SiMe_3)_2-)]$ ).<sup>120</sup>

In the last decade, there was only one report on the synthesis of title compounds. In 2017, Sasamori, Tokitoh and coworkers synthesized 1,3-digerma-2-silaallene **64** in which the allenic  $>Ge=Si=Ge<$  moiety is a part of the cyclic system.<sup>121</sup> **64** was prepared by the exhaustive reductive dechlorination of tetrachloro-2,5-digerma-1-silacyclopentane with  $KC_8$  (Scheme 24). The SiGe<sub>2</sub>C<sub>2</sub>-ring in **64** is planar, and the Ge=Si bond lengths of 2.2681(18) and 2.2900(18) Å are typical for the Ge=Si double bonds. However, the <sup>29</sup>Si NMR chemical shift of the allenic Si atom in **64** was found at unusually high-field ( $-16.5$  ppm), thus being exceptionally shielded compared to that of Kira 1,3-digerma-2-silallene (236.6 ppm).<sup>120b</sup> This points to a crucial contribution of the  $[>Ge: \rightarrow Si^0 \leftarrow :Ge<]$  "silylone" resonance form of **64** featuring Si<sup>0</sup> character for its central silicon atom, caused by rather acute Ge-Si-Ge bond angle ( $80.1^\circ$ ) as a result of Ge-Si-Ge unit incorporation into the rigid five-membered ring skeleton. This was

Scheme 24

further backed by computations which showed highly polarized  $\text{Ge}^{d+}\text{-Si}^{d-}$  bonds with clear charge separation (NPA charges):  $-0.27$  (for Si) and  $+0.90/+0.91$  (for Ge), implying a significant s-donation from the germanium atoms to the silicon atom.

Compounds of the type  $>\text{E}=\text{C}=\text{C}<$  ( $\text{E}=\text{Si, Ge}$ ), that is 1-sila- and 1-germaallenes, are known since 1993 when West and coworkers reported the very first 1-silaallene.<sup>122</sup> This was followed by the synthesis of the first stable 1-germaallene by the same research group,<sup>123</sup> and a new 1-silaallene by Pietschnig and coworkers.<sup>124</sup>

As the recent development in the field, one can mention anionic lithium 1-silaallenolate [ ${}^t\text{Bu}_2\text{MeSi}({}^t\text{BuMe}_2\text{Si})\text{C}=\text{C}=\text{Si}(\text{SiMe}{}^t\text{Bu}_2)\text{OLi}$ ] **65** synthesized by Apeloig and coworkers by the reaction of  ${}^t\text{Bu}_2\text{MeSi}({}^t\text{BuMe}_2\text{Si})\text{C}=\text{C}=\text{Si}(\text{SiMe}{}^t\text{Bu}_2)\text{Li}$  with carbon monoxide.<sup>125</sup> As is typical for allenes, the  $\text{Si}-\text{C}-\text{C}$  bond angle of  $175.0^\circ$  only very slightly deviate from the required linearity ( $180^\circ$ ), whereas the  $\text{Si}=\text{C}$  and  $\text{C}=\text{C}$  bond lengths of  $1.711(5)$  and  $1.324(3)$  Å, respectively, are normal for 1-silaallenes. The allenic atoms in **65** resonated in the expected fields, at 50.0 ppm (for  $\text{Si}=\text{C}=\text{C}$ ), 301.7 ppm (for  $\text{Si}=\text{C}=\text{C}$ ), and 160.6 ppm (for  $\text{Si}=\text{C}=\text{C}$ ). Featuring an anionic moiety, **65** can still be functionalized at O atom: thus, reaction of **65** with  $\text{Me}_3\text{SiCl}$  produced a novel 1-silaallene  ${}^t\text{Bu}_2\text{MeSi}({}^t\text{BuMe}_2\text{Si})\text{C}=\text{C}=\text{Si}(\text{SiMe}{}^t\text{Bu}_2)\text{OSiMe}_3$  [NMR chemical shifts ( $\delta$ ): 61.7 ppm ( $\text{Si}=\text{C}=\text{C}$ ), 282.3 ppm ( $\text{Si}=\text{C}=\text{C}$ ), and 165.2 ppm ( $\text{Si}=\text{C}=\text{C}$ )].

#### 1.03.3.2.3.2 Hybrid group 14/group 15 element derivatives $>\text{E}=\text{E}'=\text{E}''-$ ( $\text{E, E}' = \text{group 14 element, E}'' = \text{group 15 element}$ )

Grützmacher and coworkers were the first to report such derivative, stannaketenimine  $\text{R}_2\text{Sn}=\text{C}=\text{NMe}_s$  [ $\text{R} = 2,4,6\text{-}(\text{CF}_3)_3\text{-C}_6\text{H}_2$ ] which exists in equilibrium with the stannylene  $\text{R}_2\text{Sn}$ : and isocyanide:  $\text{C}=\text{NMe}_s$ .<sup>126</sup> The first silaketenimines featuring true  $>\text{Si}=\text{C}=\text{N}-$  allenic character were synthesized by Kira and Iwamoto,<sup>127</sup> and this was followed by the report from Sekiguchi group on the synthesis of bis(silaketenimine).<sup>128</sup>

Unusual silaketenimine anionic derivatives **66** were reported by Cui and coworkers.<sup>129</sup> Both **66a** and **66b** were uniformly prepared from a masked lithiosilylene with isocyanides RNC: ( $\text{R} = 2,6\text{-}{}^i\text{Pr}_2\text{-C}_6\text{H}_3$ , 1-adamantyl) (**Scheme 25**). The allenic atoms resonated at very high-field for silicon nucleus reflecting its negatively-charged nature [ $\delta(^{29}\text{Si}) = -144.0/-162.4$  ppm], and at very low-field for carbon nucleus [ $\delta(^{13}\text{C}) = +235.7/+227.0$  ppm]. The  $\text{Si}=\text{C}$  and  $\text{C}=\text{N}$  bonds in **66a,b** were relatively short and relatively long:  $1.725(4)/1.730(2)$  Å and  $1.285(4)/1.279(3)$  Å, respectively. The  $\text{Si}-\text{C}-\text{N}$  bond angles of  $160.6/157.4^\circ$  in **66a,b** are remarkably smaller than the one required for the classical allenic system ( $180^\circ$ ). Based on the structural and computational data, the authors described their compounds **66a,b** as allenic systems  $\text{B}-\text{Si}=\text{C}=\text{N}-\text{R}$ .

Allenic systems with phosphorus atoms of the type  $>\text{E}=\text{C}=\text{P}-$  ( $\text{E}=\text{Si, Ge, As}$ ) were all prepared by Escudié and coworkers by dehalogenation of the corresponding precursors: phosphasilaallene  $\text{Tip}(\text{Ph})\text{Si}=\text{C}=\text{PMes}^*$  ( $\text{Mes}^* = 2,4,6\text{-}{}^t\text{Bu}_3\text{-C}_6\text{H}_2$ ) stable below  $-30^\circ\text{C}$ ,<sup>130a</sup> phosphagermaallene  $\text{Tip}({}^t\text{Bu})\text{Ge}=\text{C}=\text{PMes}^*$  stable at room temperature,<sup>130b</sup> and arsagermaallene  $\text{Tip}({}^t\text{Bu})\text{Ge}=\text{C}=\text{AsMes}^*$  also stable at room temperature.<sup>130c</sup> Since then and to date, no further progress to the field has been made.

Despite some recent reports on the generation of donor/acceptor-stabilized 1-silaketenes  $>\text{C}=\text{Si}=\text{O}$ ,<sup>131</sup> isolable derivatives of this type, free from the high electronic perturbation caused by the intra/intermolecular donor/acceptor coordination, are still elusive, thus remaining to be the next highly attractive challenge.

#### 1.03.3.2.4 Vinylidene analogues

Vinylidenes  $\text{R}_2\text{C}=\text{C}$ : are the valence isomers of alkynes  $\text{RC}\equiv\text{CR}$  featuring a naked terminal carbon atom (substituents-free) being as such extraordinarily reactive. To stabilize this low-coordinate center, use of external base, such as NHC, is particularly effective, and therefore almost all examples of the isolated heavy group 14 analogues of vinylidenes of the type  $\text{R}_2\text{E}=\text{E}'$ : ( $\text{E, E}' = \text{heavy group 14 elements}$ ), except for the digermavinylidenes, were stabilized in this way by the external NHC-coordination.

The first breakthrough in the field came from the Scheschkewitz group who reported the very first isolable compound of this type, namely, NHC-stabilized silagermenylidene  $\text{Tip}_2\text{Si}=\text{Ge}:(\leftarrow\text{NHC})$  ( $\text{NHC} = 1,3\text{-diisopropyl-4,5-dimethylimidazol-2-ylidene}$ ) **67** prepared by the co-reduction of  $\text{Tip}_2\text{SiCl}_2$  and NHC  $\rightarrow \text{GeCl}_2$  complex with lithium naphthalenide.<sup>132</sup> The  $\text{sp}^2\text{-Si}$  center of **67** is expectedly deshielded [ $\delta(^{29}\text{Si}) = 158.9$  ppm], the  $\text{Si}=\text{Ge}$  bond is short [ $r_{\text{Si}=\text{Ge}} = 2.2521(5)$  Å] well-fitting within the range

Scheme 25

of the typical silagermenes, and the Si atom has planar configuration ( $\Sigma = 359.8^\circ$ ). The Si=Ge bond is nearly undistorted ( $\tau = 3.1^\circ$ ) thus allowing for an effective  $p_\pi-p_\pi$  orbital overlap, and the NHC-ligand coordinates to Ge center in nearly orthogonal manner ( $C_{\text{NHC}}-\text{Ge}-\text{Si}$  bond angle =  $98.9^\circ$ ) to maximize their  $n_{\text{lone pair NHC}}-p_{\text{Ge}}$  orbital interaction. Following their original report, the same group subsequently synthesized another NHC-stabilized silagermenylidene  $\text{Tip}_2\text{ClSi}-(\text{Tip})\text{Si}=\text{Ge}:(\leftarrow \text{NHC})$  (NHC = 1,3-diisopropyl-4,5-dimethylimidazol-2-ylidene) **68**.<sup>133</sup> Being structurally similar to **67**, **68** manifested spectral and structural characteristics that were reminiscent to those of **67**, namely:  $\delta(^{29}\text{Si}) = 162.5$  ppm,  $r_{\text{Si}=\text{Ge}} = 2.2757(10)$  Å,  $C_{\text{NHC}}-\text{Ge}-\text{Si}$  bond angle =  $101.9^\circ$ .

Silicon analogues of **67** and **68**, that is disilavinylidenes were reported by Filippou and coworkers. The first one,  $\text{Tbb}(\text{Br})\text{Si}=\text{Si}:(\leftarrow \text{NHC})$  (NHC = 1,3-bis(2,6-diisopropylphenyl)imidazoline-2-ylidene) **69** was prepared by the reduction of NHC-stabilized bromo(silyl)silylene  $\text{Tbb}(\text{Br}_2)\text{Si}-(\text{Br})\text{Si}:(\leftarrow \text{NHC})$  with  $\text{KC}_8$ .<sup>134</sup> The  $sp^2$ -Si atoms resonated at 34.6 and 86.0 ppm, the disilavinylidene core was almost planar with the sum of the bond angles around the tricoordinate Si atom of  $360.0^\circ$  and the twist angle about the Si=Si bond of  $2.7^\circ$ , and NHC coordinated to the Si=Si bond nearly orthogonally with the  $C_{\text{NHC}}-\text{Si}-\text{Si}$  bond angle =  $97.6^\circ$ . The Si=Si bond in **69** of 2.167(2) Å was very short corroborating the presence of the genuine double bond, which was further supported by the NBO and NRT calculations (Si=Si: WBI = 1.79, NRT bond order = 1.91). The presence of a stereochemically active lone pair (77% s-character) at the naked Si atom was confirmed by the NBO calculations.

Applying this synthetic approach, the same group succeeded also in the synthesis of the NHC-stabilized phosphasilenyldiene  $\text{Mes}^*\text{P}=\text{Si}:(\leftarrow \text{NHC})$  **70** (NHC is the same as the one in the above paragraph) available by the reaction of  $\text{Cl}_2\text{Si}:(\leftarrow \text{NHC})$  with  $\text{LiP}(\text{Mes}^*)\text{SiMe}_3$  ( $\text{Mes}^* = 2,4,6\text{-}t\text{Bu}_3\text{-C}_6\text{H}_2$ ).<sup>135</sup> **70** displayed structural features that are typical for vinylidene systems, namely: short  $r_{\text{Si}=\text{P}}$  bond of 2.1188(7) Å that is typical for phosphasilenes, acute  $C_{\text{NHC}}-\text{Si}-\text{P}$  bond angle of  $92.7^\circ$ , planar Si=P bond with the twist angle of only  $1.9^\circ$ . Spectroscopic data for **70** are also in line with its formulation as phosphasilenyldiene: both Si and P nuclei are strongly deshielded being observed at 267.3 and 402.4 ppm, respectively. The  $^1J(^{29}\text{Si}-^{31}\text{P})$  coupling constant of 170.4 Hz is large, expectedly for the Si=P doubly bonded system, which was further supported by the NBO calculations (WBI for Si-P bond is 1.68).

The latest example of isolable disilavinylidene, compound **71**, was reported by Iwamoto group. **71** was synthesized by the co-reduction of a mixture of their tetrabromodisilane and NHC (NHC = 1,3-di-*tert*-butylimidazol-2-ylidene) with metallic sodium (Scheme 26).<sup>136</sup> The doubly bonded Si atoms resonated at 160.8 and 65.0 ppm, for the tricoordinate silicon and NHC-

Scheme 26

coordinated terminal silicon nuclei, respectively. As is typical for disilavinylidenes, the Si=Si bond in **71** is short [ $r_{\text{Si}=\text{Si}} = 2.1787(8)$  Å], tricoordinate silicon has a planar geometry ( $\Sigma = 359.7^\circ$ ), and Si=Si bond is only slightly twisted ( $\tau = 7.2^\circ$ ). Interestingly, when **71** was treated with  $\text{N}_2\text{O}$  followed by  $\text{B}(\text{C}_6\text{F}_5)_3$ , unique disilaacetolactone **72** was formed in which the Si=O bond is *push-pull* coordinated to NHC (for Si) and  $\text{B}(\text{C}_6\text{F}_5)_3$  (for O) (Scheme 26).<sup>136</sup>

The first digermavinylidene **73** reported by Aldridge group in 2016 is remarkable because it is free from any external NHC-coordination, unlike the case of the above-described NHC-supported silagermenylidenes and disilavinylidenes (*vide supra*).<sup>137</sup>

Digermavinylidene **73** was synthesized by the reaction of the NHC-stabilized boryl(chloro)germylene with K or  $\text{KC}_8$  followed by the oxidation of the intermediate dianionic species by  $[\text{Ph}_3\text{C}][\text{B}(\text{C}_6\text{F}_5)_4]$  (Scheme 27). The Ge=Ge double bond in **73** is practically planar, as the four atoms (two Ge and two B atoms) lie within a single plane. The Ge=Ge distance of 2.312(1) Å is reasonably short to formulate it as a double bond. In the solid state, there are also weak stabilizing interactions between one of the flanking aryl  $\pi$ -systems of each of the boryl substituent and the vacant *in-plane*  $\pi$ -orbital at the one-coordinate Ge atom. The HOMO of **73** is represented by the Ge-Ge  $\pi$ -bond, whereas the HOMO-1 is mostly naked Ge atom lone pair. The longest wavelength UV-absorption in **73** at 460 nm corresponds to a Ge=Ge double bond  $\pi-\pi^*$  electronic transition.

Another digermavinylidene **74** was very recently reported by Wesemann and coworkers.<sup>138</sup> **74** was available by the reduction of intramolecularly phosphine-stabilized chloro(germyl)germylene with  $[(^{\text{Mes}}\text{Nacnac})\text{Mg}]_2$  ( $^{\text{Mes}}\text{Nacnac} = \{[(2,4,6\text{-Me}_3\text{-C}_6\text{H}_2)\text{N}(\text{Me})\text{C}_2\text{CH}\}^-]$ ) or metallic sodium (Scheme 28). The Ge=Ge bond of 2.3060(2) Å is marginally shorter than that in Aldridge digermavinylidene **73**, being in the range of the typical Ge=Ge double bonds. Except for the substituents, the bicyclic molecule is nearly planar, and the tricoordinate Ge atom manifests practically planar geometry ( $\Sigma = 358.8^\circ$ ). Formulation of the germanium-

Scheme 27

Scheme 28

germanium interaction in 74 as a double bond was further supported by consideration of its frontier orbitals: HOMO and LUMO represent bonding and antibonding  $\pi$ - and  $\pi^*$ -orbitals of the  $Ge=Ge$  double bond. However, alternatively the bonding situation in 74 can be interpreted as a double Lewis base-stabilized Ge atom in the formal oxidation state 0, that is,  $Ge^0$ . As such, digermavinylidene 74 can serve as a source for a single  $Ge^0$  atom transfer by the germanium atom abstraction reactions.

#### 1.03.3.2.5 $E(0)=E(0)$ : Derivatives ( $E=Si, Ge, Sn$ )

This exciting class of low-coordinate group 14 element derivatives, featuring central elements E in their formal oxidation state 0, has emerged recently. The first milestone report in the field was published by Robinson and coworkers in 2008, describing  $[NHC \rightarrow Si^0=Si^0 \leftarrow NHC]$  ( $NHC = 1,3\text{-}(2,6\text{-}iPr_2\text{-}C_6H_3)_2\text{-imidazol-2-ylidene}$ ).<sup>139</sup> This breakthrough was quickly followed by the synthesis of its heavier analogues,  $[NHC \rightarrow Ge^0=Ge^0 \leftarrow NHC]$  ( $NHC = 1,3\text{-}(2,6\text{-}iPr_2\text{-}C_6H_3)_2\text{-imidazol-2-ylidene}$  or  $1,3\text{-}(2,4,6\text{-}Me_3\text{-}C_6H_2)_2\text{-imidazol-2-ylidene}$ ) and  $[NHC \rightarrow Sn^0=Sn^0 \leftarrow NHC]$  ( $NHC = 1,3\text{-}(2,6\text{-}iPr_2\text{-}C_6H_3)_2\text{-imidazol-2-ylidene}$ ), by Jones and coworkers.<sup>140</sup>

As the most recent development in the field, one can mention *N*-heterocyclic silylene(NHSi)-stabilized digermanium(0) complex 75, prepared by So and coworkers by the reduction of  $NHSi-GeCl_2$  complex with  $KC_8$  (Scheme 29).<sup>141</sup> NHSi-ligands in 75 coordinate to the:  $Ge=Ge$ : moiety almost perpendicularly ( $Si-Ge-Ge$  bond angle  $92.0^\circ$ ), and the  $Ge=Ge$  bond of  $2.3518(16)$  Å is still in the range of the typical  $Ge=Ge$  double bonds in digermenes. In contrast to the above-described  $[NHC \rightarrow Ge^0=Ge^0 \leftarrow NHC]$ ,<sup>140a</sup> 75 features *p*-back-bonding interaction of the  $Ge=Ge$   $\pi$ -bond and vacant *p*(Si)-orbital of the NHSi ligand stabilizing the whole molecule, as was evidenced by the frontier molecular orbital (HOMO) and AIM analyses.

Scheme 29

## 1.03.3.3 Triply bonded derivatives

## 1.03.3.3.1 Homonuclear derivatives –E≡E– (E=Si, Ge, Sn, Pb)

## 1.03.3.3.1.1 Disilynes –Si≡Si–

The quest for the stable alkyne analogues of the heavy group 14 elements has a long history dating back to the early 1990s when Masamune and coworkers described disilyne R–Si≡Si–R among the greatest challenges for silicon chemists in their seminal review.<sup>142</sup> However, it took more than a decade when the first isolable disilynes R<sub>3</sub>Si–Si≡Si–SiR<sub>3</sub> were independently reported by Wiberg (R<sub>3</sub>Si=SiMe(Si<sup>*t*</sup>Bu)<sub>2</sub>)<sup>143</sup> and Sekiguchi (R<sub>3</sub>Si=Si<sup>*i*</sup>Pr[CH(SiMe<sub>3</sub>)<sub>2</sub>]<sub>2</sub>)<sup>144</sup> groups in 2004. These historical achievements were followed by the subsequent synthesis of a couple of other stable disilynes, unsymmetrically substituted bis(silyl)disilyne R<sub>3</sub>Si–Si≡Si–SiR'<sub>3</sub> (R<sub>3</sub>Si=Si<sup>*i*</sup>Pr[CH(SiMe<sub>3</sub>)<sub>2</sub>]<sub>2</sub>, R'<sub>3</sub>Si=Si(CH<sub>2</sub><sup>*t*</sup>Bu)[CH(SiMe<sub>3</sub>)<sub>2</sub>]<sub>2</sub>)<sup>145</sup> by Sekiguchi and coworkers and diaryldisilyne Bbt–Si≡Si–Bbt (Bbt = 2,6-[(Me<sub>3</sub>Si)<sub>2</sub>CH]<sub>2</sub>-4-[(Me<sub>3</sub>Si)<sub>3</sub>C]-C<sub>6</sub>H<sub>2</sub>)<sup>146</sup> by Tokitoh and coworkers.

Since 2013, a few other examples of the stable disilynes were reported. As a remarkable new entry to the stable disilynes family, Iwamoto group reported the first dialkyldisilyne R–Si≡Si–R [R=C(SiMe<sub>3</sub>)<sub>2</sub>(CH<sub>2</sub><sup>*t*</sup>Bu)] **76**.<sup>147</sup> As is uniform for disilynes, **76** was prepared by the exhaustive dehalogenation of the tetrabromodisilane precursor R–SiBr<sub>2</sub>–SiBr<sub>2</sub>–R with KC<sub>8</sub>. The triply bonded Si atoms in **76** resonated at 31.8 ppm, that is at higher field compared to those in bis(silyl)disilynes (89.9 ppm<sup>144</sup> and 62.6/106.3 ppm<sup>145</sup>) but at lower field than that in diaryldisilyne (18.7 ppm).<sup>146</sup> The Si≡Si triple bond in **75** of 2.0863(13) Å is in-between those of bis(silyl)disilynes (2.0622(9) Å<sup>165</sup> and 2.0569(12) Å<sup>145</sup>) and diaryldisilyne (2.108(5) Å<sup>90</sup>). The *trans*-bent angle C–Si≡Si in **76** of 132.1° is again intermediate between those of bis(silyl)disilynes (137.4°<sup>144</sup> and 137.9/138.8°<sup>145</sup>) and diaryldisilyne (133.0°<sup>146</sup>).

The second diaryldisilyne Tbb–Si≡Si–Tbb (Tbb = 2,6-[(Me<sub>3</sub>Si)<sub>2</sub>CH]<sub>2</sub>-4-<sup>*t*</sup>Bu-C<sub>6</sub>H<sub>2</sub>) **77** was synthesized by Sasamori and coworkers by the reduction of 1,2-dibromodisilene precursor (*E*)-Tbb(Br)Si=Si(Br)Tbb with KC<sub>8</sub>.<sup>148</sup> **77** manifested spectral and structural features that are typical for disilynes, namely: <sup>29</sup>Si NMR resonance at 16.2 ppm, short Si≡Si bond of 2.1050(15) Å, and a notable *trans*-bending angle C<sub>aryl</sub>–Si≡Si of 131.4°.

An interesting three-membered ring MgSi<sub>2</sub> compound **78**, featuring cyclic Si=Si double bond (magnesium disilacyclopropene) and as such considered as the doubly reduced disilyne derivative, was recently reported by Cui and coworkers.<sup>149</sup> This dianionic disilyne magnesium complex **78** was available by the reduction of (NHBoryl)tribromosilane with activated magnesium (Scheme 30). The anionic Si atoms in **78** expectedly resonated in very low-field at 204.1 ppm, as is characteristic for disilenides. The Si=Si

Scheme 30

bond of 2.223(17) Å in **78** is also in line with its formulation as a double bond, and both Si atoms have nearly planar geometry ( $\Sigma = 355.7$  and  $359.9^\circ$ ). The dianionic character of the Si<sub>2</sub>-core in **78** was further confirmed by the NPA charge calculations: –0.61 and –0.63 (for Si atoms) and +1.59 (for Mg atom).

## 1.03.3.3.1.2 Digermyne –Ge≡Ge–

The first isolable digermene Ar–Ge≡Ge–Ar [Ar = 2,6-(2,6-<sup>*i*</sup>Pr<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>)<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>] was reported by Power group in 2002,<sup>150</sup> and this was followed by the synthesis of another stable diaryldigermyne Bbt–Ge≡Ge–Bbt (Bbt = 2,6-[(Me<sub>3</sub>Si)<sub>2</sub>CH]<sub>2</sub>-4-[(Me<sub>3</sub>Si)<sub>3</sub>C]-C<sub>6</sub>H<sub>2</sub>) by Tokitoh and coworkers.<sup>151</sup>

A couple of other stable digermynes were reported since 2013. The first one, bis(amido)digermyne R–Ge≡Ge–R {R = N(Si<sup>*i*</sup>Pr<sub>3</sub>)[2,6-(CHPh<sub>2</sub>)<sub>2</sub>-4-<sup>*i*</sup>Pr-C<sub>6</sub>H<sub>2</sub>]} **79**, was synthesized by Jones and coworkers by the reduction of the monomeric germylene R(Cl)Ge: with [(<sup>*Me*</sup>Nacnac)Mg]<sub>2</sub>.<sup>152</sup> However, given the Ge–Ge bond distance of 2.3568(3) Å in **79** that is much longer than those of previously reported diaryldigermynes (2.2850(6) Å<sup>150</sup> and 2.2060(7)/2.2260(7) Å<sup>151</sup>), the very formulation of **79** as a digermene casts some doubts on it. It is very likely that **79** is better viewed as a digermene derivative (WBI = 1.75),<sup>152</sup> rather than a digermene one.

By contrast, triply bonded constitution of another digermene Tbb–Ge≡Ge–Tbb (Tbb = 2,6-[(Me<sub>3</sub>Si)<sub>2</sub>CH]<sub>2</sub>-4-<sup>*t*</sup>Bu-C<sub>6</sub>H<sub>2</sub>) **80** prepared by the reduction of 1,2-dibromodigermene (*E*)-Tbb(Br)Ge=Ge(Br)Tbb with KC<sub>8</sub> as reported by Sasamori, Tokitoh and coworkers, was firmly established.<sup>153</sup> **80** has short Ge≡Ge bond of 2.2410(9)/2.2221(9) Å and *trans*-bent C<sub>aryl</sub>–Ge–Ge angle of 130.5/130.7°.

## 1.03.3.3.1.3 Distannyne –Sn≡Sn–

The first stable distannyne Ar–Sn≡Sn–Ar [Ar = 2,6-(2,6-<sup>*i*</sup>Pr<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>)-C<sub>6</sub>H<sub>3</sub>] was reported by Power group in the same year 2002, when the first digermene was reported by the same group.<sup>150</sup> Since then, several bis(amido)-substituted ditin derivatives were

claimed as distannynes.<sup>155</sup> However, again, based on their exceptionally long Sn–Sn separations of 3.1429(7) Å<sup>155a</sup> and 3.0638(7) Å<sup>155b</sup> (cf.: 2.6675(4) Å in Power distannyne<sup>154</sup>), these compounds should be classified as the singly bonded bis(stannylenes), and therefore their formulation as distannynes is somewhat misleading.

Power group has recently authenticated another diaryldistannyne Ar–Sn≡Sn–Ar [Ar = 2,6-(2,4,6-*i*Bu<sub>3</sub>-C<sub>6</sub>H<sub>2</sub>)<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>] **81** prepared by the standard procedure, namely, by the reduction of the corresponding chlorostannylene Ar(Cl)Sn: with KC<sub>8</sub>.<sup>156</sup> The Sn≡Sn bond in **81** is short (2.7621(6) Å) although being the longest one observed in distannynes, and the C<sub>aryl</sub>–Sn–Sn *trans*-bending angle is narrow (119.1/119.8°) being comparable to that in the first Power distannyne (125.2°).<sup>154</sup> No solution <sup>119</sup>Sn NMR resonance for the triply bonded Sn atoms in **81** were observed due to the anisotropy of the chemical shift tensor, as in the case of other distannynes.

#### 1.03.3.3.1.4 Diplumbyne –Pb≡Pb–

The first diplumbyne Ar–Pb≡Pb–Ar [Ar = 2,6-(2,4,6-*i*Pr<sub>3</sub>-C<sub>6</sub>H<sub>2</sub>)-C<sub>6</sub>H<sub>3</sub>], which was actually the very first example of the formal heavy group 14 element alkyne analogues, was reported by Power and coworkers in 2000.<sup>157</sup> However, given its peculiar structural features (very long Pb–Pb separation of 3.1881(1) Å and nearly orthogonal arrangement of the aryl substituents in relation to the Pb–Pb bond with the C<sub>aryl</sub>–Pb–Pb bond angle of 94.3°), the compound was formulated as the *trans*-bent singly bonded diplumbylene Ar–Pb:–Pb:–Ar, rather than the triply bonded diplumbyne Ar–Pb≡Pb–Ar.

Very recently, Power group reported a series of novel “diplumbynes” ArPbPbAr [Ar = 2,6-(2,6-*i*Pr<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>)<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>, 2,6-(2,4,6-*i*Pr<sub>3</sub>-C<sub>6</sub>H<sub>2</sub>)<sub>2</sub>-3,5-*i*Pr<sub>2</sub>-C<sub>6</sub>H, 2,6-(2,4,6-*i*Bu<sub>3</sub>-C<sub>6</sub>H<sub>2</sub>)<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>, 2,6-(2,6-*i*Pr<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>)<sub>2</sub>-4-SiMe<sub>3</sub>-C<sub>6</sub>H<sub>2</sub>].<sup>158</sup> These compounds were prepared by the reduction of aryl(bromo)plumbylene dimers {Ar(*m*-Br)Pb:}<sub>2</sub> with (<sup>t</sup>Bu<sub>2</sub>AlH)<sub>2</sub> forming intermediate hydrides [{Ar(*H*)Pb:}]<sub>2</sub> which subsequently eliminate H<sub>2</sub> thus forming ArPbPbAr, or alternatively by the reduction of [Ar(*m*-Br)Pb:]<sub>2</sub> with [(<sup>Mes</sup>Nacnac)Mg]<sub>2</sub>. All diplumbynes (except for the one with the bulkiest Ar substituent, 2,6-(2,4,6-*i*Pr<sub>3</sub>-C<sub>6</sub>H<sub>2</sub>)<sub>2</sub>-3,5-*i*Pr<sub>2</sub>-C<sub>6</sub>H) are unstable, surviving only at the temperatures as low as –20 °C/–30 °C. The Pb–Pb separation in these diplumbynes was in the range 3.0382(6)–3.2439(9) Å, with the shorter bonds being still notably longer than the typical Pb–Pb single bonds in diplumbanes but rather comparable to the Pb=Pb double bonds in diplumbenes. The *trans*-bending angles C<sub>aryl</sub>–Pb–Pb were in the range 95.2–116.0°.

#### 1.03.3.3.2 Heteronuclear derivatives –E≡C– and –E≡P

Heteronuclear heavy alkyne analogues featuring different group 14 elements of the type –E≡E'– (E, E' = C–Pb) were the subject of permanently high interest of the main group chemists. However, despite many research efforts, no such stable derivatives were isolated to date. The closest approach to the compounds of interest is represented by the metastable silyne –Si≡C– (stable in solution only below –30 °C), which has rather peculiar substituents pattern and in which the intramolecularly phosphine-stabilized Si≡C bond is very short (1.667(3) Å) being notably shorter than the conventional Si=C double bonds. This compound was reported by Kato, Baccaredo and coworkers in 2010.<sup>159</sup>

An equal, if not even more, attractive synthetic challenge are hybrid group 14/15 element alkyne analogues of the type R–E≡E' (E = group 14 element, E' = group 15 element). Accordingly, the search for the room-temperature stable compounds of this type, first of all, of the heavy nitriles R–E≡N and heavy phosphalkynes R–E≡P types (E = heavy group 14 element), intrigued Main Group elements community for at least a couple of last decades. However, stabilization of such fascinating species appeared to be exceptionally challenging, especially given that only ONE substituent R is available for stabilization (both thermodynamic and kinetic) of otherwise exceptionally reactive E≡N and E≡P triple bonds. The extraordinary difficulties in stabilization of such species was recently experimentally verified by the research of Hinz and Goicoechea, who attempted synthesis of the phosphagermyne R–Ge≡P and phosphastannyne R–Sn≡P derivatives.<sup>160</sup> Accordingly, to date, there is no success in the field of compounds of the type R–E≡E' (E/E' = group 14/group 15 elements), but one can expect progress in this field in the future.

### 1.03.4 Low-coordinate compounds of heavier group 15 elements

#### 1.03.4.1 Introduction

The chemistry of low-coordinate compounds of heavier Group 15 elements has seen remarkable progress. As for low-coordinate compounds of heavier Group 15 elements, the field of the multiple bonded compounds correspond to one of the most popular categories. Up to date, numerous literatures for heteroaromatics such as phosphole (C<sub>4</sub>H<sub>5</sub>P) and phosphine (PC<sub>5</sub>H<sub>5</sub>) derivatives, multiple bonded systems, e.g., phosphalkenes (>C=P–), phosphalkynes (–C≡P), and diphosphenes (–P=P–), have been reported together with their heavier analogues. In this chapter, we will discuss the synthesis and structural features of diphosphenes and related heavier analogues between 2016 and 2020.

#### 1.03.4.2 Diphosphene derivatives

Remarkable advances have been made in low-valent main-group chemistry, providing new insights into bond making and breaking processes. Among heavier Group 15 elements, dipnictenes have attracted considerable attention. Since the preparation of the first stable diphosphene Mes\*–P=P–Mes\* (Mes\* = 2,4,6-*i*Bu<sub>3</sub>-C<sub>6</sub>H<sub>2</sub>) by Yoshifuji and coworkers in 1981,<sup>5</sup> the field of low-coordinate

**Table 1** Selected structural parameters of diphosphene derivatives.

compounds of heavier Group 15 elements has rapidly expanded by using steric protection of bulky substituents. Thus, the concept of kinetic stabilization by sterically demanding substituents provided a breakthrough in the field of multiple bonded compounds based on heavier Group 15 elements. This section covers recent progress for substantial synthesis of diphosphenes and their structural information as summarized in **Table 1**.

The first stable boryl-substituted diphosphene derivative was successfully synthesized by Yamashita and coworkers.<sup>161</sup> Reductive coupling reaction of boryldichlorophosphine precursor with magnesium metal afforded boryl-substituted diphosphene **82** in 47% yield. In the <sup>31</sup>P NMR spectrum in C<sub>6</sub>D<sub>6</sub>, two magnetically equivalent phosphorus nuclei were observed at +605 ppm, which are comparable, albeit slightly low-field-shifted, to the resonances of carbon-substituted *trans*-diphosphenes (477–600 ppm). Furthermore, the solid-state structure of **82** was determined by single-crystal X-ray diffraction analysis. The P–P bond of 2.0655(17) Å is slightly longer than those of previously reported carbon-substituted diphosphenes (1.985–2.051 Å). The five-membered rings containing a boron atom are oriented almost perpendicular to the planar B–P=P–B moiety (**Scheme 31**).

Goicoechea and coworkers reported that photolysis converted boryl-substituted phosphaketene to 2,3-dihydro-1*H*-1,3,2-diazaboryl-substituted diphosphene **83**.<sup>162</sup> The <sup>31</sup>P NMR spectrum showed a singlet resonance at 596.0 ppm. Orange crystals of **83** suitable for single crystal X-ray diffraction could be obtained by cooling a concentrated hexane solution of the product. The single crystal X-ray structural analysis reveals a diphosphene with a relatively short P–P bond distance of 2.027(1) Å, which is in line with the expected distance for a P=P double bond (**Scheme 32**).

Slootweg reported that diphosphetanedione derivative is converted to cyclopropenyl-substituted diphosphene **84** in 99% yield upon UV irradiation.<sup>163</sup> The <sup>31</sup>P NMR spectrum exhibited a signal at +585.3 ppm. The molecular structure of **84**, determined by

**Scheme 31**

Scheme 32

Scheme 33

a single-crystal X-ray analysis, shows a centrosymmetric diphosphene with the P–P and P–C bond lengths of 2.0210(6) and 1.8778(12) Å, respectively (Scheme 33).

Tsurusaki and Kamikawa reported that diphosphene **85** possessing an axially chiral 1,1'-binaphthyl moiety was synthesized.<sup>164</sup> Enantiomerically pure substrate can be converted into diphosphene **85** without any loss of enantiomeric purity (Scheme 34).

Bertrand and co-workers demonstrated that bis-phosphinidene unit stabilized by imidazol-2-yl carbene could be isolated.<sup>165</sup> Since then, persistent unsaturated species with *N*-heterocyclic carbenes based on heavier Group 15 elements have been synthesized.

Scheme 34

Grützmacher<sup>166</sup> and Weigand<sup>167</sup> independently reported synthesis and structural characterization of NHC-substituted diphosphenes **86** and **87**, respectively. They succeeded in the formation of a P=P double bond via a chloride abstraction of the corresponding chlorodiphosphanide precursor. Treatment of precursors with GaCl<sub>3</sub> afforded diphosphene **86** or **87**, respectively. The <sup>31</sup>P NMR spectrum of diisopropylamino-substituted diphosphene **86** showed two coupled doublets (*J* = 525 Hz) at 492.1 and 158.1 ppm. In the molecular structure of **86**, the P–P distance of **86** was 2.0611(7) Å, being slightly longer than those of previously reported carbon-substituted diphosphenes. In the case of **87**, the <sup>31</sup>P NMR spectrum showed an AX spin system at 398.1 (P<sub>A</sub>) and 605.8 (P<sub>X</sub>) ppm with <sup>1</sup>*J*<sub>PP</sub> = –577.9 Hz. The P<sub>A</sub> and P<sub>X</sub> can be assigned to the imidazoliumyl- and the imidazolyl-substituted phosphorus atoms, respectively. The molecular structure of **87** revealed, the P–P bond length (2.038(1) Å) typical for diphosphenes. The C–P–P angle involving the imidazoliumyl-substituent (C–P–P: 105.0(1)1°) is larger than that involving the Dipp-substituent (C–P–P 95.1(1)1°). This might be a result of a higher degree of π-bonding interactions involving the more electron withdrawing imidazoliumyl-group, or the large steric demand of the imidazoliumyl-substituent (Schemes 35 and 36).

*N*-Heterocyclic carbene coordinated diphosphene **88** was also prepared by chloride abstraction from the corresponding singly-bonded derivative with GaCl<sub>3</sub>.<sup>168</sup> The <sup>31</sup>P NMR spectrum of **88** exhibited a higher-order AB spin system at 438.5 and 440.1 ppm with 543 Hz. The solid-state structure of diphosphene **88** was confirmed by X-ray crystallographic analysis. The P–P bond length of 2.1897(4) Å falls in a range for the reported diphosphenes (Scheme 37).

Tamm and coworkers reported that diphosphenes **89** and **90** bearing *N*-heterocyclic carbenes were synthesized by a chloride abstraction by the reduction with magnesium powder or by Lewis acid, respectively.<sup>169,170</sup> The <sup>31</sup>P NMR spectrum of **89** revealed a broad signal at very low field (+434 ppm), which is characteristic of sterically protected diaryldiphosphenes. In the solid-state structure, diphosphene **89** exhibit the typical (*E*)-geometry with the P–P bond length of 2.0530(5) Å. In the case of **90**, The <sup>31</sup>P

Scheme 35

Scheme 36

Scheme 37

NMR spectrum in  $\text{THF-}d_8$  showed two doublets at 403 and 456 ppm ( $J = 554$  Hz). The molecular structure for **90** was determined by XRD analysis. The P–P length is 2.0565(9) Å, which is comparable to those of reported diphosphenes (Schemes 38 and 39).

Stephan reported that reaction of a *N*-heterocyclic carbene with three equivalents of *t*-Bu-substituted phosphalkyne afforded vinyl-substituted diphosphenide **91a** as purple crystals in 74% yield.<sup>171</sup> In the case of the reaction with 1-adamantyl-substituted

Scheme 38

Scheme 39

Scheme 40

phosphaalkyne, diphosphene **91b** was also isolated as pink powder in 68% yield. The <sup>31</sup>P NMR spectra of **91a** and **91b** in CDCl<sub>3</sub> exhibited resonances at 530.1 and 524.0 ppm, respectively. The molecular structures were unambiguously confirmed by single crystal X-ray diffraction. The P–P bond lengths of **91a** and **91b** exhibited 2.0453(6) and 2.041(1) Å, respectively, which are in the typical range of diphosphenes (Scheme 40).

Ghadwal and coworkers reported synthesis and characterization of new divinylidiphosphene compounds.<sup>172</sup> Reduction of dichlorovinylphosphanes with magnesium leads to the formation of divinylidiphosphenes **92a** and **92b** as crystalline solids. The <sup>31</sup>P{<sup>1</sup>H} NMR spectrum of each of **92a** (+380 ppm) and **92b** (+414 ppm) exhibits a signal characteristic for the reported diphosphenes. Molecular structures of **92a** and **92b** were determined by single-crystal X-ray diffraction studies, which reveal their *trans*-configurations along the P=P bonds. The P–P bond lengths of 2.062(1) (92a) and 2.055(1) Å (92b), which are in the typical range of diphosphenes (Scheme 41).

Scheme 41

New *C*-dichlorofluorosilyl-functionalized dialkyldiphosphene was also synthesized by Jones, du Mont and coworkers.<sup>173</sup> Treatment of fluorophosphaalkene with 1,1,1-trichloro-2,2,2-trimethylsilane in pentane at 40 °C finally afforded diphosphene **93** bearing silylmethyl groups. The <sup>31</sup>P NMR spectrum of **93** exhibited four lines at +560.1 ppm as an AA'XX' system with *J*<sub>PF</sub> = 100.3 Hz. The solid-state structure of **93** exhibited intramolecular P⋯F–Si contacts. The P–P bond lengths of **93** are 2.0369(5) and 2.0423(4) Å, which are in a range of those for the reported carbon-substituted diphosphenes (Scheme 42).

Stephan and coworkers synthesized a new di-1,2-dihydro-1,2-diphosphete-substituted diphosphene by oligomerization of phosphalkynes mediated by bulky *N*-heterocyclic carbenes.<sup>174</sup> Reaction of a phosphalkyne with *N*-heterocyclic carbene afforded di-1,2-dihydro-1,2-diphosphete-substituted diphosphene **94** as purple crystals (Scheme 43).

Scheme 42

Scheme 43

A germyliumylidene-substituted diphosphene was synthesized by Driess and coworkers.<sup>175</sup> Photolysis of phosphaketonylgermyliumylidene borate with UV for 2 h at room temperature afforded bis(germyliumylidene)diphosphene **95** as deep red crystals in 10% yield. Diphosphene **95** is insoluble in common organic solvents and no solution NMR data could be obtained. In the solid-state, <sup>31</sup>P NMR spectrum of **95** exhibited a singlet signal at 903.5 ppm, which is strongly shifted downfield compared with those of other reported diphosphene species. The observed low-field shift indicates strong electron-withdrawing property of the germyliumylidene moieties of **95**. The molecular structure of **95** was determined by single-crystal X-ray diffraction analysis. The P–P bond length is 2.045(1) Å, which is slightly longer than those of previously reported carbon-substituted diphosphenes (1.985–2.051 Å) (Scheme 44).

Scheme 44

Photolysis of germylenyl- and stannylenyl-phosphaketenes stabilized with sterically hindered groups afforded diphosphenes **96a** and **96b**, respectively.<sup>160</sup> The <sup>31</sup>P NMR resonances were found at +745.7 (**96a**) and +797.8 ppm (**96b**), which are characteristically downfield shifted as is typical for diphosphene derivatives. The single crystal diffraction experiment of **96b** confirmed the presence of a diphosphene-type structure with a typical short P–P distance of 2.053(2) Å (Scheme 45).

New diphosphene-iron, palladium, and platinum complexes were also synthesized by Weigand and coworkers.<sup>176</sup> A sequence of reduction of dichlorophosphine precursor and reaction with transition metal complexes such as Fe<sub>2</sub>(CO)<sub>9</sub>, Pd(PPh<sub>3</sub>)<sub>4</sub>, and Pt(PPh<sub>3</sub>)<sub>4</sub> afforded diphosphene-metal complexes **97a–c**. The molecular structures of **97a–c** were confirmed by X-ray crystallographic analysis. In the solid-state, the η<sup>2</sup>-coordination of the corresponding metal by the diphosphene ligand is observed. In the cases of **97b** and **97c**, Pd/Pt atoms are in a distorted square-planar bonding environment. In addition, complexes **97a–c** reveal that the imidazoliumyl-substituents of the diphosphene ligand are arranged in a *trans*-configuration with the C–P–P–C of

Scheme 45

Scheme 46

149.205(1)° (**97a**)/148.393° (**97b**)/147.088° (**97c**). The P–P bond lengths are only marginally shorter (2.1340(12) Å for **97b** and 2.1562(9) Å for **97c**) compared to that of complex **97a** (2.1684(7) Å) (Scheme 46).

In 2019, new  $\eta^2$ -diphosphene titanocene complex was synthesized from a cyclic triphosphane precursor.<sup>177</sup> Diphosphene–titanium complexes **98a** and **98b** were prepared by the reaction of the corresponding triphosphane with titanium bis(trimethylsilyl) acetylene complex in benzene. In  $C_6D_6$  solution, the  $^{31}P$  NMR spectra of **98a** and **98b** showed signals at 290.7 and 283.8 ppm, respectively, which are high-field shifted as compared with that of *trans*-diphosphene Tip–P=P–Tip (Tip = 2,4,6-*i*Pr<sub>3</sub>C<sub>6</sub>H<sub>2</sub>) (517.4 ppm, in  $C_6D_6$ ).<sup>177</sup> In the crystal structures, the aryl groups of **98a**/**98b** are oriented in a *trans*-conformation. Complexes **98a** and **98b** showed the P–P distance of 2.1826(7) and 2.1699(5) Å, respectively, which are intermediate between the typical P–P single and double bonds. This structural feature can be explained by the  $\pi$ -back-donation from d-orbitals of the metal into the  $\pi^*$ -orbital of the P=P unit (Scheme 47).

Scheme 47

Goicoechea and co-workers reported that gallium carbenoid-substituted diphosphene **99** was synthesized by UV-promoted decarbonylation of phosphaketene derivative using a 600 W broadband UV lamp.<sup>178</sup> Diphosphene **99** displayed a  $^{31}P$  NMR resonance at +596.2 ppm. The solid-state structure showed that the P–P bond distance of 2.037(1) Å is in the expected range of a double bond and the Ga–P distance of 2.340(1) Å is consistent with a single bond. The Ga–P–P bond angle of 99.04(3)° is comparable to that of boryl-substituted diphosphene **84** (Scheme 48).

### 1.03.4.3 Heavier dipnictene derivatives

In this section, examples of stable diphosphene and their heavier congeners such as arsaphosphene, diarsene, distibene and dibismuthene are discussed.

New arsaphosphene **100** bearing *N*-heterocyclic carbenes was prepared by chloride abstraction from the corresponding As–P single bond derivative with GaCl<sub>3</sub>.<sup>170</sup> The  $^{31}P$  NMR spectrum of **100** exhibited a broad singlet at 456 ppm. The  $^1H$  NMR spectrum

Scheme 48

of **100** showed signals at 7.78 and 8.64 ppm for the protons of the *N*-heterocyclic carbene units. The solid-state structures of arsa-phosphene **100** were confirmed by X-ray crystallographic analysis. The As–P bond length of 2.1577(7) Å falls in a range for the reported arsa-phosphenes such as Mes\*–P=As–Mes\* (2.141(5) Å, Mes\* = 2,4,6-*t*Bu<sub>3</sub>-C<sub>6</sub>H<sub>2</sub>), Mes–P=As–(2,6-Tip<sub>2</sub>C<sub>6</sub>H<sub>3</sub>) (2.134(2) Å), and Mes\*–P=As–CH(SiMe<sub>3</sub>)<sub>2</sub> (2.125(1) Å) (Scheme 49).

Diarsene **101** and distibene **102** bearing *N*-heterocyclic carbenes were also synthesized by Tamm and co-workers.<sup>169</sup> Dihalogenated compounds were employed for the preparation of the corresponding diarsene and distibene species by reductive coupling

Scheme 49

reaction. The molecular structures of **101** and **102**, were established by X-ray diffraction analysis, and they exhibited the typical (*E*)-geometry. The As–As and Sb–Sb bond lengths are 2.2882(8) and 2.6632(3) Å, which are in good agreement with known diarsene and distibene compounds such as Mes\*–As=As–Mes\* (2.2634(3) Å), (2,6-Mes<sub>2</sub>C<sub>6</sub>H<sub>3</sub>)–E=E–(2,6-Mes<sub>2</sub>C<sub>6</sub>H<sub>3</sub>) (2.276(3) Å; E=As, 2.668(2) Å; E=Sb), (2,6-Trip<sub>2</sub>C<sub>6</sub>H<sub>3</sub>)E=E(2,6-Trip<sub>2</sub>C<sub>6</sub>H<sub>3</sub>) (2.285(3) Å; E=As, 2.668(2) Å; E=Sb), Tbt–Sb=Sb–Tbt (2.642(1) Å, Tbt = 2,4,6-[(Me<sub>3</sub>Si)<sub>2</sub>CH]<sub>3</sub>C<sub>6</sub>H<sub>2</sub>), and Tbb–Sb=Sb–Tbb (2.6677(3) Å, Tbb = 4-*t*Bu-2,6-[(Me<sub>3</sub>Si)<sub>2</sub>CH]<sub>3</sub>C<sub>6</sub>H<sub>2</sub>) (Scheme 50).

Ghadwal reported synthesis of the first divinyl-diarsenes **103a,b** by magnesium reduction of the corresponding dichloroarsines.<sup>179</sup> The molecular structures of **103a,b** were established by X-ray diffraction analysis. Both exhibit a *trans*-geometry along

Scheme 50

Scheme 51

the As=As double bond and the C–As–As–C unit is planar. The As=As bond lengths of **103a** (2.296(3) Å) and **103b** (2.290(1) Å) compare well with those of the known diarsenes (2.276(3)–2.358(4) Å).

Since 2016, many research groups approached diphosphenes and their heavier analogues possessing a doubly-bonded system, new dipnictenes were involved in the field of chemistry of low-coordinate heavier Group 15 elements, which will be linked to the discovery of new applications (Scheme 51).

### 1.03.5 Low-coordinate compounds of heavier group 16 elements

Heavier group 16 elements in nature mainly bound to metal atoms in minerals. Elemental sulfur is produced as a volcanic product. Elemental selenium and tellurium are produced as by-products of metal refining. Besides, there are numerous organic sulfur, selenium, and tellurium compounds, and they have a wide range of applications. For example, thiourea with a double bond between carbon and sulfur atoms is an excellent synthetic raw material for resins, pharmaceuticals, and agricultural chemicals. In addition, the elemental heavier group 16 elements are widely used for trapping reaction of low-valent p-block element species to afford polarized double bonds such as  $E^{\delta+}=Ch^{\delta-}$  (Ch=S, Se, Te). Herein, we will discuss the synthesis and structural features of p-block element species containing multiple bonding to heavier group 16 elements.

#### 1.03.5.1 Multiple bonds between group 13 element and heavier group 16 element

The multiple bonds between group 13 element and group 16 element are highly polarized due to the large difference in their electronegativities, providing aggregates to balance the polarity. Monomeric oxoboranes (R–B=O, R = monoanionic substituent) and

Scheme 52

their heavy analogues ( $R-B=Ch$ ,  $Ch=S$ ,  $Se$ ,  $Te$ ) are labile and elusive under normal laboratory conditions.<sup>180</sup> Only platinum oxoboryl complexes ( $[Pt]-B=O$ , **104**, **Scheme 52**) are structurally characterized as  $R-B=X$  ( $X=O$ ,  $S$ ,  $Se$ ,  $Te$ ) monomers.<sup>181</sup> Because heavier analogues  $R-E=Ch$  ( $E=B$ ,  $Al$ ,  $Ga$ ,  $In$ ) of oxoboranes also easily dimerize/oligomerize, the isolation of their monomeric states requires fine molecular design. Fundamental concepts for the isolation of  $R-E=Ch$  monomers containing multiple bonds between group 13 element and group 16 element are illustrated in **Scheme 52**.<sup>182</sup> Lewis base ligand(s) ( $L$ ) on group 13 element center complement the electron deficiency on the element ( $A$ ,  $B$ ,  $D$ ,  $F$ ,  $G$ , and  $H$ ). Metals, Lewis acids, and Brønsted acids ( $M$ ) quench the negative charge on chalcogen atoms ( $D$ ,  $E$ ,  $F$ , and  $H$ ). Sterically hindered and/or electron-donor groups attached on group 13 element also contribute to prevent the aggregation of  $R-E=Ch$  monomers. Types  $F-H$  have been especially applied for the combination of heavier group 13 and group 16 element.<sup>183–185</sup> In this section, types  $A-C$  containing multiple bonds between group 13 element and heavier group 16 element are focused on, where group 13 element possess the trigonal-planar geometry and only chalcogen atoms bound for group 13 element.

**Scheme 53** Examples of neutral  $R-E=Ch$  monomers. Ar = 2,6-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>; Mes = 2,4,6-Me<sub>3</sub>C<sub>6</sub>H<sub>2</sub>.

Types  $A$ ,  $B$ , and  $C$  are classified into neutral,<sup>186</sup> cationic,<sup>187</sup> and anionic<sup>188</sup>  $R-E=Ch$ , respectively. In 2010, Cui and coworkers reported the first isolable monomeric thioxo- and selenoxoboranes **105** with type  $A$  form (**Scheme 53**).<sup>186a</sup> The bond lengths of  $B-S$  (1.741(2) Å) and  $B-Se$  (1.896(4) Å) were significantly shorter than those of  $B-S$  and  $B-Se$  single bonds. The  $B$  atoms had trigonal-planar geometries. The  $B=S$  double bond character was supported by theoretical calculations. Thioxoborane **106** was prepared by desulfurization of boron polysulfides.<sup>186b</sup> The <sup>11</sup>B NMR signal was observed at 50.3 ppm which was downfield-shifted relative to **105-S** (36.79 ppm), indicating the increase of  $B$  and  $S$  bond order due to decreasing the number of  $\pi$ -donor ligands on  $B$  atom. This trend was also observed for carbene coordinated acyclic thioxo- and selenoxoboranes **107**. The  $B-S$  (1.739(2) Å, **107-S**) and  $B-Se$  (1.876(4) Å, **107-Se**) bonds were slightly shorter than those of **105-S** and **105-Se**, and the <sup>11</sup>B NMR signals were observed at 66.4 and 73.5 ppm for **107-S** and **107-Se**, respectively.<sup>186c</sup> For **108-S**, the  $B-S$  bond length was shortened to 1.714(2) Å.<sup>186d</sup> Strong  $\pi$ -donating  $N$ -heterocyclic imine (NHI) ligand stabilized neutral  $R-B=Ch$  in Lewis acid absent form (**109**), shifting their <sup>11</sup>B NMR signals to 35.2 (**109-S**) and 35.8 (**109-Se**).<sup>186e,g</sup> For compound **109**, both of canonical structures

**Scheme 54** An example of cationic R–E=Ch monomer.

corresponding to types A and C can be considered. Multiple canonical structures (types A–C) were considered for **110** bearing bis(phosphinimino)amide ligand.<sup>186f</sup>

In 2014, Inoue and co-workers reported cationic thioxoborane **111-S** by using NHI ligands, which complied with stabilization type B and C (**Scheme 54**).<sup>187</sup> The B–S (1.710(5) Å) bond length was comparable to that of **108-S**, in contrast, the <sup>11</sup>B NMR signal was observed at 33.9 ppm which was up-field-shifted relative to that of **109-S** bearing one NHI ligand.

Anionic R–E=Ch monomers (type C in **Scheme 52**) were obtained in their separated ion-pair form (**Scheme 55**). Thioxoborane anion **112-S**, isoelectronic with thiourea, was reported by Aldridge and co-workers.<sup>188a</sup> The B–S (1.774(1) Å) bond was longer than

**Scheme 55** Examples of anionic R–E=Ch monomers. Crypt = cryptand; Dip = 2,6-*t*-Pr<sub>2</sub>C<sub>6</sub>H<sub>3</sub>.

those found in neutral and cationic thioxoborane monomers (**Schemes 53 and 54**). The <sup>11</sup>B NMR signals was observed at 33.1 ppm which was comparable to **111-S**. For thioxoborane anion **113-S**, bearing the acenaphthene-annulated 1,3,2-diazaborole skeletal, the B–S bond length was shortened to 1.7682(17) Å, and the <sup>11</sup>B NMR signals was observed at 36.3 ppm.<sup>188b</sup> The heavier analogue of carbonyl moiety containing an Al–Se bond was reported by Coles and coworkers (**114-Se**).<sup>188c</sup> The Al–Se (2.2032(6) Å) bond length was comparable to the calculated value for the sum of the covalent molecular double bond radii,  $r_2$  ( $\sum(r_2) = 2.20$  Å),<sup>189</sup> and significantly shorter than those of Al–(μ-Se)–Al group (2.319(1) Å) in which Al atoms had trigonal-planar geometries.<sup>190</sup> The <sup>77</sup>Se NMR signal (–563 ppm) was up-field-shifted relative to those of **105-Se** (–195.6 ppm),<sup>186a</sup> terminal Al–SeH (–419 to –339 ppm),<sup>191</sup> and Al–(μ-Se)–Al group (–535 to –414 ppm) in which Al atom had tetrahedral geometry.<sup>191</sup>

### 1.03.5.2 Multiple bonds between group 14 element and heavier group 16 element

Oxidation of low-valent group 14 species by elemental chalcogens provides multiple bonds between group 14 elements and heavier group 16 elements, and the multiply bonded species have been isolated even if no metals and Lewis acids are attached on terminal group 16 elements (**Scheme 2, A–D**).

**Scheme 56**

Scheme 57

Heavier analogues  $\text{R}_2\text{E}=\text{Ch}$  ( $\text{E}=\text{C}, \text{Si}, \text{Ge}, \text{Sn}$ ;  $\text{Ch}=\text{S}, \text{Se}, \text{Te}$ ; **Scheme 56, A**) of carbonyl compound ( $>\text{C}=\text{O}$ ) can be obtained by trapping reaction of in situ generated tetrylene ( $>\text{E}$ ) with elemental chalcogens.<sup>192,193</sup> For examples, a variety of chalcogenour-eas have been prepared from N-heterocyclic carbenes (NHC) and elemental chalcogens, which have been applied as a ligand for main-group elements and transition metals.<sup>192,194</sup> It is worth noting that the  $\pi$ -acceptor properties of carbenes can be experimentally estimated by measuring the  $^{77}\text{Se}$  NMR chemical shifts of their selenium adducts.<sup>194,195</sup> In contrast, there are still a few reports on isolable heavier ketone analogues consisting of heavier group 14 and heavier group 16 elements, the details are described in **Section 1.03.3** and recent review papers.<sup>192,193</sup> Oxidation of zero-valent heavier group 14 species afford B and C, which can be viewed as heavier congeners of  $\text{SiO}_2$  monomers and dimers, respectively (**Scheme 56**).<sup>196–198</sup> Heterocumulenes  $\text{R}_2\text{C}=\text{Ch}=\text{CR}_2$  ( $\text{Ch}=\text{S}, \text{Se}$ ) containing heavier group 16 elements have been also obtained from the reaction of carbenoid and elemental chalcogens (**Scheme 56, D**).<sup>199</sup> Sugamata and coworkers reported heterocumulenes 115 containing internal  $\text{C}=\text{Ch}=\text{C}$  multiple bonds with bent geometries (**Scheme 57**). The multiple bond characters were caused by the three-center four-electron ( $3c-4e$ )  $\pi$ -bond. The heterocumulenes 115 reacted with  $\text{AuCl}(\text{SMe}_2)$  to afford dinuclear (chalcogeno)(silyl)carbene gold(I) complexes with an accompanying elimination of  $\text{MePh}_2\text{SiCl}$ .<sup>199c</sup>

### 1.03.5.3 Multiple bonds between group 15 element and heavier group 16 element

Covalently bonded compounds of heavier group 15 element and heavier group 16 element have been investigated as molecular precursors of binary materials  $\text{E}_2\text{Ch}_3$  ( $\text{E}=\text{Sb}, \text{Bi}$ ;  $\text{Ch}=\text{S}, \text{Se}, \text{Te}$ ).<sup>200</sup> The multiply bonded heavier group 15 and 16 compounds can be classified into types A–C as monomers (**Scheme 58**). The compounds of type A are well-known and can be obtained by the reaction of  $\text{R}_3\text{E}$  ( $\text{E}=\text{P}, \text{As}, \text{Sb}, \text{Bi}$ ) with elemental chalcogen to afford  $\text{R}_3\text{E}=\text{X}$  ( $\text{E}=\text{P}, \text{As}, \text{Sb}$ ;  $\text{X}=\text{O}, \text{S}, \text{Se}, \text{Te}$ ), in which the double bonds  $\text{R}_3\text{E}=\text{X}$  are (partially) polarized  $\text{R}_3\text{E}^+-\text{X}^-$ .<sup>201</sup> The multiply bonded group 15 and 16 compounds  $\text{R}-\text{E}=\text{Ch}$  (type B) are labile and elusive. In 1993, Yoshifuji and coworkers reported phosphinothioylidene 116-S by using the bulky substituent and

Scheme 58

the intramolecular coordination to P center.<sup>202</sup> Pincer type ligands have also been applied to stabilize R–E=Ch form as monomers.<sup>203</sup> Organodithioxophosphoranes R–P(=S)<sub>2</sub> (type C) were isolated without ligand coordination(s) (117-S, 118-S, and 119-S).<sup>204</sup> In contrast, for Se analogues, only ligand-coordinated (L)R–P(=Se)<sub>2</sub> have been isolated and structurally determined.<sup>205</sup> These differences are most likely due to polarization of  $\pi$ -bond caused by poor  $\pi$ -overlap between P and Se atoms.

### 1.03.5.4 Multiple bonds between group 16 element and heavier group 16 element

Elemental chalcogens form several allotropes in Ch<sub>n</sub> (Ch=S, Se, Te) states. Although multiply bonded diatomic Ch=Ch

**Scheme 59**

compound is the smallest unit (**Scheme 59**, A), their electronic and structural characteristics are difficult to elucidate experimentally. In 1981, Stang and Maas reported the oxidation of thioureas to afford NHC-coordinated dicationic disulfides [(L)Ch–Ch(L)]<sup>2+</sup> (type B).<sup>206</sup> Se analogues were reported by Devillanova and coworkers in 1996.<sup>207</sup> Te analogues were recently discovered by Ishii, Nakata, and coworkers.<sup>208</sup> It is noteworthy that two chalcogen moieties maintain the  $\sigma$ (Ch–Ch) bond despite charge repulsion. For diatomic radical cations (type C), the Ch–Ch bonds were shorter than Ch–Ch single bonds. Beckmann and coworkers reported one-electron oxidation of dichalcogenides ArCh–ChAr to provide the corresponding radical cations **120** and **121**.<sup>209</sup> The Ch–Ch bonds (**120-S**, 1.998(2) Å; **121-S**, 2.014(3) Å), Se–Se (**120-Se**, 2.289(1) Å; **121-Se**, 2.289(7) Å), and Te–Te (**121-Te**, 2.662(1) Å) were shorter than those of corresponding neutral dichalcogenides, as well as significantly shorter than those of NHC-coordinated dicationic disulfides. The Wiberg bond indices of Ch–Ch bonds were between 1.216 and 1.315 for the [(PhCh)<sub>2</sub>]<sup>+</sup> (Ch=S, Se, Te) and between 1.176 and 1.282 for the [(C<sub>6</sub>F<sub>5</sub>Ch)<sub>2</sub>]<sup>+</sup> (Ch=S, Se, Te). The singly occupied molecular orbital of [(C<sub>6</sub>F<sub>5</sub>Se)<sub>2</sub>]<sup>+</sup> was predominantly represented by the  $\pi^*$ (Se–Se) and  $\pi$ (C<sub>6</sub>F<sub>5</sub>) orbitals. For radical cations **120** and **121**, these insights resulted in the double bond characters in Ch–Ch bonds (odd-electron  $\pi$ -bonds).

### 1.03.6 Summary

Combination of experimental and theoretical approaches to low-coordinate compounds with a multiple bond between heavier main group elements revealed essential properties of their chemical bondings. Summarizing the findings described in this chapter leads to the following conclusion: the classical multiple-bond indicators in organic chemistry, e.g., the shorter bond lengths and higher bonding energies, have almost no meanings for the multiple bonds between heavier atoms and they are valid for only 2nd-row elements such as carbon. The bonding characters of multiple bonds of heavier main group elements described above are reasonably interpreted in terms of unfavorable *s-p* hybridization of the heavier atoms. The understanding of the feature of heavier atoms suggested that sterically demanding substituents should be required in order to kinetically stabilize and isolate

the heavier multiply-bonded compounds. Indeed, the concept of kinetic stabilization using bulky substituents led to the significant progress in the chemistry of unsaturated compounds with heavier main group elements. However, important synthetic targets remain in main group element chemistry. For example, a hexasilabenzene ( $R_6Si_6$ ), a silicon-analogue of a benzene, should be one of the important targets, for establishment of a concept of “aromaticity” of heavier main group elements. It is expected that the combination of “organic chemistry”, “transition metal chemistry”, and “main group element chemistry” will open up a new field of chemistry by the use of the characters of every element in the periodic table.

### Abstract

In this article, we review the concept of biradical(oid)s from a theoretical as well as experimental perspective. In particular, we analyze the “two electrons in two orbitals” model, which is frequently used to describe the electronic structure of biradical(oid)s, with special emphasis on systems with a small HOMO-LUMO gap, so-called open-shell singlet biradicals or singlet biradicaloids. We then revise the chemistry of main group analogs of cyclobutane-1,3-diyls and cyclopentane-1,3-diyls as typical examples of singlet biradical(oid)s. Lastly, it is shown how some of these biradicals can be applied as molecular switches by switching the biradical character on and off.

### 1.04.1 Introduction

To be radical is to grasp things by the root.

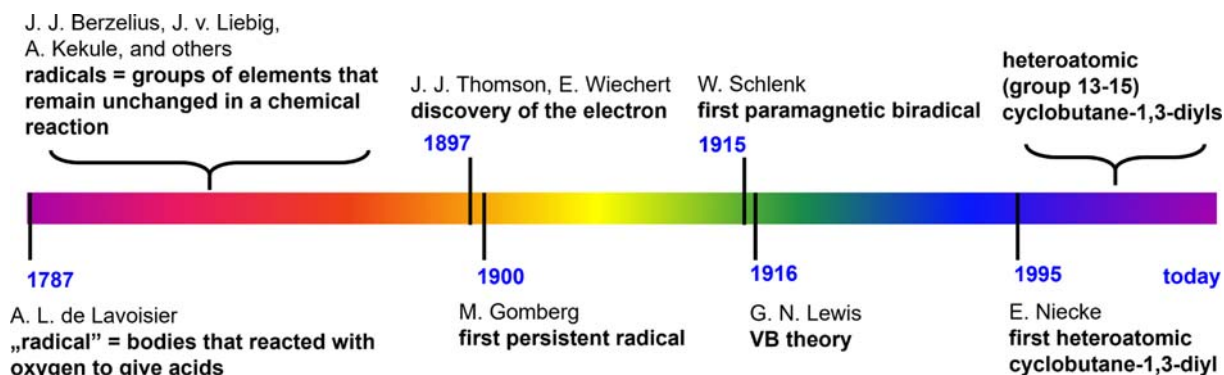

Karl Marx in Critique of Hegel's Philosophy of Right (1844).<sup>1</sup>

The word “radical” is borrowed from the Latin word *radix* (English: root) and originally meant “going to the origin, essential.” The word appeared in several European languages at the end of the 14th century, mostly in a philosophical context. The “root sign” of mathematics was introduced in the 1680s.<sup>2</sup> In chemistry, the word appears for the first time at the end of the 18th century, when

Lavoisier spoke of organic compounds as “oxides of radicals” (components of an acid).<sup>3</sup> The meaning of the word changed over time in everyday language (radical = extreme) as well as in chemistry. Let’s look a little closer at the historical development of the term radical in chemistry.<sup>4</sup> Lavoisier used the term radical for an atom or a group of atoms bound to oxygen in oxygen compounds (Fig. 1), “the residue of a body freed from oxygen.” Sulfur and phosphorus were the radicals of sulfuric acid and phosphoric acid. Moreover, he called organic compounds “oxides of radicals” composed of at least two elements, and according to Berzelius the main difference in composition between inorganic and organic compounds seemed to be that the former contained simple, the latter compound radicals. This concept was given a more definite and real form by investigations into cyanogenic compounds, above all by those carried out by Gay-Lussac in 1815,<sup>5,6</sup> from which it emerged that the radical composed of carbon and nitrogen (cyanogen) behaves entirely like an element and passes from one compound into the other, and can even be deposited in free form. At that time, however, cyanogenic compounds had not yet found their proper place among organic compounds. This radical concept gave rise to the first comprehensive theory for the inner composition of organic compounds which was mainly introduced by Liebig and Wöhler in 1832.<sup>7</sup> It should be noted that the word “radical” has two meanings in chemistry today, which, however, developed at different times.<sup>8</sup> On the one hand, it is understood to mean the part of a molecule that remains unchanged during a chemical transformation (e.g., an alkyl or aryl group); on the other hand, certain fragments of molecules that occur as intermediates in chemical reactions are called “free radicals.”<sup>3</sup> Today, according IUPAC Gold Book,<sup>9</sup> a radical is “a molecular entity such as  $\cdot\text{CH}_3$ ,  $\cdot\text{SnH}_3$ ,  $\text{Cl}\cdot$  possessing an unpaired electron.” With respect to the two meanings, as mentioned above, it is recommended: “In the past, the term “radical” was used to designate a substituent group bound to a molecular entity, as opposed to “free radical,” which nowadays is simply called radical. The bound entities may be called groups or substituents, but should no longer be called radicals.”<sup>9</sup>

Interestingly, the term “radical” was introduced long before a corresponding theoretical basis, so it is not surprising that the original meaning referred to an atomic group in the sense of a substituent. The electron was not discovered until 1897. Shortly afterwards, Gomberg<sup>10</sup> published his work on the first persistent radical (Scheme 1), while the first paramagnetic biradical was synthesized by Schlenk in 1915 (Scheme 2).<sup>11</sup> Furthermore, Gomberg’s groundbreaking work also showed the typical reaction behavior of radicals, such as dimerization at lower temperatures or the reaction with oxygen to give a peroxide (Scheme 1). This is all the more astonishing because the birth of a modern bond theory or a theoretical basis for today’s radical definition was only laid in 1916 by Lewis<sup>12</sup> with the introduction of the valence-bond (VB) method. In terms of VB theory, a biradical bond situation is in some ways the opposite of a bond. If you break a bond in a molecule, you have a biradical or at least its relative, a zwitterion (see below).

**Fig. 1** Timeline of important dates leading to the modern description of biradicals.

**Scheme 1** Gomberg's persistent radical.

**Scheme 2** Schlenk's paramagnetic biradical.

What's in a name? That which we call a rose by any other name would smell as sweet.

William Shakespeare in *Romeo and Juliet* (1597).<sup>13</sup>

Unfortunately, there are many names and classifications for biradicals; even the IUPAC does not offer a consistent definition.<sup>14–16</sup> According to the “Gold Book,” a “biradical”<sup>14</sup> is a molecule with two radical centers that act nearly independently of each other, i.e., singlet and triplet state are nearly degenerate. In the case of a particularly weak interaction between the two electrons, such species are best described as a pair of radicals (two local doublets) that are connected by a linker of some sort (**Scheme 3**). In case of a significant interaction between the radical centers (here: antiferromagnetic coupling), the term “biradicaloid” is proposed. Conversely, a “diradical”<sup>15</sup> is a molecule with two “unpaired electrons,” in which a distinct singlet (electron-paired) and triplet (electron-unpaired) state can be identified. Hence, the electrons display antiferromagnetic (or ferromagnetic) coupling, respectively. According to the above definitions, the terms “diradical” and “biradicaloid” could be regarded as synonyms.

To make matters more complicated, a different definition by the IUPAC exists,<sup>16</sup> stating that the terms “biradical” and “diradical” are to be considered synonymous and describe an “even-electron molecular entity with two (possibly delocalized) radical centers,” whereas the terms “biradicaloid” and “diradicaloid” are synonyms for “species in which the two radical centers interact significantly.”

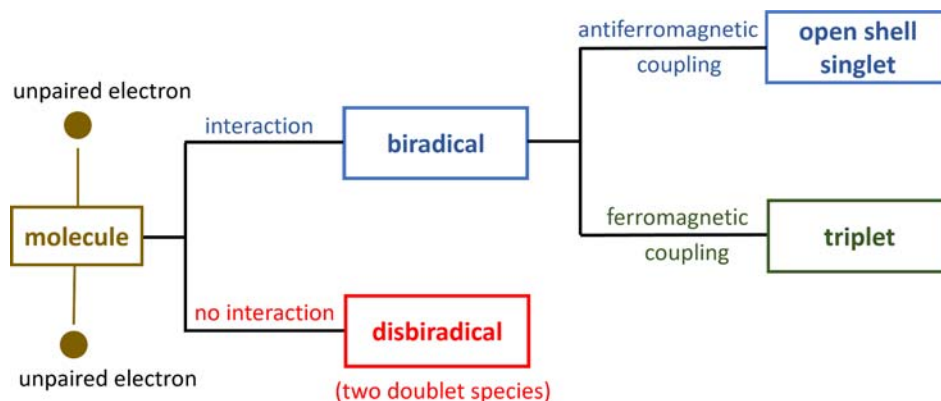

In the literature, we often find yet another definition<sup>18–20</sup>: While the expressions “biradical” or “diradical” are used to indicate species with degenerate frontier molecular orbitals (e.g., dioxygen or trimethylenemethane), the terms “biradicaloid” or “diradicaloid” refer to species with a small HOMO–LUMO gap, which may be regarded as somewhere in between an open-shell biradical and a closed-shell singlet species. While this classification is of course equally valid, it is worthy to note that the various definitions presented here rely on different properties of the electronic structure of biradical(oid)s, so they are not always identical.

To use a uniform notation, we recently proposed to use the term “disbiradical”<sup>21</sup> (using the Latin prefix “dis-”: asunder, apart) for the two-doublet species (almost no coupling) and “(singlet/triplet) biradical” for all other cases. As stated above, ferromagnetic coupling between the two electrons leads to a triplet biradical, whereas antiferromagnetic coupling results in an (open-shell) singlet biradical (**Scheme 4**). Since there is no defined limit to the degree of interaction, there is no real need to use the term “di-/biradicaloid” unless theory presents us with a clear dividing line. In fact, the transitions between biradical → biradicaloid → closed-shell singlet species are smooth in terms of electronic interaction.<sup>22</sup> For this reason, a corresponding distinction between (singlet) biradicals and biradicaloids is not made in this text.

Nonetheless, we will explore the electronic structure of biradicals in detail and point out various descriptors that help to understand the nature of different “types” of biradicals. This includes, but is not limited to, the HOMO–LUMO gap, the singlet–triplet gap (ST gap), the bonding situation (e.g., with regard to the conjugation of  $\pi$  bonds), whether the radical sites are localized or

**Scheme 3** Examples of biradicals according to the “Gold Book” definition. Adapted from Abe, M. *Diradicals*. Chem. Rev. 2013, 113 (9), 7011–7088.

**Scheme 4** Definition for biradicals and disbiradicals used in this article.

delocalized, etc. The different types and classifications of biradicals are discussed in detail throughout [Section 1.04.2](#) and, particularly, in [Sections 1.04.2.10](#) and [1.04.2.11](#).

In [Section 1.04.3](#), we will discuss cyclic four-membered and five-membered biradicals, namely so-called **cyclobutane-1,3-diyls** and **cyclopentane-1,3-diyls**,<sup>21</sup> for which there are experimental studies and in which at least one of the carbon atoms of the central ring fragment is substituted by a main group heteroatom. Furthermore, the radical centers should be centered within the four- and five-membered ring system, respectively, and be in 1,3-position to each other. Cyclic triplet carbenes, which can be understood as 1,1-diyls, are therefore not part of the present work. Cyclic heavier analogs containing double bonds, such as the disilene<sup>23</sup> investigated by Glasovac et al., which can be regarded as 1,2-diyls, are also not discussed. Furthermore, cage compounds that can formally be derived from cyclobutanediyls, such as [1.1.1]propellane derivatives,<sup>22,24,25</sup> are also not included in our review. We will discuss why the classes of compounds presented are biradicals and describe the synthesis and reactivity of these special molecules.

In [Section 1.04.4](#), the application of heterocyclopentane-1,3-diyls as molecular switches is shortly discussed. This very recent field of research offers new possibilities to control chemical equilibria by outside stimuli such as irradiation with visible light.

## 1.04.2 Theoretical description of biradicals

### 1.04.2.1 Scope of this section

This section aims to convey a principal understanding of the electronic structure of biradicals and is targeted at readers who have a basic understanding of Hartree-Fock (HF) and Density Functional Theory (DFT). First, we will cover fundamentals such as two-configuration wavefunctions, and then discuss implications of the theoretical description on our understanding of biradicals, especially regarding their classification in different subsets. Lastly, we will shortly discuss the popular “broken-symmetry” approach, which may be used to describe biradicals using UHF/UKS wavefunctions, and its connection to multireference wavefunctions.

The discussion presented in this section is partly adapted from the excellently worked-out analyses of Salem/Rowland,<sup>18</sup> Bonačić/Koutecký/Michl,<sup>19,26</sup> Lineberger/Borden,<sup>27</sup> Stuyver/Chen/Zeng/Hoffmann<sup>20</sup> and their co-workers.

### 1.04.2.2 Dynamic vs. non-dynamic correlation

Before we start our exploration of the electronic structure of biradicals, a quick revision of the concept of “electron correlation” is in order<sup>28</sup>. Electron correlation describes the instantaneous interaction of each electron with all other electrons of a many-electron wavefunction. Consequently, it cannot be described by a single molecular orbital (MO) configuration, such as a Hartree-Fock (HF) Slater determinant. Remember that in HF self-consistent field (SCF) calculations, the MOs are variationally optimized as one-electron eigenfunctions of the Fock operator and include only the averaged repulsion with the mean field of all other electrons/orbitals (expressed as a sum over Coulomb integrals  $J_{ij}$ ) as well as the exchange interaction (which is a correlation effect between same-spin electrons as a result of the antisymmetrized Slater determinant, expressed as a sum over exchange integrals  $K_{ij}$ ). Thus, the correlation energy can be defined as the difference between the HF limit ( $E_{\text{HF}}$ , i.e., the HF-SCF energy at the basis set limit) and the true ground state energy ( $E_{\text{exact}}$ , i.e., the exact solution of the non-relativistic Schrödinger equation):

$$E_{\text{corr}} = E_{\text{exact}} - E_{\text{HF}} \quad (1)$$

To include electron correlation and thus lower the energy of a given system, it is necessary to express the wavefunction  $\Psi$  not as a single Slater determinant, but as a linear combination of several Slater determinants  $\Psi_i$ :

$$\Psi = c_1\Psi_1 + c_2\Psi_2 + c_3\Psi_3 + \dots \quad (2)$$

This linear combination is, in general, called a “configuration interaction” (CI) wavefunction, with CI coefficients  $c_i$  defining the contribution of each determinant to the CI expansion. Note if  $\langle \Psi_i | \Psi_j \rangle = \delta_{ij}$  (i.e., if the Slater determinants are orthonormal, which is typically the case), then  $\sum c_i^2 = 1$ .

For many molecular systems, the leading contribution  $\Psi_1$  is the HF wavefunction  $\Psi_{\text{HF}}$  (also called HF reference in this context). Even though the correlation might be large, it is usually composed of a sum of individually small contributions from all other determinants, that is,  $c_1$  is much larger than all other coefficients. (The other determinants  $\Psi_2, \Psi_3$ , etc. are then typically generated by “exciting” one or more electrons from occupied to unoccupied HF orbitals.) This type of electron correlation is called “dynamic correlation,” and the wavefunction can still be approximately described using a single configuration.

There are, however, instances in which two (or more) coefficients  $c_i$  in Eq. (2) are much larger than the other coefficients. In these cases, a single electronic configuration is unsuitable to describe the wavefunction of the system! Thus, the HF reference is an insufficient approximation, and we must use two-configurational (or multireference) wavefunctions for a qualitatively correct representation of the electronic structure. This type of electron correlation is called “non-dynamic” or “static correlation” and is key to the understanding of biradicals (or polyradicals).

For readers who are unfamiliar with the concept of two-configurational or multireference wavefunctions, the idea that several configurations are needed to describe the electronic wavefunction of a molecule might be astounding. Thus, we must stress once more that the representation of the wavefunction as a single electronic configuration (i.e., a single Slater determinant) is the central approximation of HF theory, and as such simply does not hold for every molecular system. As the variational principle of quantum mechanics allows us to express the electronic wavefunction in arbitrary form, it is mathematically justified to use linear combinations of determinants as in Eq. (2) if this lowers the total energy of the system.<sup>28</sup> Two-configurational or multireference wavefunctions follow that logic and use two or several determinants to describe non-dynamic correlation that single determinants fail to represent.

In the next sections, we will learn when and why multireference wavefunctions are needed, as we begin our journey of the electronic structure of biradicals.

### 1.04.2.3 Two electrons in two orbitals

As indicated by the discussion of the term “biradical” in Section 1.04.1, several properties of biradicals need to be considered to gain an understanding of their electronic structure. First and foremost, it is important to realize that the interaction between the radical electrons (ferromagnetic/antiferromagnetic coupling) dictates the spin multiplicity of the electronic ground state<sup>29</sup> (spin-dipole and spin-orbit couplings will be ignored for the sake of simplicity). Thus, biradicals may adopt either a singlet or a triplet ground state. Yet, as the extent of the interaction between the radical centers is directly linked to the singlet-triplet energy gap ( $\Delta E_{\text{ST}}$ ), both singlet and triplet state must be considered to understand the electronic structure, as these two states ultimately define the reactivity of a biradical.<sup>20</sup> In this vein, “disbiradicals” could be regarded as a special case, where the lack of magnetic coupling between the unpaired electrons results in degenerate singlet and triplet states. Typical examples of disbiradicals are dihydrogen ( $\text{H}_2$ ) at its dissociation limit (see below) or bisnitroxides with long linkers as depicted in Scheme 3.

From an MO viewpoint, a prerequisite and characteristic feature of biradicals is the (near) degeneracy of the frontier molecular orbitals (FMOs), as opposed to classical closed-shell species with typically large HOMO-LUMO gaps. The electronic structure of biradicals is therefore best described by the “two electrons in two orbitals” picture<sup>20,27</sup>. The two “radical electrons” can be distributed among the two (nearly) degenerate orbitals  $\psi_a$  and  $\psi_b$ , in six different ways; that is, there are six possible determinants that need to be considered for the description of the different electronic states of biradicals (Fig. 2; note that all orbitals outside the two-orbital “active space” are omitted for clarity).

### 1.04.2.4 Two degenerate frontier orbitals

Initially, we will assume that the two orbitals are exactly degenerate (by symmetry). Note that the first two determinants in Fig. 2,  $|\psi_a^\alpha \psi_b^\alpha\rangle$  and  $|\psi_a^\beta \psi_b^\beta\rangle$ , correspond to the  $M_S = \pm 1$  configurations of a triplet (T):

$$\Psi_{T_{+1}} = |\psi_a^\alpha \psi_b^\alpha\rangle \quad (3)$$

$$\Psi_{T_{-1}} = |\psi_a^\beta \psi_b^\beta\rangle \quad (4)$$

**Fig. 2** When distributing two electrons among two degenerate orbitals  $\psi_a$  and  $\psi_b$ , six different SLATER determinants need to be considered.

The last two determinants  $|\psi_a^2\rangle$  and  $|\psi_b^2\rangle$  are closed-shell singlet configurations. Due to the degeneracy of  $\psi_a$  and  $\psi_b$ , however, neither one of these configurations alone is sufficient to describe the corresponding singlet states, but linear combinations of the two configurations must be formed:

$$\Psi_{S_{TC+}} = \frac{1}{\sqrt{2}} (|\psi_a^2\rangle + |\psi_b^2\rangle) \quad (5)$$

$$\Psi_{S_{TC-}} = \frac{1}{\sqrt{2}} (|\psi_a^2\rangle - |\psi_b^2\rangle) \quad (6)$$

Note that  $\Psi_{S_{TC+}}$  and  $\Psi_{S_{TC-}}$  are two-configuration (TC) wavefunctions and the formally paired electrons are therefore strongly (non-dynamically) correlated. Thus, the wavefunction cannot be accurately described using single-determinantal methods such as HF or post-HF methods relying on a single HF reference. (The same applies to typical Kohn-Sham DFT methods; however, this also depends on the approximation used for the exchange-correlation functional as discussed in [Section 1.04.2.10](#)) One could argue that the inability of HF theory to properly describe the wavefunction of singlet biradicals is one of their defining features! In this context, it is worthy to note that triplet biradicals *can* be described using a single determinant as evidenced by Eqs. (3) and (4), so the “problem” of non-dynamic correlation due to the degeneracy of the orbitals  $\psi_a$  and  $\psi_b$  only arises in the case of singlet biradicals.

Lastly, the two determinants at the center of [Fig. 2](#),  $|\psi_a^\alpha\psi_b^\beta\rangle$  and  $|\psi_a^\beta\psi_b^\alpha\rangle$ , do not correspond to pure spin states, but their linear combinations define the  $M_S = 0$  configuration of the triplet state (antisymmetric spatial wavefunction, symmetric spin wavefunction) and the so-called “open-shell” singlet configuration (symmetric spatial wavefunction, antisymmetric spin wavefunction):

$$\Psi_{T_0} = \frac{1}{\sqrt{2}} (|\psi_a^\alpha\psi_b^\beta\rangle + |\psi_a^\beta\psi_b^\alpha\rangle) = \frac{1}{2} [\psi_a(1)\psi_b(2) - \psi_b(1)\psi_a(2)] [\alpha(1)\beta(2) + \beta(1)\alpha(2)] \quad (7)$$

$$\Psi_{S_{OS}} = \frac{1}{\sqrt{2}} (|\psi_a^\alpha\psi_b^\beta\rangle - |\psi_a^\beta\psi_b^\alpha\rangle) = \frac{1}{2} [\psi_a(1)\psi_b(2) + \psi_b(1)\psi_a(2)] [\alpha(1)\beta(2) - \beta(1)\alpha(2)] \quad (8)$$

The three triplet configurations  $\Psi_{T_{+1}}$ ,  $\Psi_{T_0}$ , and  $\Psi_{T_{-1}}$  are, of course, degenerate in the absence of a magnetic field when neglecting the small spin-dipole coupling between the unpaired electrons. Thus, usually only  $\Psi_{T_{+1}}$  is considered in MO calculations. On the other hand, the three singlet configurations  $\Psi_{S_{TC+}}$ ,  $\Psi_{S_{TC-}}$ , and  $\Psi_{S_{OS}}$  are, in general, not degenerate. Thus, these three singlet states and the triplet state define the four lowest energy states of every biradical ([Fig. 3](#)). Their relative ordering and especially the singlet-triplet gap  $\Delta E_{ST} = E_S - E_T$  between the lowest-lying singlet and triplet state define some of the most important characteristics of biradicals.

### 1.04.2.5 Energetic ordering of the biradical states

The energy of the triplet state is given by the usual expression

$$E_T = \langle \Psi_T | H | \Psi_T \rangle = h_a + h_b + J_{ab} - K_{ab} \quad (9)$$

where  $h_a$  and  $h_b$  are the one-electron energies of the orbitals  $\psi_a$  and  $\psi_b$  exclusive of the interelectronic interaction, and  $J_{ab}$  as well as  $K_{ab}$  are the Coulomb and exchange integrals

$$J_{ab} = (aa|bb) = \iint \psi_a^2(1) \frac{1}{r_{12}} \psi_b^2(2) dr_1 dr_2 \quad (10)$$

$$K_{ab} = (ab|ab) = \iint \psi_a(1)\psi_b(1) \frac{1}{r_{12}} \psi_a(2)\psi_b(2) dr_1 dr_2 \quad (11)$$

which arise from the interelectronic repulsion term  $\sum_{ij} 1/r_{ij}$  of the Hamiltonian acting on the determinantal wavefunction (all expressions in atomic units). Eq. (9) implies that the Coulomb repulsion energy  $J_{ab}$  between the two spin-unpaired electrons is

**Fig. 3** The four lowest energy states of a biradical are expressed as linear combinations of the six determinants in [Fig. 2](#). Note that all singlet states of a biradical are linear combinations of two determinants; thus, they cannot be described by single-determinantal methods such as HF. Normalization constants omitted for clarity.

reduced by the exchange interaction energy  $K_{ab}$  (which is always positive).<sup>30</sup> This circumstance is usually interpreted in terms of the so-called “Fermi hole” around each electron, which means that electrons of equal spin tend to avoid each other, thus reducing their mutual repulsion in the triplet state.

The situation is different for the singlet states. In HF theory, we learn that there is no exchange interaction between opposite-spin electrons.<sup>28</sup> However, this is a result of the single-determinantal nature of the HF wavefunction! When evaluating the interelectronic repulsion operator for the two-determinantal singlet wavefunction  $\Psi_{S_{OS}}$ , one can easily show that the exchange interaction between the two electrons leads to an increase of the interelectronic repulsion:

$$\begin{aligned} \langle \Psi_{S_{OS}} | \frac{1}{r_{12}} | \Psi_{S_{OS}} \rangle &= J_{ab} + K_{ab} \\ \Rightarrow E_{S_{OS}} = \langle \Psi_{S_{OS}} | H | \Psi_{S_{OS}} \rangle &= h_a + h_b + J_{ab} + K_{ab} \end{aligned} \quad (12)$$

Thus, the electrons of opposite spin tend to localize in the same region of space, i.e., their movement is strongly correlated, resulting in a larger repulsive term. In consequence, the triplet state  $\Psi_T$  is  $2K_{ab}$  lower in energy than the open-shell singlet  $\Psi_{S_{OS}}$ , if (and only if!) the optimal MOs for singlet and triplet state are identical. Moreover, note that dynamic electron correlation (which is neglected in our derivation) may also impact the energy difference between open-shell (OS) singlet and triplet.<sup>29</sup>

The energies of the two-configurational (TC) singlet states may be derived in a similar manner, resulting in the following expression:

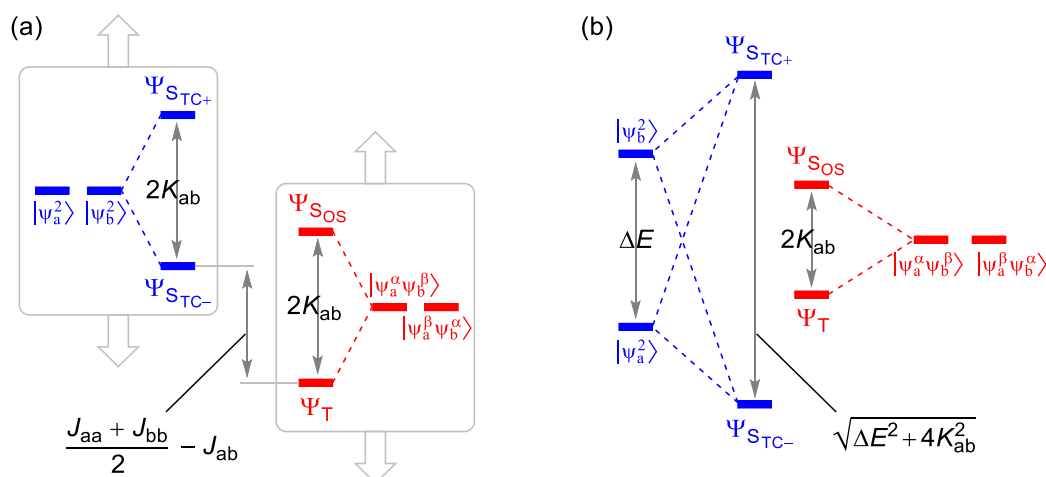

$$E_{S_{TC\pm}} = \langle \Psi_{S_{TC\pm}} | H | \Psi_{S_{TC\pm}} \rangle = h_a + h_b + \frac{J_{aa} + J_{bb}}{2} \pm K_{ab} \quad (13)$$

Thus, the energy of the singlet state  $\Psi_{S_{TC-}}$  is  $2K_{ab}$  lower than the energy of the  $\Psi_{S_{TC+}}$  state. Moreover, the energy difference between the singlet  $\Psi_{S_{TC-}}$  and triplet  $\Psi_T$  can be expressed solely in terms of the one-site and two-site Coulomb integrals:

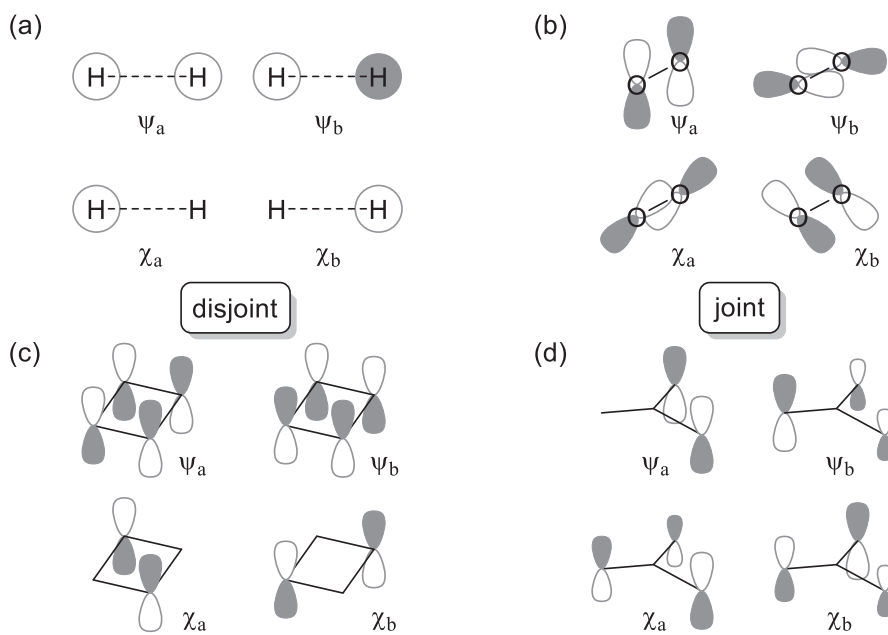

$$E_{S_{TC-}} - E_T = \frac{J_{aa} + J_{bb}}{2} - J_{ab} \quad (14)$$

Again, note that these considerations are only valid under the approximation that the same set of orbitals can be used to describe all four electronic states. As pointed out by Stuyver et al.,<sup>20</sup> it is then obvious that the four electronic states can be grouped in two pairs, namely  $\Psi_T/\Psi_{S_{OS}}$  and  $\Psi_{S_{TC-}}/\Psi_{S_{TC+}}$  (Fig. 4A). The two states in each pair have a constant energy separation of  $2K_{ab}$ , while the energetic position of the two pairs relative to each other is determined by Eq. (14). Thus, the final order of the states depends on the magnitude of the Coulomb and exchange integrals.

According to Hund’s rule, the triplet state is usually the ground state of a biradical with a set of degenerate frontier orbitals. To decide whether the singlet-triplet (ST) gap is small or large, let us take a closer look at the nature of the two orbitals  $\psi_a$  and  $\psi_b$ . We started our discussion by assuming that the two orbitals are a degenerate set of MOs, such as the two  $\pi^*$  valence orbitals of the  $O_2$  molecule, or the  $\sigma$  and  $\sigma^*$  orbitals of  $H_2$  stretched to the dissociation limit (Fig. 5). However, this is not the only acceptable choice! As the two-configurational wavefunctions discussed here are of the “complete active space” (CAS) type (i.e., all possible configurations of two electrons in the two “active” orbitals are considered, basically a full-CI within the active space), they are invariant to arbitrary orbital rotations within the active space (the CI coefficients being rotated accordingly). Thus, any normalized set of linear

**Fig. 4** Relative energy levels of the four electronic states of a biradical. (A) Two degenerate orbitals  $\psi_a$  and  $\psi_b$ . The position of the formal closed-shell (blue) and open-shell (red) states depends on the Coulomb and exchange integrals. (B) Small energy gap between orbitals  $\psi_a$  and  $\psi_b$  ( $\Psi_{S_{TC-}} = c_1|\psi_a^2\rangle - c_2|\psi_b^2\rangle$ , cf. Section 1.04.2.7). Adapted from Stuyver, T.; Chen, B.; Zeng, T.; Geerlings, P.; De Proft, F.; Hoffmann, R. Do Diradicals Behave Like Radicals? *Chem. Rev.* **2019**, *119* (21), 11291–11351.

**Fig. 5** Examples of MOs and corresponding GVB orbitals. (A) H<sub>2</sub> orbitals at the dissociation limit ( $r_{\text{HH}} \rightarrow \infty$ ). Due to zero overlap of the atomic 1s orbitals, the MOs  $\psi_a$  and  $\psi_b$  are degenerate. (B) Degenerate set of  $\pi^*$  orbitals in the O<sub>2</sub> molecule. The GVB orbitals correspond to a 45° rotation of the MO set. (C) Although the GVB orbitals of square cyclobutadiene ( $D_{4h}$ ) are not localized on single atoms, both are localized on different sets of atoms and therefore do not share a considerable region of space. (D) The MOs of trimethylmethylene (TMM) cannot be localized in the GVB picture.<sup>20,27</sup>

combinations of the orbitals  $\psi_a$  and  $\psi_b$  is an equally acceptable choice. We may therefore define a different set of orthogonal, degenerate orbitals

$$\chi_a = \frac{1}{\sqrt{2}}(\psi_a + \psi_b), \chi_b = \frac{1}{\sqrt{2}}(\psi_a - \psi_b) \quad (15)$$

which is also referred to as “generalized valence bond” (GVB) orbitals.<sup>20,27,31</sup> This orbital transformation has important implications for the chemical interpretation of the different electronic states, as we will discuss in a moment. First, note that the transformed orbitals  $\chi_a$  and  $\chi_b$  might be localized on different atoms (as in case of H<sub>2</sub>, Fig. 5A) or still be delocalized (as in case of O<sub>2</sub>, Fig. 5B). If the transformed orbitals are localized, the biradical is a so-called “disjoint” biradical<sup>17,20</sup> and the ST gap is generally small, that is,  $\Psi_{\text{SIC}}$  and  $\Psi_{\text{T}}$  have similar energies. Thus, the interaction between the radical centers is weak (cf. Section 1.04.2.10). If, however, the orbitals cannot be localized, the biradical belongs to the group of so-called “joint” or “non-disjoint” biradicals.<sup>17,20</sup> They exhibit a large ST gap, and the triplet state is the ground state according to Hund’s rule (see also Section 1.04.2.6). The radical centers of these biradicals are therefore said to be ferromagnetically coupled.

We need to stress again that dynamic electron correlation (including orbitals/electrons outside the “active space” of two electrons in two orbitals) may also influence the ordering of the states (as is the case, for example, in square cyclobutadiene which possesses a singlet ground state).<sup>32–34</sup> This phenomenon has been dubbed “dynamic spin polarization” and/or “dynamic charge polarization” by different authors, and the reader is referred to the literature for an in-depth analysis of these correlation effects.<sup>27,29,32,33</sup>

#### 1.04.2.6 Chemical interpretation of the biradical states

Let us now consider the orbital transformation laid out in Eq. (15) in more detail. It should be clear that we can equivalently write

$$\psi_a = \frac{1}{\sqrt{2}}(\chi_a + \chi_b) \quad (16)$$

$$\psi_b = \frac{1}{\sqrt{2}}(\chi_a - \chi_b) \quad (17)$$

Substituting Eqs. (16) and (17) in Eq. (6) yields

$$\begin{aligned}
 \Psi_{S_{TC-}} &= \frac{1}{\sqrt{2}} (|\psi_a^2\rangle - |\psi_b^2\rangle) \\
 &= \frac{1}{2} [\psi_a(1)\psi_a(2) - \psi_b(1)\psi_b(2)] [\alpha(1)\beta(2) - \beta(1)\alpha(2)] \\
 &= \frac{1}{2} [\chi_a(1)\chi_b(2) + \chi_b(1)\chi_a(2)] [\alpha(1)\beta(2) - \beta(1)\alpha(2)] \\
 &= \frac{1}{\sqrt{2}} (|\chi_a^\alpha\chi_b^\beta\rangle - |\chi_a^\beta\chi_b^\alpha\rangle) = \Psi'_{S_{OS}}
 \end{aligned} \tag{18}$$

that is, the closed-shell, two-configurational singlet wavefunction  $\Psi_{S_{TC-}}$  transforms into an open-shell singlet wavefunction  $\Psi_{S_{OS}}$  in the GVB basis!<sup>20,27</sup> Conversely, the open-shell singlet wavefunction  $\Psi_{S_{OS}}$  in the MO basis transforms into a closed-shell, two configurational singlet wavefunction  $\Psi_{S_{TC-}}$  in the GVB basis, as evidenced by substituting Eqs. (16) and (17) in Eq. (8):

$$\begin{aligned}
 \Psi_{S_{OS}} &= \frac{1}{\sqrt{2}} (|\psi_a^\alpha\psi_b^\beta\rangle - |\psi_b^\beta\psi_a^\alpha\rangle) \\
 &= \frac{1}{2} [\psi_a(1)\psi_b(2) + \psi_b(1)\psi_a(2)] [\alpha(1)\beta(2) - \beta(1)\alpha(2)] \\
 &= \frac{1}{2} [\chi_a(1)\chi_a(2) - \chi_b(1)\chi_b(2)] [\alpha(1)\beta(2) - \beta(1)\alpha(2)] \\
 &= \frac{1}{\sqrt{2}} (|\chi_a^2\rangle - |\chi_b^2\rangle) = \Psi'_{S_{TC-}}
 \end{aligned} \tag{19}$$

Thus,  $\Psi_{S_{TC-}}$  and  $\Psi_{S_{OS}}$  have exchanged their character upon orbital transformation. The assignment of a singlet state as “closed-shell” or “open-shell” is therefore dependent on the orbital basis, and the latter must be specified if the terms “closed-shell” and “open-shell” singlet are to be used to describe the electronic structure of any biradical.<sup>27</sup> Arguably, any two-configurational singlet could be regarded as “open-shell” singlet<sup>18,19</sup> due to the ambiguity of the wavefunction depending on the orbital basis.

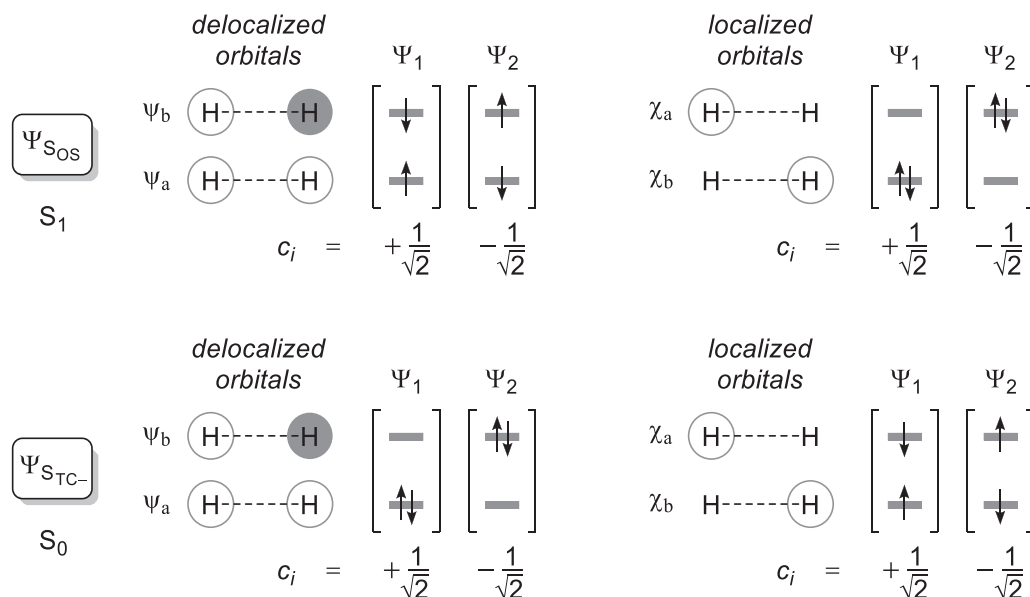

Now, one may ask why this change of character is remarkable, especially when we noted before that the choice of orbital basis is arbitrary. Yet, the transformed orbitals  $\chi_a$  and  $\chi_b$  are often localized on different atoms of a molecule (i.e., they can be regarded as “localized orbitals” in many instances) and therefore guide us to a chemical interpretation of the wavefunction. The two-configurational wavefunction  $\Psi_{S_{TC-}}$ , which has two electrons in either of the two delocalized MOs  $\psi_a$  and  $\psi_b$ , can thus be viewed as a “biradical” state, as we find one electron in each of the localized orbitals  $\chi_a$  and  $\chi_b$ . By localizing on two different sites, the two non-dynamically correlated electrons avoid each other. *It is exactly this correlated movement of the electrons that results in biradical character.* In contrast, the formal open-shell wavefunction  $\Psi_{S_{OS}}$ , which has one electron in each of the delocalized MOs, is actually a zwitterionic state, since the two electrons will always occupy the same orbital,  $\chi_a$  or  $\chi_b$ , in the localized picture.<sup>18</sup>

Let us once again consider dihydrogen ( $H_2$ ) at its dissociation limit as an example:  $\Psi_{S_{TC-}}$  is the lowest-energy singlet ( $S_0$ ) wavefunction and the two formally spin-paired electrons are distributed equally across the two delocalized MOs  $\psi_a$  and  $\psi_b$  (Fig. 6, bottom). This electronic situation is chemically hard to interpret. In the localized picture, however, one electron is localized in each of the two hydrogenic 1s orbitals ( $\chi_a$  and  $\chi_b$ ), in agreement with our anticipation that we find two H radicals at the dissociation limit. (Notice that in this special example, singlet and triplet state are degenerate, resulting in a true “disbiradical.”) Conversely, the first excited singlet state ( $S_1$ ) is described by  $\Psi_{S_{OS}}$ , which corresponds to the ionic dissociation limit as shown by the orbital transformation to the localized orbital basis (Fig. 6, top). The localized picture therefore offers a straightforward description of the electronic structure in a sense that it is often easier to understand in chemical terms. We must stress, though, that neither orbital basis (MO or GVB) is more “right” or “wrong” than the other; they merely represent different sides of the same coin.

As mentioned before, the transformed orbitals are not always nicely localized (cf. joint biradicals, Fig. 5). In such cases, an interpretation of the wavefunction is more difficult; however, one can still choose the more localized set of orbitals (i.e.,  $\chi_a$  and  $\chi_b$ ) to decide whether an electronic state has larger biradical or zwitterionic character. There will, however, always remain an ambiguity with respect to the biradical and zwitterionic nature of the singlet states of joint biradicals.<sup>20</sup> Note that  $O_2$  is a special case; here, the GVB orbitals correspond to a 45° rotation of the molecule around the O–O axis; thus, the GVB and MO description are equivalent. Consequently,  $\Psi_{S_{TC-}}$  and  $\Psi_{S_{OS}}$  are degenerate by symmetry and it is no longer possible to classify these states as biradical or zwitterionic states. The situation is similar for TMM in  $D_{3h}$  symmetry.<sup>20,27</sup>

The attentive reader will have noticed that we have not yet discussed the remaining two states of a biradical,  $\Psi_{S_{TC+}}$  and  $\Psi_T$ . These states do not change their character upon orbital transformation:

$$\begin{aligned}
 \Psi_{S_{TC+}} &= \frac{1}{\sqrt{2}} (|\psi_a^2\rangle + |\psi_b^2\rangle) \\
 &= \frac{1}{2} [\psi_a(1)\psi_a(2) + \psi_b(1)\psi_b(2)] [\alpha(1)\beta(2) - \beta(1)\alpha(2)] \\
 &= \frac{1}{2} [\chi_a(1)\chi_a(2) + \chi_b(1)\chi_b(2)] [\alpha(1)\beta(2) - \beta(1)\alpha(2)]
 \end{aligned}$$

**Fig. 6** H<sub>2</sub> at its dissociation limit in the delocalized (MO) and localized (GVB) orbital picture. The CAS-Cl wavefunctions are given by  $\Psi = \sum c_i \Psi_i$ . Note that the orbitals  $\psi_a$  and  $\psi_b$  as well as  $\chi_a$  and  $\chi_b$  are degenerate.

$$= \frac{1}{\sqrt{2}} (|\chi_a^2\rangle + |\chi_b^2\rangle) = \Psi'_{S_{TC+}} \quad (20)$$

$$\begin{aligned} \Psi_T &= |\psi_a^\alpha \psi_b^\alpha\rangle \\ &= \frac{1}{\sqrt{2}} [\psi_a(1)\psi_b(2) - \psi_b(1)\psi_a(2)][\alpha(1)\alpha(2)] \\ &= \frac{1}{\sqrt{2}} [\chi_b(1)\chi_a(2) - \chi_a(1)\chi_b(2)][\alpha(1)\alpha(2)] \\ &= |\chi_b^\alpha \chi_a^\alpha\rangle = \Psi'_T \end{aligned} \quad (21)$$

Therefore, the triplet wavefunction  $\Psi_T = \Psi'_T$  corresponds to a biradical state, whereas the singlet wavefunction  $\Psi_{S_{TC+}} = \Psi_{S_{TC+}}'$  is zwitterionic.

Let us finally come back to the ordering of the states as depicted in Fig. 4A. We already mentioned that disjoint and joint biradicals differ in that they display small or large ST gaps, respectively. This is intuitively understandable; if the orbitals are localized in different regions of space, the interaction between the electrons and thus the ST gap will be small. Conversely, if the orbitals cannot be localized, the interaction between the electrons and thus the ST gap will be large. Still, we have not yet answered the question whether  $\Psi_{S_{Os}}$  or  $\Psi_{S_{TC-}}$  is lower in energy and therefore defines the ST gap.

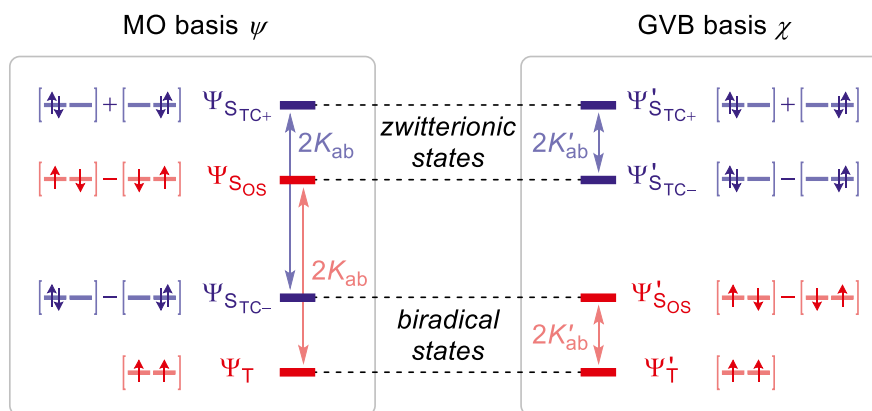

Once again, considering the (possibly localized) GVB orbitals gives us an easy answer. Notice that, as we did not make any restrictions to the choice of orbitals in our derivation of the biradical states in Sections 1.04.2.4 and 1.04.2.5, the same energetic relations apply within the sets of the “original” and “transformed” states, i.e., regardless of whether we use MOs  $\psi$  or GVB orbitals  $\chi$  (Fig. 7). However, recall that  $\Psi_{S_{TC-}}$  (using orbitals  $\psi$ ) equals  $\Psi_{S_{Os}}'$  (using orbitals  $\chi$ ) and vice versa, so the Coulomb and exchange integrals will, of course, have different magnitudes depending on the orbital basis. If we now consider a disjoint biradical (with orbitals  $\chi_a$  and  $\chi_b$  localized on different sites), the exchange integral  $K_{ab}'$  between those two orbitals will typically be small. Thus, the energy difference between  $\Psi_{S_{Os}}'$  and  $\Psi'_T$

$$E'_{S_{Os}} - E'_T = 2K'_{ab} \quad (22)$$

will also be small. Conversely, the energy splitting between  $\Psi_{S_{TC-}}'$  and  $\Psi'_T$  as given by Eq. (14)

$$E'_{S_{TC-}} - E'_T = \frac{J'_{aa} + J'_{bb}}{2} - J'_{ab} \quad (23)$$

will be large, since the one-site Coulomb integrals  $J'_{aa}$  and  $J'_{bb}$  will be much larger than the two-site Coulomb integral  $J'_{ab}$ . Therefore, the formal “open-shell” singlet  $\Psi_{S_{Os}}'$  will be the lowest-energy singlet state, and the ST gap will be determined by Eq. (22).

**Fig. 7** The four biradical states expressed in the (fully delocalized) MO basis and the (possibly localized) GVB basis. The states that are formed from open-shell determinants are printed in red, those that are formed from closed-shell determinants are printed in blue. If the GVB orbitals are localized,  $K_{ab}'$  is small. Otherwise,  $K_{ab}'$  is larger, but generally smaller than  $K_{ab}$ . Note that  $H_2$  at its dissociation limit and  $O_2$  can be regarded as “extreme” cases of disjoint and joint biradicals: For dissociated  $H_2$ ,  $K_{ab}' = 0$  (i.e.,  $\Delta E_{ST} = 0$ ), whereas for  $O_2$ ,  $K_{ab}' = K_{ab}$  (i.e.,  $E_{S_{TC-}} = E_{S_{OS}}$ ).

Transforming the orbitals back to the delocalized MOs  $\psi_a$  and  $\psi_b$ , it becomes clear that  $\Psi_{S_{TC-}} = \Psi_{S_{OS}}'$  will be the lowest-energy singlet state, and the ST gap will be given by Eq. (14). Hence,

$$\Delta E_{ST} = 2K_{ab}' = \frac{J_{aa} + J_{bb}}{2} - J_{ab} \quad (24)$$

that is, the exchange integral in the GVB basis is related to the Coulomb integrals in the MO basis and vice versa.

The same reasoning holds true for joint biradicals. Even if the transformed orbitals  $\chi_a$  and  $\chi_b$  are not perfectly localized on different sites, the exchange integral  $K_{ab}'$  between the localized orbitals will generally be smaller than the exchange integral  $K_{ab}$  between the delocalized orbitals, because the localized orbitals only share a smaller region of space.<sup>19,20</sup> Therefore,  $\Psi_{T}'$  and  $\Psi_{S_{OS}}'$  will generally be lower in energy than  $\Psi_{S_{TC-}}'$  and  $\Psi_{S_{TC+}}'$ , the former being assigned biradical and the latter being assigned zwitterionic character as discussed before (Fig. 7).

#### 1.04.2.7 Two nearly degenerate frontier orbitals

Up to this point, we have assumed that the two orbitals  $\psi_a$  and  $\psi_b$  are exactly degenerate (thus, the resulting biradicals have a biradical character of 100%, cf. Section 1.04.2.10). This degeneracy is often induced by symmetry, but there are numerous examples of biradicals with lower symmetry than  $D_{2d}$  or  $C_3$ , that is, these systems do not possess orbital degeneracy required by symmetry. Therefore, many (if not the majority of) biradicals possess at least a small energy gap between the two orbitals  $\psi_a$  and  $\psi_b$ , which are then typically referred to as HOMO and LUMO, the so-called frontier molecular orbitals (FMOs). These species with a small HOMO-LUMO gap are also referred to as “di-/biradicaloids” in the literature<sup>17–20,22,24–26,35–37</sup> (see also our discussion of different designations of biradicals in Section 1.04.1).

In the following discussion, we assume that the radical centers are, just as before, connected by some symmetry operation, such as inversion or rotation (this has been dubbed the “homosymmetric” case by Salem and Rowland),<sup>18</sup> that is, the orbitals  $\psi_a$  and  $\psi_b$  are typically derived from symmetry-adapted linear combinations (SALCs) of atomic orbitals (basis functions) at the radical sites. Thus, the orbitals are perfectly delocalized (Fig. 8). When the energy gap between  $\psi_a$  and  $\psi_b$  is increased ( $h_a < h_b$ ), the configuration  $|\psi_a^2\rangle$  with two electrons in the lower-energy orbital  $\psi_a$  becomes energetically favored, considering that all other configurations place at least one electron in the higher-energy orbital  $\psi_b$ . In the limiting case of a large HOMO-LUMO gap, a closed-shell singlet ground state is expected, i.e., the configuration  $|\psi_a^2\rangle$  alone is sufficient to describe the ground state wavefunction (when disregarding dynamic correlation, of course). Thus, increasing the HOMO-LUMO gap results in a decreasing biradical character (cf. Section 1.04.2.10), until a closed-shell species is obtained (Fig. 9).

Obviously, this means that the mixing (i.e., the “interaction”) of the configurations  $|\psi_a^2\rangle$  and  $|\psi_b^2\rangle$  in  $\Psi_{S_{TC-}}$  (Eq. 6) must decrease when the HOMO-LUMO gap is increased, up to the point where the contribution of  $|\psi_b^2\rangle$  can be neglected and a closed-shell species is obtained. To account for varying HOMO-LUMO separations, we therefore introduce the CI coefficients  $c_1$  and  $c_2$ ,

$$\Psi_{S_{TC-}} = c_1 |\psi_a^2\rangle - c_2 |\psi_b^2\rangle \quad (25)$$

where  $c_1 \geq c_2 > 0$  and  $c_1^2 + c_2^2 = 1$  for normalization of the wavefunction. (Notice that by this definition, we explicitly state that the second term on the r.h.s. of Eq. (25) is negative. In a general CI expansion of the type  $\Psi = \sum c_i \Psi_i$ , the value of  $c_2$  of  $\Psi_{S_{TC-}}$  would have a negative sign, cf. Figs. 8 and 9) Conversely,

$$\Psi_{S_{TC+}} = c_2 |\psi_a^2\rangle + c_1 |\psi_b^2\rangle \quad (26)$$

**Fig. 8** Examples of symmetric biradicals with a small HOMO-LUMO gap. The CAS-Cl wavefunctions are given by  $\Psi = \sum c_i \Psi_i$ , where  $\Psi_1 = |\psi_a^2\rangle$  and  $\Psi_2 = |\psi_b^2\rangle$ .

**Fig. 9** Dissociation of  $\text{H}_2$ . The CAS-Cl wavefunctions of the different structures along the dissociation curve are given by  $\Psi = \sum c_i \Psi_i$ . At its equilibrium structure,  $\text{H}_2$  is a typical “closed-shell” molecule ( $c_2 \approx -0.1$ , so the contribution of the second determinant  $\Psi_2$  would be considered dynamic correlation). When the H-H distance  $r$  is increased, the overlap of the atomic  $1s$  orbitals decreases, and so does the HOMO-LUMO gap. For  $r \rightarrow \infty$ , the overlap integral between the atomic orbitals vanishes, so the MOs  $1\sigma$  and  $1\sigma^*$  become degenerate and a “perfect” biradical is obtained. Notice that there is no clear distinction between closed-shell and biradical(oid); the biradical character increases smoothly with increasing  $r$ .

that is, the second term on the r.h.s. of Eq. (26) is always positive. In case of  $c_1 = c_2 = 1/\sqrt{2}$ , we have the limiting case of degenerate orbitals  $\psi_a$  and  $\psi_b$  as discussed in the previous sections, and in case of  $c_1 = 1$  and  $c_2 = 0$ , a closed-shell species is obtained:

$$\Psi_{\text{S}_{\text{TC}^-}} = |\psi_a^2\rangle$$

$$\Psi_{\text{S}_{\text{TC}^+}} = |\psi_b^2\rangle$$

Thus, if the quotient  $c_1/c_2$  is large, the system resembles a closed-shell system, and if  $c_1/c_2$  approaches unity, the molecule becomes more biradical-like.<sup>20</sup>

The formal open-shell wavefunctions  $\Psi_{\text{T}}$  and  $\Psi_{\text{S}_{\text{OS}}}$  remain, of course, unaffected by the HOMO-LUMO energy gap, as one electron is placed in each orbital, irrespective of the relative orbital energies.

Let us once again look at the energies of the four biradical states. To simplify the mathematical description, we first introduce the energies  $H_{aa}$  and  $H_{bb}$  of the configurations  $|\psi_a^2\rangle$  and  $|\psi_b^2\rangle$ , respectively.<sup>20</sup>

$$H_{aa} = \langle \psi_a^2 | H \psi_a^2 \rangle = 2h_a + J_{aa} \quad (27)$$

$$H_{bb} = \langle \psi_b^2 | H \psi_b^2 \rangle = 2h_b + J_{bb} \quad (28)$$

In Eqs. (27) and (28),  $h_a$  and  $h_b$  are the one-electron energies of the orbitals  $\psi_a$  and  $\psi_b$  exclusive of the interelectronic repulsion, and  $J_{aa}$  as well as  $J_{bb}$  are the one-site Coulomb integrals (as discussed above). It is straightforward to show that the energy  $E_{\text{S}_{\text{TC}^-}}$  of the two-configurational wavefunction  $\Psi_{\text{S}_{\text{TC}^-}}$  as defined in Eq. (25) is given by

$$\begin{aligned}
 E_{S_{TC-}} &= \langle \Psi_{S_{TC-}} | H | \Psi_{S_{TC-}} \rangle \\
 &= c_1^2 \cdot \langle \psi_a^2 | H | \psi_a^2 \rangle + c_2^2 \cdot \langle \psi_b^2 | H | \psi_b^2 \rangle - c_1 c_2 \cdot \langle \psi_a^2 | H | \psi_b^2 \rangle - c_2 c_1 \cdot \langle \psi_b^2 | H | \psi_a^2 \rangle \\
 &= c_1^2 H_{aa} + c_2^2 H_{bb} - 2c_1 c_2 K_{ab}
 \end{aligned} \tag{29}$$

where  $K_{ab} = \langle \psi_a^2 | H | \psi_b^2 \rangle = \langle \psi_b^2 | H | \psi_a^2 \rangle$  is the exchange integral between orbitals  $\psi_a$  and  $\psi_b$ . In case that  $c_1 = c_2 = 1/\sqrt{2}$  (i.e., if the orbitals are degenerate), Eq. (29) reduces to

$$\begin{aligned}
 E_{S_{TC-}} &= \frac{1}{2} H_{aa} + \frac{1}{2} H_{bb} - K_{ab} \\
 &= h_a + h_b + \frac{J_{aa} + J_{bb}}{2} - K_{ab}
 \end{aligned}$$

which is identical to the expression derived in Eq. (13). Similarly, the energy of the wavefunction  $\Psi_{S_{TC+}}$  amounts to

$$E_{S_{TC+}} = \langle \Psi_{S_{TC+}} | H | \Psi_{S_{TC+}} \rangle = c_2^2 H_{aa} + c_1^2 H_{bb} + 2c_1 c_2 K_{ab} \tag{30}$$

The energies of  $\Psi_T$  and  $\Psi_{S_{OS}}$  remain the same as those given in Eqs. (9) and (12), respectively:

$$E_T = \langle \Psi_T | H | \Psi_T \rangle = h_a + h_b + J_{ab} - K_{ab}$$

$$E_{S_{OS}} = \langle \Psi_{S_{OS}} | H | \Psi_{S_{OS}} \rangle = h_a + h_b + J_{ab} + K_{ab}$$

Clearly, for a system with non-degenerate orbitals  $\psi_a$  and  $\psi_b$  (i.e.,  $c_1 > c_2$ ), Eqs. (27) and (29) show that the energy of  $\Psi_{S_{TC-}}$  is dominated by the energy  $H_{aa}$ , and thus the one-electron energy  $h_a$  of orbital  $\psi_a$ . In contrast, as shown by Eqs. (9) and (12), the energies of  $\Psi_T$  and  $\Psi_{S_{OS}}$  are dependent on the formal average of the one-electron energies  $h_a$  and  $h_b$ , whereas the energy of  $\Psi_{S_{TC+}}$  is a function of the one-electron energy  $h_b$ , as demonstrated by Eq. (30). Given that orbital  $\psi_a$  is the lower-energy orbital, the singlet state  $\Psi_{S_{TC-}}$  is usually the ground state, followed by the triplet state  $\Psi_T$  and the “open-shell” singlet  $\Psi_{S_{OS}}$ , while  $\Psi_{S_{TC+}}$  is the highest-energy state of the four states of a biradical (Fig. 4B).

The energy difference between the two “closed-shell” states  $\Psi_{S_{TC-}}$  and  $\Psi_{S_{TC+}}$  amounts to

$$E_{S_{TC+}} - E_{S_{TC-}} = (c_1^2 - c_2^2) \cdot (H_{bb} - H_{aa}) + 4c_1 c_2 K_{ab} \tag{31}$$

which reduces to  $2K_{ab}$  for  $c_1 = c_2 = 1/\sqrt{2}$ . The energy difference between the two “open-shell” states  $\Psi_T$  and  $\Psi_{S_{OS}}$  is  $2K_{ab}$  as discussed before.

Let us now consider Eqs. (29) and (30) in more detail. The integrals  $H_{aa}$ ,  $H_{bb}$ , and  $H_{ab} = H_{ba} = K_{ab}$  (if real orbitals are used, which is normally the case) are the matrix elements of a CI matrix with double substitutions in the active space (i.e., orbitals  $\psi_a$  and  $\psi_b$ ).<sup>28</sup> To find an optimal set of coefficients  $c_i$ , the energy of the system must be minimized ( $\partial E / \partial c_i = 0$ ).<sup>28,38</sup> Thus, we need to solve for the energy eigenvalues  $E$  of the matrix equation

$$\mathbf{H}\mathbf{c} = E\mathbf{S}\mathbf{c} \tag{32}$$

where  $\mathbf{H}$  is the CI matrix

$$\mathbf{H} = \begin{pmatrix} H_{aa} & H_{ab} \\ H_{ba} & H_{bb} \end{pmatrix} \tag{33}$$

$\mathbf{S}$  (here  $S_{ij} = \delta_{ij}$ ) is the overlap matrix, and  $\mathbf{c}$  are the eigenvectors associated with the CI coefficients  $c_i$  of the general two-configuration CI wavefunction

$$\Psi = c_1 |\psi_a^2\rangle + c_2 |\psi_b^2\rangle \tag{34}$$

Note that in Eq. (34),  $c_2 < 0$  for  $\Psi_{S_{TC-}}$ . The energy eigenvalues are obtained by diagonalizing the CI matrix, that is, by solving the corresponding secular equation,<sup>28</sup>

$$\begin{vmatrix} H_{aa} - E & H_{ab} \\ H_{ba} & H_{bb} - E \end{vmatrix} = 0 \tag{35}$$

$$\begin{aligned}
 (H_{aa} - E)(H_{bb} - E) - K_{ab}^2 &= 0 \\
 \Rightarrow E_{\pm} &= \frac{H_{aa} + H_{bb}}{2} \pm \frac{1}{2} \sqrt{(H_{bb} - H_{aa})^2 + 4K_{ab}^2}
 \end{aligned} \tag{36}$$

where  $E_- = E_{S_{TC-}}$  and  $E_+ = E_{S_{TC+}}$ . It becomes evident from Eq. (36) that  $E_- = H_{aa}$  if  $K_{ab} = 0$ , and consequently,  $E_- < H_{aa}$  if  $K_{ab} > 0$ . Thus,  $\Psi_{S_{TC-}}$  is typically lower in energy than the single configuration  $|\psi_a^2\rangle$ , but certainly never higher in energy. That is, the two-configurational wavefunction  $\Psi_{S_{TC-}}$  improves upon the single-determinantal description of the RHF wavefunction, and the

energy lowering is directly connected to the magnitude of  $K_{ab}$ . Similarly,  $\Psi_{S_{TC+}}$  is generally higher in energy than the single configuration  $|\psi_b^2\rangle$  (cf. Fig. 4B).

Using Eq. (36), we can now express the energy difference between the two “closed-shell” states  $\Psi_{S_{TC-}}$  and  $\Psi_{S_{TC+}}$  as

$$E_{S_{TC+}} - E_{S_{TC-}} = \sqrt{(H_{bb} - H_{aa})^2 + 4K_{ab}^2} \quad (37)$$

whereas the singlet-triplet energy gap  $\Delta E_{ST}$  amounts to

$$\begin{aligned} \Delta E_{ST} &= E_{S_{TC-}} - E_T \\ &= 2K'_{ab} + K_{ab} - \frac{1}{2}\sqrt{(H_{bb} - H_{aa})^2 + 4K_{ab}^2} \end{aligned} \quad (38)$$

with

$$2K'_{ab} = \frac{J_{aa} + J_{bb}}{2} - J_{ab} \quad (39)$$

by analogy with Eq. (24). Thus, the singlet-triplet gap depends on the exchange integral, the one- and two-site Coulomb integrals, as well as the energy difference between the configurations  $|\psi_a^2\rangle$  and  $|\psi_b^2\rangle$ , which again is related to the HOMO-LUMO gap (Fig. 10).

As indicated above, the CI coefficients  $c_i$  of the two-configuration wavefunction are typically computed as eigenvectors  $\mathbf{c}$  of the CI matrix  $\mathbf{H}$ . For the sake of our discussion, though, it is advantageous to re-write the CI wavefunction in Eq. (34) as

$$\Psi_\tau = \cos(\tau)|\psi_a^2\rangle + \sin(\tau)|\psi_b^2\rangle \quad (40)$$

where

$$\cos(\tau) = c_1 \quad (41)$$

$$\sin(\tau) = c_2 \quad (42)$$

Note that  $\cos^2(\tau) + \sin^2(\tau) = 1$  for any value of  $\tau$ , that is, the normalization condition is always fulfilled. The energy of the wavefunction in Eq. (40) is then given by

$$E = \langle \Psi_\tau | H \Psi_\tau \rangle = \cos^2(\tau)H_{aa} + \sin^2(\tau)H_{bb} + \sin(2\tau)K_{ab} \quad (43)$$

Note that  $\sin(2\tau) = 2 \cos(\tau) \sin(\tau)$ . We can calculate  $\tau$  by minimizing the energy,  $\partial E / \partial \tau = 0$ ,

$$\tan(2\tau) = -\frac{2K_{ab}}{H_{bb} - H_{aa}} \quad (44)$$

$$\Rightarrow \tau_n = -\frac{1}{2} \arctan\left(\frac{2K_{ab}}{H_{bb} - H_{aa}}\right) + \frac{n\pi}{2} \quad (45)$$

**Fig. 10** Singlet-triplet gap  $\Delta E_{ST}$  as a function of  $H_{bb} - H_{aa}$ . The exchange integral is arbitrarily fixed at  $K_{ab} = 0.1 E_h$ . The quantity  $K_{ab}'$ , which corresponds to the exchange integral between the localized orbitals  $\phi_a$  and  $\phi_a$  (cf. Section 1.04.2.8), is set to  $K_{ab}' = 0.025 E_h$ . If  $\Delta E_{ST} > 0$ , the triplet state is the ground state; if  $\Delta E_{ST} < 0$ , the ground state is a singlet. In the region where  $\Delta E_{ST} \approx 0$ , the species is best described as a “disbiradical”, i.e., a molecule with two independent radical sites. When the difference  $H_{bb} - H_{aa}$  increases, the singlet ground state is stabilized, and the molecule gradually becomes a closed-shell species.

where  $n \geq 0$  is an integer (even  $n$  correspond to  $\Psi_{S_{TC-}}$ , odd  $n$  to  $\Psi_{S_{TC+}}$ ).<sup>19</sup> Thus, the CI coefficients  $c_i$  as defined in Eqs. (41) and (42) depend on the energy difference  $H_{bb} - H_{aa}$ , which is related to the HOMO-LUMO gap, as well as the exchange integral  $K_{ab}$ , which depends on the shape of the orbitals (whether or not they share a significant region of space).<sup>19</sup> In particular, the multireference character of the wavefunction is significant (i.e.,  $c_1 \approx -c_2 \approx 1/\sqrt{2}$ ) when the quotient on the r.h.s. of Eq. (44) becomes large, that is, when the exchange integral  $K_{ab}$  is large and the energy difference between  $H_{aa}$  and  $H_{bb}$  is small. However, notice that in case of a vanishing exchange integral,

$$\begin{aligned} \lim_{K_{ab} \rightarrow 0} \tau_0 &= 0 \\ \Rightarrow c_1 &= \cos(\tau_0) = 1 \\ c_2 &= \sin(\tau_0) = 0 \end{aligned}$$

a closed-shell wavefunction is obtained, even if the HOMO-LUMO gap is small. While this usually does not occur in “homo-symmetric” species (here, the orbitals  $\psi_a$  and  $\psi_b$  share a significant region of space due to symmetry), it may well be the case in non-symmetric species (cf. Section 1.04.2.9), e.g., if the HOMO is localized on a ligand and the LUMO is localized on a metal center.

In case of a vanishing energy difference  $\Delta E = H_{bb} - H_{aa}$ , we have

$$\begin{aligned} \lim_{\Delta E \rightarrow 0} \tau_0 &= -\frac{\pi}{4} \\ \Rightarrow c_1 &= \cos(\tau_0) = +\frac{1}{\sqrt{2}} \\ c_2 &= \sin(\tau_0) = -\frac{1}{\sqrt{2}} \end{aligned}$$

which is, of course, a biradical with degenerate orbitals  $\psi_a$  and  $\psi_b$ . Clearly, as it has already been implied throughout this section, the CI coefficients can be taken as a measure of biradical character, seeing that the limiting cases  $c_2 = 0$  and  $c_2 = -1/\sqrt{2}$  correspond to a “pure” closed-shell species and a “pure” biradical, respectively. While we will postpone our discussion of different measures of biradical character to Section 1.04.2.10, it is still worthy to appreciate the interrelation between  $c_2$  and the biradical character of the wavefunction  $\Psi_{S_{TC-}}$  at this stage. In Fig. 11, the evolution of  $c_2$  (and thus the biradical character) is plotted as a function of the energy difference  $H_{bb} - H_{aa}$  and the exchange integral  $K_{ab}$  according to Eqs. (42) and (45). The plots nicely demonstrate that the contribution of  $|\psi_b^2\rangle$  to the wavefunction (34) decreases with an increasing HOMO-LUMO gap, even more so when  $K_{ab}$  is small (Fig. 11, left). Conversely, as the exchange integral  $K_{ab}$  becomes larger, the multireference character of the wavefunction grows (Fig. 11, right). This is in line with the typical observation that two orbitals  $\psi_a$  and  $\psi_b$  correlate most strongly when they are a pair of bonding and antibonding MOs,<sup>20</sup> because they have a large exchange integral  $K_{ab}$  due to their localization in the same region of space.<sup>19</sup>

Allow us to make a last comment on Eq. (45): It is worthy to note that  $\cos(\tau_0) = \sin(\tau_1)$  and  $\sin(\tau_0) = -\cos(\tau_1)$ . Thus, if we define  $\cos(\tau_0) = c_1$  and  $\sin(\tau_0) = -c_2$ , we get

**Fig. 11** Dependence of the CI coefficient  $c_2 = \sin(\tau_0)$  of  $\Psi = c_1|\psi_a^2\rangle + c_2|\psi_b^2\rangle$  on the energy difference  $\Delta E = H_{bb} - H_{aa}$  and exchange integral  $K_{ab}$  (note that  $c_2 < 0$ , i.e.,  $\Psi = \Psi_{S_{TC-}}$ ). Left:  $c_2$  vs.  $\Delta E$ , with isolines for different values of  $K_{ab}$ . The contribution of the second determinant  $|\psi_b^2\rangle$  decreases with an increasing energy difference, especially if  $K_{ab}$  is small. Right:  $c_2$  vs.  $K_{ab}$ , with isolines for different values of  $\Delta E$ . In case of a small energy difference, the contribution of  $|\psi_b^2\rangle$  rises quickly even for small values of  $K_{ab}$ . The circles indicate  $H_2$  at its equilibrium structure ( $-c_2 = 0.111$ ,  $\Delta E = 1.24 E_h$ ,  $K_{ab} = 0.14 E_h$ ) and dissociation limit ( $-c_2 = 1/\sqrt{2}$ ,  $\Delta E = 0$ ,  $K_{ab} = 0.31 E_h$ ).<sup>39</sup> The horizontal gray line indicates  $2c_2^2 = 0.1$ , i.e., a biradical character of 10%.

$$\Psi_{S_{TC-}} = \cos(\tau_0)|\psi_a^2\rangle + \sin(\tau_0)|\psi_b^2\rangle = c_1|\psi_a^2\rangle - c_2|\psi_b^2\rangle$$

$$\Psi_{S_{TC+}} = \cos(\tau_1)|\psi_a^2\rangle + \sin(\tau_1)|\psi_b^2\rangle = c_2|\psi_a^2\rangle + c_1|\psi_b^2\rangle$$

which proves our previous statement in Eqs. (25) and (26).

#### 1.04.2.8 More orbital transformations

We now understand the effect of a small HOMO-LUMO gap on the energies of the four biradical states, and how an increasing HOMO-LUMO gap leads us to the limiting case of a closed-shell species. However, we have only discussed the case of delocalized orbitals  $\psi_a$  and  $\psi_b$  so far, yet for a chemical interpretation of the electronic structure, localized orbitals are the preferred choice.

For reasons of simplicity, let us continue to discuss a homosymmetric biradical. We can then use a similar approach as discussed in the previous sections for orbital localization. However, since the MOs  $\psi_a$  and  $\psi_b$  are no longer degenerate, some additional considerations must be made. Let us re-consider the orthogonal orbital transformation scheme laid out in Eq. (15), i.e.

$$\chi_a = \frac{1}{\sqrt{2}}(\psi_a + \psi_b), \chi_b = \frac{1}{\sqrt{2}}(\psi_a - \psi_b)$$

As discussed in Section 1.04.2.5, the transformed orbitals  $\chi_a$  and  $\chi_b$  correspond to the generalized valence bond (GVB) orbitals if (and only if) the orbitals  $\psi_a$  and  $\psi_b$  are degenerate. In case of non-degenerate orbitals  $\psi_a$  and  $\psi_b$ , the GVB transformation<sup>20,31</sup> depends on the CI coefficients  $c_i$  of the wavefunction

$$\Psi_{S_{TC-}} = c_1|\psi_a^2\rangle - c_2|\psi_b^2\rangle$$

and is given by

$$\chi_a = k_1\psi_a + k_2\psi_b, \quad \chi_b = k_1\psi_a - k_2\psi_b \quad (46)$$

where

$$k_1 = \sqrt{\frac{c_1}{c_1 + c_2}}, k_2 = \sqrt{\frac{c_2}{c_1 + c_2}}$$

Thus, in case of  $c_1 = c_2 = 1/\sqrt{2}$ , Eq. (46) is identical to Eq. (15). When applying the GVB transformation in Eq. (46) to  $\Psi_{S_{TC-}}$  we get

$$\begin{aligned} \Psi_{S_{TC-}} &= c_1|\psi_a^2\rangle - c_2|\psi_b^2\rangle \\ &= \frac{1}{\sqrt{2}}[c_1\psi_a(1)\psi_a(2) - c_2\psi_b(1)\psi_b(2)][\alpha(1)\beta(2) - \beta(1)\alpha(2)] \\ &= \frac{c_1 + c_2}{\sqrt{2}} \cdot \frac{1}{2}[\chi_a(1)\chi_b(2) + \chi_b(1)\chi_a(2)][\alpha(1)\beta(2) - \beta(1)\alpha(2)] \\ &= \frac{c_1 + c_2}{\sqrt{2}} \cdot \frac{1}{\sqrt{2}}(|\chi_a^\alpha\chi_b^\beta\rangle - |\chi_b^\beta\chi_a^\alpha\rangle) = \Psi'_{S_{OS}} \end{aligned} \quad (47)$$

where the prefactor  $(c_1 + c_2)/\sqrt{2}$  is required for normalization (since  $\chi_a$  and  $\chi_b$  are, in general, no longer orthogonal). Thus,  $\Psi_{S_{TC-}}$  transforms into an open-shell wavefunction in the GVB basis, and in the limiting case  $c_1 = c_2 = 1/\sqrt{2}$ , we obtain the same result as in Eq. (18).

Thus, in principle, we can draw the same conclusions as before:  $\Psi_{S_{TC-}}$  is generally a biradical state, and the system can be classified either as disjoint biradical if the GVB orbitals are localized on different atoms, or as joint biradical if they cannot be localized. In the latter case, it is less straightforward to assign biradical or ionic character to the wavefunction, as discussed before.

Notice how the overlap between  $\chi_a$  and  $\chi_b$  depends on the CI coefficients (and thus on the HOMO-LUMO gap, cf. Section 1.04.2.7):

$$\langle\chi_a|\chi_b\rangle = \frac{c_1 - c_2}{c_1 + c_2} \quad (48)$$

In the limiting case of a “perfect” biradical ( $c_1 = c_2 = 1/\sqrt{2}$ ), we have  $\langle\chi_a|\chi_b\rangle = 0$ , i.e., the orbitals are orthogonal (and, in case of a disjoint biradical, perfectly localized). Conversely, a “perfect” closed-shell species ( $c_1 = 1$  and  $c_2 = 0$ ) has an overlap integral  $\langle\chi_a|\chi_b\rangle = 1$ , i.e.,  $\chi_a$  and  $\chi_b$  are identical and correspond to the delocalized HOMO  $\chi_a$  according to Eq. (46). Thus, with an increasing HOMO-LUMO gap, the GVB orbitals gradually become more and more delocalized across the radical centers (Fig. 12), which makes chemical interpretation of the wavefunction in terms of “biradical” and “ionic” contributions impractical in the GVB basis. In fact, it is exactly this delocalization of the GVB orbitals that describes the ionic contributions that are inherent to any covalent bond.<sup>31</sup> (In the closed-shell limit, i.e., using a single determinant to describe a closed-shell wavefunction, the wavefunction has 50% covalent and 50% ionic character, see below.)<sup>18</sup>

To overcome the “problem” of the partly delocalized GVBs in biradicals with non-degenerate frontier orbitals  $\psi_a$  and  $\psi_b$ , different localization methods may be used, such as Foster-Boys localization.<sup>40,41</sup> In the case of homosymmetric species, this is equivalent to

$$\phi_a = \frac{1}{\sqrt{2}}(\psi_a + \psi_b), \phi_b = \frac{1}{\sqrt{2}}(\psi_a - \psi_b)$$

which is mathematically identical to the orbital transformation laid out in Eq. (15). Note that due to the non-degeneracy of  $\psi_a$  and  $\psi_b$ , the transformed orbitals  $\phi_a$  and  $\phi_b$  are no longer the GVB orbitals, but rather orthonormal, (semi-)localized orbitals (Fig. 12) that minimize the exchange integral  $K_{ab}$ .<sup>19</sup> Applying this orbital transformation to the singlet wavefunction  $\Psi_{S_{TC-}}$  yields

$$\begin{aligned} \Psi_{S_{TC-}} &= c_1 |\psi_a^2\rangle - c_2 |\psi_b^2\rangle \\ &= \frac{1}{\sqrt{2}} [c_1 \psi_a(1)\psi_a(2) - c_2 \psi_b(1)\psi_b(2)] [\alpha(1)\beta(2) - \beta(1)\alpha(2)] \\ &= \frac{c_1 + c_2}{\sqrt{2}} \cdot \frac{1}{2} [\phi_a(1)\phi_b(2) + \phi_b(1)\phi_a(2)] [\alpha(1)\beta(2) - \beta(1)\alpha(2)] \\ &\quad + \frac{c_1 - c_2}{\sqrt{2}} \cdot \frac{1}{2} [\phi_a(1)\phi_a(2) + \phi_b(1)\phi_b(2)] [\alpha(1)\beta(2) - \beta(1)\alpha(2)] \\ &= \frac{c_1 + c_2}{\sqrt{2}} \cdot \frac{1}{\sqrt{2}} (|\phi_a^\alpha \phi_b^\beta\rangle - |\phi_a^\beta \phi_b^\alpha\rangle) + \frac{c_1 - c_2}{\sqrt{2}} \cdot \frac{1}{\sqrt{2}} (|\phi_a^2\rangle + |\phi_b^2\rangle) \end{aligned} \quad (49)$$

Thus, the wavefunction can be written as

$$\Psi_{S_{TC-}} = c_{cov} |\Psi_{cov}\rangle + c_{ion} |\Psi_{ion}\rangle \quad (50)$$

with

$$\frac{c_1 + c_2}{\sqrt{2}} = c_{cov}, \frac{c_1 - c_2}{\sqrt{2}} = c_{ion} \quad (51)$$

Using the localized orbitals  $\phi_a$  and  $\phi_b$ , it becomes clear that the singlet ground state wavefunction  $\Psi_{S_{TC-}}$  possesses covalent (biradical) and ionic character, if the delocalized frontier orbitals  $\psi_a$  and  $\psi_b$  are non-degenerate. In fact, in the limiting case of a “perfect” biradical (i.e.,  $c_1 = c_2 = 1/\sqrt{2}$ ) we have  $c_{cov} = 1$  and  $c_{ion} = 0$ , whereas the limiting case of a “perfect” closed-shell with an infinite HOMO-LUMO gap (i.e.,  $c_1 = 1$  and  $c_2 = 0$ ) is defined by  $c_{cov} = c_{ion} = 1/\sqrt{2}$ . Thus, the wavefunction varies from purely covalent in the “perfect” biradical limit to 50% covalent and 50% ionic in the closed-shell limit.

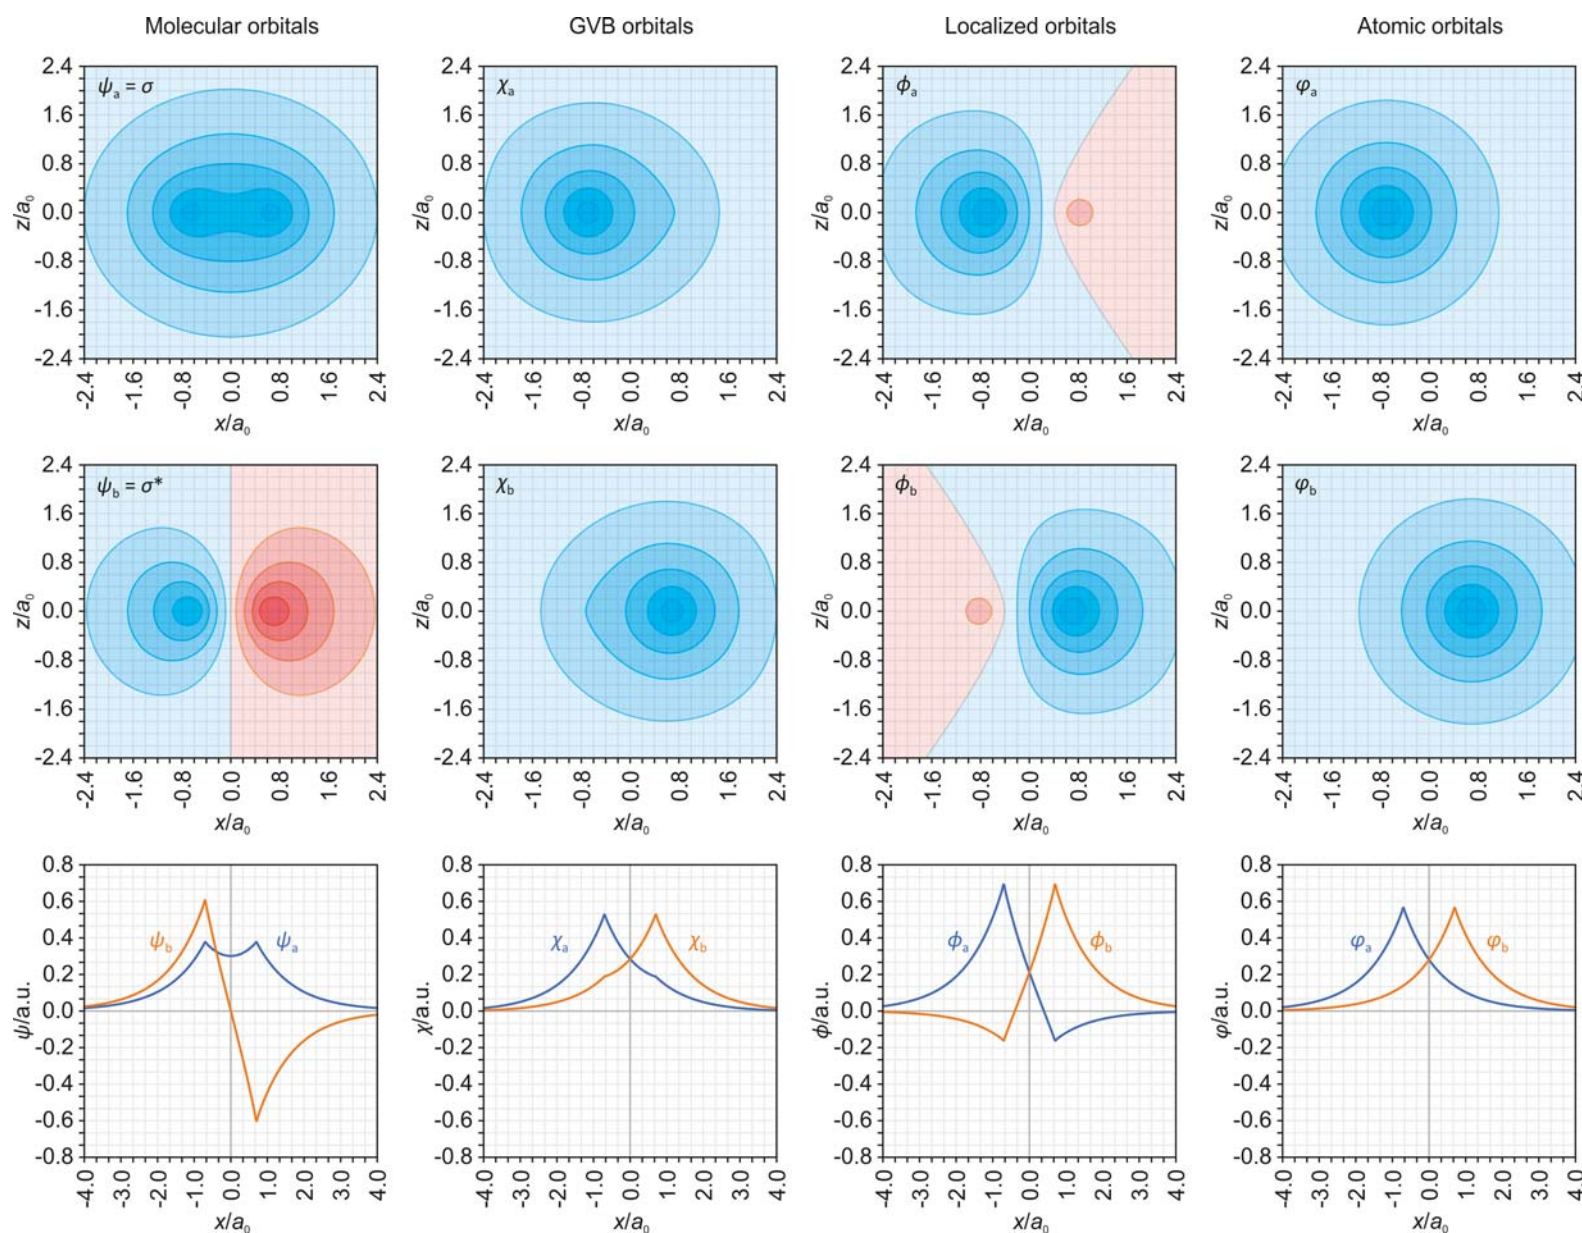

In case the radical centers can be fully localized on two single atoms, it is also possible to use atomic (hybrid) orbitals  $\varphi_a$  and  $\varphi_b$  as localized orbitals (Fig. 12).<sup>18</sup> Again assuming a homosymmetric system, the MOs can then be expressed as linear combinations

$$\psi_a = \frac{1}{\sqrt{2 + 2S_{ab}}}(\varphi_a + \varphi_b), \psi_b = \frac{1}{\sqrt{2 - 2S_{ab}}}(\varphi_a - \varphi_b) \quad (52)$$

where the prefactor  $1/\sqrt{2 + 2S_{ab}}$  ensures normalization of the MOs, and  $S_{ab} = \langle \varphi_a | \varphi_b \rangle$  is the overlap integral between the atomic orbitals  $\varphi_a$  and  $\varphi_b$  (notice that the atomic orbitals are, in general, not orthogonal to each other). It is straightforward to show that

$$\begin{aligned} \Psi_{S_{TC-}} &= c_1 |\psi_a^2\rangle - c_2 |\psi_b^2\rangle \\ &= \frac{1}{\sqrt{2}} [c_1 \psi_a(1)\psi_a(2) - c_2 \psi_b(1)\psi_b(2)] [\alpha(1)\beta(2) - \beta(1)\alpha(2)] \\ &= \left[ \frac{c_1}{2 + 2S_{ab}} + \frac{c_2}{2 - 2S_{ab}} \right] \frac{1}{\sqrt{2}} [\varphi_a(1)\varphi_b(2) + \varphi_b(1)\varphi_a(2)] [\alpha(1)\beta(2) - \beta(1)\alpha(2)] \\ &\quad + \left[ \frac{c_1}{2 + 2S_{ab}} - \frac{c_2}{2 - 2S_{ab}} \right] \frac{1}{\sqrt{2}} [\varphi_a(1)\varphi_a(2) + \varphi_b(1)\varphi_b(2)] [\alpha(1)\beta(2) - \beta(1)\alpha(2)] \\ &= \left[ \frac{c_1}{2 + 2S_{ab}} + \frac{c_2}{2 - 2S_{ab}} \right] (|\varphi_a^\alpha \varphi_b^\beta\rangle - |\varphi_a^\beta \varphi_b^\alpha\rangle) + \left[ \frac{c_1}{2 + 2S_{ab}} - \frac{c_2}{2 - 2S_{ab}} \right] (|\varphi_a^2\rangle + |\varphi_b^2\rangle) \end{aligned} \quad (53)$$

Thus, the wavefunction is composed of covalent and ionic contributions just as in case of the orthogonal, localized orbitals  $\phi_a$  and  $\phi_b$ . Note, however, that due to the non-orthogonality of the atomic orbitals  $\varphi_a$  and  $\varphi_b$ , the covalent and ionic contributions to the wavefunction are also not orthogonal and a partitioning scheme is needed to assign their overlaps either to the covalent or the ionic contribution.<sup>20</sup> Also note that Eq. (53) is mathematically equivalent to the valence bond (VB) wavefunction of the system.

**Fig. 12** Molecular orbitals of  $\text{H}_2$  ( $r = 1.4$  a.u.,  $\Psi = 0.994|\psi_a^2\rangle - 0.111|\psi_b^2\rangle$ ).<sup>39</sup> Top and middle row: Contour plots of the orbitals in the  $xz$  plane. Bottom row: Section of the orbitals along the  $x$ -axis (i.e.,  $y = z = 0$ ). Left column: Canonical (delocalized) MOs  $\psi_a$  and  $\psi_b$ . Center left column: GVB orbitals  $\chi_a$  and  $\chi_b$ . The two electrons are mainly located at opposite nuclei, demonstrating their correlated motion. However, notice the small (positive) cusp at the position of the second H atom, indicating that the orbitals are still somewhat delocalized and there is a certain probability of finding both electrons at the same nucleus. Center right column: Orthogonal localized orbitals  $\phi_a$  and  $\phi_b$ . The negative cusps are the so-called “orthogonalization tails,” ensuring that  $\langle\phi_a|\phi_b\rangle = 0$ . Right column: Atomic orbitals  $\varphi_a$  and  $\varphi_b$ . Like the GVB orbitals, the atomic orbitals are not orthogonal. At infinite separation of the H nuclei (i.e., a “perfect” biradical), GVB orbitals, localized orbitals, and atomic orbitals are identical.

In fact, as we have not made any mathematical restrictions on the orbitals  $\varphi_a$  and  $\varphi_b$ , the orbital transformation in Eq. (52) holds true for *any* choice of (semi-)localized orbitals, so Eq. (53) is valid for *all* the cases discussed above. For example, if  $S_{ab} = 0$  (i.e., if the orbitals  $\varphi_a$  and  $\varphi_b$  are orthogonal), we obtain the same solution as in Eq. (49). Moreover, if the overlap integral is

$$S_{ab} = \frac{2c_1}{c_1 + c_2} - 1 = 1 - \frac{2c_2}{c_1 + c_2} \quad (54)$$

Eq. (53) transforms into Eq. (47), i.e., the GVB wavefunction.

#### 1.04.2.9 Non-symmetric biradicals

Up to this point, we have restricted our discussion to “homosymmetric” biradicals (radical centers localized on symmetry equivalent sites). If, however, the radical centers are inequivalent, the singlet ground state wavefunction (in the basis of the canonical molecular orbitals  $\psi_a$  and  $\psi_b$ ) takes the general form

$$\Psi_S = c_1 |\psi_a^2\rangle - c_2 |\psi_b^2\rangle + c_3 \cdot \frac{1}{\sqrt{2}} \left( |\psi_a^\alpha \psi_b^\beta\rangle - |\psi_a^\beta \psi_b^\alpha\rangle \right) \quad (55)$$

where the last term on the r.h.s. of Eq. (55) is responsible for distributing the electrons unevenly between the two radical sites; that is,  $c_3 = 0$  for homosymmetric and  $c_3 > 0$  for non-symmetric species. In the basis of localized orbitals  $\phi_a$  and  $\phi_b$ , this will result in two different ionic contributions, since the probabilities of finding both electrons at either radical site “a” or “b” will, in general, not be the same<sup>20</sup>:

$$\Psi_S = c_{\text{cov}} \cdot \frac{1}{\sqrt{2}} \left( |\phi_a^\alpha \phi_b^\beta\rangle - |\phi_a^\beta \phi_b^\alpha\rangle \right) + c_{\text{ion},1} |\phi_a^2\rangle + c_{\text{ion},2} |\phi_b^2\rangle \quad (56)$$

with

$$\phi_a = \cos(\alpha) \cdot \psi_a + \sin(\alpha) \cdot \psi_b$$

$$\phi_b = \sin(\alpha) \cdot \psi_a - \cos(\alpha) \cdot \psi_b$$

where  $\alpha$  is the “rotation angle” that transforms the MOs  $\psi_a$  and  $\psi_b$  into the localized orbitals  $\phi_a$  and  $\phi_b$  (for homosymmetric species,  $\alpha = 45^\circ$ ). The different ionic terms in Eq. (56) are typically due to different electronegativities of the atoms involved, i.e.,  $\phi_a$  might have a lower orbital energy than  $\phi_b$  (and thus higher occupation number), resulting in an overall polarization.

In this regard, we see fit to introduce another type of delocalized orbitals which is often used to represent multiconfigurational wavefunctions, the so-called natural orbitals (NOs)  $\omega_i$ . These are often the default orbitals in CASSCF-type calculations, and are defined as the eigenfunctions of the 1-electron reduced density operator  $\Gamma$ ,<sup>20,42,43</sup>

$$\Gamma \omega_i = n_i \omega_i \quad (57)$$

with eigenvalues  $n_i$  that correspond to the occupation numbers of the NOs, and the density operator being defined as

$$\Gamma = |\Psi\rangle\langle\Psi| \quad (58)$$

For the wavefunction in Eq. (55), the density operator is

$$\Gamma = (2c_1^2 + c_3^2) |\psi_a\rangle\langle\psi_a| + (2c_2^2 + c_3^2) |\psi_b\rangle\langle\psi_b| + \sqrt{2}(c_1c_3 - c_2c_3) (|\psi_a\rangle\langle\psi_b| + |\psi_b\rangle\langle\psi_a|) \quad (59)$$

with the corresponding density matrix

$$\rho = \begin{pmatrix} 2c_1^2 + c_3^2 & \sqrt{2}(c_1c_3 - c_2c_3) \\ \sqrt{2}(c_1c_3 - c_2c_3) & 2c_2^2 + c_3^2 \end{pmatrix} \quad (60)$$

The diagonal elements correspond to the occupancy of orbitals  $\psi_a$  and  $\psi_b$ , while the off-diagonal elements indicate the “bond order” between these orbitals<sup>19</sup> (clearly, this value makes more sense if the density matrix is constructed for localized orbitals). The NOs diagonalize the density matrix, so all off-diagonal elements become zero in the NO basis.

Note that for a homosymmetric biradical ( $c_3 = 0$ ), all off-diagonal elements of the density matrix in the MO basis are zero, so the density matrix is already diagonalized<sup>20</sup>:

$$\rho = \begin{pmatrix} 2c_1^2 & 0 \\ 0 & 2c_2^2 \end{pmatrix}$$

$$\Gamma = 2c_1^2 |\psi_a\rangle\langle\psi_a| + 2c_2^2 |\psi_b\rangle\langle\psi_b|$$

Thus, the NOs of a homosymmetric biradical are just the regular canonical MOs. In all other cases, though, the NOs are distinctly different (but often similar in shape). By diagonalizing the density matrix, the NO basis offers the most compact representation of any multireference state, i.e., the wavefunction in Eq. (55) becomes

$$\begin{aligned}\Psi_S &= c_1|\psi_a^2\rangle - c_2|\psi_b^2\rangle + c_3 \cdot \frac{1}{\sqrt{2}} \left( |\psi_a^\alpha\psi_b^\beta\rangle - |\psi_a^\beta\psi_b^\alpha\rangle \right) \\ &= c'_1|\omega_a^2\rangle - c'_2|\omega_b^2\rangle\end{aligned}\quad (61)$$

Hence, only two determinants are needed to express the singlet ground state wavefunction in the NO basis, irrespective of molecular symmetry.

#### 1.04.2.10 Biradical character

Our discussion up to this point has already hinted several times at a fundamental concept of biradicals, namely the quantification of the biradical character. There are a lot of different ways to do so; thus, discussing all different indices lies outside the scope of this article. Nonetheless, we are going to cover some of the most fundamental approaches and give some selected examples.

In **Section 1.04.2.7**, we have already discussed that the CI coefficients can act as a measure of biradical character: Using delocalized orbitals (usually the MOs or NOs), that is,

$$\Psi_{S_{TC-}} = c_1|\psi_a^2\rangle - c_2|\psi_b^2\rangle \quad (62)$$

the limit of a “perfect” biradical is given by  $c_1 = c_2 = 1/\sqrt{2}$ , whereas the closed-shell limit is defined by  $c_1 = 1$  and  $c_2 = 0$ . Thus, if we find a function that normalizes  $c_2$  in the limit of a “perfect” biradical, it can serve as a measure of biradical character that ranges from 0 to 1. However, while the end points of such a scale are clearly defined, it remains unclear how to interpolate between these values.<sup>20</sup>

Conversely, using localized orbitals  $\phi_a$  and  $\phi_b$ , we find

$$\Psi_{S_{TC-}} = c_{cov}|\Psi_{cov}\rangle + c_{ion}|\Psi_{ion}\rangle \quad (63)$$

where  $c_{cov}$  and  $c_{ion}$  can be derived from  $c_1$  and  $c_2$  as described in Eq. (51). Here, the “perfect” biradical limit is defined by  $c_{cov} = 1$  and  $c_{ion} = 0$ , while the closed-shell limit is given by  $c_{cov} = c_{ion} = 1/\sqrt{2}$ .

Using these limits, one can devise many different normalized indicators of biradical character, such as

$$\gamma = \sqrt{2} \cdot c_2 = c_{cov} - c_{ion} \quad (64)$$

$$d = 2c_1c_2 = c_{cov}^2 - c_{ion}^2 \quad (65)$$

$$\beta = 2c_2^2 = (c_{cov} - c_{ion})^2 \quad (66)$$

The first indicator in Eq. (64)<sup>44</sup> simply measures the amplitude of the configuration  $|\psi_b^2\rangle$ , which corresponds to the excess of the covalent amplitude relative to the ionic contribution. To understand the second indicator in Eq. (65), we note that when using orthonormal orbitals (which is usually the case), the configurations  $|\psi_a^2\rangle$  and  $|\psi_b^2\rangle$  or  $|\Psi_{cov}\rangle$  and  $|\Psi_{ion}\rangle$  are also orthonormal, and thus  $\sum c_i^2 = 1$ . Therefore, the squared CI coefficients correspond to the relative weight (i.e., the probability) of each contribution to the CI expansion. Thus, the indicator in Eq. (65)<sup>45</sup> describes the difference between the probabilities of the covalent and ionic contributions. The last indicator in Eq. (66)<sup>43</sup> is directly related to the probability of  $|\psi_b^2\rangle$ , which (if natural orbitals are used, see below) also corresponds to the occupation number of  $\psi_b$ .

The indices in Eqs. (65) and (66) were also modified for general CI wavefunctions that contain more than two coefficients<sup>45,46</sup>:

$$\Psi = \sum_{i=1}^N c_i \Psi_i = c_1 \Psi_1 + \underbrace{c_2 \Psi_2 + \dots + c_N \Psi_N}_{\sqrt{c_1^2 + c_2^2} \cdot \Psi_{S_{TC\pm}}} \quad (67)$$

This may be the case if the active space is chosen larger than the simple “two electrons in two orbitals” [i.e., CAS(2,2)] model discussed here, or even within the CAS(2,2) picture if the biradical is non-symmetric [cf. Eq. (56)]. The coefficients  $c_3 \dots c_N$  are typically small and describe dynamic electron correlation. Note that the notation used in Eq. (67) implies that  $c_2 < 0$  for the singlet ground state.

Due to the inclusion of dynamic correlation, the relative contribution of the original two-configuration wavefunction  $\Psi_{S_{TC-}}$  to the total CI wavefunction is  $c_1^2 + c_2^2$ . Thus, the factor  $1/(c_1^2 + c_2^2)$  is introduced in Eqs. (65) and (66) to normalize the biradical character:

$$d = 2 \sqrt{\frac{c_1^2 c_2^2}{c_1^2 + c_2^2}} \quad (68)$$

$$\beta = \frac{2c_2^2}{c_1^2 + c_2^2} \quad (69)$$

The different biradical indicators are depicted in Fig. 13. It becomes clear that  $\beta$  predicts the smallest, while  $d$  predicts the highest numerical values of biradical character.

Notice that in the localized picture, i.e., when considering the covalent and ionic coefficients  $c_{\text{cov}}$  and  $c_{\text{ion}}$ , all biradical indicators discussed above depend on *both* coefficients. This is noteworthy insofar as the “covalent” and “ionic” structures  $|\Psi_{\text{cov}}\rangle$  and  $|\Psi_{\text{ion}}\rangle$  can be translated to the valence bond (VB) picture, where the “covalent” structure is usually drawn as a dot-dot structure. However, this should not be regarded solely as a biradical contribution, as  $|\Psi_{\text{cov}}\rangle$  clearly describes a purely “bonding” situation in the closed-shell limit. Thus, even though one might draw a Lewis structure with two dots at the radical centers, the weight of this structure (i.e.,  $c_{\text{cov}}^2$ ) alone is not a suitable measure of biradical character.

A last note of caution: As we have discussed in quite some detail in the previous sections, the CI coefficients depend on the choice of orbitals, thus they are not uniquely defined! There are many more possible choices than those we have discussed,<sup>19</sup> and therefore it is not necessarily straightforward to compare the biradical character of different molecules, especially among different publications by different authors, who might have used different computational methods and orbital bases.

Another popular indicator of biradical character is derived from the occupation numbers of the natural orbitals (NOs). The NOs are uniquely defined for a given system (cf. Section 1.04.2.9), independently of the orbitals that were used to derive the multireference wavefunction. If NOs are used to represent the CAS(2,2) wavefunction, the occupancy of the lowest unoccupied NO (LUNO) is equal to  $2c_2^2$ , as the NOs diagonalize the density matrix. Thus, its occupancy varies from 0 in the closed-shell limit to 1 in the limit of a “perfect” biradical and it is therefore a natural indicator of biradical character. The occupancy of the HONO (highest occupied NO), on the other hand, varies from 2 to 1, with  $n_{\text{HONO}} = 2 - x$  and  $n_{\text{LUNO}} = x \leq 1$ , and thus  $n_{\text{HONO}} + n_{\text{LUNO}} = 2$ .

In a general CI wavefunction, i.e., using larger active spaces than (2,2), the LUNO is the orbital with the highest occupation number smaller than 1, while the HONO corresponds to the orbital with the smallest occupation number larger than 1. Orbitals with smaller occupancy than the LUNO, in the order of decreasing occupation numbers, are called LUNO+1, LUNO+2, ..., while orbitals with increasing occupancy are named HONO-1, HONO-2, etc.<sup>20</sup> Typically, each pair of HONO- $i$  and LUNO+ $i$  corresponds to a pair of delocalized bonding and anti-bonding orbitals. The equality  $n_{\text{HONO}-i} + n_{\text{LUNO}+i} = 2$  holds strictly for “broken-symmetry” UHF or UDFT calculations (see below), while it is approximately satisfied for general multireference wavefunctions.<sup>20</sup> In this vein, the occupation numbers can be generalized to polyradical indicators, the occupancy of the LUNO indicating biradical character as explained above, the occupancy of LUNO+1 indicating tetradical character and so on. Note that apart from non-dynamic correlation, dynamic correlation in highly correlated calculations (e.g., when using large active spaces or a multireference configuration interaction (MRCI) approach) can also influence the occupation numbers.

One advantage of NOs is certainly that they can be calculated using almost all computational methods, especially UHF or UDFT, which come with a much smaller computational cost than CI methods. Using the “broken-symmetry” formalism, one can approximately describe a multiconfigurational wavefunction by single-determinantal methods. For instance, the “broken-symmetry” UHF wavefunction of a singlet biradical (ignoring all paired electrons) is given by

$$\Psi_{\text{BS}} = |\chi_a^\alpha \chi_b^\beta\rangle \quad (70)$$

where the orbitals  $\chi_a$  and  $\chi_b$  are the GVB orbitals localized at the radical sites “a” and “b” as defined in Eq. (46):

**Fig. 13** Examples of biradical indicators based on the CI coefficients. While  $y$  is proportional to the amplitude  $c_2$ ,  $\beta$  is proportional to the probability  $c_2^2$ . Note that both  $y$  and  $d$  predict a significant biradical character for  $|c_2| = 0.1$ , which is typically considered dynamic correlation ( $y = 14\%$ ,  $d = 20\%$ ,  $\beta = 2\%$ ; cf.  $\text{H}_2$  at  $r_{\text{eq}} = 1.4$  a. u.,  $\Psi = 0.994|\psi_a^2\rangle - 0.111|\psi_b^2\rangle$ ).<sup>39</sup> Thus, numerical values of the different indicators cannot be compared directly.

$$\chi_a = k_1\psi_a + k_2\psi_b, \chi_b = k_1\psi_a - k_2\psi_b$$

As discussed above,  $\psi_a$  and  $\psi_b$  are the delocalized frontier orbitals, and the coefficients  $k_1 = \cos \theta$ ,  $k_2 = \sin \theta$ .

Obviously, the wavefunction in Eq. (70) is physically wrong, since it introduces unphysical spin polarization. The correct wavefunction using the GVB orbitals would, of course, be given by Eq. (47). In fact, using the GVB orbital transformation we can show that

$$\Psi_{\text{BS}} = \underbrace{\cos^2\theta|\psi_a^2\rangle - \sin^2\theta|\psi_b^2\rangle}_{\Psi_{\text{SIC-}}} + \sin\theta \cos\theta \cdot \underbrace{\left(|\psi_b^\alpha\psi_a^\beta\rangle + |\psi_b^\beta\psi_a^\alpha\rangle\right)}_{\Psi_{\text{T}}} \quad (71)$$

Hence, the “broken-symmetry” UHF wavefunction is really a mixture of singlet and triplet wavefunctions, leading to the well-known problem of spin contamination.<sup>20,28,47</sup> It changes from a closed-shell singlet in the limit  $\theta = 0$

$$\Psi_{\text{BS}} = |\psi_a^2\rangle$$

to an equal mixture of singlet and triplet in the limit  $\theta = \pi/4$  (i.e., a “perfect” biradical)

$$\Psi_{\text{BS}} = \frac{1}{2}(|\psi_a^2\rangle - |\psi_b^2\rangle) + \frac{1}{2}\left(|\psi_b^\alpha\psi_a^\beta\rangle + |\psi_b^\beta\psi_a^\alpha\rangle\right)$$

The density operator of the UHF wavefunction is given by

$$\begin{aligned} \Gamma &= |\chi_a\rangle\langle\chi_a| + |\chi_b\rangle\langle\chi_b| \\ &= |\cos\theta\cdot\psi_a + \sin\theta\cdot\psi_b\rangle\langle\cos\theta\cdot\psi_a + \sin\theta\cdot\psi_b| \\ &\quad + |\cos\theta\cdot\psi_a - \sin\theta\cdot\psi_b\rangle\langle\cos\theta\cdot\psi_a - \sin\theta\cdot\psi_b| \\ &= 2\cos^2\theta\cdot|\psi_a\rangle\langle\psi_a| + 2\sin^2\theta\cdot|\psi_b\rangle\langle\psi_b| \end{aligned}$$

Thus,  $\psi_a$  and  $\psi_b$  are the natural orbitals of the UHF wavefunction with occupancies  $n_{\text{HONO}}$  and  $n_{\text{LUNO}}$ :

$$n_{\text{HONO}} = 2\cos^2\theta = 1 + \langle\chi_a|\chi_b\rangle$$

$$n_{\text{LUNO}} = 2\sin^2\theta = 1 - \langle\chi_a|\chi_b\rangle$$

The latter, however, is not a good indicator of biradical character, since it suffers from spin contamination. This can be remedied by projecting out the spin-contaminants, as proposed by Yamaguchi<sup>47</sup>:

$$\gamma_0 = n_{\text{LUNO}}^{\text{p}} = \frac{n_{\text{LUNO}}^2}{1 + \langle\chi_a|\chi_b\rangle^2} = \frac{2n_{\text{LUNO}}^2}{n_{\text{HONO}}^2 + n_{\text{LUNO}}^2} \quad (72)$$

Here,  $n_{\text{LUNO}}^{\text{p}}$  is the spin-projected occupation number of the LUNO. The occupation number of other NOs can also be corrected using a generalized version of Eq. (72):

$$\gamma_i = n_{\text{LUNO}+i}^{\text{p}} = \frac{2n_{\text{LUNO}+i}^2}{n_{\text{HONO}-i}^2 + n_{\text{LUNO}+i}^2} \quad (73)$$

There are many more bi- and polyradical indicators based on natural occupancies. The interested reader is referred to the excellent review of Stuyver/Chen/Zeng/Hoffmann and co-workers.<sup>20</sup>

Lastly, the biradical character is often also related to the singlet-triplet gap  $\Delta E_{\text{ST}}$ ,<sup>48,49</sup> which in turn is related to the magnetic coupling between the two radical sites. The magnetic coupling between two electrons can be described by the phenomenological Heisenberg-Dirac-van-Vleck Hamiltonian<sup>29,45,49,50</sup>

$$H_{\text{HDvV}} = -2J_{ij} S_i \cdot S_j \quad (74)$$

where  $J_{ij}$  is the magnetic exchange coupling constant (not to be confused with the Coulomb integral  $J_{\text{ab}}$ ) and  $S_i$  and  $S_j$  are the local spin operators on radical sites “i” and “j”. Note that some authors also use the definition  $H_{\text{HDvV}} = -J_{ij} S_i \cdot S_j$ ,<sup>29,51</sup> which changes the magnitude of  $J_{ij}$  by a factor of two. When comparing values between different publications, it is therefore paramount to check which definition was used! We will continue to use the definition in Eq. (74).

The exchange coupling constant  $J_{ij}$  can be computed from  $\Delta E_{\text{ST}}$ :

$$\Delta E_{\text{ST}} = E_{\text{S}} - E_{\text{T}} = 2J_{ij} \quad (75)$$

Thus, if  $\Delta E_{\text{ST}} \approx 0$ , there is no magnetic coupling between the electrons, and the species is best understood as a disbiradical, i.e., a molecule with two independent radical sites. If  $\Delta E_{\text{ST}} > 0$  (and thus  $J_{ij} > 0$ ), the electrons are ferromagnetically coupled and the ground state is a triplet. Conversely, if  $\Delta E_{\text{ST}} < 0$  (i.e.,  $J_{ij} < 0$ ), the electrons are antiferromagnetically coupled and the ground state is a singlet. Depending on the magnitude of the coupling constant  $J_{ij}$ , it may either be a singlet biradical (in the weak coupling region) or a closed-shell singlet in the limit of strong coupling. Note that for a “perfect biradical,” we have

$$\Delta E_{\text{ST}} = 2K'_{\text{ab}} = 2J_{ij} \quad (76)$$

that is, the magnetic exchange coupling constant  $J_{ij}$  is equal to the exchange integral  $K'_{\text{ab}}$  between the localized orbitals  $\chi_{\text{a}}$  and  $\chi_{\text{b}}$ .

While the ST gap  $\Delta E_{\text{ST}}$  is most accurately computed using multireference methods that include dynamic correlation,<sup>29,32-34</sup> it may also be inferred from “broken-symmetry” UDFT (or UHF) calculations.<sup>52,53</sup> In the latter case, it is typically necessary to correct the computed ST gap using spin-projection to account for the spin-contamination of the “broken-symmetry” singlet wavefunction  $\Psi_{\text{BS}}$ . While several schemes for spin projection exist, we only want to discuss the most generally applicable formula here<sup>49,50,54</sup>:

$$J_{ij} = \frac{E_{\text{BS}} - E_{\text{T}}}{\langle S^2 \rangle_{\text{T}} - \langle S^2 \rangle_{\text{BS}}} \quad (77)$$

$E_{\text{BS}}$  and  $E_{\text{T}}$  are the SCF energies of the “broken-symmetry” singlet and triplet state, respectively, while  $\langle S^2 \rangle_{\text{T}}$  and  $\langle S^2 \rangle_{\text{BS}}$  are the expectation values of the  $S^2$  operator, *viz*

$$\langle S^2 \rangle_{\text{T}} = \langle \Psi_{\text{T}} | S^2 | \Psi_{\text{T}} \rangle$$

$$\langle S^2 \rangle_{\text{BS}} = \langle \Psi_{\text{BS}} | S^2 | \Psi_{\text{BS}} \rangle$$

Typically,  $\langle S^2 \rangle_{\text{T}} \approx 2$ , whereas  $\langle S^2 \rangle_{\text{BS}}$  may range from 0 in the closed-shell limit to 1 in the limit of a “perfect” biradical. Remember that in the biradical limit,  $\Psi_{\text{BS}}$  is a 50:50 mixture of singlet and triplet; thus,  $\langle S^2 \rangle_{\text{BS}}$  is then also the average of the actual eigenvalues of a singlet (0) and a triplet (2). In consequence, the ST gap  $\Delta E_{\text{ST}} = 2J_{ij}$  is twice the difference  $E_{\text{BS}} - E_{\text{T}}$  in the case of a “perfect” biradical, while in the closed-shell limit, it is just the normal difference  $E_{\text{BS}} - E_{\text{T}} = E_{\text{S}} - E_{\text{T}}$ .

On a final note, some care should be taken when using the “broken-symmetry” formalism to detect biradical character. As implied by our discussion above, biradical character will induce “symmetry-breaking” of the Hartree-Fock or Kohn-Sham wavefunction (i.e., the non-dynamic correlation is represented by localization of the  $\alpha$  and  $\beta$  spin orbitals in different regions of space). However, DFT methods are typically able to describe biradicals with small to moderate biradical character (depending on the choice of density functional) using a restricted approach,<sup>20,28,55</sup> as the electron correlation is incorporated into an effective potential. Thus, “symmetry-breaking” of Kohn-Sham wavefunctions usually only occurs when the biradical character is already quite significant. Therefore, when comparing the biradical character of different molecules, it is imperative to use consistent indices and electronic structure methods!

#### 1.04.2.11 Different classifications of biradicals

Lastly, we wish to give a few more notes on the classification of biradicals in addition to what is written in the introduction as well as in Section 1.04.2.5, where the distinction between disjoint and non-disjoint (or joint) biradicals is discussed in some detail. There are, however, other possibilities to classify different types of biradicals.

Typically,  $\pi$ -conjugated biradicals are categorized as either “Kekulé” or “non-Kekulé” molecules, depending on whether a classical Kekulé structure (i.e., a structure without radical electrons) can be drawn in the Lewis representation. For example, *o*- and *p*-quinodimethane (QDM, Scheme 5) are typical Kekulé molecules, whereas trimethylenemethane (TMM) or tetramethyleneethane (TME) are archetypical examples of Non-Kekulé structures. Note that TMM is a joint biradical, while TME is a disjoint biradical.

Often, the term “non-Kekulé biradicals” is used synonymously with “delocalized biradicals,”<sup>22,24</sup> because the radical sites cannot be localized on a single set of two atoms. Moreover, Kekulé molecules can also be regarded as delocalized biradicals, since it is usually possible to draw different resonance structures where the radical sites are localized at different atoms (Scheme 5).<sup>17</sup> Additionally, antiaromatic compounds can also be classified as delocalized biradicals. (Note that planar, highly symmetric structures of antiaromatic compounds often correspond to an excited triplet state, which distorts in the singlet ground state due to a second-order Jahn-Teller effect. A typical example is cyclobutadiene, which has a rectangular equilibrium structure.)<sup>56</sup> The term “localized” biradicals, on the other hand, refers to molecules whose radical sites are not conjugated by a classical  $\pi$  system, so each radical electron can be localized at a single atom.<sup>17,24</sup> Typical examples of localized biradicals are cyclobutane-1,3-diyl and cyclopentane-1,3-diyl (Scheme 5).

Another important classification is based on the orbital symmetry of the frontier orbitals, specifically regarding their bonding and antibonding character. Usually (at least in most closed-shell molecules), the bonding orbital is lower in energy than the corresponding anti-bonding orbital. However, depending on the relative strengths of the so-called “through-space” and “through-bond” interactions in cyclic biradicals,<sup>17,22</sup> the transannular antibonding orbital can be the HOMO, whereas the bonding orbital is the LUMO (Fig. 14), effectively inverting the typical order of the orbitals. Abe classified biradicals with a bonding HOMO and anti-bonding LUMO as “type-1 biradicals,” whereas those with an anti-bonding HOMO and bonding LUMO were classified as “type-2 biradicals.”<sup>17</sup>

It should be noted that, when the two radical centers are on the same atom, the species are most often referred to by their generic names: carbenes, nitrenes, etc. rather than biradicals.

As we have discussed in detail, the transition between closed-shell, biradical(oid)s and “perfect” biradicals is continuous. Thus, biradicals can, depending on their biradical character, singlet-triplet gap, orbital symmetry etc. undergo typical radical reactions (i.e., stepwise reactions, or reactions that take place solely at one radical site) as well as typical closed-shell reactions (i.e., concerted reactions that involve both radical centers). While closed-shell reactivity is confined to the singlet energy surface, (bi-)radical reactivity

**Scheme 5** Classification of biradicals as localized, delocalized, Kekulé and non-Kekulé biradicals.

can take place both on the singlet as well as triplet energy surface. Less coupling between the electrons (i.e., stronger non-dynamic correlation) will lead to more radical-like reactivity and vice versa. This has very recently been thoroughly reviewed by Stuyver/Chen/Zeng/Hoffmann,<sup>20</sup> so we will not further discuss the matter here but refer the interested reader to that excellent review article.

Nonetheless, the following sections will showcase various reactions of heterocyclobutane-1,3-diyls as well as heterocyclopentane-1,3-diyls that give a good impression of the versatility of biradical reactivity.

### 1.04.3 Main group biradicals

#### 1.04.3.1 General aspects

In main group molecular chemistry, the activation of small molecules plays a central role. In recent years, many new concepts have been introduced for this, e.g., the utilization of bulky substituents to introduce kinetic stabilization,<sup>57–74</sup> weakly coordinating anions,<sup>75–84</sup> as well as unusual reaction media,<sup>85</sup> such as ionic liquids,<sup>86–91</sup> neat (Brønsted and Lewis) acids (e.g.,  $\text{SO}_2$ ,<sup>92,93</sup> oleum<sup>94,95</sup>) and bases (e.g.,  $\text{NH}_3$ <sup>96–101</sup>). However, the generation of unusual bonding situations such as in frustrated Lewis acid/Lewis base pairs (FLPs),<sup>102–105</sup> *N*-heterocyclic carbene stabilized fragments,<sup>106–114</sup> adducts<sup>115</sup> with large substituents (e.g.,  $\text{B}(\text{C}_6\text{F}_5)_3$ ),<sup>116–119</sup> low-valent main group species<sup>120</sup> with open coordination sites, persistent radicals<sup>120</sup> or the use of biradicals led to new ways in molecular activation. The latter concept of biradicals was introduced in a series of publications by Niecke, who can be considered a pioneer in this field, in the 1990s. Beyond the exact definition of the different bonding situations in biradicals (cf. Section 1.04.2), the use of such open-shell species for molecule activation can or should also be understood as a *concept*.

The concept of the open-shell singlet biradicals is sometimes met with doubt and questions are raised as to how an open-shell singlet biradical can be identified spectroscopically. There is no such defined experiment (unless there is a very low-lying triplet state), but there are indicators that can be derived from both theory and experiment. Theoretically derived biradical indicators are (see also Section 1.04.2.10): (1) a restricted Hartree-Fock  $\rightarrow$  unrestricted Hartree-Fock wavefunction instability, i.e., no closed shell wavefunction is found, (2) a small singlet-triplet gap ( $\Delta E_{\text{S-T}}$ ), (3)  $\beta$  value<sup>46</sup>  $> 15\%$  and (4) biradical and zwitterionic Lewis representations in the valence bond description, e.g., obtained from NRT calculations (NRT = natural resonance theory). Experimentally, rather long bonds, unusual chemistry (molecular activation such as reversible  $\text{H}_2$  addition) and molecular switching behavior are often observed. Moreover, such biradicals can be easily oxidized to persistent (mono)radicals or reduced to anions. In addition, biradicals also usually exhibit a small splitting between their lowest energy and first excited singlet states ( $\Delta E_{\text{S1-S0}}$ ). Biradicals often occur when bonds are formed or broken and can therefore also be regarded as compounds with an extraordinarily stretched bond, which also results in the unusual observed reactivity. The latter aspect plays an essential role when it comes to

**Fig. 14** Schematic MO diagram of cyclobutane-1,3-diyl.<sup>17,22,25</sup> The singly occupied atomic orbitals (left) are combined to a bonding and anti-bonding symmetry adapted linear combination (SALC, sometimes also referred to as “group orbital”). The bonding orbital is somewhat lower in energy due to the orbital interaction (the “through-space” interaction). The  $b_{1u}$  SALC interacts with the SALCs of corresponding symmetry at the  $CR_2$  bridges (depicted on the far right), which are part of the formal  $\sigma(C-R)$  bonding system (thus, this interaction is called “through-bond” interaction). In consequence, the transannular bonding orbital is raised in energy, and depending on the magnitude of the different interactions, it may lie above or below the anti-bonding orbital. (For reasons of clarity, the C–H anti-bonding  $b_{2g}$  orbital is not depicted.)

molecular switching properties as found for the pnictogen-centered cyclopentane-1,3-diyl analogs (cf. Sections 1.04.3.3.2 and 1.04.4).

In this book chapter we will mainly focus on main group analogs of cyclobutane-1,3-diyls and cyclopentane-1,3-diyls. Both localized biradical species have two well-defined radical substructures that are not conjugated by a  $\pi$ -system (Scheme 6).

### 1.04.3.2 Main group analogs of cyclobutane-1,3-diyls

Cyclobutane-1,3-diyls (**1**) are very unstable compounds. Singlet cyclobutanediyls were predicted as extremely short-lived transition states for the ring inversion of bicyclo[1.1.0]butanes (Scheme 7). For a long time, experimental observation was not possible. The singlet state of **1** is quantum chemically predicted as the transition state of the inversion reaction from bicyclo[1.1.0]butane **1'** by homolytic cleavage of the transannular bond (Scheme 7). The calculated activation barrier for the inversion is between  $46 \text{ kcal mol}^{-1}$  and  $52 \text{ kcal mol}^{-1}$ , depending on the method and basis set used.<sup>121</sup> According to calculations by Dougherty et al., the singlet ground state of **1** is  $1.7 \text{ kcal mol}^{-1}$  higher than the triplet state (CASSCF(2,2)).<sup>122</sup> In 1984, Dougherty et al. reported the detection of the first cyclobutanediyl derivative (**1Me**), which was substituted with methyl groups at the radical centers, by EPR spectroscopy (electron paramagnetic resonance). This triplet molecule was generated by irradiating the diazo compound in a solid matrix below 25 K (Scheme 8).<sup>123</sup>

In the following years, further derivatives of **1** could be observed (Scheme 8).<sup>124</sup> However, the unsubstituted parent compound **1H** could not be detected so far.<sup>125</sup> The triplet species **1R** are very short-lived and react via formation of a transannular bond to the bicyclic isomers **1'R** and to other products.<sup>124,125</sup> On the way to stable cyclobutane-1,3-diyls, attempts were made to enlarge the transannular bond in bicyclo[1.1.0]butane by introducing substituents, thereby possibly forcing the system into the planar, biradical form.<sup>126,127</sup> Calculations by Schleyer et al. show that the exchange of the hydrogen atoms on the geminal carbon atoms in bicyclo[1.1.0]butane for heteroatoms leads to a significant lengthening of the transannular carbon-carbon bond. However, the resulting compounds are still preferentially angled and feature weak elongated bonds.<sup>128</sup>

**Scheme 6** Left: Cyclobutane-1,3-diyl, right: cyclopentane-1,3-diyl.

**Scheme 7** Inversion of bicyclo[1.1.0]butane **1'** via a planar transition state that represents a planar biradical.

### 1.04.3.2.1 Niecke's 1,3-diphospha-cyclobutane-2,4-diyl

In 1995, Niecke published his first report on a main group analog of cyclobutane-1,3-diyl,  $[\text{Cl-C}(\mu\text{-P-Mes}^*)]_2$ , which was a landmark in main group as well as biradical chemistry (cf. [Section 1.04.3.2.2](#)).<sup>129</sup> The reactivity of 1,3-diphospha-cyclobutane-2,4-diyls has been studied in detail by the Niecke group and later by Ito et al., who introduced air-tolerant 1,3-diphospha-cyclobutane-2,4-diyls obtained by direct arylation ([Section 1.04.3.2.2](#)).<sup>37,130</sup> It should be noted that probably the first heteroatom-substituted cyclobutanediyl derivative to be synthesized is 4-membered cyclic disulfur-dinitride ( $\text{S}_2\text{N}_2$ ), however the biradical character of  $\text{S}_2\text{N}_2$  was/is heavily discussed in the literature ([Section 1.04.3.2.4](#)).<sup>131</sup>

Ever since the discovery of Niecke's biradical, cyclobutane-2,4-diyl analogs have been intensively studied,<sup>16,17,20–22,24,25,29,35,132–138</sup> which we will also systematically describe in more detail below. Before we begin, however, we want to shed light on the "intrinsic" reactivity, i.e., what possibilities such biradical systems themselves have to avoid a biradical electronic structure. We would like to discuss this using  $[\text{E}^2(\mu\text{-E}^1\text{R})]_2$  ( $\text{E}^{1,2}$  = pnictogen, [Scheme 9](#)) as an example.

Species such as  $[\text{E}^2(\mu\text{-E}^1\text{R})]_2$  are easily generated by reduction of  $[\text{Cl-E}^2(\mu\text{-E}^1\text{R})]_2$  with e.g., magnesium chips forming either a planar 4-membered heterocycle featuring open-shell biradical character or a closed-shell, non-planar butterfly species with a transannular bond ([Scheme 9](#)). Both species are singlet species, that is, the spin density is precisely zero at each and every point in space (i.e., both are NMR active but EPR silent). If a bond is formed across the ring, one obtains a puckered butterfly molecule that has no radical character at all. Interestingly, according to calculations, when  $\text{E}^1$  is a nitrogen atom, the planar  $6\pi$ -electronic biradical is always energetically favored, while in all other cases the closed-shell bicyclic butterfly species are the global minima on the energy surface.<sup>139,140</sup> Such butterfly species, e.g., with four phosphorus atoms,<sup>141</sup> have been known for more than 30 years and exhibit a normal transannular covalent bond.<sup>142</sup>

The question now arises, what is the origin of these structural and electronic differences? Essentially, three things are important: (i) first, better delocalisation of the  $6\pi$ -electrons in the case of nitrogen favors a planar situation.<sup>143–146</sup> (ii) second, and Ugalde et al. have drawn attention to this, is the fact that angular strain is reduced in the case of the nitrogen species in the planar structure because nitrogen prefers a larger bond angle. Therefore, the angular strain is not compensated by the  $\text{E}^2\text{-E}^2$  bond across the ring, as is the case in the butterfly structure ([Scheme 9](#)).<sup>140</sup> When nitrogen is replaced by heavier pnictogen atoms (P–Bi), the angular strain of the bond is reduced, a transannular bond is formed and the butterfly compound becomes the most stable isomer.<sup>142</sup> (iii) When a small substituent is used, oligomerisation—mainly dimerization—occurs, leading to the formation of different types of dimers, as shown in [Scheme 9](#).<sup>145–147</sup> Therefore, to protect the four-membered biradical from oligomerisation, kinetic protection must be provided (e.g., by a terphenyl = Ter = 2,6-bis(2,4,6-trimethylphenyl)-phenyl, Bbp = 2,6-bis[bis(trimethylsilyl)methyl]phenyl, hypersilyl = Hyp = bis-tris(trimethylsilyl)silyl group). Besides the buried volume,<sup>69,108,148,149</sup> the cone angle<sup>71,72</sup> is a good measure of the steric hindrance introduced by the bulky substituent on the nitrogen atom. For example, the cone angle decreases along the series  $232^\circ$  (terphenyl),  $230^\circ$  (Bbp) to  $213^\circ$  (hypersilyl).<sup>58</sup> The smallest cone angle for kinetic stabilization of biradicals of the type  $[\text{E}^2(\mu\text{-E}^1\text{R})]_2$  is about  $200^\circ$ . Even for the hypersilyl-substituted biradical, dimerization occurs slowly in polar solvents (forming the  $\alpha$ -cage dimer), but can be suppressed if nonpolar solvents are used.<sup>145,146</sup> Furthermore, the charge transfer of the substituent into the four-membered ring plays a crucial role in reactivity, e.g., it increases for  $[\text{P}(\mu\text{-NR})]_2$  (R = Ter, Bbp, Hyp) from the terphenyl- ( $0.4e$ ) to the hypersilyl-substituted ( $1.2e$ ) species, which is the most reactive species among these three compounds.

### 1.04.3.2.2 Hetero-cyclobutane-1,3-diyls with radical centers on elements of group 13

#### 1.04.3.2.2.1 Boron centered biradicals: $[\text{R}^1_2\text{P}(\mu\text{-BR}^2)_2\text{PR}^1_2]$

The first 1,3-diphospha-2,4-dibora-cyclobutane-2,4-diyl,  $2\text{-}^t\text{Bu-}^t\text{Bu}$ , was synthesized in 2002 by the group of Bertrand,<sup>150</sup> starting from correspondingly substituted 1,2-dichlorodiboranes ([Scheme 10](#), path a).<sup>150</sup> The biradical is formed by the addition of two equivalents of lithium diisopropyl phosphide to the diborane. Investigations of the mechanism suggest that the chlorine

**Scheme 8** Generation of triplet cyclobutanediyl **1R** by photolysis of an  $\text{N}_2$  bridged precursor.

**Scheme 9** Oligomerization and transannular bond formation in  $[E^2(\mu-E^1R)]_2$  depending on the size of R and the element E ( $E^{1,2} = \text{pnictogen}$ ).

substituents on the diborane are first replaced by diisopropyl phosphane groups through the elimination of LiCl. The resulting *trans*-butadiene structure subsequently isomerizes to form the four-membered ring.<sup>151</sup>

Quantum chemical calculations for  $2\text{-}^t\text{Bu-}^t\text{Bu}$  are interpreted differently in the literature. Calculations by Bertrand's group confirm the singlet state as the energetic minimum ((U)B3LYP/6-31G\*). If the substituents on the boron and phosphorus atoms are replaced by protons, the planar structure is no longer an energetic minimum, but the transition state of the inversion of the bicyclic compound (B3LYP/6-31++G\*\*).<sup>150</sup> It is noteworthy that for the molecule  $2\text{-}^t\text{Bu-}^t\text{Bu}$  the formal HOMO describes the transannular bonding situation and the LUMO the corresponding antibonding one. This is true for all 1,3-diphospha-2,4-diboracyclobutane-2,4-diyls, but the reverse is true for the other heteroatomic cyclobutanediyl analogs described in this article (see Sections 1.04.3.2 and 1.04.3.3).<sup>150,153,154</sup> Cramer et al. calculated a singlet-triplet gap of  $-23.4 \text{ kcal mol}^{-1}$  (B3LYP/6-31G(d)) for  $2\text{-}^t\text{Bu-}^t\text{Bu}$ , as well as the occupation numbers of the HONO (1.81) and the LUNO (0.19) (GVVB(2,2)/6-31G(d)).<sup>154</sup> Jung and Head-Gordon determined a singlet-triplet gap of  $-33.7 \text{ kcal mol}^{-1}$  (SF-TD-DFT/TDA/6-31G(d)) and an occupation number of the LUNO of 0.17 electrons (UB3LYP/6-31G(d)). They conclude that  $2\text{-}^t\text{Bu-}^t\text{Bu}$  is clearly below known organic biradicals in terms of biradical character, but above normal closed-shell compounds.<sup>155</sup> Cheng and Hu conclude from their calculations (taking into account a singlet triplet gap of  $-28.4 \text{ kcal mol}^{-1}$ , B3LYP/6-31G\*) that 1,3-diphospha-2,4-diboracyclobutane-2,4-diyls are not biradicals but have a long  $\pi$ -bond between the boron atoms.<sup>156</sup>

According to Bertrand et al. the biradical character of  $2\text{-}^t\text{Bu-}^t\text{Bu}$  is clearly shown by its reactivity. With  $\text{CDCl}_3$ , one chlorine atom is added to each of the radical centers in a reaction over 3 days at room temperature. This produces a mixture of the *cis* and *trans*

**Scheme 10** Syntheses of  $2\text{-}^t\text{Bu-}^t\text{Bu}$  (route a,  $R^1 = ^t\text{Bu}$ ) and  $2\text{-Ph-Ph}$  (route b,  $R^1 = \text{Ph}$ ).<sup>150,152,153</sup>

compound (ratio 3:1). A spontaneous reaction takes place with  $\text{HSnMe}_3$  and leads to the *trans*-2,4 adduct. With elemental selenium, the two radical centers are bridged by a selenium atom, resulting in a [1.1.1]bicycle.<sup>157</sup>

In addition to the *t*Bu-substituted biradical **2\_’Bu\_’Bu**, the phenyl-substituted compound **2\_Ph\_Ph** was also synthesized in the group of Bertrand.<sup>152</sup> Here, in contrast to **2\_’Bu\_’Bu**, the diborane is not used as the starting material, but a cyclic 2,4-dichloro-substituted compound, generated from P1 and B1 building blocks (**Scheme 10**, route **b**), in which the four-membered ring is pre-formed. The chlorine atoms are abstracted by reduction with lithium naphthalide and the violet biradical **2\_Ph\_Ph** is formed. Like **2\_’Bu\_’Bu**, this is sensitive to air, but stable in the solid state in the absence of air. In solution, an equilibrium can be observed between the open-shell form **2\_Ph\_Ph** and the closed-shell variant **2’\_Ph\_Ph** (**Scheme 11**).<sup>152</sup>

With the help of NMR investigations, it could also be determined that at high temperatures the closed-shell (transannular bonded) species is preferred (room temperature, ratio 7:1 [**2’\_Ph\_Ph**:**2\_Ph\_Ph**]) and at low temperatures the open-shell species ( $-145\text{ }^\circ\text{C}$ , ratio 1:3). The trend is confirmed by temperature-dependent UV-vis investigations. It is crucial to note that the bicyclic **2’\_Ph\_Ph** is colorless in contrast to the violet biradical **2\_Ph\_Ph**. The observed absorption decreases with increasing temperature. The bond formation at higher temperatures is explained by entropy effects, since, for example, the phenyl substituents in the closed-shell species are freely rotatable; in the biradical they lie co-planar to the four-membered ring.<sup>152</sup>

In addition to the “monomeric” biradical compounds **2\_’Bu\_’Bu** and **2\_Ph\_Ph**, Bertrand et al. succeeded in linking two biradical units via a phenyl linker and thus synthesizing the formal tetraradical *para*-3.<sup>158</sup> The synthesis is similar to route **a** shown in **Scheme 10**, again utilizing a diborane. However, here two diborane units are already linked to each other via a phenyl ring in the *para* position. Bromine serves as leaving group on the boron atoms. Hence, the violet, phenyl linked biradical *para*-3 is obtained by reaction with lithium diisopropylphosphide (**Scheme 12**).<sup>158</sup>

In the solid state, only the open-shell species is observed. The phenyl ring lies in one plane with the two four-membered rings. In solution, however, as with **2\_Ph\_Ph**, an equilibrium is formed between the open-shell form *para*-3 and the closed-shell compound *para*-3’ (**Scheme 13**). Here, too, the open-shell compound is preferentially present at low temperatures, and the closed-shell compound at high temperatures.<sup>158</sup>

The synthesis as shown in **Scheme 12** can also be carried out with the two diborane groups in the *meta* position. In this case, however, the open-shell tetraradical *meta*-3 is not obtained, but only the closed-shell isomer *meta*-3’, both in solution and in the solid state.<sup>158</sup> This difference is attributed to the fact that *meta*-phenyl is a ferromagnetic linker, whereas *para*-phenyl is an anti-ferromagnetic linker. Antiferromagnetic linkers favor a coupling between radical centers more strongly than ferromagnetic ones.<sup>159</sup> In the *para*-substituted compound, the coupling or “communication” between the individual biradical units is therefore stronger than in the *meta*-substituted isomer. This argument is supported by further experimental findings of Bertrand et al. The asymmetrically substituted biradicals **2’\_’Bu\_Ph** (cf. **Scheme 10**, route **a**:  $\text{R}^1 = \text{’Bu}$ ,  $\text{R}^2 = \text{Ph}$ ) and **2’\_’Bu\_Npht** (cf. **Scheme 10**, route **a**:  $\text{R}^1 = \text{’Bu}$ ,  $\text{R}^2 = \text{Npht}$ ; Npht = 2-naphthyl) exist in solution and in the solid state only as closed-shell compounds.<sup>160</sup> From this observation it was concluded that the combination of a *t*Bu substituent and an aromatic radical does not sufficiently stabilize the open-shell species. In order to exclude the possibility that the electronic effect of the second  $\text{P}_2\text{B}_2$  unit on the phenyl ring in

**Scheme 11** Equilibrium between open-shell species **2\_Ph\_Ph** and bicyclic **2’\_Ph\_Ph** in solution, as a function of temperature.<sup>152</sup>

**Scheme 12** Synthesis of *para*-3.<sup>158</sup>

**Scheme 13** Equilibrium between open-shell form *para*-3 and closed-shell form *para*-3’ in solution, as a function of temperature.<sup>158</sup>

*para*-3 alone is decisive for the stabilization of the biradical form, a methyl group was introduced on the linking phenyl ring in the *ortho*-position of one or both P<sub>2</sub>B<sub>2</sub> units. The result is a closed-shell system. Through steric interactions, the methyl groups prevent the phenyl ring from lying co-planar to the P<sub>2</sub>B<sub>2</sub> units, which means that communication via the π-system is no longer possible. These results indicate an existing communication between the biradical units in *para*-3, which is essential for the stabilization of the open-shell singlet species.<sup>160</sup>

#### 1.04.3.2.2.2 Aluminum centered biradical: [R<sup>1</sup>P(μ-AIR<sup>2</sup>)<sub>2</sub>PR<sup>1</sup>]

The synthesis of the 1,3-diphospha-2,4-dialumina-cyclobutane-2,4-diyl (**4**) was published in 2009 by Schnöckel et al.<sup>161</sup> For the formation of **4**, a LiP(<sup>t</sup>Bu)<sub>2</sub> solution in toluene is overlaid with an AlCl solution in a toluene-diethyl ether mixture (Scheme 14). As AlCl is metastable, elemental aluminum and AlCl<sub>3</sub> are formed over time by disproportionation reactions. The reactive intermediate is thought to be Al<sub>3</sub>Cl<sub>7</sub>(OEt<sub>2</sub>)<sub>5</sub>.<sup>161</sup>

Biradical **4** is only obtained in low yields in the form of green crystals. Additionally, colorless by-products are formed. The low yield can be attributed to the instability of the biradical compound **4**, both in the solid state and in solution. Characterization of **4** was only possible by X-ray crystal structure analysis. Further investigations (including EPR spectroscopy) were not carried out due to the complex synthesis and low yields, therefore further conclusions could only be drawn from quantum chemical calculations.<sup>161</sup> The open-shell character of biradical **4** was confirmed by calculations of UV-vis spectra (BP86/def2-TZVP). It is assumed that green colored **4** is a triplet biradical that is stabilized by reaching the singlet state through spin reversal, which results in the direct formation of the transannular Al–Al bond to give **4'**.<sup>162</sup> Stabilization through dimerization is not possible due to steric hindrance (see Section 1.04.3.2). The singlet state is between 1.0 and 1.4 kcal mol<sup>-1</sup> lower in energy than the triplet state (vertical energy gap at the triplet structure), depending on the methods and basis sets used for the calculations (CASSCF(2,2); MRCI).<sup>162</sup> The adiabatic singlet-triplet gap ranges between –16.3 and –18.3 kJ/mol depending on the method (PB86, TPSS, B3LYP with def2-TZVP basis). Thus, **4'** with a transannular Al–Al bond is the equilibrium ground state structure.<sup>161</sup>

#### 1.04.3.2.3 Hetero-cyclobutane-1,3-diyls with radical centers on elements of group 14

##### 1.04.3.2.3.1 Carbon centered biradicals: [R<sup>1</sup>P(μ-CR<sup>2</sup>)<sub>2</sub>PR<sup>1</sup>]

1,3-Diphospha-cyclobutane-2,4-diyl, Niecke's biradical (Scheme 15),<sup>163</sup> was the first carbon centered biradical within a [P<sub>2</sub>C<sub>2</sub>]-four-membered heterocycle and, in a sense, the prototype for the chemistry of the four-membered biradicals that followed in the subsequent period of time. Starting from Mes\*P=CCL<sub>2</sub> (Mes\* = 2,4,6-<sup>t</sup>Bu<sub>3</sub>C<sub>6</sub>H<sub>2</sub>), the biradical 5<sub>Cl</sub>Cl is obtained when reacted with half an equivalent of <sup>n</sup>BuLi and LiCl is eliminated.

Further biradicals of a similar structure can be synthesized through subsequent reactions starting from 5<sub>Cl</sub>Cl. In this case, the phosphorus atoms are always substituted with Mes\*, however, different substituents can be attached to the carbon atoms. By adding Hg(TMS)<sub>2</sub>, the exchange of a chlorine substituent for a TMS group is achieved leading to 5<sub>Cl</sub>TMS (Scheme 15). The second chlorine substituent can be abstracted with <sup>n</sup>BuLi. Addition of <sup>t</sup>BuOH yields the hydrogen-substituted biradical 5<sub>H</sub>TMS as a red, crystalline solid.<sup>164</sup> 5<sub>H</sub>TMS is thermally very stable under inert conditions. However, when a solution of 5<sub>H</sub>TMS is irradiated with a mercury vapor lamp at –25 °C, the closed-shell isomer 5'<sub>H</sub>TMS with a transannular C–C bond is formed (Scheme 16). When this bicyclus in solution is heated to 150 °C, ring opening and formation of a butadiene derivative occurs (Scheme 16).<sup>164</sup>

By adding LDA (lithium diisopropylamide) to the protonated biradical 5<sub>H</sub>TMS, the likewise red, deprotonated anion [5<sub>TMS</sub>]<sup>–</sup> is generated (Scheme 16). In the solid state, under inert atmosphere, the lithium salt of [5<sub>TMS</sub>]<sup>–</sup> is stable. In THF solution, however, the protonated species is re-formed within 1 day.<sup>165</sup> During the reaction of [5<sub>TMS</sub>]<sup>–</sup> with AlCl<sub>3</sub>, the water-sensitive Lewis acid adduct [5<sub>AlCl<sub>3</sub>TMS</sub>]<sup>–</sup> is formed (Scheme 16). The proton in 5<sub>H</sub>TMS can be replaced by another TMS group after reaction with two equivalents of LDA and subsequent addition of TMS-Cl. This leads to the symmetrically substituted biradical 5<sub>TMS</sub>TMS. Irradiation of this compound, however, does not cause the formation of a transannular bond to give 5'<sub>TMS</sub>TMS (cf. 5<sub>H</sub>TMS); instead, homolytic cleavage of the bond between a phosphorus atom and a Mes\* substituent occurs.<sup>166</sup>

Yoshifuji and Ito have expanded the class of 1,3-diphospha-cyclobutane-2,4-diyl compounds by being able to introduce a wide variety of substituents at the P atom, starting from phospho-alkynes,<sup>167</sup> in contrast to Niecke's biradicals, which are limited to the Mes\* substituent at the P atom (cf. Scheme 15 compound 5 and Scheme 17 compound 6). Thus, the 1,3-diphospha-cyclobutane-2,4-diyls synthesized in the working groups of Yoshifuji and Ito differ from those of Niecke by the arrangement of the substituents (Scheme 17, compound 6), that is, in Yoshifuji's and Ito's biradicals the carbon atoms are always Mes\*-substituted, since Mes\*-CP is always utilized in the synthesis. Until today, various substitution patterns are known for the phosphorus atoms. This diversity is

Scheme 14 Synthesis of **4**.

**Scheme 15** Synthesis of **5\_Cl\_Cl**, **5\_Cl\_TMS** und **5\_H\_TMS** ( $\text{Mes}^* = 2,4,6\text{-}t\text{Bu}_3\text{C}_6\text{H}_2$ ,  $\text{TMS} = \text{SiMe}_3$ ).<sup>163,164</sup>

**Scheme 16** Reactivity of **5\_H\_TMS** and synthesis of **5\_TMS\_TMS**, **[5\_TMS]<sup>-</sup>** as well as **[5\_AlMe<sub>3</sub>\_TMS]<sup>-</sup>**.<sup>164–166</sup>

made possible by the new synthesis route (**Scheme 17**), which allows the introduction of the substituents at the phosphorus atoms in two successive steps. The phosphalkyne,  $\text{Mes}^*\text{CP}$ , is reacted with half an equivalent of the lithium compound of the first substituent ( $\text{LiR}^1$ ). This leads to the formation of the anionic  $[\text{C}_2\text{P}_2]$ -four-membered ring **7**, which subsequently reacts with an alkyl-halogenide ( $\text{R}^2\text{-X}$ ,  $\text{X} = \text{halogen}$ ) of the desired second substituent ( $\text{R}^2$ ) to form the biradical **6** (**Scheme 17**). The majority of the examples of compound class **6** were generated by this two-step reaction pathway. However, some compounds are obtained only by subsequent reactions at the substituent  $\text{R}^2$ .<sup>168–170</sup> If  $\text{R}^2$  is an aromatic substituent (**Table 2**),  $\text{R}^2$  is introduced via the intermediate

**Scheme 17** General synthesis route of compound class **6** according to YOSHIFUJI and ITO.<sup>167</sup>

formation of an arine.<sup>171</sup> Almost all biradicals of this type and synthesized by this procedure can be handled in air, and some are stable in air for more than 6 months.<sup>37,167–170,172–180</sup>

The first example of this class of biradicals was 6-<sup>t</sup>Bu-Me. To prepare 6-<sup>t</sup>Bu-Me, the phosphalkyne, Mes\*CP, was reacted with <sup>t</sup>BuLi and MeI according to the synthetic route shown in Scheme 17, resulting in the formation of a deep blue-purple solution of biradical 6-<sup>t</sup>Bu-Me.<sup>167</sup> This biradical shows extremely high stability. It can be handled in air and decomposes only after some time after treatment with water, which is explained by kinetic stabilization due to the steric hindrance of the Mes\* substituents.<sup>167</sup> In contrast to the 1,3-diphospha-cyclobutane-2,4-diyl 5-H-TMS of Niecke, no reaction is observed when 6-<sup>t</sup>Bu-Me is irradiated with a mercury lamp.<sup>167</sup> Numerous examples are known of compounds of type 6. For an overview, the biradicals are divided into categories depending on their substituents R<sup>1</sup> and R<sup>2</sup> and listed in Tables 1–4. The reactivity of the biradicals is summarized below using selected examples.

The reactivity of diphospha-cyclobutanediyls is strongly dependent on the substituents at the phosphorus atoms. In the following, selected examples are presented that reflect the most important reactivities of this class of compounds. Despite the exceptional stability of the biradicals synthesized by Yoshifuji and Ito et al., decomposition of the compounds is observed upon prolonged heating in solution. Depending on the nature of the substituents, the starting material Mes\*-CP is released again or ring expansion occurs (Scheme 18).<sup>177,181</sup>

In the case of the heteroatom-substituted biradical 6-N<sup>i</sup>Pr<sub>2</sub>-Me, reaction with TEMPO (2,2,6,6-tetramethylpiperidinyloxy) under irradiation leads to the transfer of an oxygen atom to the methyl-substituted phosphorus atom (Scheme 19). This reactivity is not observed with the aliphatically substituted biradical 6-<sup>t</sup>Bu-Me.<sup>181</sup> The reaction of 6-N<sup>i</sup>Pr<sub>2</sub>-Me with elemental sulfur leads to the analogous product with a sulfur atom on the methyl-substituted phosphorus atom (Scheme 19).<sup>176</sup> Again, also this reaction with the aliphatically substituted biradical 6-<sup>t</sup>Bu-Me is not observed.

The reaction of 6 with LiAlH<sub>4</sub> can lead to different products. Depending on the substituents, either a hydride ion is transferred to a phosphorus atom so that the cyclic anion 8 is formed (Scheme 20) or the cyclic anion 7 is formed by eliminating a hydrogenated substituent R<sup>2</sup>H (Scheme 21).<sup>168,183</sup> Both reactions can be observed for compounds 6-<sup>t</sup>Bu-CH<sub>2</sub>CH=CMe<sub>2</sub> and 6-<sup>t</sup>Bu-CH<sub>2</sub>-(E)-CH=CHPh.<sup>168</sup>

In the case of the hydrogenated four-membered ring 8, protonation can then take place by adding methanol. The proton is added to the second phosphorus atom affording 9 (Scheme 20). Formally, the reaction product 9 can be seen as the addition of molecular hydrogen. However, the hydrogen atoms are not bound to the carbon atoms where the radical electrons were previously located, but to the phosphorus atoms. According to Yoshifuji and Ito et al., the reaction with molecular hydrogen was attempted in a 1:1 stoichiometry as well as under increased pressure, but this has not yet been further elaborated in the literature.<sup>183</sup>

For numerous other compounds of class 6, the reaction with LiAlH<sub>4</sub> leads to the cleavage of a substituent, whereby the anion 7 is obtained, which also occurs as an intermediate in the synthesis of the biradicals. When MeI is added, this reacts to form a biradical with a methyl substituent. In the overall reaction, R<sup>2</sup> is exchanged for a methyl group (Scheme 21, cf. Scheme 17).<sup>168</sup>

Some compounds of type 6 add hydrogen fluoride, HF, reversibly yielding 10 (Scheme 22). Different HF sources are possible. Reactions were carried out with HF · NEt<sub>3</sub> and the mixture of C<sub>5</sub>F<sub>5</sub>N and HNEt<sub>2</sub>, among others. As in the reaction with LiAlH<sub>4</sub> and the subsequent protonation (Scheme 20), the hydrogen and fluorine atoms are transferred to the two phosphorus atoms, although the radical centers are located on the carbon atoms. The elimination of HF takes place in each case by the addition of NaH and crown ether (15-crown-5).<sup>171,182</sup>

In contrast to the biradicals presented above, 6-<sup>t</sup>Bu-C(O)Ph reacts with HF with the addition of the fluorine atom to the <sup>t</sup>Bu-substituted phosphorus atom and of the hydrogen atom to a carbon atom.<sup>182</sup> In addition to the reactions presented so far, different reactivities of various representatives of 6 towards <sup>t</sup>BuLi have been observed.<sup>169</sup> In the context of an EPR study, the groups of Yoshifuji and Ito have also succeeded in oxidizing the biradical 6-<sup>t</sup>Bu-Me with tris(4-bromophenyl)ammonium hexachloridoantimonate to a radical cation.<sup>184</sup> Some derivatives have also been investigated with regard to their suitability as semiconductors in field-effect transistors.<sup>173,185</sup>

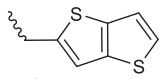

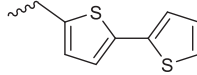

In addition to the numerous biradicals summarized in Tables 1–4, biradical compounds of type 6 were also synthesized in which two or three biradical units are linked (Scheme 23). The synthesis does not deviate significantly from the route shown in Scheme 17. The anion 7 is reacted with a di- or tri-brominated linker (Scheme 23, bromine atoms instead of the biradical units R). For some derivatives, it is necessary to react a still brominated intermediate with the anion 7 again. The resulting tetra- or hexaradicals are summarized in Table 5.<sup>175,178,180</sup> The tetra- and hexaradicals isolated by Yoshifuji and Ito et al. have non-conjugated moieties as linkers (Scheme 23). This means that no communication of the biradical units via a conjugated π-system is possible, but only covalent and electrostatic “communication.” An equilibrium between the biradical and the closed-shell isomer with a transannular bond (as depicted in Scheme 9) is also not observed in contrast to Bertrand’s boron centered biradical 2.

#### 1.04.3.2.3.2 Silicon centered biradicals: [R<sup>1</sup>N(μ-SiR<sup>2</sup>)<sub>2</sub>NR<sup>1</sup>]

The silicon-centered biradical, a 1,3-diaza-2,4-disilacyclobutane-2,4-diyl derivative (11), was presented by Sekiguchi’s group in 2011. The synthesis was achieved by reacting a disilyne with an azo compound (Scheme 24).<sup>186</sup> The violet biradical 11 is sensitive to air and water. The biradical character was derived from the planarity of the central four-membered ring and the increased Si-Si distance in the X-ray structure as well as the absence of a bond-critical point between the silicon atoms in AIM (atoms in molecules) calculations on a model system (phenyl groups at N, TMS groups at Si, RB3LYP/6-31G(d)). The calculated singlet-triplet gap of the model compound of 12.8 kcal mol<sup>-1</sup>, the absence of an EPR signal and the smooth recording of NMR spectra indicate the singlet character of the biradical.<sup>186</sup>

**Table 1** 1,3-Diphospha-cyclobutane-2,4-diyls according to Yoshifuji and Ito et al. (Scheme 17) in which the substituents R<sup>1</sup> and R<sup>2</sup> are linked to the phosphorus atoms via non-aromatic carbon atoms.

If **11** is reacted with methanol, the *cis* addition product is formed in which one silicon atom is additionally substituted with a hydrogen atom and the other with a methoxy group (**12**). With CCl<sub>4</sub>, both silicon atoms are chlorinated forming the *trans* isomer (**13**, Scheme 25).<sup>186</sup>

#### 1.04.3.2.3.3 Silicon centered biradicals: [R<sup>1</sup><sub>2</sub>C(μ-SiR<sup>2</sup>)<sub>2</sub>CR<sup>1</sup><sub>2</sub>]

The synthesis and characterization of a singlet delocalised 2,4-diimino-1,3-disila-cyclobutane-1,3-diyl, [LSi(μ-CNAr)<sub>2</sub>SiL] (**14a**), and a silylenyl-sila-imine, [LSi(=NAr)SiL] (**14b**), were published by So et al. (Scheme 26, L = PhC(N<sup>t</sup>Bu)<sub>2</sub>, Ar = 2,6-<sup>i</sup>Pr<sub>2</sub>C<sub>6</sub>H<sub>3</sub>).<sup>187</sup> The reaction of three equivalents of the disilylene [LSiSiL] with two equivalents of Ar-N=C=N-Ar in toluene at room temperature for 12 h gave biradical **14a** and [LSi(=NAr)SiL] (**14b**) in a ratio of 1:2. Compounds **14a** and **14b** were characterized by NMR spectroscopy and X-ray crystallography.

Pure **14a** was found in the form of dichromic yellow-brown crystals in 25.7% yield. Compounds **14a** and **14b** are stable in solution or in the solid state at room temperature under inert atmosphere. They are soluble in toluene and THF. The four-membered Si<sub>2</sub>C<sub>2</sub> ring in **14a** is planar. The Si–C bonds (1.834(5)–1.829(5) Å) are almost identical and are between the Si–C single (1.87 Å)

and double (1.70 Å) bond lengths. The Si...Si distance (2.553(2) Å) is significantly longer than a typical Si–Si single bond ( $\Sigma r_{\text{cov}}(\text{Si}–\text{Si}) = 2.32$  Å).<sup>188</sup> Theoretical studies show that compound **14a** has a singlet biradical character with extensive electronic delocalisation via the  $\text{Si}_2\text{C}_2$  four-membered ring and exocyclic  $\text{C}=\text{N}$  bonds. The energy difference between the singlet and triplet states of **14a** was calculated at the B3PW91/6-31G(d) level with the singlet state being more stable than the triplet state by 30.1 kcal mol<sup>-1</sup>. The complete active space self-consistent field CASSCF(4,6) calculations show that there are two dominant contributions to the configuration interaction (CI) wave function for the <sup>1</sup>A state with occupation numbers of 1.86 in the HONO and of 0.13 in the LUNO, clearly indicating open-shell singlet biradical character for **14a**.<sup>187</sup>

#### 1.04.3.2.3.4 Silicon centered biradicals: $[\text{R}_2^1\text{Si}(\mu\text{-SiR}^2)_2\text{SiR}_2^3]$

In 2020, Scheschkewitz et al. reported on the isolation and characterization of all-silicon cyclobutane-1,3-diyls as singlet species (**15**) obtained from the reversible reactions of cyclotrisilene,  $\text{cycloSi}_3\text{Tip}_4$  (Tip = 2,4,6-triisopropylphenyl) with the heterocyclic silylenes  $\text{cyclo}[(\text{CR}_2\text{CH}_2)(\text{N}^t\text{Bu})_2]\text{Si}$ : ( $R$  = H or methyl) with saturated backbones (**Scheme 27**).<sup>189</sup> At elevated temperature, tetrasilacyclobutenes are obtained from these equilibrium mixtures. However, in the first reaction step biradical **15** is formed upon treatment of cyclotrisilene with one equivalent of heterocyclic silylene in toluene at room temperature yielding a red-brown solution. Storage of such a concentrated solution in toluene gave dark purple single crystals of **15** ( $R$  = H) in 63% yield. Dissolution of single crystals of **15** re-establishes the equilibrium (**Scheme 27**). An X-ray diffraction study of the crystals revealed the structure of the homonuclear biradical **15** with a cyclic  $\text{Si}_4$  subunit. The four-membered ring is essentially planar with a strikingly

**Table 5** Bis- and tris-1,3-diphosphacyclobutane-2,4-diyls according to Yoshifuji and Ito et al. in which two or three biradical units (R) are linked together via a linker (Scheme 23).

**Scheme 26** Synthesis of **14** (Ar = 2,6-*i*-Pr<sub>2</sub>C<sub>6</sub>H<sub>3</sub>).

long distance between the three-coordinated silicon atoms ( $\text{Si}\cdots\text{Si}$  2.871(1) Å), which is significantly longer than, for example, the very long Si–Si bond length in  ${}^t\text{Bu}_3\text{Si-Si}^t\text{Bu}_3$  with 2.697 Å<sup>190</sup> (cf.  $\Sigma r_{\text{cov}}(\text{Si-Si}) = 2.32$  Å),<sup>188</sup> suggesting a very weak interaction.

The singlet ground state of **15** is confirmed by the well-resolved NMR spectra at low temperature and by the absence of an EPR signal at RT, 193 K and in the frozen state in toluene solution.<sup>189</sup> This is confirmed by DFT calculations, which determine the singlet state of **15** to be 8.4 kcal mol<sup>-1</sup> lower in energy than the triplet (B3LYP-D3(bj)/6-311G(d,p)/SCRF = toluene). The calculated HOMO-LUMO energy gap is 2.21 eV, where the HOMO can be associated with a weak transannular  $\pi$ -bond (bond order 0.57) over the two silicon centers. Already Fischer and Frenking *et al.* identified such transannular  $\pi$ -bond, which is not supported by an underlying  $\sigma$ -bond, in a cyclic  $\text{Ge}_2\text{Ga}_2$  biradical (see biradical **18**).<sup>191</sup>

Time-resolved electron paramagnetic resonance (TR-EPR) spectra recorded after pulse laser excitation of **15** in frozen solution at 80 K together with a spectral simulation revealed a broad signal centered at about 340 mT, a value that compares well with reported silicon-centered biradicals.<sup>189</sup> A dipolar coupling between two unpaired electrons in a triplet state is assumed. Furthermore, the shape of the signal suggests that this triplet state is not in Boltzmann equilibrium, but rather spin-polarized. Spectra with these properties indicate the formation of a triplet state through intersystem crossing from an excited singlet state after photoexcitation.<sup>189</sup>

#### 1.04.3.2.3.5 Germanium centered biradicals: $[\text{R}^1\text{N}(\mu\text{-GeR}^2)_2\text{NR}^1]$

The germanium-centered biradical, a 1,3-diaza-2,4-digermacyclobutane-2,4-diyl derivative (**16**) was first synthesized by the Power group in 2004.<sup>192</sup> The heavy analog of Sekiguchi's silicon biradical with two germanium atoms is obtained when a sterically very demanding digerma-alkyne is reacted with trimethylsilyl azide (Scheme 28). The resulting biradical **16** has a deep violet color and is very sensitive to air and water. With solvents, it reacts within a few days, which is evident by decolorisation of the solution.<sup>192</sup> The planarity of the  $\text{N}_2\text{Ge}_2$  ring, the large distance between the germanium atoms, the absence of signals on EPR investigation and the ease of investigation of **16** by NMR spectroscopy indicate a singlet biradical character for the electronic ground state. Using a model system (SiH<sub>3</sub> groups at N, methyl groups at Ge), quantum chemical calculations were performed to characterize **16**. The HOMO of the compound is antibonding with respect to the transannular Ge-Ge interaction, while the LUMO is bonding. A HOMO-LUMO gap of 57.97 kcal mol<sup>-1</sup> and a singlet-triplet gap of 17.51 kcal mol<sup>-1</sup> were determined for the model compound (UB3LYP/6-31G\*, broken symmetry approach).<sup>192</sup>

Furthermore, Power *et al.* observed that biradical **16** reacts with molecular hydrogen in solution at room temperature and 1 bar, assuming that the hydrogen is added to the germanium atoms of **16**, which results in two tetravalent Ge atoms as parts of the four-membered ring.<sup>192</sup>

#### 1.04.3.2.3.6 Germanium centered biradicals: $[\text{O}(\mu\text{-GeR}^2)_2\text{NR}^1]$

In 2009, Power *et al.* described the synthesis of the first 1-oxa-3-aza-2,4-digerma-cyclobutane-2,4-diyl, a substituted asymmetric biradical (**17**), which is obtained when a bulky digerma-alkyne is treated with a nitroso-arene (Scheme 29).<sup>193</sup> The properties of the resulting biradical are very similar to those of the symmetrical germanium biradical **16** in Scheme 28. Biradical **17** is also violet and highly sensitive to air and water. In the experimental structure, the biradical character is implied by the planarity of the ring system and a large Ge-Ge distance. In addition, there is the measurability of NMR spectra as well as the absence of signals in EPR spectra that indicate the singlet character of the biradical.<sup>193</sup> Quantum chemical calculations of a model system (nitrogen substituted with a hydrogen atom, germanium substituted with methyl groups) show, as for compound **16**, a transannular antibonding HOMO localized at the two germanium atoms in **17**. The HOMO-LUMO gap of the model compound is 55.3 kcal mol<sup>-1</sup> (UB3LYP/6-31G\*<sup>193</sup>).

**Scheme 27** Equilibrium reactions of a cyclotrisilene and a heterocyclic silylenes yielding biradical **15** (R = H or methyl).

**Scheme 28** Synthesis of **16** ( $\text{Ar}' = 2,6\text{-Dipp}_2\text{C}_6\text{H}_3$ ;  $\text{Dipp} = 2,6\text{-}^i\text{Pr}_2\text{C}_6\text{H}_3$ ).<sup>192</sup>

**Scheme 29** Synthesis of **17** ( $\text{Ar}' = 2,6\text{-Dipp}_2\text{C}_6\text{H}_3$ ;  $\text{Dipp} = 2,6\text{-}^i\text{Pr}_2\text{C}_6\text{H}_3$ ).<sup>193</sup>

#### 1.04.3.2.3.7 Germanium centered biradicals: $[\text{R}_2\text{Ga}(\mu\text{-Ge})_2\text{GaR}_2]$

Fischer and Frenking reported on the reduction of  $\text{GeCl}_2$  with  $\text{Ga}(\text{DDP})/\text{KC}_8$  and the properties of a possible biradical  $\text{Ge}_2[\text{Ga}(\text{DPP})]_2$  (**18**) (**Scheme 30**,  $\text{DDP} = \text{HC}(\text{CMeNC}_6\text{H}_3\text{-2,6-}^i\text{Pr}_2)_2$ ) that is formed in the course of this reaction.<sup>191</sup> Compound **18** shows a planar, four-membered  $\text{Ge}_2\text{Ga}_2$  ring with the two  $\text{R}_2\text{Ga}$  moieties in a bridging position. The planar, four-membered  $\text{Ge}\text{--Ga}$  rhombic ring of **18** has two sets of equivalent  $\text{Ga}\text{--Ge}$  bonds of 2.3899(8) and 2.4113(8) Å which are shorter than the sum of the covalent radii (cf.  $\Sigma r_{\text{cov}}(\text{Ga}\text{--Ge}) = 2.45$  Å). The  $\text{Ge}\cdots\text{Ge}$  distance of 2.8714(11) Å, however, is much longer than the value of elemental germanium (2.45 Å) as well the sum of the covalent radii (cf.  $\Sigma r_{\text{cov}}(\text{Ga}\text{--Ge}) = 2.45$  Å).<sup>188</sup> BP86/SVP AIM computations show four  $\text{Ge}\text{--Ga}$  bond paths and one ring critical point but there is no  $\text{Ge}\text{--Ge}$  bond path. The unusual bonding situation in **18** is described in terms of the  $\text{Ge}\cdots\text{Ge}$  interaction by a transannular  $\pi$ -bond but no  $\sigma$ -bonding, which is supported by NBO and ELF (electron localization function) analyzes. Alternatively, the authors describe the bond situation by two unpaired electrons (in p atomic orbitals) at the Ge atoms possessing opposite spin which are weakly coupled.<sup>191</sup> This in turn means **18** can be understood as a singlet biradical (**Scheme 30**).

#### 1.04.3.2.3.8 Tin centered biradicals: $[\text{R}^1\text{N}(\mu\text{-SnR}^2)_2\text{NR}^1]$

The Lappert group synthesized 1,3-diaza-2,4-distanna-cyclobutane-2,4-diyl **19** in 2004 (**Scheme 31**).<sup>194</sup> Biradical **19** was isolated from a reaction of a nitrogen-tin precursor,  $[(\text{TMS})_2\text{N-Sn}(\mu\text{-Cl})_2]$ , when treated with silver cyanate. It is assumed that  $\text{Ag}$  and  $\text{CO}_2$  are eliminated. Biradical **19** was shown to be diamagnetic in the crystal and in solution, in accord with computational studies, showing that the singlet ground state is substantially favored over the triplet. The solid-state structure of the colorless compound shows a planar heterocycle. Quantum chemical calculations indicate that **19** can be assumed to be biradical with singlet-triplet gaps of 18.2 kcal mol<sup>-1</sup> (non-relativistic) and 13.6 kcal mol<sup>-1</sup> (relativistic).<sup>194</sup>

### 1.04.3.2.4 Hetero-cyclobutane-1,3-diyls with radical centers on elements of group 15

#### 1.04.3.2.4.1 Nitrogen/Pnictogen centered biradicals: $[\text{N}(\mu\text{-NR}^2)_2\text{Pn}]$

1,2,3-Triaza-4-pnicta-cyclobutane-2,4-diyls (**20**) have both a nitrogen-centered radical center and a further pnictogen ( $\text{Pn} = \text{P}, \text{As}, \text{Sb}, \text{and Bi}$ ) radical center. They can be prepared starting from terphenyl (Ter)-substituted triazenides. The pnictogen atom is introduced by reaction with the respective pnictogen trichloride affording **21**. Upon reduction of acyclic compound **21** either with magnesium or  $\text{KC}_8$ , the cyclic biradical **20** is formed (**Scheme 32**).<sup>195</sup> The stability of the biradicals **20\_Pn** decreases along the series  $\text{P} > \text{As} > \text{Sb} > \text{Bi}$ . For example, the red biradical **20\_Bi** is only stable for a few minutes in solution, while the other compounds **20\_P** (yellow), **20\_As** (yellow), **20\_Sb** (red) could be isolated in substance and completely characterized. They are sensitive to water and air. X-ray crystal structure analysis shows that all three derivatives have a planar, kite-shaped distorted four-membered ring. The distortion increases with the atomic number of the pnictogen. However, none of the compounds shows reactivity towards small molecules with double or triple bonds, as has been observed with similar compounds (see below). This speaks against a pronounced biradical character of the compounds.<sup>195</sup> Only the reaction of **20\_P** and **20\_As** with the isonitrile  $\text{CN-Dmp}$  leads to the expected

**Scheme 30** Synthesis and schematic description of the bonding situation in the four-membered ring of **18**. Only a Lewis representation with the spin-coupled lone-electrons, describing a transannular  $\pi$  bond, is shown ( $\text{DDP} = \text{HC}(\text{CMeNC}_6\text{H}_3\text{-2,6-}^i\text{Pr}_2)_2$ ).

**Scheme 31** Synthesis of **19**.<sup>194</sup>

insertion of the carbon atom into the four-membered ring. The insertion takes place selectively in the nitrogen-phosphorus or nitrogen-arsenic bond and not in the nitrogen-nitrogen bond (for further information on similar insertion reactions, see below).<sup>196</sup>

Calculations on model compounds of **20\_Pn** (Ph substituents instead of Ter) show a decrease of the biradical character  $\beta$  from the phosphorus- to the bismuth-containing compound (**20\_P** 15%, **20\_As** 10%, **20\_Sb** 6%, and **20\_Bi** 0%) (M06-2X/aug-cc-pVDZ, CASSCF(2,2)). The larger the atomic number of the pnictogen, the more strongly the bonding situation is described by closed-shell, zwitterionic resonance formulae. Some of the possible Lewis representations within the resonance are illustrated in **Scheme 33**.<sup>195</sup>

#### 1.04.3.2.4.2 Pnictogen centered biradicals: $[\text{Pn}^1(\mu\text{-NR})_2\text{Pn}^2]$ (Pn = P, As, Sb, Bi)

1,3-Diaza-2,4-dipnicta-cyclobutane-2,4-diyls (**22**) of the type  $[\text{Pn}^1(\mu\text{-NR})_2\text{Pn}^2]$  are biradicals with exclusively pnictogen-centered radical sites (notation: **22\_Pn<sup>1</sup>Pn<sup>2</sup>\_R** means  $\text{Pn}^{1,2}$  = pnictogen, R = bulky substituent in  $[\text{Pn}^1(\mu\text{-NR})_2\text{Pn}^2]$ ). All these biradicals with the pnictogen in the oxidation state +II are discussed together here, as are the biradicals with two different pnictogens as radical centers. Due to similar synthetic routes, properties and reaction behavior, 1,3-diaza-2,4-diphosphacyclobutane-2,4-diyls (**22\_PP**), 1,3-diaza-2,4-diarsacyclobutane-2,4-diyls (**22\_AsAs**) and 1,3-diaza-2-phospha-4-arsacyclobutane-2,4-diyls **22\_PAs** are grouped together in this section, all of which were synthesized by us.<sup>21</sup> The first examples of this biradical class to be presented in 2011 were the biradicals **22\_PP\_Ter** and **22\_PP\_Hyp** (Hyp =  $(\text{Me}_3\text{Si})_3\text{Si}$ ), **Scheme 34**.<sup>143</sup>

The synthesis of **22** is possible via two reaction paths, depending on the substituent R, which are shown in **Scheme 34**. The first route starts with the chlorinated heterocycle which can be transformed into the biradical by reduction with magnesium,  $(\text{Cp}_2\text{TiCl})_2$  or  $\text{Cp}_2\text{Ti}(\text{BTMSA})$  (BTMSA = bis(trimethylsilyl)acetylene; **Scheme 34**, route a). This synthetic route can be used for the phosphorus-containing biradicals **22\_PP\_Ter**,<sup>143</sup> **22\_PP\_Hyp**,<sup>143,145</sup> **22\_PP\_CPh<sub>3</sub>**,<sup>197</sup> the arsenic-containing derivative **22\_AsAs\_Ter**<sup>144</sup> and the mixed biradical **22\_PAs\_Ter**.<sup>199</sup> For the substituent Bbp (2,6-bis[bis(trimethylsilyl)methyl]phenyl), a different synthetic route is used. Here, the Bbp amine substituted twice with the pnictogen (phosphorus or arsenic) is reduced with magnesium (**Scheme 34**, route b), which gives access to the symmetrical biradicals **22\_PP\_Bbp** and **22\_AsAs\_Bbp**.<sup>198</sup> Heavier derivatives, i.e., the symmetrical biradicals of antimony and bismuth (**22\_SbSb** and **22\_BiBi**) as well as the asymmetrical phosphorus-antimony biradical (cf. **22\_PsB**), could only be observed *in situ* due to their intrinsic instability. However, their existence could be proven by reaction with trapping reagents such as alkynes.<sup>200,201</sup>

Most of these biradicals show strong coloration: **22\_PP\_Ter** orange, **22\_PP\_Hyp** pink, **22\_PP\_CPh<sub>3</sub>** yellow, **22\_PP\_Bbp** yellow, **22\_AsAs\_Ter** violet, **22\_AsAs\_Bbp** greenish yellow, **22\_PAs\_Ter** violet. All are sensitive to water and air, but are thermally extremely stable ( $> 100^\circ\text{C}$ ) in the solid state under an inert atmosphere. The central heterocycles of all these biradicals are planar and the

**Scheme 32** Synthesis of **20** (Pn = P, As, Sb, Bi; Ter = 2,6-Mes<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>, Mes = 2,4,6-Me<sub>3</sub>C<sub>6</sub>H<sub>2</sub>).<sup>195</sup>

**Scheme 33** Closed-shell, zwitterionic resonance structures of **20** besides a biradical Lewis representation.<sup>195</sup>

**Scheme 34** Synthesis of biradicals **22\_PP**, **22\_AsAs** und **22\_PAs** [route a: R = Ter, Hyp, CPh<sub>3</sub>, Pn<sup>1</sup>, Pn<sup>2</sup> = P, As; route b: R = Bbp, Pn = P, As (Hyp =  $(\text{Me}_3\text{Si})_3\text{Si}$ , Bbp = 2,6-bis[bis(trimethylsilyl)methyl]phenyl)].<sup>143-145,197-199</sup>

transannular pnictogen-pnictogen distance in each case is significantly larger than the sum of the covalent radii of the atoms.<sup>143–145,197–199</sup>

Singlet-triplet gaps of 22.6 and 29.8 kcal mol<sup>-1</sup> were calculated for **22\_PP\_Ter** and **22\_PP\_Hyp**, respectively (UB3LYP/6-311+G(d,p)//6-31G(d)), as well as a LUNO occupation number of 0.3 electrons and a biradical character  $\beta = 25\%$  for **22\_PP\_Ter** (UHF and CASSCF(2,2)/6-31G(d)).<sup>143</sup> For the Bbp-substituted biradicals **22\_PP\_Bbp** and **22\_AsAs\_Bbp**, biradical characters of 23% and 28%, respectively, could be calculated utilizing CASSCF(6,4) computations; also, the occupation numbers of the LUNOs were calculated for **22\_PP\_Bbp** (0.24) and **22\_AsAs\_Bbp** (0.29).<sup>198</sup> The singlet-triplet gap of **22\_AsAs\_Ter** is 19.8 kcal mol<sup>-1</sup> (UB3LYP/6-311+G(d,p)//6-31G(d,p)) and a biradical character of 32% was determined (CASSCF(2,2)/6-31G(d,p)).<sup>144</sup> For the mixed biradical **22\_PAs\_Ter**, the biradical character is 28% and an occupation number of the LUNO of 0.3 electrons [CASSCF(2,2)] was estimated.<sup>199</sup> It should be noted that DFT calculations can only give an estimate of the singlet-triplet gap due to their limitations with respect to multi-configurational systems (cf. Section 1.04.2.10).

The heavier congeners, **22\_SbSb** and **22\_BiBi** possess even higher biradical character (36% and 39%, respectively, for model compounds with R = H). The biradical character of the series **22\_PnPn\_H** was also computed by us using high-level MRCI calculations that include the effect of dynamic correlation on the wavefunction.<sup>198</sup> While the absolute numbers ( $\beta = 17\text{--}30\%$ ) are somewhat smaller than in case of a CASSCF calculation, the MRCI calculations confirm the trend that the biradical character increases with atomic number. This can nicely be rationalized by a change in the through-bond interaction (cf. Section 1.04.2.11) between the radical sites, owing to the increasing size of the heteroatoms (Fig. 15).

Especially the reactivity of the Ter-substituted compounds **22\_PP\_Ter** and **22\_AsAs\_Ter**, but also the reactivity of **22\_PP\_Hyp** and **22\_PAs\_Ter** were studied in detail, paying attention to the activation of small molecules. In the reaction of **22\_PP\_Ter** and **22\_AsAs\_Ter** with a variety of molecules, containing single, double and triple bonds, the addition of the molecules to the phosphorus or arsenic atoms is mostly observed (Scheme 35). For example, molecules with single bonds such as chalcogens (sulfur, selenium and tellurium), with double bonds (e.g., acetone, CS<sub>2</sub>, diphenyl-diazene and diphenyl-diphosphene), and with triple bonds (acetylene, tolane, acetonitrile and various sulfanyl-acetylenes) add easily forming [2.1.1]bicyclic structures (**23**) in almost quantitative yields at ambient temperatures.<sup>144,146,201–205</sup> Molecules with sterically too high demands are not activated. For example, no reaction is observed between **22\_PP\_Ter** and the bulky alkyne BTMSA. Most of the addition reactions can be understood as a formal [2 + 2] reaction (Scheme 35).

Interestingly, if the substituent on the alkyne is small, such as R = H, the addition product (**23**, [2.1.1]bicyclic) slowly isomerizes to a [3.1.0]bicyclic species (**24**, Scheme 35) upon thermal treatment, which is not observed for bulkier substituents (e.g., R = Ph).<sup>202</sup> X-ray structure elucidation shows that the alkyne is inserted into the four-membered Pn<sub>2</sub>N<sub>2</sub> ring and initially forms a six-membered heterocycle, which is also a pnictogen-centered biradical. In this case, however, a transannular covalent bond is formed, giving **24** with a three-membered dipnicta-aziridine and a fused planar five-membered ring that is almost perpendicular to the three-ring.

The addition reaction of molecular hydrogen to **22\_PP\_Ter** takes place under H–H bond breaking yielding exclusively the *cis* product (**25**, Scheme 36). Interestingly, this addition is reversible. At room temperature (and even lower temperatures), dihydrogen

**Fig. 15** Schematic MO diagram of the  $\pi$  orbitals of **22\_PnPn\_H**. Only the configuration with the largest contribution to the CI wavefunction is shown. Due to the through-bond interaction (i.e., the interaction between the two  $b_{1u}$  SALCs; see also Fig. 14), the LUMO  $\pi_4$  is transannular bonding in character. With increasing size of the Pn atom, the overlap between the  $p$  orbitals at the Pn and N atoms (i.e., the  $b_{1u}$  SALCs) decreases, resulting in an energetic lowering of the orbital  $\pi_4$ . Thus, the HOMO-LUMO gap decreases, resulting in an increase in biradical character.<sup>198</sup>

is added to the biradical; at elevated temperatures (above 60 °C), dihydrogen is slowly eliminated again.<sup>206</sup> Regarding the activation of hydrogen, Zhivonitko et al. carried out investigations with *para*-hydrogen to check the potential suitability of **22\_PP\_Ter** for signal amplification via Phip (*para*-hydrogen-induced polarization) in NMR spectroscopy.<sup>207</sup> Indeed, **22\_PP\_Ter**, provides pronounced <sup>1</sup>H and <sup>31</sup>P hyperpolarization while activating the *para*-hydrogen molecules. It was the first time, in general, that a metal-free compound of a biradical structure was shown to produce hyperpolarized nuclear spins, introducing a new class of *para*-hydrogen activators for NMR signal enhancement. This observation also proved that the mechanism of H<sub>2</sub> activation with **22\_PP\_Ter** is pairwise, i.e., the two hydrogen atoms of an H<sub>2</sub> molecule follow each other through all elementary steps of the activation process. An up to 300-fold signal amplification was observed in <sup>31</sup>P NMR spectra of **22\_PP\_Ter**.<sup>207</sup> Similar results were obtained for **22\_PAs\_Ter** and **22\_AsAs\_Ter**.<sup>208</sup>

Hydrogen (pseudo)halides HX (X = Cl, CN, NCO, N<sub>3</sub>, PCO) cleanly add to the biradical **22\_PP\_Ter**. Upon addition, the H–X bond is broken, and exclusively the *cis* product is formed (**26**, **Scheme 37**).<sup>209</sup> In the case of HPCO, the addition product isomerizes to a [3.1.1]bicyclic compound (**27**, **Scheme 37**). When **22\_PP\_Ter** is treated with the free acid of a weakly coordinating anion such as Jutzi's acid, H[B(C<sub>6</sub>F<sub>5</sub>)<sub>4</sub>]·2Et<sub>2</sub>O, the biradical is protonated at one phosphorus atom, yielding a (closed-shell) phosphonium cation (**28**). Treating this cation with an X<sup>–</sup> source again results in the formation of the formal HX adduct **26**.<sup>209</sup>

A special reactivity is observed in the reaction of **22\_PP\_Ter** and **22\_PAs\_Ter** with CO or isocyanides. Although these molecules also contain multiple bonds, they do not add to the radical centers as shown in **Scheme 35** (forming a [2.1.1]bicyclic species), but insert into the heterocycle (in the case of **22\_PAs\_Ter** selectively into the nitrogen-arsenic and not into the nitrogen-phosphorus bond, **Scheme 38**). This insertion reaction was also observed for 1,2,3-triaza-4-pnicta-cyclobutane-2,4-diyls (see above).<sup>196,210,211</sup> Both, the insertion of CO and the electronically very similar isocyanides lead to the formation of a five-membered heterocycle (**29**), which is also a biradical, which will be discussed in detail in **Section 1.04.3.3.2**. Since the insertion only takes place via the carbon atom, one can speak of a carbene-like reactivity.

For example, the reaction of **22\_PP\_Ter** with CO at a CO pressure of 60 bar yields the five-membered biradical **29\_PP\_Ter** as the main product. This reacts to a small extent with another equivalent of CO, which bridges the two radical centers with the carbon atom yielding a [2.1.1]bicyclic species (**Scheme 38**, **30\_PP\_Ter**).<sup>210</sup> The reaction of **22\_PP\_Ter** with CN-<sup>t</sup>Bu gives a similar result (see also **Section 1.04.3.3.2**). In all cases, there is an equilibrium between the formal mono-adduct (**29**, i.e., the five-membered biradical) and di-adduct (**30**, i.e., the bridged five-membered ring). On heating, the four-membered biradical **22\_PP\_Ter** can also be observed in the mixture. With CN-Dmp, the reaction is more selective due to a larger steric hindrance of the Dmp

**Scheme 35** Reactivity of **22\_PnPn\_Ter** (Pn = P, As) towards small molecules (XY) containing single, double and triple bonds, and isomerization of alkyne adducts with small substituents R (e.g., XY = R-CC-R).

**Scheme 36** Reversible reaction of **22\_PP\_Ter** with molecular hydrogen.<sup>206</sup>

**Scheme 37** Reaction of **22\_PP\_Ter** with Brønsted acids (X = Cl, CN, NCO, N<sub>3</sub>, PCO).<sup>209</sup>

**Scheme 38** Reactivity of **22\_PPn\_Ter** towards CO and isocyanides (Pn = P, As; R = O, N<sup>t</sup>Bu, NDmp).<sup>196,210,211</sup>

substituent. Only the five-membered biradical is formed. No double addition was observed.<sup>211</sup> The reaction with CN-Dmp was also carried out with **22\_PAs\_Ter**. Here, as with **22\_PP\_Ter**, only the insertion of one isocyanide molecule is observed, which, however, selectively inserts into the nitrogen-arsenic bond.<sup>196</sup> In the case of **22\_PP\_Hyp**, the reaction with sterically demanding CN-Ter leads to biradical **29\_PP\_Hyp**, while smaller isocyanides yield a cyclic diene due to migration of one Hyp substituent (see [Section 1.04.3.3.2](#), [Scheme 56](#)).<sup>212</sup>

Furthermore, **22\_PP\_Ter** reacts with molecular oxygen and KMnO<sub>4</sub> yielding not a [2.1.1]bicyclic species as illustrated in [Scheme 39](#), but only one P atom is oxidized. That is, both oxygen atoms are transferred to one phosphorus atom affording **31**.<sup>146</sup> In the reaction with CO<sub>2</sub>, one oxygen atom is transferred to a phosphorus atom and CO is released leading to the formation of **32**. The reaction with ammonia leads to the cleavage of a nitrogen-phosphorus bond. A hydrogen atom is transferred to the nitrogen atom, and an NH<sub>2</sub> group is transferred to the phosphorus atom yielding **33** ([Scheme 39](#)).<sup>206</sup>

Phosphorus-centered biradicals **22\_PP\_R** (R = Ter, Hyp) were also treated with ionic azides (AgN<sub>3</sub> and Hg(N<sub>3</sub>)<sub>2</sub>), leading to the formation of diazides, [N<sub>3</sub>-P(μ-NR)]<sub>2</sub> (R = Ter), and reduced metal in a redox process, while triaza-diphospha-pentadienes (**34**) could be isolated when covalent azides were added to **22\_PP\_R** (R = Ter, Hyp; [Scheme 39](#)).<sup>213</sup> Theoretical studies of the azide addition reaction showed a very soft potential energy surface with a large number of different isomers. This reaction can be understood as a novel Staudinger reaction. The classical STAUDINGER reaction consists of two steps: (i) the *trans*-azide, RN<sub>3</sub>, attacks the P<sup>III</sup> atom of a phosphane, R<sub>3</sub>P, and forms a chain-like *cis*-intermediate, R<sub>3</sub>P-NNN-R (*cis*-PNNN and *trans*-NNNR unit),<sup>214</sup> and (ii) this intermediate forms a four-membered PN<sub>3</sub> ring, which readily separates into N<sub>2</sub> and R<sub>3</sub>P=NR, forming a P<sup>V</sup> atom. Due to the mostly very flat potential energy surface in the second step, the Staudinger reaction essentially requires one step to release N<sub>2</sub>, which means that mostly no intermediates can be isolated. In contrast, the potential energy surface for the reaction of biradical **22\_PP\_R** with R-N<sub>3</sub> has several reaction channels, including classical Staudinger-type reactions with the formation of four-membered N<sub>3</sub>P rings followed by the release of molecular nitrogen.<sup>213</sup> Since there is also a second P atom present in the molecular skeleton, oxidation to a P<sup>V</sup> species does not take place (in contrast to the classical Staudinger reaction), but rather the formation of a triaza-diphospha-pentadiene (**34**, [Scheme 39](#)) with two P<sup>III</sup> atoms. Since both P atoms are described with the formal oxidation state +II in the biradical, each P atom is oxidized by the loss of one electron. This also means a total loss of two electrons in accordance with the oxidation of P<sup>III</sup> to P<sup>V</sup> in the typical Staudinger reaction when only one P<sup>III</sup> atom is involved. In terms of the oxidation process and mechanism, the reaction of the phosphorus-centered biradical with a covalent azide represents a new variant of the Staudinger reaction.<sup>213</sup>

In addition, **22\_PP\_Ter** can also be used as a radical scavenger. Moreover, since biradicals of the type **22** possess also zwitterionic character they can be utilized in reactions either as Lewis acid and/or base.<sup>215,216</sup> Finally, a short word on **22\_PP\_Hyp**, which takes on a special role as far as reactivity is concerned. First, the dimerization of the biradical to a cage compound is observed here in polar solvents.<sup>145</sup> Such a dimerization is known from reduction reactions with sterically less demanding substituents such as <sup>t</sup>Bu or Dmp (see [Section 1.04.3.2](#), [Scheme 9](#)).<sup>203,217</sup>

Finally, cyclo-1,3-dipnicta-2,4-diazane-1,3-diyls of the type [Pn(μ-NTer)<sub>2</sub>Pn] (**22**, Pn = P, As) can undergo a one-electron oxidation utilizing silver salts of weakly coordinating anions such as [AgL<sub>n</sub>][B(C<sub>6</sub>F<sub>5</sub>)<sub>4</sub>]<sup>-</sup> (L = donor solvents) to afford the cyclic radical cations, [E(μ-NTer)<sub>2</sub>E]<sup>•+</sup>. The bonding situation in the radical cations features a rare example of a transannular one-electron π-bond without having a σ bond (cf. Frenking's biradical **18**).<sup>218</sup>

#### 1.04.3.2.4.3 Phosphorus centered biradical dianions

The only example so far of a biradical with tetravalent phosphorus atoms (**35**, [Scheme 40](#)) was presented by Wright and co-workers. For its preparation, the four-membered ring **36**, which is already substituted on the phosphorus atoms with sulfur and chlorine, is reduced with sodium, yielding the anionic biradical **35** as *trans* isomer ([Scheme 40](#)). The *cis* isomer (possibly also the *trans* isomer) reacts with polymerization to form a macrocycle. Both reactions run parallel.<sup>219</sup> Biradical salt **35** is a colorless compound. The appearance of sharp NMR signals confirms the singlet character of the biradical. For the model substance of the biradical **35** (R = methyl), occupation numbers of 1.21 *e* for the HONO and 0.79 *e* for the LUNO were calculated (CASSCF(2,2), MRCI methods; base set: aug-cc-pVDZ).<sup>219</sup>

**Scheme 39** Products of the reaction of **22\_PP\_Ter** with O<sub>2</sub> (**31**), CO<sub>2</sub> (**32**), NH<sub>3</sub> (**33**) and Mes-N<sub>3</sub> (**34** as an example).

**Scheme 40** Synthesis of **35**.

#### 1.04.3.2.4.4 NHC stabilized phosphorus centered biradicals

In 2017, two groups independently presented synthesis options for a phosphorus centered biradical **37** (**Scheme 41**), where the  $C_2P_2$  four-membered rings are stabilized by NHC (*N*-heterocyclic carbene) ligands. In contrast to the 1,3-diphosphacyclobutanediyls **5** and **6** synthesized by Niecke and Yoshifuji/Ito et al. biradical **37** also features a  $C_2P_2$  four-membered ring, however, both radical centers are located on both phosphorus instead of on the carbon atoms. The synthesis procedure of the Grützmacher group begins with a phospho-allene, which is reduced by  $KC_8$  (**Scheme 41**). The substituent of the phosphorus atom serves as a leaving group which leaves the molecule upon reduction. The terminal carbon atom of the phospho-allene is part of the *N* heterocycle that stabilizes the biradical after the reaction. The reaction is possible with a saturated backbone in the heterocycle as well as with an unsaturated backbone. This gives rise to the biradicals **37a** and **37b**, which differ by one  $\pi$ -bond in the ligand.<sup>220</sup>

An alternative synthesis for **37a** was developed by Ghadwal et al. (**Scheme 42**). An *N*-heterocyclic olefin is reacted with  $PCl_3$  in the presence of  $NEt_3$ . On elimination of  $HCl$ , a  $C_2P_2$  four-membered ring is formed, which affords, after reduction with  $KC_8$ , the biradical **37a** (see **Scheme 42**).<sup>221</sup>

Biradicals of type **37a** and **37b** are sensitive to air and water, but thermally stable under an inert atmosphere. While **37a** has a dark green color, **37b** is yellow. The planarity of the central 4-ring as well as the rather large distance between both phosphorus atoms suggest a biradical character within these species.<sup>220,221</sup> AIM calculations on a model system of **37a** (nitrogen atoms substituted by methyl groups) show a ring-critical point between the phosphorus atoms but no bond-critical point (BP86/def2-TZVPP).<sup>220</sup>

Grützmacher and Li et al. conducted first investigations on the reactivity of biradical **37** (**Scheme 43**).<sup>220</sup> **37** was shown to react with molecular hydrogen at atmospheric pressure yielding an addition product (**38b**) with one hydrogen atom at each phosphorus atom of the biradical. With ferrocenium ions, both biradicals are oxidized to radical cations as illustrated in **Scheme 43**. The positive charge of the cation (**39a/b**) sits in both *N*-heterocycles and the overall positive charge of the radical cation is compensated by the  $BARF^-$  anion.

Moreover, biradical **37b** was treated with alkyl iodides, leading to the formation of cyclic phosphonium ions **40**, which can be further reacted with  $Me_2Zn$  to give the dialkyl substituted ring system (**Scheme 44**).<sup>222</sup> The reaction of **37b** with diketones leads to the corresponding [4 + 2] addition products (**41**).<sup>223</sup> Biradical **37b** can also activate C–H, N–H, and O–H bonds, leading to cyclic

**Scheme 41** Synthesis of **37** (**a** = unsaturated backbone, **b** = saturated) according to Grützmacher et al.<sup>220</sup>

**Scheme 42** Synthesis of **37a** according to Ghadwal et al.<sup>221</sup>

**Scheme 43** Reactivity of **37** towards oxidation (Fc = Fe(C<sub>5</sub>H<sub>5</sub>)<sub>2</sub>; BARF<sup>-</sup> = [B(3,5-(CF<sub>3</sub>)<sub>2</sub>C<sub>6</sub>H<sub>3</sub>)<sub>4</sub>]<sup>-</sup>).<sup>220</sup>

products of the type [HP(μ-C(NHC))<sub>2</sub>P-ER] (**42**, E = C, N, O).<sup>224</sup> Lastly, biradicals **37a/b** can act as η<sub>4</sub> ligand in transition metal complexes (**43**).<sup>225</sup>

#### 1.04.3.2.4.5 Pnictogen centered biradical anions: [Pn<sub>4</sub>]<sup>2-</sup>

Cyclic tetrapnictide anions of the type [Pn<sub>4</sub>]<sup>2-</sup> can formally be derived from the archetypical inorganic biradicaloid S<sub>2</sub>N<sub>2</sub> (see **Section 1.04.3.2.4**) by substituting the group 16 atoms (i.e., S) with group 15 atoms. The first experimentally characterized derivative was [Bi<sub>4</sub>]<sup>2-</sup> in the salt [K(crypt)]<sub>2</sub>[Bi<sub>4</sub>] (crypt = [2.2.2]cryptand) by Corbett and co-workers in 1977.<sup>226</sup> The same group later also published the Sb derivative [K(crypt)]<sub>2</sub>[Sb<sub>4</sub>].<sup>227</sup> The As and P species were reported in 2002 and 2003, respectively, by Korber et al. as the alkali metal salts [Na(NH<sub>3</sub>)<sub>5</sub>]<sub>2</sub>[As<sub>4</sub>]·3NH<sub>3</sub> and Cs<sub>2</sub>[P<sub>4</sub>]·2NH<sub>3</sub>.<sup>228,229</sup> All compounds were characterized by single-crystal X-ray diffraction. The structure of all four-membered ring systems is nearly ideally square planar, with equal Pn–Pn bond lengths within the uncertainty of the structure elucidation, and Pn–Pn–Pn bond angles of nearly 90° (deviation less than 0.5°).

The biradical character of the tetrapnictide anions was recently investigated by Coburger et al. by means of CASSCF(6,4) calculations.<sup>230</sup> All species possess a medium-low biradical character, with *n*(LUNO) = 0.11 (P), 0.14 (As), 0.16 (Sb) and 0.19 (Bi). Due to the D<sub>4h</sub> symmetry of the anions, there are two biradicaloid Lewis structures with equal weights (A, B in **Scheme 45**), which the authors determined by localizing the active orbitals (cf. **Sections 1.04.2.8 and 1.04.2.10**). In total, the two biradicaloid structures contribute more than 40% to the total wavefunction (P: 41%, As: 43%, Sb: 45%, Bi: 47%).

Furthermore, the aromaticity of the [Pn<sub>4</sub>]<sup>2-</sup> anions was investigated on the basis of the Shannon aromaticity index (SAI),<sup>231</sup> revealing a somewhat lower aromaticity than benzene.<sup>230</sup>

#### 1.04.3.2.5 Hetero-cyclobutane-1,3-diyls with radical centers on elements of group 16

In this article on chalcogen-centered cyclobutanediyl analogs, we found only one neutral compound, S<sub>2</sub>N<sub>2</sub>, which could also have been discussed in the section on nitrogen centered biradicals. Although molecular oxygen<sup>232–236</sup> is a triplet radical in its ground state and ozone, O<sub>3</sub>, also shows (open-shell singlet) biradical character,<sup>237,238</sup> there is no compound with oxygen that can be

**Scheme 44** Reactivity of **37** towards alkyl iodides R-I (R = Me, Et, <sup>*i*</sup>Bu),<sup>222</sup> a diketone,<sup>223</sup> compounds with polarized E–H bonds (e.g., Ph-CC-H, 4-NC-C<sub>6</sub>H<sub>4</sub>-NH<sub>2</sub>, 4-F<sub>3</sub>C-C<sub>6</sub>H<sub>4</sub>-NH<sub>2</sub>, MeOH, PhOH),<sup>224</sup> and metal complexes ([M] = Cr(CO)<sub>3</sub>, Mo(CO)<sub>3</sub>, Co(CO)<sub>2</sub>, NiBr<sub>2</sub>).<sup>225</sup>

**Scheme 45** Most important Lewis structures of  $[\text{Pn}_4]^{2-}$  and their corresponding weights in the entire resonance.<sup>230</sup>

regarded as cyclobutenediyl analog, even though  $\text{N}_2\text{O}_2 = 2 \text{NO}$ , which is isovalence electronic to  $\text{S}_2\text{N}_2$ , is of course a radical that, however, does not exist as a ring but only as a NO molecule or as its non-cyclic dimer at lower temperatures.

#### 1.04.3.2.5.1 Sulfur-nitrogen centered biradical: $[\text{N}(\mu\text{-S})_2\text{N}]^-$

One of the first heteroatom-substituted cyclobutenediyl derivatives to be synthesized is  $\text{S}_2\text{N}_2$ , disulfurdinitride (**44**, **Scheme 46**), the biradical character of which was/is discussed in the literature.<sup>20,239,240</sup> It can be obtained by decomposing  $\text{S}_4\text{N}_4$  on silver wool, followed by freezing out the product. At room temperature, **44** polymerizes to the chain-like polythiazyl  $(\text{SN})_x$ .<sup>131</sup> By means of single crystal X-ray structural analysis of **44** in 1975, it was shown that the  $\text{S}_2\text{N}_2$  ring is planar.<sup>131</sup> The electronic structure, on the other hand, is still disputed today.<sup>131,239–243</sup> Among other things, the aromatic character of **44** is in question. While the molecule fulfills the criteria of a Hückel aromatic compound due to its formal six  $\pi$ -electrons and planarity, Head-Gordon et al. conclude from their calculations that it is merely a  $2\pi$ -aromatic system.<sup>244</sup> Another point of discussion is the biradical character of **44**. While Head-Gordon et al. do not attribute any significant biradical properties to the molecule,<sup>244</sup> other groups discuss the question of where the radical centers are localized. Gerratt et al. see these at the sulfur atoms (Lewis representation **B**), while Harcourt, Schulz and Klapötke conclude from their calculations a stronger localization at the nitrogen atoms (**A**), which has the advantage that no formal charges are needed.<sup>239,245,246</sup> Furthermore, it is argued that the electronic situation in **44** can only be described properly by resonance between two biradical (Lewis representation **A** and **B**) and further zwitterionic structures (**C–F**, **Scheme 46**). In addition to the resonance forms shown in **Scheme 46**, further formulae can be formulated, utilizing *d*-type orbitals (extension of the electron octet), which, however, have a very small contribution to the description of the ground state.<sup>239,240</sup> In 2012, Hiberty and Braida et al. calculated the contributions of the individual resonance formulae using different methods and concluded that the biradical form with the radical centers on the nitrogen atoms (**A**) has the largest weight. This is followed by the four degenerate, zwitterionic structures (**C–F**). However, the biradical formula with the radical centers on the sulfur atoms (**B**) also has a non-negligible contribution.<sup>240</sup> One further essential statement of this work regarding aromaticity versus biradical character is that the biradical structure indicates that aromaticity and biradical are not mutually exclusive, contrary to what is usually claimed.

Apart from VB-type calculations with localized orbitals, the biradical character of **44** was also estimated on the basis of CI coefficients and the LUNO occupancy (i.e., in the delocalized picture). For example, Tuononen et al. reported comprehensive CAS(22,16) computations, which correlate all orbitals in the valence space.<sup>247,248</sup> They report the CI coefficients  $c_1$  and  $c_2$  from which  $\beta = 7\%$  can be estimated, and they also conclude that resonance structure **A** has the largest weight. More recently, Coburger et al. reported a LUNO occupancy of 0.14 electrons, as derived from CAS(6,4) calculations including all  $\pi$ -type orbitals in the valence space.<sup>230</sup>

#### 1.04.3.2.5.2 Chalcogen biradicals $[\text{E}_4]^{2+}$ (E = S, Se, and Te)

Starting from an isoelectronic substitution of the nitrogen atoms by one  $\text{E}^+$  ion each in  $\text{S}_2\text{N}_2$  leads to the substance class of  $[\text{E}_4]^{2+}$  cations (E = chalcogen = S-Te), which also have  $6\pi$  electrons. Since this substance class has already been described in a large number of reviews,<sup>81,86,249–253</sup> we would like to focus here on its biradical character. To begin with, let us shortly summarize the synthesis of salts bearing these chalcogen polycations. The first synthesis of a chalcogen polycation may have been carried out in 1798, when Klaproth described that tellurium dissolves gradually in sulfuric acid to give a red solution.<sup>254</sup> However, it was Gillespie and Bjerrum et al. who first synthesized and characterized polycations of the type  $[\text{E}_4]^{2+}$ .<sup>249,255</sup> There are a variety of established methods for the synthesis of such polycations, which all use strongly polar media such as  $\text{H}_2\text{SO}_4$ , anhydrous HF,  $\text{HSO}_3\text{F}$ , liquid  $\text{SO}_2$ , molten salts, e.g.,  $\text{Na}[\text{AlCl}_4]$ , or  $\text{GaX}_3$  benzene media (X = Br, Cl).<sup>86</sup> The chalcogens can be transformed into the cations either by oxidation with suitable oxidants such as  $\text{AsF}_5$  or  $\text{SbF}_5$ , or synproportionation reactions in the presence of a strong halide ion acceptor such as  $\text{AlX}_3$  (X = Cl, Br, I). Recently, room-temperature ionic liquids have been used as a new alternative reaction medium

**Scheme 46** Resonance formulae to describe the electronic situation of **44**.<sup>239,240</sup>

for the synthesis of such polycations.<sup>86</sup> In any case, a suitable oxidizing agent is needed to oxidize the chalcogen to the  $[E_4]^{2+}$  ion and a suitable anion, e.g., weakly coordinating anions that can stabilize these cations.<sup>81</sup>

With regard to the electronic situation in the  $[E_4]^{2+}$  ion, it strongly resembles the  $S_2N_2$  biradical. Hiberty and Braida et al. pointed out that for all cations ( $E = S, Se, \text{ and } Te$ ) the cumulative weights of the two possible biradical structures (**Scheme 47**, representations **H** and **I**) are always important and close to 50%, making these molecular cations comparable to ozone in terms of biradical character.<sup>240</sup> As the two biradical structures are degenerate in the  $[E_4]^{2+}$  dications, they have equal weights in contrast to the situation in the neutral and heteroatomic ring  $S_2N_2$ . The biradical character increases slightly with increasing atomic number.

### 1.04.3.3 Main group 15 analogs of cyclopentane-1,3-diyls

The parent system of the five-membered 1,3-diyls is cyclopentane-1,3-diyl (**45**), which is also known as the Closs biradical named after Closs and co-workers who first synthesized it (**Scheme 48**).<sup>256</sup> Biradical **45** was detected as a reaction product after irradiation of 2,3-diazabicyclo[2.2.1]hept-2-ene **46** with UV light at 5.5 K in a cyclohexane matrix by EPR spectroscopy. At 5.5 K, **45** has a half-life of approx. 30 min. The EPR signal behaves almost unchanged in the range from 1.3–20 K, suggesting a triplet ground state,<sup>257</sup> in accord with quantum mechanical studies. On the singlet energy hypersurface (**Fig. 16**), the bicyclo[2.1.0]pentane (housane, **47**) represents a minimum structure, while the planar isomer, which has the same point group as cyclopentane-1,3-diyl, is a transition state.<sup>256,258</sup> By heating the cyclopentane-1,3-diyl **45**, housane **47** can be detected as the main product,<sup>259</sup> as well as a small amount of 0.5% cyclopentene **48** as the Wagner-Meerwein rearrangement product.<sup>260</sup> Kinetic investigations of the formation of cyclopentane-1,3-diyl and its decay were carried out by Engel and co-workers using Raman spectroscopy.<sup>261</sup> Since then, a large number of experimental investigations have been carried out in which the protons of the cyclopentane-1,3-diyl parent system were replaced by organic substituents.<sup>17,262–264</sup> However, to the best of our knowledge, it was never possible to achieve sufficient stabilization solely by substituting the protons to obtain cyclopentane-1,3-diyls that are stable at room temperature. The next section summarizes the experimental investigations in which additional substitutions of the carbon atoms by heteroatoms were carried out to stabilize the corresponding biradicals.

#### 1.04.3.3.1 Hetero-cyclopentane-1,3-diyls with radical centers on elements of group 14

##### 1.04.3.3.1.1 Carbon centered biradicals: 1,2-Diaza-cyclopentane-3,5-diyls

Starting from the parent compound cyclopentane-1,3-diyl **45**, both, the carbon atoms can be substituted by heteroatoms and the protons by other groups. First studies on heteroatom-substituted systems, in which the carbon atoms are substituted in the 4- and 5-position by nitrogen atoms, were carried out by Arnold et al. in the late 1960s.<sup>265–267</sup> In their syntheses, they started from various isopyrazole derivatives **49a–d** and reacted them in a cycloaddition with 4-phenyl-1,2,4-triazoline-3,5-dione (PTAD) **50Ph** yielding **51a–e** (**Scheme 49**). From the reaction products **51a–e**, the transient biradicals **52a–d** can be generated by light-induced  $N_2$  elimination ( $\lambda = 253.7 \text{ nm}$ ).

With **51b** and **51c** in hand, the biradical species **52b** and **52c** could be investigated in solution after previous irradiation at 77 K. The two compounds **52b** and **52c** are green and by means of EPR spectroscopy it could be shown that **52b** and **52c** exist as triplet biradicals in the ground state. At 77 K the biradicals are stable for several hours, but decompose within a short time at 190 K. Compounds **52a** and **52d** are of lower stability and could only be detected as triplet species after previous irradiation at 4 K by EPR spectroscopy.

When irradiation of **51a–e** occurs at room temperature, the biradicals **52a–e** immediately react further with transannular bond formation to form the housane derivatives **52'a–e**. In the case of **52'a** and **52'd**, isolation and extensive characterization of the compounds were successful. Compounds **52'b** and **52'c** could be detected by low-temperature  $^1\text{H}$  NMR spectroscopy or by the trapping reaction with **50Ph** to give **53b** and **53c**. It could be shown by time-dependent  $^1\text{H}$  NMR spectroscopy that the housane

**Scheme 49** Synthesis of **52a-e**.

derivatives **52'a-e** are in thermal equilibrium with the isomers **52''a-d**. In the case of **52'e**, the reaction to **52''e** is irreversible. For the respective conversion between the two isomers, a reaction path via the biradical **52a-e** is discussed.

Abe et al. were able to show with quantum mechanical calculations at the UB3LYP/6-31G(d) level that in the systems studied by Arnold et al. a substitution of the substituents  $R^3$  and  $R^4$  by electron-withdrawing groups (-F, -OH) leads to an energetic lowering of the singlet state and that this singlet state is even more stable than the triplet state.<sup>268,269</sup>

Preparatively, such a modification of the system was carried out in 2006 by Abe et al.<sup>270</sup> Analogous to the work of Arnold et al., the synthesis is based on an isopyrazole derivative **54** (Scheme 50). The difference is that the quaternary carbon of the isopyrazole ring is no longer saturated with alkyl substituents (see **49a-d**), but with electron-withdrawing methoxy groups. The cycloaddition of **54** with **50Ph** leads to the diazoalkane **55**. Irradiation with short-wave light ( $\lambda = 360\text{--}440$  nm) forms the 1,2-diazacyclopentane-3,5-diyl 4,4-dimethoxy-3,5-diphenylpyrazolidine-3,5-diyl **56** as a short-lived compound under  $\text{N}_2$  elimination. Biradical **56** is in rapid thermal equilibrium with **56'** and irreversibly decomposes to **57**.

By laser flash photolysis ( $\lambda_{\text{excitation}} = 355$  nm,  $\lambda_{\text{observation}} = 640$  nm), **58** was shown to have a lifetime of  $9.67 \pm 0.007$  ms in toluene at 298 K and to react in a 1st order reaction to **57**. In contrast to compounds **52a-e** introduced by Arnold et al., **56** is a singlet biradical, as demonstrated by EPR inactivity at 77 K in a 2-methyltetrahydrofuran (MTHF) matrix and quantum mechanical calculations at the UB3LYP/6-31G(d) level. Furthermore, the presence of oxygen leads to no change in the lifetime and with PTAD (**50Ph**) the addition product **59** is formed. The housane species **56'** was also detected by laser flash photolysis and time-resolved IR spectroscopy (TRIR).<sup>271</sup> Using TRIR, rate constants and free enthalpy were determined. In toluene, the formation of

**Scheme 50** Synthesis and reaction behavior of 4,4-dimethoxy-3,5-diphenylpyrazolidine-3,5-diyl (**56**).

**56'** at 293 K is exergonic ( $\Delta G^\circ_{293} = -1.3 \text{ kJ mol}^{-1}$ ), while in acetonitrile it is endergonic ( $\Delta G^\circ_{293} = 0.2 \text{ kJ mol}^{-1}$ ). (BS)-CAM-B3LYP/6-31G(d) calculations show an exergonic reaction course for the formation of **56'** ( $\Delta G^\circ_{293} = -1.4 \text{ kJ mol}^{-1}$ ) for the gas phase. Due to the rapid reaction of **56'** via **56** to **57**, a more comprehensive characterization is not possible. The decay product **57** can be isolated in 70% yield and its structure could be confirmed by 2D NMR spectroscopy (HMBC, HMQC).<sup>270</sup>

In protic solvents, such as ethanol, a different reaction behavior is shown after irradiation of **55**, in which first a cation **60** is formed, with cleavage of a methanolate anion, and then **61** is formed by reaction with the solvent. The lifetime of the cation **60** could be determined by laser flash photolysis and is  $607 \pm 18 \text{ ms}$ . The formal ethanol addition product **61** can be isolated in 48% yield.

#### 1.04.3.3.1.2 Carbon centered biradicals: 1,2-Diaza-4-silacyclopentane-3,5-diyls

In 2010, Abe et al. found another possibility to stabilize the singlet state with respect to the triplet state by substituting the carbon atom in position 2 by a silicon atom in the 2-position of the cyclopentane-1,3-diyl (**Scheme 51**).<sup>269</sup> The synthesis starts with 3,6-diphenyl-1,2,4,5-tetrazine **62**, which is reacted with the silirane **63** at  $125^\circ\text{C}$  for 3 days.<sup>272</sup> The reaction leads to the formation of silylene **64** in situ, which reacts with **62** under elimination of  $N_2$  to give diazasilol **65**. **65** can be isolated in 27% yield after purification by column chromatography. Reaction of **65** with PTAD (**50Ph**) or 4-methyl-1,2,4-triazoline-3,5-dione (**50Me**) at  $60^\circ\text{C}$  in threefold excess leads to the isolatable compounds **66Ph**, and **66Me** in yields of 53%, and 90%, respectively. During the reaction, the Diels-Alder product, azo compound **67**, could not be observed by NMR spectroscopy. Abe et al. therefore assumed that the denitrogenation of the azo compounds **67Ph** and **67Me** to the biradicals **68Ph** and **68Me** proceeds faster than their formation by the Diels-Alder reaction.

Quantum mechanical calculations for biradical formation at the UB3LYP/6-31G(d) level assume a stepwise elimination of nitrogen with an activation energy of  $22 \text{ kcal mol}^{-1}$ . Furthermore, neither the biradicals **68Ph** and **68Me**, nor the housane derivatives **68'Ph** and **68'Me** derived from the biradicals could be observed by NMR spectroscopy. Since no change in reactivity was observed under  $O_2$  atmosphere and no EPR signals were observed during the reaction, Abe et al. were able to show that **68'Ph** and **68'Me** are singlet biradicals, in accord with quantum mechanical calculations at the UB3LYP/6-31G(d) level.<sup>269</sup>

#### 1.04.3.3.1.3 Carbon-centered biradicals: 1,2-Dithiolylium-4-olates

Another substance class with biradicaloid compounds are the 1,2-dithiolylium-4-olates **69** (**Scheme 52**). The synthesis of the first 1,2-dithiolylium-4-olate, the 3,5-diphenyl-1,2-dithiolylium-4-olate **69g** was described in 1969 by Frese et al.<sup>273</sup> However, the authors assumed the presence of the open-chain form, the 1,3-thioxacetone (1,2-diphenyl-1,3-thioxacetone, **70**). An initial formulation of **69g** in its mesoionic, cyclic form was made the following year by Frese et al. as this better explained UV-vis and IR spectra.<sup>274</sup> That is, mesoionic 3,5-diphenyl-1,2-dithiolylium-4-olate was considered a valence isomer of 2-oxo-1,3-dithio-1,3-diphenyl-propane. Using single crystal X-ray structural analysis, the cyclic structure in the solid state was finally established.<sup>275,276</sup>

However, depending on substituents  $R^1$  and  $R^2$ , the open-chain 1,3-thioxacetone **70** rather than the cyclic species, 1,2-dithiolylium-4-olate **69**, can also be stabilized (**Scheme 52**).<sup>276–284</sup> Experimental and theoretical studies on the valence isomeric structure types **69** and **70** have shown that the cyclic biradical structure **69** is preferred by acceptor substituents (and to a lesser extent by phenyl groups), while the acyclic species **70** is energetically preferred by donor substituents.<sup>278</sup> The open-shell singlet biradical nature of the 1,2-dithiolylium-4-olates was studied and established by Fabian et al. for the phenyl-substituted system **69g** and the

**Scheme 51** Preparation and reactivity of in situ generated 1,2-diaza-4-silacyclopentane-3,5-diyls **68Ph** and **68Me**.

**Scheme 52** Literature known 1,2-dithiolium-4-olates **69**, which possess some biradical character, and 1,3-thioxacetones **70**.

*para*-dimethylaminophenyl-substituted system **69h** using quantum mechanical calculations.<sup>48</sup> Thus, a singlet-triplet splitting energy  $\Delta E_{\text{ST}}$  of 0.88 eV could be calculated in the case of **69g** and of 0.87 eV for **69h** at the B3LYP/6-31G\* level. However, for both systems an expectation value  $\langle S^2 \rangle = 0.0$  was calculated for the  $S^2$  operator at the UB3LYP/6-31G\* level, indicating that the biradical character is small to moderate at most (cf. Section 1.04.2.10). Furthermore, an antiaromatic character in the center of the molecules was calculated with a NICS(0) value of about +10 ppm, in which the authors see a further indication of the biradical character of the compounds. The authors conclude that the compounds have a low biradical character, but this has not been further quantified. Likewise, the authors do not comment on the influence of substituents  $R^1$  and  $R^2$  on the biradical character of 1,2-dithiolium-4-olates **69**.<sup>48</sup>

Interestingly, biradicals of the type **69** are very stable. It is remarkable that despite the biradical character present, only a low reactivity of e.g. **69g** towards oxygen was observed.<sup>273</sup> Studies on reactions with alkynes were carried out by White et al. leading to different classes of substances that were obtained as products depending on the alkyne.<sup>275</sup> Preparatively, 1,2-dithiolium-4-olates **69** are accessible via a variety of synthetic routes summarized in the *Science of Synthesis* book series.<sup>285</sup> To give one example, **69g** can be prepared via the reaction of 1,1,3,3-tetrabromo-1,3-diphenylacetone<sup>273,274</sup> (**71Br**) or 1,1,3-tribromo-1,3-diphenylacetone<sup>275</sup> (**72H**) with potassium *O*-ethylthiocarbonate in ethanol at 50–60 °C (Scheme 53). The products **69** can be isolated in yields of 26–50%. It should be noted that White et al. doubt on the basis of experimental data that 1,1,3,3-tetrabromo-1,3-diphenylacetone was really used in the synthesis described by Frese et al.<sup>275</sup> Synthesis of biradical **69h** starts with 1,3-dichloropropane-2-one **73**, which is thiolated in DMF at 0 °C in the presence of triethylamine and then alkylated with methyl iodide (Scheme 54).<sup>278</sup> The resulting 3,5-bis(methylthio)-1,2-dithiolium-4-olate **74** is then converted to the target product with *N,N*-dimethylaniline in boiling acetic acid with 2 eq. of pyridine.<sup>284</sup> The product **69h** can be isolated in 18% yield.

### 1.04.3.3.2 Hetero-cyclopentane-1,3-diyls with radical centers on elements of group 15

Five-membered biradicals with radical centers at atoms of the 15th group were obtained by serendipity when investigating the reaction behavior of pnictogen-centered cyclobutane-1,3-diyl (**22**) with unsaturated compounds (Scheme 38). While the reaction with alkynes and nitriles, for example, leads to bridging of the radical centers (Scheme 35; compound **23**), an insertion reaction was observed in the reaction with carbon monoxide and the isovalence-electronic isonitriles, which in some cases leads to the formation of room-temperature-stable five-membered biradicals as shown by us (Scheme 38, compound **29**).<sup>21</sup>

**Scheme 53** Synthesis of **69g** starting from 1,1,3,3-tetrabromo-1,3-diphenylacetone **71Br** or 1,1,3-tribromo-1,3-diphenylacetone **71H**.<sup>226,227</sup>

**Scheme 54** Synthesis of **69h**.

#### 1.04.3.3.2.1 Phosphorus-centered heterocyclopentane-1,3-diyls - Generated by CO insertion

The reactivity towards carbon monoxide was investigated with the cyclo-1,3-diphospha-2,4-diazane-1,3-diyl [ $\text{P}(\mu\text{-N}(\text{Ter})_2)_2\text{P}$ ] (**22\_PP\_Ter**, Ter = terphenyl = 2,6-bis(2,4,6-trimethylphenyl)-phenyl).<sup>210</sup> Carbon monoxide reacts completely within 48 h (60 bar, RT) in benzene to give the insertion product **75** derived from cyclopentane-1,3-diyl (**Scheme 55**). Biradical **75** can be obtained with 80% yield in the form of red crystals. The same reaction already takes place at 1 bar CO pressure, but here only a 75% reaction conversion could be observed by  $^{31}\text{P}$  NMR spectroscopy after 24 h reaction time. Single crystal X-ray diffraction revealed a planar  $\text{P}_2\text{N}_2\text{C}$  heterocycle with an exocyclic CO bond. Interestingly, under light the crystal slowly decomposed, which was studied further. UV-vis studies revealed the formation of a housane type species **75'** upon irradiation in accord with quantum mechanical calculations at the PBE/6-31G(d,p) level. A biradical character  $\beta = 22\%$  was calculated for biradical **75** using CASSCF(2,2) calculations according to Xantheas et al.<sup>46</sup>

Biradical **75** exhibits a diverse reaction behavior, which is summarized in **Scheme 55**. For example, the reaction of **75** with CO gives the formal addition product **76** that was only observed as a by-product in the  $^{31}\text{P}$  NMR spectra, but it decomposes rapidly to **75** and CO when the CO pressure drops so that isolation has not yet been possible.<sup>210</sup>

As already mentioned above, a “decomposition” of the biradical under light was observed at very low temperatures ( $-100^\circ\text{C}$ ) on the diffractometer. This led to a detailed investigation, as a result of which it was found that biradical **75** behaves like a molecular

**Scheme 55** Synthesis and reactivity of **75**.

switch (see Section 1.04.4). An intramolecular reaction can be observed when 75 is irradiated with light affording housane 75'. Under decolorisation of the reaction solution, the housane-type isomer 75' with a transannular P–P bond is formed, which reacts back thermally yielding the red-colored biradical 75 again. The reaction can be traced easily by  $^{31}\text{P}$  NMR spectroscopy. The initial assumption of decomposition of biradical 75 under irradiation was therefore not correct, but only showed the molecular switching under the influence of light. Calculations on the structure at the PBE/6-31G(d,p) level show that the bond formation significantly shortens the P–P distance within the five-membered ring of 75', which is now in the range of a typical P–P single bond, and leads to a bending of the planar ring along the P–P bond axis. However, housane species 75' could not be isolated.<sup>210</sup> The reaction of 75 with two equivalents of silver tetrafluoroborate leads to 77, which is accompanied by the loss of the biradical character, and the fluorination of the two P atoms (Scheme 55). Furthermore, elemental silver and gaseous trifluoro borane is formed. Since the two P atoms in 75 are prochiral, several isomers of 77 are conceivable, three of which could be detected by  $^{31}\text{P}$  NMR spectroscopy. Structural evidence was obtained for one of the isomers by single-crystal X-ray diffraction.<sup>210</sup> As depicted in Scheme 55, the reaction of 75 with *tert*-butylphosphaalkyne,  $^t\text{Bu-PC}$ , selectively leads to 78. Only one isomer with respect to the connectivity of the bridge was found by an X-ray structure analysis.<sup>210</sup> Unlike the reactions of 75 presented so far, the reaction with elemental sulfur results in the elimination of CO in the course of the reaction.<sup>210</sup> The resulting  $\text{S}_2$ -bridged product 79 can also be obtained by the direct reaction of 22\_PP\_Ter with elemental sulfur.<sup>146</sup>

#### 1.04.3.3.2.2 Pnictogen-centered heterocyclopentane-1,3-diyls - Generated by isonitrile insertion

Isonitriles, R-NC, that are isovalent to carbon monoxide show a similar reaction behavior, which, however, is strongly dependent on the type of the R-NC species (Scheme 56). Still, this is precisely the advantage of isonitriles over CO, since the former can be modified both sterically and electronically via the R substituent.

With the terphenyl-substituted system  $[\text{P}(\mu\text{-N}^i\text{Ter})]_2$  (22a), it could be shown that the steric demand of the substituent  $\text{R}^2$  on the isonitrile must match the steric demand of the system in order to achieve a selective insertion. For example, no reaction could be observed in the reaction of 22a with the sterically very demanding terphenyl isonitrile, Ter-NC. The sterically less demanding 2,6-dimethylphenylisonitrile (Dmp-NC) selectively inserts with the carbon atom into the phosphorus-nitrogen bond to give the intensely blue colored compound 29a. The reaction of the relatively small  $^t\text{Bu-NC}$  first leads to the insertion into the P–N bond to the blue-green insertion product 29b. Moreover, the addition of another equivalent of  $^t\text{Bu-NC}$  to the two phosphorus atoms takes place to form 30a. The reactions are equilibrium reactions. By using a large excess of  $^t\text{Bu-NC}$ , 30a can be isolated in the form of colorless crystals from a green reaction solution in benzene. However, re-dissolving the colorless crystals again leads to a green solution in which both 29b and 30a were detected by  $^{31}\text{P}$  NMR spectroscopy and even 22a at temperatures above 50 °C. The analogous equilibrium was detected upon insertion of  $\text{Me}_3\text{Si-NC}$  yielding 22a, the simple insertion product 29c, and the bridged derivative 30b.<sup>286</sup>

Another factor influencing the equilibrium and product distribution is the stability of the isonitrile. According to  $^{31}\text{P}$  NMR spectroscopic studies, the use of  $(\text{SiMe}_3)_2\text{N-NC}$  led to a large number of products among which the insertion product 29d could only be identified as a by-product.<sup>211</sup>

Further studies were concerned with the reactivity of 22a towards various phenyl isonitriles (80a-e), which, however, do not have substituents in the 2- and 6-position (Scheme 56). The electron-rich isonitriles phenyl-isonitrile (Ph-NC) 80a, *para-N,N*-dimethylaminophenyl-isonitrile 80b, *para-tert*-butylphenyl-isonitrile 80c are activated by equimolar reaction with 22a in the *ortho*-position to the isonitrile function, resulting in the formation of the phospho-indole-derived structures 81a-c. In the case of *para-N,N*-dimethylaminophenyl-isonitrile, crystals could be isolated from which the structure could be clarified beyond doubt by means of single-crystal X-ray diffraction. Interestingly, compounds of the type 30d-f could be detected when the isonitriles were used in excess. Here, the derivative of *para-tert*-butylphenyl-isonitrile 30f could be crystallized. When *para*-nitrophenyl-isonitrile 80d was reacted with  $[\text{P}(\mu\text{-N}^i\text{Ter})]_2$  (22a), a hitherto unknown product formation occurred, which, according to the  $^{31}\text{P}$  NMR data, indicates an oxidized phosphorus species, which could neither be further characterized nor isolated. The reaction of the electron-deficient 3,5-dis(trifluoromethyl)phenyl-isonitrile 80e with  $[\text{P}(\mu\text{-N}^i\text{Ter})]_2$  (22a) initially led to the formation of a mixture in which the heterocyclopentane-1,3-diyl 29e could also be identified by  $^{31}\text{P}$  NMR spectroscopy. Within 48 h, however, the formation of the phospho-indane-like compound 81d also occurred here.<sup>286</sup>

The reaction behavior between the biradical  $[\text{P}(\mu\text{-NR})]_2$  and the isonitriles is not only dependent on the isonitriles but also on the substituent at the nitrogen atom. For example, the hypersilyl-substituted biradical  $[\text{P}(\mu\text{-NHyp})]_2$  (22b, hypersilyl = Hyp = tris(trimethylsilyl)silyl) showed a different reactivity with some isonitriles than the terphenyl-substituted system.<sup>212</sup> In contrast to  $[\text{P}(\mu\text{-N}^i\text{Ter})]_2$ , a reaction of  $[\text{P}(\mu\text{-NHyp})]_2$  with terphenyl-isonitrile Ter-NC could be observed, leading to heterocyclopentane-1,3-diyl 29f. However, isolation failed. When reacting  $[\text{P}(\mu\text{-NHyp})]_2$  with the sterically less demanding isonitriles  $^t\text{Bu-NC}$ , Dmp-NC and Mes-NC (Mes = 2,4,6-trimethylphenyl), heterocyclopentadienes 82a-b are obtained. The latter are formed by migration of the hypersilyl substituent to the nitrogen atom of the isonitrile (Scheme 56). According to our computations, the dienes are the thermodynamically favored products and are best understood as closed-shell species ( $\beta = 10\%$ , CASSCF(8,6)/def2-TZVP).<sup>212</sup>

Another approach to obtain new five-membered biradicals 29 (by insertion of isonitriles starting from the four-membered biradical 22) is to vary the pnictogens within the starting material: Thus, using four-membered biradicals with two identical heavier pnictogens such as 22c<sup>144,201</sup> and with two different pnictogens (22d-f, cf. Section 1.04.3.2.3)<sup>195,199,200</sup> as starting materials, we attempted to synthesize the corresponding five-membered biradicals 29 by insertion of Dmp-NC.<sup>196</sup> The system with two arsenic atoms 22c did not react to form the desired product. Likewise, no insertion reaction with Dmp-NC was observed for the mixed-

**Scheme 56** Reactivity of **22** and **29** towards isonitriles.

centered biradicals with antimony and nitrogen, and with antimony and phosphorus.<sup>196</sup> However, for the lighter triazene derivative **22d** with arsenic and nitrogen as biradical centers, an insertion reaction with Dmp-NC to give **29g** was observed. The product could be isolated in the form of red crystals. Interestingly, X-ray structure analysis revealed two different isomers within the unit cell. A mixture of the expected five-membered biradical **29g** and the corresponding housane structure **29'g** was found. This means that two molecular structures, namely **29g** and **29'g**, were obtained with one measurement on one crystal.<sup>196</sup>

In the reaction of Dmp-NC with the phosphorus- and nitrogen-centered biradical **22e**, the analogous reaction to **29h** was observed. Here, too, structural elucidation by means of single-crystal X-ray structural analyzes was successful, but no partial housane (**29'h**) formation was observed. The same reaction behavior was found for the arsenic- and phosphorus-centered biradical **22f** in

which a selective insertion into the arsenic-phosphorus bond could be observed with the formation of the five-membered biradical **29i**.<sup>196</sup> Here, the isomerisation in the solid state could be investigated by single crystal X-ray structural analysis. In a simple measurement of a crystal, two isomers could be found in a disordered arrangement. The structure is dominated by the heterocyclopentane-1,3-diyl **29i**, which is present to 86%. The housane-like structure **29'i** was found as the second layer of the disorder (Fig. 17).

In all cases, the mixed-centered four-membered biradicals of type **22** (Scheme 56) reacted with the isonitrile to five-membered biradicals **29** in which the insertion of the carbon atom of the isonitrile takes place at the element-nitrogen bond of the heavier pnictogen of the two radical centers. An insertion into the other bond could not be observed. For all biradicals of type **29**, the calculated biradical characters and coefficients of the CASSCF wavefunction (with  $c_i \geq 0.1$ ) are listed in Table 6. These data show that the biradical character of the biradicals **29** ranges between 10 and 33%. Analogous to the five-membered biradical **75**, which is obtained by insertion of CO, the structural isomerism between the heterocyclopentane-1,3-diyl **29** and the housane-like, transannular bonded structure **29'** could also be observed.

When the crystal of **29i** was exposed to light for a longer time on the X-ray diffractometer, a reversal of the ratio between the two isomers was observed. Thus, after 12 h of irradiation, 95% of the crystal exhibited the housane species **29'i**.<sup>196</sup> During the formation of the housane derivative, a structural change occurs within the molecules. The central five-membered ring angles along the phosphorus-arsenic axis and the phosphorus-arsenic distance decreases, forming finally a covalent bond. The structural change leads only to minor changes within the molecular packing, so that only minor stresses occur within the crystal and it remains intact as a single crystal during the transformation and X-ray measurement. In solution, only the heterocyclopentane-1,3-diyl **29i** could be detected by <sup>31</sup>P NMR spectroscopy so far. However, recent studies show that for some biradicals of type **29**, the housane **29'** can be detected by NMR spectroscopy after irradiation with low-energy radiation, such as light in the visible range. More detailed studies on the isomerism between **29** and **29'** were carried out by us using the phosphorus-centered system **29a**.<sup>287</sup> The heterocyclopentane-1,3-diyl **29a** can be isolated in good yields in the form of blue crystals. Using UV-vis spectroscopy and quantum mechanical calculations, it was found that red light leads to a conversion of **29a** to **29a'** ( $\lambda_{\text{max}} = 643 \text{ nm}$ ). Irradiation leads to the formation of the colorless isomer **29a'**, which shows no absorption at 643 nm. After irradiation, a thermally induced reverse reaction occurs. This behavior is also called *molecular switching*, which we will examine in detail in Section 1.04.4. Unlike the arsenic/phosphorus-centered biradical **29i**, for biradical **29a** it was impossible to induce a transformation between the two isomers while maintaining an intact single crystal on the diffractometer. Accordingly, the transformation between the two isomers was accompanied by such large mechanic stress that the crystal split, as can be seen clearly in Fig. 18. Due to this internal stress in the crystal caused by light, the measurement of a complete data set of **29a** was only possible in complete darkness and revealed the planar biradical species. Attempts to crystallize the housane derivative, for example under light, failed.<sup>287</sup>

The reactivity of the heterocyclopentane-1,3-diyls synthesized by insertion of isonitriles was investigated in detail for a large number of molecules utilizing the terphenyl-substituted biradicals (Scheme 57).<sup>196,211</sup> The reaction of *tert*-butylphosphaalkyne with the phosphorus-centered biradicals **29a**<sup>211</sup> and **29b**<sup>211</sup> and the mixed, arsenic/phosphorus-centered derivative<sup>196</sup> **29i** lead to a selective bridging of the two radical centers, whereby bonds to the phosphorus atom and carbon atom of the phosphaalkyne

are formed. In the addition reaction to products **83a**, **83b** and **83c**, complete selectivity was achieved in all cases, with the substituent on the phosphalkyne always localized on the side of the inserted isonitrile. The selectivity could be proven by <sup>31</sup>P NMR spectroscopic data. It was also possible to isolate all compounds in yields between 52% and 70% and to describe the solid state structure by single crystal X-ray diffraction. A reversible loss of the phosphalkyne by prolonged irradiation with light of different wavelengths could not be detected in investigations on **83b**.<sup>288</sup> This speaks for a stronger binding of the phosphalkyne compared to the bridging isonitriles. No reaction was observed when the arsenic/nitrogen-centered derivative **29g** and the phosphorus/nitrogen-centered derivative **29h** was reacted with <sup>t</sup>Bu-PC. This agrees with the comparatively low biradical character of the two compounds (Table 6).

For acetylene, which also contains a triple bond, a similar reactivity towards **29a** was observed as for <sup>t</sup>Bu-NC. Thus, activation of the triple bond occurs with bond formation with the two phosphorus atoms. The product **84** resulting from the reaction could be fully characterized. Whether the addition is reversible as in the case of isonitriles or irreversible as in the case of phosphorus atoms has not been investigated in detail.<sup>211</sup>

By reacting **29b** with dichloromethane, one of the two C–Cl bonds could be activated, forming **85** with elimination of the isonitrile. The same reaction product can be observed when **22a** is reacted with dichloromethane.<sup>211</sup> Halogenation of the phosphorus-centered biradical **29a** was possible with elemental iodine or carbon tetrachloride to form compounds **86a** and **86b**. However, the reaction products could not be isolated, but only detected by mass spectrometry and NMR spectroscopy.<sup>211</sup> The reaction of the one-electron oxidant Ag[B(C<sub>6</sub>F<sub>5</sub>)<sub>4</sub>] with **29a** leads to the formation of the radical cation **87** under elimination of the isonitrile.<sup>211</sup> The same radical cation is generated by the direct reaction of Ag[B(C<sub>6</sub>F<sub>5</sub>)<sub>4</sub>] with **22a**.<sup>218</sup>

Moreover, it was possible to show that a diisonitrile **88** can insert into two four-membered heterocyclobutane-1,3-diyls such as **22a** (Scheme 58) affording tetraradical **89**. Very similar NMR spectroscopic data to **29a** suggest that the two biradical units do not interact significantly with each other, which is not surprising as both phenyl rings are linked by a methylene group. Due to the hindered rotation around the CN double bond, three different isomers for **89** are conceivable, of which only two could be detected in solution. Photoisomerisation could also be observed for **89** after irradiation. In addition to two isomers of the double housane species **89'**, the isomer in which only housane formation took place, could also be detected in the <sup>31</sup>P NMR studies. The tetraradical **89** reacts analogously to the biradicals of type **29** with *tert*-butylphosphalkyne to **90**. Here, an addition to the two biradical centers occurs (Scheme 58). By means of NMR spectroscopy, three different isomers could be detected. Whether the addition is reversible has not yet been investigated.<sup>211</sup>

**Fig. 18** Left: Crystal of **29a** before irradiation with red light; right: the same crystal shortly after irradiation where the blue **29a** was converted to the colorless housane isomer **29'a**.<sup>287</sup>

**Scheme 57** Reactivity of heterocyclopentane-1,3-diyl derivatives **29**.

#### 1.04.3.3.2.3 Phosphorus-centered benzo-fused cyclopentane-1,3-diyls

Heterocyclopentane-1,3-diyl derivatives of type **29** often eliminate the isonitrile moiety, R-NC, upon activation of small molecules, reforming the corresponding heterocyclobutane-1,3-diyl (**22**), which was used to synthesize **29**. Therefore, we developed 5-membered phosphorus-centered biradicals that are significantly more stable with regard to an elimination reaction. For this reason, the related benzo-fused cyclopentane-1,3-diyls (i.e., hetero-indanediyls **91**, **Scheme 59**), which also provide aromatic stabilization, were introduced.<sup>289</sup>

The synthesis of biradical **91** was carried out in two steps (**Scheme 59**).<sup>289</sup> In the first step, a suitable precursor (**92**) for the biradical was synthesized: In analogy to the synthesis of **22** (**Scheme 34**), chlorinated azadiphospha-indanes (**92**) were prepared by reacting primary amines with 1,2-bis(dichlorophosphino)benzene under HCl elimination. For different substituents (Dmp, Ter, <sup>t</sup>BuBhp), the *cis* isomer of **92** (*cis* with respect to the Cl atoms) was obtained (<sup>31</sup>P NMR:  $\delta = 147\text{--}149$  ppm). The synthesis of the hetero-indanediyls **91R** (R = Dmp, Ter, <sup>t</sup>BuBhp; <sup>t</sup>BuBhp = 2,6-bis(benzhydryl)-4-*tert*-butylphenyl) was achieved by reduction of **92R** with elemental magnesium. In the course of the reaction, the colorless solutions turned orange, indicating the formation of the desired product. This could be traced by <sup>31</sup>P NMR spectroscopy; all hetero-indanediyls **91R** could be identified by a characteristic singlet resonance ( $\delta = 280\text{--}285$  ppm). However, depending on the steric demand of R, different subsequent reactions were observed (**Scheme 59**, bottom). The biradical **91Dmp** was completely converted to an insoluble red polymer within 1 day, as demonstrated by <sup>31</sup>P NMR spectroscopy. In the case of **91Ter**, selective trimerization to (**91Ter**)<sub>3</sub> was observed. (**91Ter**)<sub>3</sub> is formed by activation of the condensed benzene ring of **91Ter** by two further equivalents of the monomeric biradical. This self-activation process can be regarded as a formal [2 + 2] addition reaction. The sterically most demanding derivative **91<sup>t</sup>BuBhp** is stable in benzene for several weeks, as verified by NMR spectroscopy. **91<sup>t</sup>BuBhp** is intensely yellow and shows absorption maxima at 407 and 424 nm in the UV-vis spectrum. The calculated biradical character (CASSCF(2,2)) of **91<sup>t</sup>BuBhp** is  $\beta = 18\%$ , while the LUNO occupancy amounts to  $n_{\text{LUNO}} = 0.21$  (CASSCF(10,9)/def2-TZVP). This is slightly lower compared to other biradicals such as **22** and **29** ( $\beta = 20\text{--}30\%$ ,  $n_{\text{LUNO}} = 0.2\text{--}0.3$ ). In contrast, the biradical character of (**91Ter**)<sub>3</sub> with 12% ( $n_{\text{LUNO}} = 0.12$ ) is significantly lower, so that it can be better described as diene.

#### 1.04.3.3.2.4 Phosphorus-carbon-centered heterocyclopentane-1,3-diyl

Lips et al. described the addition of phospho-alkyne PC-<sup>t</sup>Bu to an NHC-coordinated trisilacyclopropylidene, Si<sub>3</sub>Mes<sub>4</sub>NHC (**93**), resulting in the formation of a heavier analog (**94'**) of a bicyclo[2.1.0]pentane, a so-called housane.<sup>290</sup> The NHC used was 1,3-diisopropylimidazol-2-ylidene. In housane **94'**, the folding angle is 88.46(2)°, as expected for a housane. Upon irradiation or at

**Scheme 58** Synthesis and reactivity of tetradical **89**.**Scheme 59** Synthesis of differently substituted 2-aza-1,3-diphosphaindane-1,3-diyls **91**. Their stability depends on the sterical demand of the substituent R, as depicted in the box.<sup>289</sup>

temperatures above 60 °C, the housane isomerises to a formal cyclopentenyl anion analog, which can also be regarded as a compound with biradical character (94, Scheme 60). However, Lips et al. describe the bond as a 3c-4e  $\pi$  bond but do not comment on a possible biradical character. Nonetheless, if one looks at the HOMO (transannular antibonding) or the LUMO (transannular bonding, cf. Section 1.04.2), this corresponds exactly to the situation in typical cyclopentane-1,3-diyls such as 29, as discussed above.

#### 1.04.4 Applications of biradicals as molecular switches

Due to their peculiar electronic structure, biradicals have various (potential) applications; for example, they may be applied in small-molecule activation (see Section 1.04.3), molecular electronics,<sup>291–294</sup> singlet fission,<sup>295–300</sup> non-linear optics,<sup>35,301–303</sup> or as molecular switches.<sup>164,212,264,270,287,303–313</sup>

The concept of **switchable biradicals** is generally that a molecule can exist in two different (meta)stable states, just as is the case for “normal” molecular switches.<sup>314–317</sup> However, the biradical character is often very sensitive towards even small structural changes, so it can effectively be varied by switching the molecule between different isomers. As the biradical character is the source of many of the interesting properties outlined above, these properties can also be modified through the switching behavior. For example, if the switchable biradical is light-activated, the biradical character can effectively be switched “on” and “off” by irradiation (i.e., an outside stimulus). This will then also influence the activation chemistry, non-linear optical properties etc.

Regarding the cyclobutane-1,3-diyls and cyclopentane-1,3-diyls discussed in this article, the concept of switchable biradicals was demonstrated by us using hetero-cyclopentanediylys of type 29. As indicated in Section 1.04.3.3.2, these five-membered cyclic biradicals can be photoisomerized to housane-type species 29', which do not possess significant biradical character (Fig. 19). Thus, irradiation of biradical 29 effectively quenches the biradical nature of the compound. The housane 29' thermally reverts to the biradical isomer 29. This thermal reverse reaction was studied by variable temperature <sup>31</sup>P NMR spectroscopy,<sup>212,287,310</sup> revealing that the housane possesses a half-life of up to 1 h at ambient temperature, depending on the substituents ( $t_{1/2}$  for 29'a: 7 min, 29'b: 57 min, 29'f: 31 min).<sup>212,287</sup>

The isomerization between biradical 29 and housane isomer 29' can also be traced by UV-vis spectroscopy, as the biradical is intensely blue ( $\lambda_{\max}$  for 29a: 643 nm,<sup>287</sup> 29b: 663 nm,<sup>287</sup> 29c: 675 nm,<sup>286</sup> 29f: 595 nm,<sup>208</sup> 29i: 684 nm<sup>196</sup>), while the housane is colorless (Fig. 19). We studied the ultrafast dynamics of the photoisomerization of 29a using theoretical methods and transient absorption spectroscopy,<sup>311</sup> revealing that the photoisomerization proceeds via the first excited singlet state (Fig. 20). The excited molecules can transfer back to the ground state through a conical intersection without the emission of radiation. The conical intersection between the S<sub>1</sub> and S<sub>0</sub> surfaces is located in the vicinity of the thermal transition state between 29a and 29'a. Approx. 25% of the excited molecules isomerize to the housane isomer (quantum yield 24.6(8)%),<sup>287</sup> while the remaining 75% revert to the biradical isomer. The photoreaction is very fast (exponential time constant  $\tau = 210$  fs),<sup>311</sup> so the thermal reverse reaction does not play a role on this timescale. Thus, it is easily possible to fully convert the biradical 29a to the housane isomer 29'a.<sup>287</sup>

The switching between biradical and (closed-shell) housane isomer was exploited to influence the product formation in a thermal equilibrium reaction (Scheme 61).<sup>287,310</sup> Biradicals of type 29 can activate small molecules such as <sup>t</sup>BuNC (cf. Section 1.04.3.3.2), leading to the formation of addition products of type 30. Depending on the substituents at the biradical, this addition reaction is often an equilibrium reaction, i.e., both product 30 and starting material 29 can be identified in solution. If the biradical 29 is now switched to the housane isomer 29' by irradiation with red (or white) light, the activation chemistry is inhibited (or, to

Scheme 60 Synthesis of 94 and 94'.

**Fig. 19** Sample solution of biradical **29a** before (left) and after illumination (right) with red light. Adapted from Bresien, J.; Kröger-Badge, T.; Lochbrunner, S.; Michalik, D.; Müller, H.; Schulz, A.; Zander, E. A Chemical Reaction Controlled by Light-Activated Molecular Switches Based on Hetero-Cyclopentenediyls. *Chem. Sci.* **2019**, *10* (12), 3486–3493.

**Fig. 20** Minimum energy paths along the  $S_0$  and  $S_1$  potential energy surface (PES) of biradical **29a** (here a model system with H substituents). After excitation with red light, the excited state deactivates through a conical intersection (CInt), leading to formation of the housane **29'a** with a quantum yield of approx. 25%. The thermal reverse reaction of the housane to the biradical proceeds via a single transition state (TS) in a first-order reaction. Adapted from Völzer, T.; Beer, H.; Schulz, A.; Lochbrunner, S.; Bresien, J. Photoisomerization of a Phosphorus-Based Biradicaloid: Ultrafast Dynamics Through a Conical Intersection. *Phys. Chem. Chem. Phys.* **2021**, *23* (12), 7434–7441.

put it in different terms, the biradical **29** is removed from the equilibrium reaction), resulting in quantitative dissociation of the adduct **30**. Once the light is switched off again, the thermal equilibrium is restored, and the adduct **30** is again the main product of the reaction. This switching can be repeated several times without detectable degradation of the mixture.<sup>287,310</sup>

Lastly, it could also be shown that the isonitrile can catalyze the thermal reverse reaction. In the presence of an excess of <sup>t</sup>BuNC, the thermal isomerization of the housane **29'a** to the biradical **29a** is accelerated. The housane **29'a** forms a transient adduct with the isonitrile (95, **Scheme 62**), which quickly decays to the biradical **29a** and free <sup>t</sup>BuNC. The formal addition of the isonitrile to the housane proceeds via an  $S_N2$ -type substitution of the isonitrile at *one* P atom (one P–N bond is broken in the process), as opposed to the reactivity of the biradical, which reacts in a concerted reaction mechanism with *both* P atoms. This observation demonstrates that (i) the thermal reverse reaction can be influenced chemically, and (ii) that switching the biradical character “on” and “off” can open completely different reaction channels using the same reagent.

As discussed in **Section 1.04.3.2**, there are also examples of hetero-cyclobutane-1,3-diyls that can be thermally isomerized to a closed-shell butterfly structure. This further underlines the potential of the concept of switchable biradicals. In the future, we expect that more applications of switchable biradicals will be found, for example in the field of molecular electronics or in (metal-free) catalysis.

**Scheme 61** The activation chemistry of biradical **29** can be switched “on” and “off.” This effect has been studied by time-dependent and variable-temperature NMR spectroscopy for **29a** ( $R = \text{Ter}$ ,  $R' = \text{Dmp}$ ) and **29b** ( $R = \text{Ter}$ ,  $R' = {}^t\text{Bu}$ ).<sup>287,310</sup>

**Scheme 62** The two isomers of **29a** react differently with  ${}^t\text{BuNC}$ : The biradical **29a** undergoes a formal [2 + 1] cycloaddition reaction, while the housane **29'a** reacts in an  $S_N2$ -type substitution.<sup>310</sup>

**Scheme 63** Examples of biradicals as part of a six-membered heterocycle containing main group elements (cAAC = cyclic alkylaminocarbene, Dipp = 2,6- $i\text{Pr}_2\text{C}_6\text{H}_3$ ).<sup>333–335,341</sup>

### 1.04.5 Outlook: Beyond four and five-membered heterocyclic biradicals

The biradical chemistry of the main group elements has been enriched by many new molecules in the last decade.<sup>318–332</sup> Besides the cyclobutane-1,3-diyls and cyclopentane-1,3-diyls discussed in this book chapter, there are of course also a large number of biradicals as part of a six-membered heterocycle or even with a cage structure, which are not considered here. A few examples from recent research are shown in **Scheme 63**.<sup>324,333–335</sup>

Still a very interesting strategy for producing new biradicals is the incorporation of main group elements into organic heterocycles, e.g., into so-called acenes, which have been investigated intensively in recent years.<sup>333,336–392</sup> Acenes are an important subclass of polycyclic aromatic hydrocarbons that consist of linearly fused benzene rings (**Scheme 63**).<sup>17,337,340,348,351,363,374,375,391–395</sup> Theoretical studies predicted that (oligo)-acenes from hexacene ( $n = 2$ ) to decacene ( $n = 6$ ) no longer have closed-shell configurations, but open-shell singlet biradical ground states.<sup>17,20,295,329,333,334,396,397</sup> The reason for this is the decreasing HOMO-LUMO gap in these systems, which in turn leads to a smaller singlet-triplet energy gap.<sup>341,343</sup> Acenes larger than dodecacene therefore have polyradical character with an open-shell singlet ground state.<sup>353,355,389</sup> Therefore, as the number of condensed benzene rings increases, the acenes become p-type organic semiconductors, which makes them very relevant for organic electronic applications<sup>336,337,345,354,356,362,373,375</sup> such as field-effect transistors,<sup>374,378</sup> light-emitting diodes,<sup>365,371</sup> organic conductors,<sup>354,362</sup> and solar cells. However, the widespread use of acenes larger than pentacene in such applications is still hampered by major experimental difficulties in synthesizing large amounts of the pure acene compounds due to increasing instability and insolubility.<sup>357,361,377,384</sup> Implementation of heteroatoms such as boron into organic molecules could be another strategy to modify, for example, these pure organic biradicalic acenes.<sup>333,334,346,376,381</sup> Indeed, the implementation of boron atoms into organic molecules proved to be a quite efficient strategy to reduce their HOMO-LUMO gaps, mainly by raising the energy of the HOMO.<sup>333</sup> It is assumed that this approach may also be feasible for acenes or other organic poly-aromatics, allowing the generation of open-shell singlet systems even with a smaller number of condensed benzene rings. A similar approach is the incorporation of a biradical moiety into a stabilizing NHC system or heterocyclic system, e.g., *N*-heterocyclic olefins,<sup>221,289,331,333,335,398</sup> which are also similar in structure to acene-based biradicals. Here, too, the biradical character can be significantly enhanced by the specific incorporation of main group elements in unusual oxidation states (low valent) and chemical environments (low coordinated, bulky substituents).

### Abstract

The introduction of monoheteroatom stabilized cyclic carbenes, less than a decade after the discovery of stable acyclic and *N*-heterocyclic carbenes (NHCs), soon led to the development of complex ligands fulfilling more than a simple spectator role. Particularly the imidazol-4-ylidenes (Im4), cyclic (alkyl)(amino)carbenes (CAACs) and 1,2,3-triazol-5-ylidenes (trz) have emerged as ligands for transition metal complexes that demonstrate a noninnocent role. The advancements of these nonclassical *N*-heterocyclic carbenes as noninnocent ligands are reviewed in this contribution. A short overview of the unique (stereo)electronic features of these classes of carbenes is provided. The focus of this study is however on the impact of Im4, CAACs and trz on the metal complex reactivity in catalytic applications where the ligands exhibit a chemically or a redox noninnocent role in cooperative, bifunctional or redox-switchable catalysis. The introduction of ligand-based chirality and the role played in chiral induction are included, as well as the effect of multinuclear cooperativity in polymetallic complexes of these nonclassical carbenes. The extension of these ligands to macromolecular systems, including surface functionalization for catalytic or material applications, are showcased. Finally, the potential for the nonclassical carbenes as noninnocent ligands in non-catalytic applications, such as light emitting and biological applications, are highlighted.

### 1.05.1 Introduction

Organic transformations mediated by transition metal complexes have historically been dominated by precious metal catalysts following a metal centered reactivity profile.<sup>1–4</sup> Tailored ligand design for coordination to an appropriate metal has increasingly become a methodology that can aid or alter the classical reactivity pattern to further decrease reaction energy requirements or waste produced, or even both.<sup>5</sup> This is achieved by decorating the ligand with various functional groups that can assist in substrate manipulation, lowering the reaction energy barrier and consequently allowing for even milder reaction conditions. Furthermore, the reaction selectivity can be enhanced by using tailored ligands, thereby maximizing atom-economy to ultimately align with environmentally friendly targets. In the context of this work, ligands that do not just play a spectator role, but rather actively participate in the complex reactivity, are generally referred to as noninnocent. The noninnocent class of ligands has cemented itself as a ligand category available to the synthetic chemist towards preparation of targeted coordination compounds.<sup>5–25</sup> Beyond stabilization of reactive metal complexes, the noninnocent ligands assist in the substrate transformation process via a redox event, a multifunctional mode of action, or a chemically or light induced response, among others.

Another tool available to synthetic chemists, used generally as ligands during the preparation of organometallic compounds, is the now ubiquitous *N*-heterocyclic carbenes (NHCs).<sup>26–28</sup> These compounds, originally viewed as ‘laboratory curiosities,’ have demonstrated wide and versatile application over the past 30 years.<sup>5,29</sup> A subset of the classical NHCs that has also firmly established itself as a ligand of choice during the preparation of targeted organometallic complexes over the past two decades, is the cyclic monoheteroatom-stabilized carbenes, or nonclassical carbenes with increased basicity as a result of carbene stabilization imparted by only one nitrogen atom adjacent to the carbene carbon and not two as in the case of classical NHCs.<sup>30–51</sup> Of these nonclassical carbenes, the abnormal or mesoionic carbenes (MICs)<sup>30–44</sup> including imidazol-4-ylidenes (Im4) and 1,2,3-triazol-5-ylidenes (trz), and the cyclic (alkyl)(amino)carbene (CAAC)<sup>45–51</sup> class of carbene ligands have received growing attention compared to other nonclassical carbenes (Fig. 1). This can be attributed to the characteristic donor properties of the carbene ligands, in addition to their ease of preparation and ligand modification that allow for facile tailoring of the ligand’s electronic and steric properties. Accordingly, the merging of a nonclassical carbene with a noninnocent ligand role is not surprising, and these multifunctional, strong donor ligands have already exceeded expectations.

This chapter aims to highlight the impact of noninnocent nonclassical carbene ligands on metal complexes and their resultant reactivity. This includes a short overview of the stereoelectronic properties of the different types of nonclassical carbenes (Im4, trz and CAACs), as their electronic properties have been the subject of several recent reviews.<sup>1,2,33,35,37,38,47–49</sup> For the sake of brevity, only the five-membered cyclic (alkyl)(amino)carbenes will be reviewed, and not their derivatives such as the bicyclic CAACs (BiCAACs), cyclic (aryl)aminocarbenes (CAArCs), etc. Important also towards the foundation of this chapter, is the brief discussion with regards to the carbenes’ inherent noninnocent and stabilizing attributes. The advent of noninnocent ligand behavior of coordinated nonclassical carbenes is showcased by a non-exhaustive account of recent topical developments. Various case studies are used as examples to illustrate the state of the art of the advancements made within this topic, while the developments with possible emerging noninnocent roles in applications beyond catalysis are highlighted.

#### 1.05.1.1 Imidazol-4-ylidene

The explosive growth witnessed within the field of nonclassical carbenes, specifically for Im4, trz and CAACs, can be traced back to their early reports detailing either the preparation of a stable coordination compound or the free carbene.<sup>52–56</sup> Manifestation of an unusual bonding mode during classical NHC metal complex preparation evidenced the first example of an abnormally bound imidazolylidene, the imidazol-4-ylidene.<sup>52</sup> Abnormal C4 coordination, instead of the classical C2 mode of bonding, yielded the iridium carbene complex **2** with carbene stabilization imparted by only one heteroatom adjacent to the carbene carbon (Scheme 1, i). This was followed a few years later by the first example of a free abnormal carbene obtained by blocking of the other ring positions and C4 deprotonation of the imidazolium salt **3**, yielding **4** (Scheme 1, ii).<sup>53</sup> The electronic properties of the abnormal carbenes have been extensively investigated and reviewed to confirm increased electron donation to a metal when compared to classical NHCs.<sup>33,35,38–40,44,57</sup> The lack of a second heteroatom adjacent to the carbene carbon imparts increased electron donation towards the metal, a result of modifications to the  $\sigma$ -pull/ $\pi$ -push properties of the heterocycle.

The Im4 five-membered heterocycle has been described as more than just a spectator ligand, tasked with aiding the metal during bond manipulation processes.<sup>39,58,59</sup> It is the unique electronic structure of Im4 that permits a possible cooperative mode of action<sup>35,38–40,57–59</sup> to render the nonclassical carbene with an in-built/inherent noninnocent character. Albrecht et al. proposed a mechanism by which the Im4 could mediate a cooperative strategy. Intramolecular charge separation within

Fig. 1 Nonclassical carbenes highlighted in this contribution.

**Scheme 1** The first Im4 metal complex and free Im4.

the five-membered heterocycle would result in a vinylic metal-bound C–C fragment and a cationic amidinium unit (**Scheme 2**).<sup>35,39,58,59</sup> The vinylic M=C fragment would then be susceptible to electrophilic attack, as postulated for the treatment of a bisimidazol-4-ylidene coordinated rhodium(III) complex with D<sub>3</sub>PO<sub>4</sub>, yielding the C5 deuterated complex (**Scheme 2**, i).<sup>59,60</sup> Deuteration was observed to occur only at the C4 bound carbene of **5**, and not the classical C2 bound carbene, which results in formation of **11** when treated with D<sub>3</sub>PO<sub>4</sub> (**Scheme 2**, i). Additional mechanistic investigations, in this case using Et<sub>3</sub>SiD, supported the proposed intramolecular charge separation within the imidazol-4-ylidene heterocycle (**Scheme 2**, ii).<sup>39,58</sup> Im4 deuteration at the C5 position was noted once more, with its formation again postulated to involve the vinylic M=C fragment resulting from intramolecular charge separation.<sup>58</sup> A ligand-assisted Si–D heterolytic bond cleavage across the metal-vinylic moiety, followed by hydrolysis due to the presence of a small amount of water, yields the deuterated complex **16**. An alternative mechanism was also proposed for the reaction between **12** and Et<sub>3</sub>SiD, namely the oxidative addition of the hydrosilane across the metal, leading to formation of the intermediate rhodium(V) complex **15** (**Scheme 2**, ii), only accessible due to the donor characteristics of the nonclassical carbene.<sup>58</sup> Im4 has been suggested to stabilize metals in both low and high oxidation states, also ascribed to be a consequence of the intramolecular charge separation.<sup>33,35,38–40,44,57</sup> Subsequent tautomerization and rehybridization results in the C5 deuterated rhodium complex **14**, leading to **16** after hydrolysis (**Scheme 2**, ii).<sup>58</sup>

In yet another corroboration of the postulated intramolecular charge separation, selective C5 deuteration was evidenced under both acidic and basic conditions.<sup>61</sup> Treatment of the iridium Im4 complex **17** with DCl in D<sub>2</sub>O at 80 °C yielded the expected deuterated complex **18** (**Scheme 3**). The formation of the intermediary metalla-allyl anionic fragment **19** was postulated to account for the observed reactivity. Subjecting **17** to basic conditions also yielded the C5 deuterated product **20**, in addition to deuteration on the C2 substituted methyl group (**Scheme 3**). In the presence of NaOH and D<sub>2</sub>O, fast deuteration of the methyl group was noted, with C5 deuteration completed only after 2 days.

### 1.05.1.2 1,2,3-Triazol-5-ylidene

The first trz coordinated complex was reported by Albrecht and co-workers (**Scheme 4**, i),<sup>54</sup> while the deprotonated free trz **24** was reported 2 years later by Bertrand and co-workers (**Scheme 4**, ii).<sup>55</sup> The carbene carbon atom is flanked by one of the three nitrogen atoms in the five-membered heterocycle where the C2 carbon of the imidazolylidene is substituted with another nitrogen.<sup>30,33–38,42</sup>

**Scheme 2** Im4 heterocyclic intramolecular charge separation.

**Scheme 3** IrM4 deuteration in acidic or basic reaction media.

**Scheme 4** The first examples of (i) coordinated and (ii) free 1,2,3-triazol-5-ylidenes.

As for Im4, the donor properties of trz have also been extensively evaluated as stronger compared to classical NHCs, but are weaker when compared against Im4.<sup>33,37,38</sup>

In the case of trz, the intramolecular charge separation derived from the mesoionic nature of the heterocycle leads to the formation of the anionic M=C and the cationic NNN<sup>+</sup> fragments (**Scheme 5, i**) which facilitate bond manipulation processes cooperatively.<sup>37,39,62</sup> The intramolecular charge separation has indeed been linked to the observed water oxidation reactivity of ruthenium and iridium complexes coordinated by trz (vide infra).<sup>37,39,62,63</sup> An alternative cooperative mode of action involving the second nitrogen in the triazolylidene heterocycle has also been speculated.<sup>61</sup> Deuteration experiments by Albrecht et al. confirmed that, similar to Im4, selective deuteration occurs at the C4 position of the trz heterocycle under basic conditions, with instantaneous deuteration of **28** reported in the presence of NaOH and D<sub>2</sub>O yielding **29** (**Scheme 5, ii**). The authors described the deuteration of both the Im4 and trz heterocycles under basic conditions as reminiscent of a deprotonation followed by deuteration mechanism. This would explain the differences noted in the rate of deuteration, depending on the differences in the acidity of the protons being deprotonated. However, under acidic conditions no deuterium incorporation occurred in contrast to the reactivity displayed by Im4 (**Scheme 5, ii**). The authors described the triazolylidene as exhibiting proton/deuterium scavenging properties, with nitrogen deuteration leading to the formation of intermediate **30** proposed (**Scheme 5, ii**). Deuteration is therefore precluded

**Scheme 5** Triazolylidenes acting as more than simple spectator ligands.

at the carbenic carbon of the heterocycle, illustrating the basicity of the trz central N2.<sup>61</sup> This is similar to reported reactivity of the five-membered heterocycle, with N2 protonation leading to catalyst activation<sup>64</sup> or metal coordination by the second nitrogen,<sup>65</sup> to associate the trz heterocycle with a cooperative mode of action where the proton responsive entity acts as a proton shuttle during bond activation reactions.

Indeed, both the groups of Albrecht<sup>66</sup> and Bertrand, Grubbs and co-workers<sup>64</sup> exploited the proton scavenging ability of the trz during catalytic processes. Bertrand and Grubbs prepared the olefin metathesis catalyst **31** substituted with a trz (Scheme 6, i).<sup>64,67</sup> Catalyst initiation was mediated by the addition of trifluoroacetic acid, hypothesized to protonate the heterocycle at the N2 position with concomitant trz dissociation from **32**. A 1,3-proton shift follows to yield the active catalyst **33** and the triazolium salt **34** (Scheme 6, i).<sup>64</sup> Symmetrical ethers could be accessed very efficiently through the reductive coupling of ketones and aldehydes, employing an iridium catalyst coordinated by a C,N-bidentate trz.<sup>66</sup> The authors suggested that the trz acts as a proton shuttle during the catalytic process. Heterocycle protonation at the N2 position leads to formation of **37**, followed by substrate coordination at **38** with subsequent protodeiridation or nucleophilic substitution, yielding the active catalyst **36** and the targeted product (Scheme 6, ii). The authors also suggest an alternative catalytic mechanism, involving ligand dearomatization, which implies an intramolecular charge separation mechanism within the five-membered heterocycle rather than a proton shuttling process.<sup>66</sup>

### 1.05.1.3 Cyclic (alkyl)(amino)carbene

Cyclic (alkyl)(amino)carbenes made their debut in 2005 with the report of both the free carbene **41** and the CAAC coordinated Pd complex **42** (Scheme 7, i).<sup>56</sup> Akin to the Im4 and trz, the CAACs feature only one electronegative and  $\pi$ -donating amino-substituent neighboring the carbene. In a variation of the other nonclassical carbenes discussed, the other position adjacent the carbene carbon is an  $sp^3$ -hybridized carbon.<sup>42,45–51,68–70</sup> This results in increased  $\sigma$ -donating characteristics with negligible  $\pi$ -donating attributes from said  $\alpha$ -position. CAACs are both more nucleophilic and more electrophilic than traditional or nonclassical NHCs, as are evident from the HOMO (highest occupied molecular orbital) and LUMO (lowest unoccupied molecular orbital) energies (Scheme 7, ii). The energy gap between the frontier orbitals is smaller compared to other popular donor ligands. This has led to the dubbing of CAACs as ambiphilic carbenes.<sup>71,72</sup> Both the steric environment imparted by the CAAC substituents and the electronic structure of the frontier orbitals bestow unique reactivity profiles to this class of ligands which can be viewed as tantamount to noninnocent ligand behavior.<sup>42,45–51,68–70</sup>

The stabilizing ability of CAACs attendant to the stereoelectronic properties is well-known.<sup>42,45–51,68–70</sup> A direct consequence of the low lying LUMO (Scheme 7, ii) is the ease with which CAACs can stabilize electron-rich main group elements (Scheme 8, ii), low valent transition metals (Scheme 8, iii) and radical species (Scheme 8, iv).<sup>42,45–48,50,51,69</sup> The empty p-orbital of CAACs can accommodate  $\pi$ -electron density (**43**, Scheme 8, i), delocalizing the accumulated  $\pi$ -electron density and increasing the stability

**Scheme 6** The noninnocent role of triazolylidenes towards (i) catalyst activation and (ii) proton transfer processes.

## i) Debut of cyclic (alkyl)(amino)carbenes

## ii) Calculated HOMO and LUMO energy levels of common ligands and of the cyclic (alkyl)(amino)carbene ligand

**Scheme 7** Cyclic (alkyl)(amino)carbenes' (i) debut and (ii) calculated HOMO and LUMO energy level.<sup>48</sup> Modified from Paul, U. S. D.; Radius, U. *Eur. J. Inorg. Chem.* **2017**, 2017, 3362–3375.

of the species investigated (44, **Scheme 8**, i).<sup>46,50,51,73</sup> This attribute was irrefutably illustrated by Bertrand and co-workers, who disclosed the first example of a nucleophilic neutral trivalent boron derivative 45 that is isoelectronic with amines (**Scheme 8**, ii).<sup>74</sup> Calculations confirmed the delocalization of the boron's lone pair of electrons into the HOMO of 45, as an overlap of the boron p( $\pi$ )-orbital with the carbene atomic p( $\pi$ )-orbital (**Scheme 8**, ii). The groups of Bertrand, Roesky and others extended the range of well-defined isolable reactive species by utilizing CAACs.<sup>42,45–48,50,51,69</sup> This includes stabilization of radicals, again possible due to the vacant p( $\pi$ )-orbital of the carbene to accommodate additional electron density through conjugated electron

**Scheme 8** Stabilization of reactive species by CAACs via  $\sigma$ -donation and  $\pi$ -backdonation.

delocalization, while the rigid scaffold prevents rearrangement and subsequent decomposition. This was illustrated very recently by nitrogen fixation<sup>75</sup> and the reductive coupling thereof (Scheme 8, iv).<sup>76</sup> Hydride transfer to and from the CAACs p( $\pi$ )-orbital has also been reported, illustrating the susceptibility of the carbene to nucleophilic hydrogen. Transition metals, and especially coinage metals, have also demonstrated unique reactivities due to the coordination of CAACs (Scheme 8, iii). Diamagnetic and paramagnetic main group elements, persistent radicals and transition metals of varying oxidation states that were previously not accessible, are now available to the chemist via CAAC coordination.<sup>42,45–51,68–70</sup>

The stereoelectronic properties of CAACs allow for reactivity profiles of the metal-free ambiphilic carbenes that mimic the reactivity of transition metals.<sup>47,49,70</sup> This includes the binding and activation of small inert molecules to catalytic transformations. In their seminal contribution, Bertrand and co-workers disclosed the facile activation of hydrogen and ammonia (Scheme 9).<sup>77</sup> The free CAAC 41 was treated with hydrogen, resulting in oxidative addition of H<sub>2</sub> across the carbene, yielding 56. The activation of H<sub>2</sub> was computationally modeled, with nucleophilic attack of the carbene lone pair of electrons into the antibonding orbital of H<sub>2</sub> at 53. This induces H<sub>2</sub> polarization, with the electrophilic hydrogen bonded to the carbene carbon. Subsequent elongation of the H–H bond provides the hydrogen not bound to the carbene carbon with increased hydridic character. After stereochemical inversion, the hydrogen featuring hydridic character coordinates to the carbene at 55 and forms the second C–H bond after H–H cleavage, leading to 56. Accordingly, nucleophilic activation is followed by hydride transfer leading to H<sub>2</sub> activation. Ammonia activation was found to be favorable even at –40 °C. Ammonia activation was reported to be similar to H<sub>2</sub> activation, with bond polarization as the intermediary step towards formation of 57 from 41.<sup>77</sup>

The activation of E–H bonds via oxidative addition across the carbenic carbon<sup>78</sup> was extended to include Si–H, B–H and P–H bonds.<sup>79</sup> Accordingly, facile oxidative addition of primary, secondary and tertiary silanes across the carbene carbon of CAAC 58 was reported (Scheme 10). Similarly, primary and secondary phosphines reacted with 58 leading to the corresponding products (62 and 63, respectively) of oxidative addition. Sterically less encumbered CAACs result in improved reactivity with silanes and phosphines compared to CAACs featuring bulky substituents. Furthermore, the authors disclosed the oxidative addition of pinacolborane across the carbene carbon of 58 yielding 64, while adduct formation was noted upon reacting 58 with BH<sub>3</sub> to yield 65.<sup>79</sup> Radius et al. also described the oxidative addition of diboron leading to the oxidized product 66,<sup>80</sup> while Turner disclosed the activation of C–H and C–F bonds with CAACs, referring to the nonclassical carbenes as chemically noninnocent.<sup>81</sup>

For efficient catalysts and catalytic processes, however, both oxidative addition and reductive elimination reactions should be viable. In support of the transition metal-like reactivity of CAACs, a recent report confirms the feasible reductive elimination at the carbene carbon of CAACs.<sup>82</sup> It was demonstrated that reductive elimination is dependent on the steric environment imposed by the ligand, with sterically encumbered menthyl-CAACs such as 67 favoring reductive elimination (Scheme 11, i). The requirement for the unique electronic properties of the CAAC ligand was verified computationally, with the prediction of the carbene p( $\pi$ )-orbital participating in the reductive elimination reaction (see formation of 41 from 67, Scheme 11, i). The stereoelectronic properties of the CAAC ligand therefore plays a crucial role during both the oxidative addition and reductive elimination processes. Reversible oxidative addition facilitated by CAACs has also been described for the activation of boronates.<sup>83</sup> Addition of arylboronate esters 74 to CAAC 68 resulted in oxidative addition of the boronate across the carbene carbon yielding 75 (Scheme 11, ii). The product of oxidative addition is in equilibrium with the reduced species, an equilibrium affected by heating or cooling of the reaction mixture (Scheme 11, ii). The above discussed examples of oxidative addition and reductive elimination further advances our understanding towards carbene carbon-centered organocatalysis.

In culmination of the work described above, the ambiphilic CAAC was employed as an organocatalyst, with oxidation and reduction reactions key steps toward closing the catalytic loop to access the organic products.<sup>84</sup> Bertrand and co-workers also reported the activation of CO leading to formation of the ketene 76 (Scheme 12, i).<sup>85</sup> The authors exploited the activation of CO with CAACs by promoting carbonylation of *o*-quinone catalytically to yield the corresponding cyclic carbonate.<sup>84</sup> Accordingly, *o*-quinone was converted under 4 atm of CO in the presence of 10 mol% 41. Both stoichiometric and computational investigations support a mechanism that involves first ketene formation through the reaction of CO with the carbene organocatalyst 41. The

**Scheme 9** Oxidative addition of H<sub>2</sub> and NH<sub>3</sub> via nucleophilic addition with subsequent hydride transfer.

**Scheme 10** Oxidative addition across the carbene carbon of CAACs.

subsequent reaction of ketene **76** with quinone **77** can lead to **78** or **79**, with **79** reported to be the resting state of the catalytic reaction. Reduction of **79** leads to reformation of the catalytically active species **78**. The final step in the catalytic mechanism involves elimination of the targeted cyclic carbonate **81** from **80**, regenerating the free CAAC. A pronounced influence exerted by the stereo-electronic properties of the selected carbene on the catalytic reaction was noted. Reduction of **79** is possible (**Scheme 12**, i), but the analogous compounds **82** (**Scheme 12**, ii) and **84** (**Scheme 12**, iii), obtained when using **68** or **83** as organocatalyst, respectively, demonstrated reluctance towards reduction. Hence, the catalytic reaction is arrested at the resting state when employing **68** or **83** as catalyst.<sup>84</sup>

**Scheme 11** Reductive elimination across the carbene carbon of CAACs.

**Scheme 12** Realizing cyclic carbonates via CAAC catalyzed carbonylation of quinone with CO.

### 1.05.2 Chemical noninnocence

Tailored ligand design for noninnocent participation in substrate activation is elegantly exemplified by various strategies, such as the established (de)aromatization process allowing for inert substrate activation.<sup>6–9,20,86–93</sup> Substrate bond manipulation is realized across the metal and the ligand, which is facilitated via aromatization/dearomatization of the ligand, with the metal remaining in the same oxidation state (**Scheme 13**, i). Another approach involves tethering of a hemilabile donor functionality to the coordinating ligand, with coordination/decoordination of the donor moiety either stabilizing the metal complex or vacating a coordination site for substrate binding (**Scheme 13**, ii).<sup>10,11,18,19,21,23,24,94,95</sup> Alternatively, multifunctional ligands containing a reactive site can be used in a Lewis acid-base pair activation strategy. Generally a reactive site such as a Lewis basic donor moiety is included in the ligand structure while the metal fulfills the acceptor role (**Scheme 13**, iii).<sup>9,12–25,87,92,94,96–102</sup>

The amalgamation of a strong donor carbene with an additional functionality to aid substrate bond activation (**Scheme 13**),<sup>5,95,96,103–107</sup> is in most instances achieved when the robust M–C bond acts as the anchor, securing the metal in close proximity to the added noninnocent moiety. Substitution of the classical NHC with a nonclassical NHC allows access to different reactivity

**Scheme 13** Tailored NHC-ligand design towards facile bond manipulation via ligand cooperativity.

profiles, and if tethered to a noninnocent moiety, new complex reactivity could be imagined. Various nonclassical NHC ligands decorated with an auxiliary functional group that manifests the carbene containing ligand as noninnocent, have been developed. These ligand functionalities range from hemilabile pendants, to chemoactive ligands, as well as ligands featuring bifunctionality to actively participate in bond making and bond breaking processes.

The nonclassical carbene ligand of interest in this section, must demonstrate chemical noninnocence, with the noninnocent functionality tethered (see Fig. 2) to the carbene donor group as a prerequisite (i.e. a metal complex coordinated by a trz, Im4 or CAAC and an independent ancillary noninnocent ligand will not be considered). The chemically cooperative nonclassical carbenes are grouped according to the periodic group of the noninnocent moiety participating in the noninnocent strategy (Fig. 2). A broad overview of the developments is presented, with various examples highlighted to emphasize either the importance of the cooperative ligand, or the mechanism by which the noninnocent ligand facilitates bond manipulation strategies, or both.

### 1.05.2.1 Group 4 donor functionalized nonclassical carbenes

#### 1.05.2.1.1 C-donor functionalized carbenes

A popular chelation strategy involves C–H bond activation, generally resulting in cyclometalation and subsequent isolation of the target complex.<sup>108</sup> Accordingly, Mandal and co-workers prepared C,C-cyclometalated complexes via a C–H activation strategy, for use as catalyst mediating various cross-coupling catalyzed reactions.<sup>31</sup> A C,C-chelated nickel complex was prepared, purposed for the catalyzed hydroheteroarylation of vinylarenes, through coordination of the phenyl substituted Im4 **85** to a Ni<sup>0</sup> precursor (Scheme 14).<sup>109</sup> Carbene coordination is followed by isomerization of 1,5-cyclooctadiene to 1,3-cyclooctadiene, with concomitant elimination of one of the cyclooctadiene (cod) ligands (Scheme 14). Subsequent C(aryl)–H bond activation results to C–H oxidative addition and formation of **87**, with ensuing hydride transfer to the remaining cod ligand, yielding the C,C-chelated nickel complex **88** with the cod ligand coordinating in a  $\eta^3$ -allyl fashion (Scheme 14). Decoordination of the phenyl carbon followed by reduction of the Ni<sup>II</sup> precatalyst **88** leads to the formation of the active Ni<sup>0</sup> catalyst **89** (Scheme 14). The postulated reaction mechanism indicates that the succeeding catalytic cycle does not involve cyclometalation of the C(phenyl)–H bond again, and therefore re-coordination of the sp<sup>2</sup> phenyl carbon does not occur during the completion of a catalytic cycle.<sup>109</sup>

In addition, Mandal et al. prepared C,C-cyclometalated dinuclear palladium complexes **91** and **92** (Scheme 15, route i), and investigated the complexes as catalysts in the Suzuki-Miyaura cross-coupling of aryl chlorides with phenylboronic acid.<sup>31,110</sup> High turnover numbers (TONs) were accessed, even when using aryl chlorides substituted with electron donating or electron withdrawing groups. Furthermore, complex **91** was determined to be catalytically active for 10 consecutive catalytic runs, while retaining its catalytic activity. Both crystal structure analysis and DFT calculations suggested a stronger palladium carbene carbon bond compared to the palladium aryl carbon bond.<sup>110</sup> Subsequent addition of excess trifluoroacetic acid (TFA) resulted in C(aryl)–Pd bond cleavage, as reported by the same group, when exploiting the analogous chloro-bridged dimer **93** as a catalyst in the hydroarylation of aromatic C–H bonds (Scheme 15, route ii), in the presence of TFA.<sup>111</sup> The catalytic addition of arenes across alkynes was realized with adequate product yields and preferential selectivity towards the *cis*-adduct. The proposed mechanism commences with substitution of the bridging chloro ligands of **93** with TFA ligands, first leading to the dimer **94**, followed by monomer (**95**) formation after addition of more TFA. Excess TFA then leads to protonation of the palladium-bound aryl carbon of **95**, with

Scheme 14 Cyclometalation and phenyl decoordination yields a hydroheteroarylation catalyst.

**Scheme 15** C–H activation towards C,C-cyclometalated dinuclear palladium complexes.

subsequent decooordination of the phenyl moiety to yield the catalytically active Pd-TFA species **96** (Scheme 15, route ii). This allows for electrophilic attack on the substrate's aromatic C–H bond, leading to the  $\sigma$ -aryl-Pd complex **97**, reported to be the first step in the catalytic cycle (Scheme 15).<sup>111</sup> The group further demonstrated the multifaceted potential of the dinuclear bridged complex, with an analogous C,C-chelated palladium dimer mediating the oxidative Heck coupling reaction of arylboronic acids with electron rich or electron deficient olefins at ambient conditions, using water as the solvent of the reaction.<sup>112</sup>

The dinuclear palladium complex **91** can additionally be utilized for the catalytic dehydrogenative cross-coupling of heteroarenes (Scheme 15).<sup>113</sup> The complex catalytically mediated the C–H activation of both heteroaryl substrates in the presence of AgOAc as oxidant. A range of stoichiometric experiments allowed insight into a possible reaction mechanism, involving again first the substitution of the chloro-bridging ligands of **91** with acetato-ligands, originating from the addition of silver acetate (Scheme 15, route iii). It was proposed that dimer **98** subsequently dissociates in the presence of solvent, leading to formation of mononuclear complex **99** that is considered to be the catalytically active species.<sup>113</sup> Next, the C–H activation of the first heteroaryl substrate (**100**, Scheme 15) results in formation of the heteroaryl-palladium(II) complex **101** with acetic acid elimination. It is proposed that the second substrate (**102**) inserts across the C(aryl)–Pd bond of **101**, yielding the corresponding phenyl substituted mono-coordinated triazolylidene palladium complex **103** with both heteroaryl substrates coordinated via a carbon-metal bond, in addition to coordination of a solvent molecule (Scheme 15). The authors further postulated that reduction of **103** yields the Pd<sup>0</sup> complex **104** with elimination of the cross-coupled product **105**, followed by oxidation of **104** with silver acetate leading to cyclometalation and the catalytically active species **99** (Scheme 15).

The C–H bond activation methodology was further implemented towards preparation of trz metal complexes.<sup>59,114–122</sup> This process was demonstrated to be reversible in some instances, albeit through the addition of a base effecting cyclometalation, while under acidic conditions, protonation occurred leading to decooordination and subsequent re-formation of the pendant moiety.<sup>123–125</sup> A variant to this is a cyclometalated ruthenium trz complex, demonstrated to activate hydrogen across the C(aryl)–metal bond with accompanying C–H insertion or phenyl decooordination.<sup>126</sup> The group of Stephan et al. prepared a series of ruthenium complexes coordinated by a trz featuring a pendant phenyl group.<sup>126–128</sup> The complexes were prepared via silver transmetalation,

**Scheme 16** Ruthenium triazolylidene complexes accessed via C–H activation.

leading to formation of various products, including the cyclometalated products **108**, **111**, **112** and **113** through phenyl C–H bond activation (Scheme 16).<sup>126,127</sup> The group further demonstrated that stirring a solution of the ruthenium hydride **109** in  $\text{CD}_2\text{Cl}_2$  resulted in hydrogen elimination with concomitant phenyl cyclometallation (Scheme 16).<sup>126</sup> Addition of  $\text{H}_2$  to the cyclometalated product **113** immediately resulted in C(phenyl)–ruthenium bond cleavage, with decooordination of the phenyl pendant and formation of the hydride **114**. Continuous exposure to hydrogen gave rise to trz protonation and dissociation yielding **115**, en route to the triazolium salt **116** and the ruthenium hydride **117**. Due to the observed reactivity, the complexes could be successfully utilized as hydrogenation catalysts. Mechanistic considerations by Stephan et al. shows a catalytic pathway initiated by fast transformation of the cyclometalated species **113** to the corresponding hydride product **114** under a hydrogen gas atmosphere (Scheme 16). The authors further hypothesized the dissociation of a phosphine ligand with olefin coordination and subsequent insertion across the metal hydride bond. Reaction with  $\text{H}_2$  leads to product formation and regeneration of the active catalyst.<sup>126</sup>

Noninnocent ligand behavior was inferred for iridium complexes catalyzing the oxidation of water, with the catalyst facilitating the prevalent process with high TONs.<sup>129</sup> Employing ligand **118** (Scheme 17), the water oxidation catalysts could be accessed through double C–H activation of the ligand salt upon reacting with  $[\text{Cp}^*\text{IrCl}_2]_2$  ( $\text{Cp}^* = \text{pentamethylcyclopentadienyl}$ ), yielding two different C,C-chelated complexes. Pyridinium  $\text{C}(\text{sp}^2)\text{--H}$  bond activation leads to the five-membered metallacycle **119**. Alternatively,  $\text{C}(\text{sp}^3)\text{--H}$  bond activation resulted in formation of an iridium-containing ylide complex **120**, which is unusual as a strong base is generally required to access the ylide in classical pyridinium chemistry.<sup>129</sup> Both experimental and computational investigations elucidated the control effected by the remote substituent on the site of cyclometallation.<sup>130</sup> Of further note is addition of acetate to the reaction mixture during the complexation of the ligand to iridium, leading to N–CH<sub>3</sub> bond activation instead of the  $\text{C}(\text{sp}^2)\text{--H}$  or  $\text{C}(\text{sp}^3)\text{--H}$  bond activation (Scheme 17).<sup>131</sup> Consequent selective methylene transfer from the pyridinium moiety to the benzyl functional group has been paralleled to the methyltransferase activity in biological systems. Based on deuteration experiments followed with NMR spectroscopic analysis, Albrecht et al. proposed a preliminary reaction mechanism illuminating the methyl transfer and insertion process. Formation of **121** through initial carbene coordination is proposed to be followed by cyclometallation, either acetate assisted or via oxidative addition, yielding C,C-chelated complexes **122** and **123** (Scheme 17). Nitrile ligand substitution by the added acetate ensues with formation of **124**. The authors speculated formation of **125** via concerted C–H bond activation and  $\text{N}_{\text{pyr}}\text{--C}$  bond cleavage in **124**, mediated by the coordinating acetate ligand. Methylene insertion across the metal–phenyl bond is then followed by acetonitrile or benzonitrile coordination, with subsequent nitrile activation through nucleophilic addition of the anionic benzyl functionality yielding the imine coordinated complex **127**. Reacting the imine-containing triazolylidene complex with HCl further resulted in immediate dissociation of the imine donor followed by Schiff base reactivity to yield the carbonyl containing complex **128**.<sup>131</sup> Accordingly, the carbonyl oxygen could also potentially act as a noninnocent moiety assisting in bond making and breaking processes.

**Scheme 17** Pyridinium-containing trz iridium complexes for water oxidation and methyltransferase activity.

Noninnocent ligand roles of the cyclic (alkyl)(amino)carbene class of the nonclassical carbenes, apart from the inherent noninnocence discussed above, have also been exploited in metal-mediated processes. The unique reactivity of CAAC-metal complexes, compared to metal complexes coordinated by inert ligands, was eloquently demonstrated by a CAAC coordinated chromium complex, reported by Zeng et al.<sup>132</sup> Chromium complexes coordinated by CAAC ligands has previously been reported.<sup>133</sup> A CAAC ligand featuring a hemilabile imine pendant, first reported by Bertrand et al. (vide infra),<sup>134</sup> was coordinated to  $\text{CrCl}_3$  yielding the corresponding C,N-chelated  $\text{Cr}^{\text{III}}$  complex **129** (Scheme 18).<sup>132</sup> Zeng and co-workers determined that the CAAC coordinated chromium complex could mediate the deoxygenative hydroboration of nitro functional groups, yielding the corresponding amine derivatives. The catalytic deoxygenative hydroboration reaction was also realized with an analogous catalyst, such as a chromium complex coordinated by a classical NHC (featuring either an imine pendant or no hemilabile group at all), in addition to a CAAC coordinated chromium complex with no tethered donor functionality on the CAAC ligand. However, diminished catalytic reactivity for these analogous catalysts was reported, highlighting the requirement for the CAAC donor ligand to feature a hemilabile pendant. Various experiments and calculations allowed for insight into the catalytic reaction mechanism (Scheme 18).<sup>132</sup> Reduction of complex **129** from  $\text{Cr}^{\text{III}}$  to the  $\text{Cr}^0$  complex **130** by Mg is marked by a catalyst induction period, which is followed by THF ligand exchange for  $\text{PhNO}_2$  yielding **131**. The oxygen lone pair of  $\text{PhNO}_2$  in **131** can subsequently coordinate the boron from the added HBpin (HBpin = pinacolborane), leading to  $\sigma$ -bond metathesis and formation of the hydride intermediate (Scheme 18). This is followed by N–O bond scission with ensuing Cr–O bond formation. The noninnocent ligand effects the following step involving hydride migration. The hydride is transferred from the metal to the carbene with accompanying reversal of the polarity of the hydride. Proton transfer from the metal-bound carbon to the boron oxygen ensues, regenerating the carbene coordinated complex **132** with concomitant elimination of HOBpin (Scheme 18). This constitutes the first deoxygenation step. The second deoxygenation step yields the chromium nitrene complex **133**, with elimination of another HOBpin molecule (Scheme 18). Both HBpin and HOBpin contribute toward the reduction of the nitrene moiety, ultimately leading to  $\text{O}(\text{Bpin})_2$  elimination and release of the aniline product in a stepwise manner, regenerating the nitro-ligated active catalyst **131** (Scheme 18). Calculations evidenced the carbene's  $\pi$ -accepting attributes to accommodate a Cr unpaired d-type electron in the vacant p-orbital, facilitating the reversible proton transfer event.<sup>132</sup> Hydride transfer from a CAAC-coordinated dinuclear copper complex to the electrophilic carbene carbon has also been reported, albeit as an irreversible migratory process.<sup>135</sup>

Ligand cooperation not only applies for bond making and breaking processes, but also towards stabilization of reactive complexes, as discussed above.<sup>136</sup> Isolation of these reactive species allows insight into transient intermediates in catalysis, facilitating a better understanding of the catalytic processes. Bertrand and co-workers coordinated the menthyl-substituted CAAC ligand **41** to rhodium, resulting to formation of a stable 14-electron T-shaped rhodium complex **135** (Scheme 19). Crystal structure and NMR analysis of the complex in solution confirm two agostic interactions which provide stabilization towards the low-valent metal complex.<sup>136</sup> Furthermore, chloride abstraction of a menthyl-CAAC coordinated palladium complex<sup>56</sup> with a silver salt, yielded

**Scheme 18** Deoxygenative hydroboration catalyzed by a CAAC-Cr complex.

**Scheme 19** Agostic interactions stabilizing low-valent metal complexes.

a stable 14-electron cationic palladium complex **136**, featuring an agostic interaction as evidenced by X-ray diffraction and NMR analysis.<sup>136</sup> The corresponding cyclohexyl-substituted CAAC rhodium and palladium complexes could not be isolated.

### 1.05.2.2 Group 5 donor functionalized nonclassical carbenes

#### 1.05.2.2.1 *N*-donor functionalized carbenes

Noninnocent ligand roles of the group 5 atom functionalized nonclassical carbenes predominantly employ N-donors, although examples of P-donor tethered carbenes are known.<sup>137,138</sup> A bifunctional ligand, featuring the strongly donating imidazol-4-ylidene and a benzimidazolato motif, was developed towards facile hydrogenation of various aromatic and aliphatic aldehydes under atmospheric hydrogen pressure, room temperature, and base-free reaction conditions in the presence of water (**Scheme 20**).<sup>139</sup> The authors postulated that the noninnocent Im4 coordinated iridium complex **137** catalyzed this transformation via a rate-determining outer-sphere hydride transfer step, followed by a fast proton transfer event (**Scheme 20**). The two hydrogen transfer steps could be realized due to the bifunctional character of the ligand, with the strong donor Im4 increasing the hydric character of the hydride ligand, resulting to enhanced hydride transfer, while the benzimidazolato functionality mediated the proton transfer step via the basic imino moiety. It was established that the aldehyde hydrogenation reaction could be catalyzed chemoselectively in the presence of various functionalities. The catalytic reaction was shown to be scalable, with a 95% yield obtained for the alcohol at a 5 mmol scale. A plausible reaction mechanism included a 'switch' between the imine nitrogen of complex **139** and an iridium coordinated amine nitrogen in **140**, facilitating the fast proton transfer step and completing the catalytic cycle, regenerating **138** and yielding the targeted product (**Scheme 20**).<sup>139</sup>

Choudhury et al. further exploited the analogous iridium complex towards storage of hydrogen at ambient pressure and subsequent release at 90 °C, via the carbon dioxide-formic acid couple.<sup>140</sup> Development of a homogeneous catalyst facilitating both the

**Scheme 20** Bifunctional imidazol-4-ylidene ligand featuring a benzimidazolato motif.

storage and release of hydrogen from a carrier liquid would contribute towards the advancement of green processes, as it allows for the risk mitigated transport of the volatile substance.<sup>141–143</sup> Accordingly, the iridium complex reported by the group of Choudhury was shown to promote both the hydrogen storage and release reactions, switching between the two processes via pH adjustment (**Scheme 21**).<sup>140</sup> Hydrogen incorporation was catalyzed by the C,N-chelated iridium complex **141** with a solution pH of 8.5, attained through the addition of base (**Scheme 21, i**). Hydrogen coordinates to the metal yielding intermediate **143** from **142**, followed by H<sub>2</sub> cleavage leading to formation of the hydride complex **144**, with base-mediated proton abstraction hypothesized. Iridium formate **145** is obtained after metal-bound hydride transfer from **144** to either CO<sub>2</sub> or in situ generated HCO<sub>3</sub><sup>−</sup>. This leads to formate release and regeneration of the active iridium catalyst **142** upon reacting with aqueous KOH. In contrast to the formation of formate, the liberation of hydrogen occurs under acidic conditions (**Scheme 21, ii**). The mechanism postulated for the release of hydrogen from formate involves the simultaneous protonation of the basic *exo* nitrogen of the benzimidazole moiety with HCO<sub>2</sub>H and coordination of HCO<sub>2</sub><sup>−</sup> to iridium. An equilibrium ensues between the metal bound anionic amido nitrogen **146** and the imino-coordinated iridium complex **147**, after imine protonation (**Scheme 21, ii**),<sup>140</sup> resembling the imine-amine switch in the aldehyde hydrogenation mechanism discussed above (see **139** and **140** in **Scheme 20**).<sup>139</sup> β-Hydride elimination proceeds from the equilibrium, releasing CO<sub>2</sub> and yielding **148** (**Scheme 20, ii**).<sup>140</sup> Presumably, HCO<sub>2</sub>H forms a hydrogen bond with the distal γ-NH of **148** leading to intermediate **149**, followed by formic acid and H<sub>2</sub> formation with subsequent release of H<sub>2</sub> yielding **146** (**Scheme 21, ii**). The noninnocent role of the ligand allows for the hydrogen transfer events, while the significance of the nonclassical carbene was illustrated upon comparison to the analogous benzimidazole tethered pyridinylidene complex which demonstrated poor catalytic performance in both reactions. The increased catalytic performance was attributed to the stronger donor characteristics of the Im4, inducing increased hydride character and a decreased hydride transfer energy barrier. The iridium catalyst was also demonstrated to facilitate the CO<sub>2</sub>-transfer hydrogenation catalysis at ambient pressure using biomass-derived alcohols such as glycerol, as the source of hydrogen.<sup>144</sup> Hydrogen storage and release,<sup>140</sup> as well as the hydrogenation of CO<sub>2</sub>,<sup>144</sup> substantiate the requirement for noninnocent ligand design with stronger donor carbenes, as both case studies demonstrate relevance towards more environmentally friendly processes.

The same group furthered investigations into switchable catalysis, in this case scrutinizing an acid/base-responsive complex towards hydrogenation of quinoxalines.<sup>145</sup> Accordingly, a nonclassical carbene tethered by a uracil motif was coordinated to iridium (**152**, **Scheme 22**). The incorporation of the uracil motif was rationalized by the possible lactam-lactim tautomerization, which would render the ligand noninnocent and subsequently aid in heterolytic H<sub>2</sub> activation towards hydrogenation. Choudhury et al. determined that the complex could catalyze the hydrogenation of quinoxaline with 1 mol% catalyst loading, under atmospheric hydrogen gas pressure at 50 °C in just 90 min. The catalyst could be switched off through the addition of base and switched back on via the addition of HCl (**Scheme 22**). Thus, charging a solution of the neutral analog of **152** (where L = Cl) with H<sub>2</sub>, yielded the corresponding iridium hydride intermediate **155** through heterolytic H<sub>2</sub> cleavage aided by the noninnocent ligand, with protonation of the uracil carbonyl moiety forming the Ir–N=C–OH fragment.<sup>145</sup> Heterolytic cleavage is followed by quinoxaline hydrogenation, which is proposed to occur via an outer-sphere mechanism. Catalysis is however halted by the addition of base, a result of the base capturing H<sup>+</sup> from the heterolytic H<sub>2</sub> cleavage process. Proton transfer to the quinoxaline is therefore ceased, which subsequently inhibits hydride transfer (**Scheme 22**). The catalyst could be switched on again through the addition of HCl, and the catalyst switching process could be repeated several times.

Tethering of a pyridine functionality to a carbene donor ligand allows for the preparation of C,N-chelating ligands, with the possibility of yielding an inert nitrogen-metal bond upon chelation. Alternatively, the coordination/decoordination of the pyridine moiety can affect a hemilabile noninnocent role,<sup>10–12,18,19,21,23,24,94,95</sup> closely resembling the contributions of the pyridine functionality in the well-known PEPPSI-type complexes (PEPPSI = Pyridine Enhanced Precatalyst Preparation Stabilization and Initiation).<sup>146–162</sup> From an electronic point of view, the trz-pyridyl combination results in increased donor strength compared to the pyridine-triazole C,N-chelating derivatives and the analogous bis-triazole and 2,2'-bipyridine N,N-chelating ligands, while lower

**Scheme 22** Acid/base switchable hydrogenation catalyst.

donating capabilities are seen when likened against the bis-trz C,C-chelating ligand<sup>163</sup> (see Fig. 4 for representative examples of the mentioned bidentate ligands). Scrutinizing the  $\pi$ -acceptor properties of the trz-pyridyl ligand reveals that only the 2,2'-bipyridine ligand has improved  $\pi$ -acceptor capabilities, with the abovementioned N,N-bistriazole, C,N- and C,C-chelating ligands demonstrating decreased  $\pi$ -acceptor properties. Arguably, these features provide a balance between donor-acceptor strength of the bidentate trz-pyridyl ligand, while at the same time providing stabilization due to chelation in addition to possible metal coordination/decoordination affecting a bifunctional role. Not surprising then is the number of documented examples of trz ligands featuring a pyridine hemilabile donor.<sup>30,33,35,37</sup>

At the onset of the previous decade, Albrecht et al. reported ruthenium complexes chelated by a trz-pyridyl ligand, with coordination of the nitrogen moiety to the metal (Fig. 3).<sup>62</sup> Similarly, the corresponding C,N-chelated iridium complexes were also disclosed (Fig. 3).<sup>63,164</sup> It was determined that in the presence of sacrificial oxidant, both the ruthenium and iridium complexes catalyzed the oxidation of water,<sup>62,63,165</sup> with the cationic pyridine coordinated ruthenium complexes displaying selectivity towards oxygen (Fig. 3), contrasting to the cymene coordinated ruthenium complexes investigated in the study which formed CO<sub>2</sub> in addition to O<sub>2</sub>.<sup>62</sup> The iridium complexes depicted in Fig. 3 displayed selectivity towards oxygen.<sup>63</sup> However, catalytic activity for the C,N-chelated complexes was still lower compared against the C-bound iridium complexes described above (see Scheme 17).<sup>129</sup> Stable complex formation due to rigid C,C-chelation versus trz-pyridyl chelation could rationalize the difference noted in catalytic activity, similar to the reported example of a trz-thiazole C,N-chelated iridium complex with increased water oxidation catalytic activity compared against an analogous benzoxazole-tethered triazolylidene iridium complex.<sup>166</sup>

The group of Albrecht et al. also described the storage and release of hydrogen from a carrier molecule<sup>167</sup> similar to the trz-pyridyl coordinated iridium complex 141 described above.<sup>140</sup> Hydrogenation and dehydrogenation of N-heteroarenes were mediated by iridium trz-pyridyl catalysts.<sup>167</sup> It was established that the two iridium complexes 164 (Fig. 3) and 177 (Scheme 23) could catalyze both the hydrogenation and the dehydrogenation of quinolines, either in the presence or absence of hydrogen, respectively (Scheme 23, i). The iridium complexes further demonstrated its functional group tolerance with the hydrogenation of a variety of quinolines with varying substituents. The authors' mechanistic consideration proposed a roll-over cyclometalation,<sup>168</sup> which in the presence of hydrogen and D<sub>2</sub>O as solvent<sup>167</sup> results in formation of a C,C-chelated iridium intermediate leading to deuteration of the C6 of the pyridyl pendant, yielding 176 (Scheme 23, ii). Dissociation and coordination of the pyridine nitrogen therefore allows for the deuteration to proceed, with selective deuteration at the C6 position. The proposed mechanism for hydrogen activation by the trz-pyridyl chelated iridium complex 164 in the presence of hydrogen and D<sub>2</sub>O is depicted in Scheme 23. Deuteration at the C6 position of the C,C-chelated complex 177 was also demonstrated. However, for complex 177, deuteration occurred at both the C6 position and the pendant phenyl substituent, with concomitant formation of 178 (Scheme 23, iii).<sup>167</sup>

Another pyridine tethered trz complex, a palladium complex 179, was reported to catalyze the intermolecular hydroamination reaction between anilines and terminal alkynes yielding the corresponding imines.<sup>169</sup> Both the classical NHC as well as the trz containing Pd-PEPSSI complexes showed no reactivity towards the intermolecular hydroamination catalyzed reaction. This clearly illustrated the requirement for both the stronger donor nonclassical carbene in conjunction with the tethered donor moiety to access noninnocent reactivity. Complex stabilization is mediated through pyridine to metal association (Scheme 24, i). Pyridine dissociation from palladium 179 opens the catalytic pocket, exposing a coordination site in the metal's first coordination sphere for subsequent  $\eta^2$ -acetylene coordination via one of the alkyne's  $\pi$ -bonds (Scheme 24, i). The decoordinated pyridine pendant arm was reported to be in close proximity to the Pd center (<5.0 Å), as requisite for successful catalysis (vide supra).<sup>169</sup> The basic nitrogen subsequently facilitates the proton transfer events between the catalyst and the catalytic intermediates, working in tandem with the Pd metal center to furnish the imines at room temperature with exclusive Markovnikov selectivity (Scheme 24, ii). The noninnocent nonclassical carbene containing palladium complex could also catalyze the Sonagashira coupling reaction between an aryl halide and a terminal alkyne.<sup>170,171</sup> This could be achieved either through employing the trz palladium complex as shown,<sup>170</sup> or in conjunction with a second palladium complex coordinated by a phosphine donor ligand.<sup>171</sup>

Sarkar and co-workers demonstrated the  $\sigma$ -donor  $\pi$ -acceptor balance of the trz-pyridyl ligand<sup>163</sup> during both the electrocatalytic H<sub>2</sub> production employing a cobalt catalyst with acetic acid as the proton source (Fig. 4, i),<sup>172</sup> as well as the oxygenation of sp<sup>3</sup> C-H bonds using iridium chelated complexes as catalysts (Fig. 4, ii).<sup>173</sup> The trz-pyridyl ligand was compared

Fig. 3 Water oxidation catalysts featuring trz-pyridyl C,N-chelating ligands.

**Scheme 23** Proposed roll-over cyclometalation leading to pendant substituent deuteration.<sup>167</sup> Modified from Vivancos, Á; Beller, M.; Albrecht, M. *ACS Catal.* **2018**, *8*, 17–21.

against C,N-, C,C- and N,N-chelating ligands, displaying superior catalytic activity for the trz-pyridyl chelated metal complexes.<sup>172,173</sup> Košmrlj and Sarkar also investigated the effect of structure variation of the trz-pyridyl ligand, introducing either a methylene spacer between the pyridine and the trz moieties [Fig. 4, iii (a)],<sup>174,175</sup> or a second nitrogen at the pyridine site yielding the corresponding pyrimidine appended trz ligand [Fig. 4, iii (b)].<sup>176</sup> When equated against the analogous

iii) Structural variation of the privileged chelate

**Fig. 4** Towards improved catalyst with trz-pyridyl and trz-pyrimidine chelating ligands.

trz-pyridyl metal complexes, improved catalytic performance was observed.<sup>174,176</sup> Enhanced selectivity in the catalyzed alcohol oxidation reaction was noted for the six-membered metallacycle complex, compared against the five-membered trz-pyridyl ruthenium complex derivatives investigated [Fig. 4, iii (a)].<sup>174</sup> Sandoval et al. also reported a similar picolyl tethered trz ruthenium complex, in addition to its catalytic transfer hydrogenation activity.<sup>177</sup> Trz-pyrimidine chelated complexes catalyzed various reduction reactions with increased catalytic activity when compared with the equivalent trz-pyridine complexes, reported to be the effect of pyridine substitution with the pyrimidine pendant [Fig. 4, iii (b)].<sup>176</sup> It is therefore evident that even minor structural variation of the privileged trz-pyridyl chelate can accomplish improved catalytic activity and/or selectivity.<sup>174,176</sup>

A slightly varied ligand design approach utilizes a pendant donor moiety, tethered to a triazolium-pyridyl C,N-bidentate proligand.<sup>178–182</sup> Chelation of the C,N-bidentate ligand results in an increased yaw angle (Scheme 25, i), which disfavors coordination of the pendant donor to the metal center, but at the same time securing the pendant donor in close proximity to the metal.<sup>178,179</sup> Substrate recognition and binding can subsequently be mediated by the noncoordinating Lewis basic pendant. Concomitantly, the metal can complete the catalytic processes while exploiting the attributes imparted by the privileged trz-pyridyl chelate to mediate

**Scheme 25** Functional group tethered trz-pyridine C,N-chelated iridium complexes.

the sought-after process/es. The design methodology centered around the Lewis acidic metal in tandem with the Lewis basic donor group, parallels the well-known frustrated Lewis acid-base pairs.<sup>183–185</sup> Accordingly, Albrecht et al. prepared triazolium-pyridyl C,N-bidentate ligand precursors containing either a phenyl or a second pyridine functionality (Scheme 25, ii).<sup>178</sup> Coordination to iridium formed the corresponding C,N-chelated iridium complexes, with the pyridine 195 or phenyl 196 pendant moiety in close proximity to the metal center, but not coordinating to the iridium coordination sphere. The complexes were determined to be catalytically active in the base- and oxidant-free oxidative dehydrogenation of amines yielding the corresponding imines. The catalytic activity and selectivity were advantageously influenced by the presence of the hemilabile pyridine moiety. Stoichiometric investigations with X-ray diffraction, NMR and IR spectroscopic analysis confirmed the noninnocent behavior of the chelating ligand, exposing the substrate to pyridine hydrogen bond formation upon coordination of an amine substrate in 197, after addition of one equivalent of silver triflate to 195 (Scheme 25, ii). Addition of a second equivalent of silver triflate yielded complex 198, with silver coordinated by the pyridine nitrogen. The use of the phenyl substituted trz-pyridyl complex 196 did not amount to any substrate recognition and binding to the ligand backbone, only substrate coordination to the metal upon addition of silver triflate, yielding 199. The elegance behind the design of the pyridine tethered trz-pyridyl ligand is rooted in the fact that dehydrogenative coupling of amines requires N–H bond activation and elimination of hydrogen. Transition metals are celebrated for mediating  $\beta$ -hydrogen elimination reactions,<sup>3</sup> while N–H bond activation necessitates a Lewis base.<sup>183–185</sup> Complex 195 features both the mentioned requirements.<sup>178</sup>

In addition to the reports above, the group of Albrecht also reported the preparation of nitrogen functionalized hemilabile trz ligand salts for complexation to a gold(I) metal center.<sup>186</sup> Bidentate ligand coordination yielding a chelated mononuclear gold(I) complex was not reported. Instead, dinuclear gold(I) complexes were formed upon ligation, with coordination of the ligand's carbene moiety to a gold atom, while the amine functionality coordinated the second gold center. The chiral biscarbene dinuclear gold(I) complexes were found to be catalytically active in the aldol condensation reaction between various aldehydes and methyl isocanoacetate. However, the catalytically active species in the aldol condensation reactions was attributed to gold nanoparticle formation upon ligand dissociation.<sup>186</sup> The diarylated nitrogen tethered trz ligand analogs were reported a few years later, with nitrogen coordination and formation of bidentate mononuclear rhodium(I) complexes (Scheme 26).<sup>187</sup> The hemilabile donor was varied between either an amine 200, dimethylamine 201 or Boc (*tert*-butyloxycarbonyl) protected amine 202, functional group. The rhodium complexes were investigated as alkyne hydrothiolation catalysts and determined to be highly selective towards the formation of the Markovnikov-type  $\alpha$ -vinyl sulfide product. The catalytic reaction mechanism was described, in the case of the amine or dimethylamine substituted ligand complexes 200 and 201, respectively, as hemilabile coordination/decoordination, stabilizing the metal center when required while yielding an active catalyst upon catalyst initiation. It was determined that the addition of  $K_2CO_3$  was required to ensure selectivity towards the  $\alpha$ -vinyl sulfide product. However, the rhodium complex 202 featuring the NBoc-protected ligand displayed a different reaction mechanism (Scheme 26). Thiol deprotonation was mediated by the Boc-protected amine moiety, yielding the HNBoc-pendant arm as well as the metal thiolate complex. This was followed by alkyne

**Scheme 26** Alkyne hydrothiolation catalyzed by nitrogen tethered triazolylidene rhodium complexes.

coordination with subsequent migratory insertion and finally, thiol protonolysis yielding the catalytically active intermediate (Scheme 26). The incorporation of the NBoc-protected ligand allowed for catalysis via a non-oxidative addition mechanism, circumventing the formation of  $\text{Rh}^{\text{III}}$  catalytic intermediates,<sup>188,189</sup> while retaining the high selectivity towards the  $\alpha$ -vinyl sulfide product. This again illustrates the importance of ligand design and noninnocent ligands, as the reaction can be completed without the addition of base which allows for an even 'greener' method towards the preparation of vinyl sulfides.<sup>187</sup>

Nonclassical carbenes have also been incorporated into the privileged pincer platform, harnessing the increased electron donating properties of the carbene moieties<sup>33</sup> and combining it with the stability imparted by a tridentate pincer into one ligand scaffold.<sup>190–199</sup> Pincer ligands featuring nonclassical carbenes have been reported,<sup>33,58,59,200–214</sup> albeit only a few exhibit a noninnocent role. One such example reports the combination of trz with the lutidine fragment, as disclosed by van der Vlugt, Elsevier and co-workers.<sup>215</sup> The incorporation of the lutidine backbone is not surprising, as this is a known motif for ligand cooperativity via aromatization/dearomatization (Scheme 13, i).<sup>6–9,20,86–93</sup> Accordingly, alkylation of both triazoles flanking the pyridine moiety yielded the corresponding bistriazolium ligand salt.<sup>215</sup> Subsequent silver transmetalation from the silver carbene complex with a ruthenium metal precursor resulted in formation of the corresponding ruthenium complex 203 (Scheme 27). The pincer ruthenium complexes were demonstrated to catalytically mediate the hydrogenation of carboxylic esters to alcohols, in the presence of base and  $\text{H}_2$ . Stoichiometric experiments involving the addition of base or acid evidenced the sought-after aromatization/dearomatization reactivity, which was postulated to participate in the catalytic hydrogenation process alongside the added base (Scheme 27). Addition of base resulted to the dearomatized complex 204, while adding HCl yielded the aromatized product 205.

Metals that are classically viewed as inert can be coerced to react under mild conditions by effective ligand tailoring. This was demonstrated by the 'remote basicity' imparted by a pincer bis(triazolylidene)carbazole ligand, which rendered a gold(I) metal site nucleophilic (206, Scheme 28).<sup>216</sup> Furthermore, 206 featured an unusual T-shaped geometry around the gold(I) metal, a result

**Scheme 27** Aromatization/dearomatization of a bistriazolylidene-lutidine ruthenium complex.

**Scheme 28** Oxidation of T-shaped gold(I) complexes towards square planar gold(III) complexes.

of the tridentate pincer ligand anchoring the metal into a constrained geometry. These main attributes allowed for protonation of the coinage metal **206** followed by mild oxidation, yielding the corresponding cationic gold(III) hydrides **207** or **208**. Protic rather than hydridic character was established for **207** upon stoichiometric treatment with either acid or base. No reactivity was noted for **207** under acidic conditions but **207** reacted cleanly with sodium hydride liberating  $H_2$  and yielding the gold(I) complex **206**. The electrophilic oxidation strategy was extended to include oxidation of the gold(I) pincer complex with electrophilic alkylating reagents (Scheme 28), leading to alkylation of either the amido nitrogen or the gold(I), and subsequent oxidation of the metal yielding the corresponding cationic gold(III) alkyl complex **211**. Reacting the T-shaped gold(I) complex with Selectfluor resulted in the first example of a stable, well-defined monomeric cationic gold(III) fluoride complex **213**.<sup>217</sup> The bis(trz)carbazolide imparts unique, unprecedented reactivity to the gold(I) metal center,<sup>216,217</sup> as an important contribution to the recent realization that mild gold oxidation can be accessed through appropriate ligand design.<sup>218–221</sup>

Gold(I) coordination to another noninnocent nonclassical carbene, in this case, a bifunctional CAAC ligand, could likewise accomplish mild oxidation.<sup>134</sup> The group of Bertrand expanded the library of CAACs to comprise a range of hemilabile functional group containing ligand salts (Scheme 29, i). The hemilabile groups consisted of various functionalities, which included an ethoxy **214**, alkenes **215** and **216**, amine **217**, iodo **219** and even a phosphine **220** containing functional group. The imine containing ligand salt **218**<sup>134</sup> introduced above,<sup>132</sup> was again of particular interest. Treatment of the corresponding gold(I) complex **221**<sup>134</sup> with  $KB(C_6F_5)_4$  followed by addition of biphenylene resulted in oxidative addition of the biphenylene substrate across the gold(I) metal, yielding the corresponding cationic gold(III) complex **223** (Scheme 29, ii), similar to the seminal report by Toste et al.<sup>222</sup> The reaction was only successful in the presence of the hemilabile functionality.<sup>134</sup> The gold(I) complex **221** and its copper analog **222** were also found to be catalytically active in the hydroarylation of  $\alpha$ -methylstyrenes with *N,N*-dimethyl aniline (Scheme 29, iii). The reaction is known to involve a proton transfer step, implicating the basic hemilabile functionality in ligand assisted coinage metal catalysis. The copper containing CAAC complex with the imine hemilabile tether (**218**) was further verified to selectively catalyze the hydroamination of phenyl acetylene with dimethylhydrazine, affording the *anti*-Markovnikov product **225** with 96% selectivity (Scheme 29, iv). The pendant imine moiety has a pronounced influence on the outcome of the reaction, as the corresponding copper complex without a tethered pendant catalyzed the aforementioned hydroamination reaction with diminished selectivity.

The imine-containing CAAC ligand **218** (Scheme 29, i)<sup>134</sup> was also coordinated to palladium, allowing for isolation of highly reactive complexes demonstrating unique reactivity.<sup>223</sup> One such reactive and elusive complex is a palladium(II) terminal imido complex (**228**, Scheme 30, i), obtained through reduction of the palladium(II) chloride **226** followed by oxidation of **227** with tosyl azide (Scheme 30, i). Reduction with  $KC_8$  in pyridine was accompanied with decoordination of the imine moiety,<sup>223</sup> yielding the 14-electron pyridine substituted palladium complex **227**.<sup>224</sup> Subsequent oxidation allows re-coordination of the pendant donor and formation of the target complex **228**.<sup>223</sup> In both examples, complex stability could be mediated, in part, by cooperation of the hemilabile pendant which stabilizes the various oxidation states of the metal either via coordination or decoordination. Additionally, it was established that the CAAC supported palladium(0) complex **227** could facilitate the reversible oxidative addition of water, isopropanol, hexafluoroisopropanol, phenol and aniline at room temperature, reactions generally deemed as unfeasible for palladium.<sup>224</sup> Accordingly, the addition of water to **227** resulted in substitution of the pyridine ligand and oxidative addition of  $H_2O$ , with concomitant imine coordination stabilizing the suggested intermediary palladium (hydrido)(hydroxo) complex **229** *en route* to **230** via hydride transfer (Scheme 30, i). Computational analysis elucidated the influence of the pendant imine on the reaction. It was determined that the hemilabile donor moderately stabilizes the transition state during the oxidative addition of water, while trapping the square planar palladium product through coordination after oxidation,<sup>224</sup> akin to the oxidative addition of biphenylene to gold (*vide supra*) (Scheme 29).<sup>134</sup> Hydride migration from the carbene carbon in **229** yields the palladium hydroxo complex **230**, which dimerizes to form the stable palladium dimer **231** (Scheme 30).<sup>224</sup> The palladium(0) complex **227** could be regenerated through the addition of excess pyridine to **230**, resulting in reduction of the dimer complex **231**,

**Scheme 29** Hemilabile substituted cyclic alkyl amino carbenes.<sup>134</sup> Modified from Chu, J.; Munz, D.; Jazzar, R.; Melaimi, M.; Bertrand, G. *J. Am. Chem. Soc.* **2016**, *138*, 7884–7887.

**Scheme 30** Palladium complexes coordinated by a CAAC ligand featuring a hemilabile imine donor.

elimination of water and decoordination of the tethered imine from palladium (**Scheme 30, i**). Reacting the palladium dimer **231** with 4-*tert*-butylphenylacetylene afforded the Pd<sup>II</sup> acetylide complex **232** with hemilabile coordination to the monomeric metal, in addition to water being eliminated from the reaction (**Scheme 30, ii**). However, addition of 4-*tert*-butylphenylacetylene to the Pd<sup>0</sup> complex **227** did not result in oxidative addition. Rather, the  $\pi$ -complex **233** was obtained with coordination of the hemilabile donor to the palladium metal (**Scheme 30, ii**). The reactivity, and outcome thereof, in the presence and absence of water illuminates the requirement of water for oxidative addition of weak C–H bonds to ensue.

The hydridic nature of the hydride migrating to the carbene carbon was evidenced upon treatment of the hydroxo complex **234** with HCl, leading first to formation of **235**, namely the palladium chloride dimer (**Scheme 30, iii**). Addition of another equivalent of HCl was followed by hydride transfer back to the palladium metal, with subsequent H<sub>2</sub> elimination, yielding palladium(II) chloride **237** with imine pendant coordination (**Scheme 30, iii**).<sup>224</sup> This contrasts the hydride transfer step noted above for the analogous chromium complex **129**, where hydride transfer from the metal to the carbene carbon was accompanied with a reversal of the polarity of the hydride ligand, and subsequent proton transfer to the substrate (see **Scheme 18** above).<sup>132</sup> The reversible and facile oxidative addition mediated by **227** was exploited in several catalytic reactions, such as the mild transfer hydrogenation reaction catalyzed without the need for additives, cross-coupling of esters with aniline and borylation of alcohols and amines with bis(pinacolato)diboron (B<sub>2</sub>Pin<sub>2</sub>) (**Scheme 30, iv**).<sup>224</sup> The oxidative addition of water was further utilized as a switch in catalytic activity, with dry reaction conditions mediating the alkyne dimerization reaction yielding enynes, while addition of water resulted to polyacetylene formation from the starting terminal alkyne (**Scheme 30, v**). As is evident from the above examples, combining the inherent noninnocent properties of the CAACs with a noninnocent hemilabile pendant, allows access to highly reactive complexes with atypical or even unknown reactivity patterns. Of particular significance is the multiple noninnocent roles fulfilled by a singular

ligand design strategy, with the noninnocent processes facilitated either by the imine pendant,<sup>134</sup> the carbene carbon,<sup>132</sup> or the mid-road taken with either the imine *or* carbene carbon directly involved in the noninnocent role.<sup>223,224</sup>

### 1.05.2.3 Chalcogen donor functionalized nonclassical carbenes

#### 1.05.2.3.1 O-donor functionalized carbenes

Incorporation of oxygen into multifunctional ligands, ultimately towards noninnocent ligand design, has also been investigated.<sup>8,14–16,23,29,97,101,122,225–230</sup> The rationale includes the acid base mismatch, imparted by the use of the hard-basic oxygen donor with the Lewis acidic metal, which constitutes a soft Lewis metal in most examples. Akin to the nitrogen donor functionalized ligands, the presence of the oxygen donor could possibly effect a hemilabile role through coordination/decoordination to the metal or provide a basic site towards electrophilic substrate recognition and binding, followed by substrate activation. Apart from the mentioned multifunctional roles, an alternative noninnocent role imparted by the oxygen donor could also be imagined. Hence, the combination of noninnocent carbenes and oxygen containing moieties are prevalent albeit less explored compared to the nitrogen based multifunctional nonclassical carbenes.

The group of Bera focused on annulated Im4,<sup>231–235</sup> and more specifically, reported on the preparation of an iridium complex coordinated by a hydroxy containing imidazo-naphthyridine ligand (**238**, Scheme 31).<sup>236</sup> It was reasoned that the strong donor characteristics of the nonclassical carbene would mediate improved hydride transfer from the metal to the substrate. Moreover, chelation of the annulated ligand would suppress ligand dissociation, while an extended  $\pi$ -conjugated system should facilitate aromatization/dearomatization processes. Most importantly, the presence of the hydroxyl functionality would mediate a proton responsive role, ensuring metal-ligand cooperativity. Accordingly, the lactam-lactim tautomerization was realized via stoichiometric addition of acid or base, with NMR and UV-vis spectroscopy confirming the reversible aromatization/dearomatization (Scheme 31). The iridium complex **238** was employed in the catalytic reductive amination of aldehydes.<sup>236</sup> It was established that **238** catalyzed the reduction reaction using one of three different hydrogen sources, either molecular hydrogen, *i*PrOH/*KO*<sup>t</sup>Bu combination or an azeotropic mixture of HCOOH/*Et*<sub>3</sub>N in a 5:2 ratio. For the catalyzed reaction utilizing the HCOOH/*Et*<sub>3</sub>N azeotrope, a turnover frequency (TOF) of 645 h<sup>-1</sup> was noted while for the catalyzed reactions using either H<sub>2</sub> or the *i*PrOH/*KO*<sup>t</sup>Bu combination, the TOF was reported to be 33 h<sup>-1</sup> and 1.82 h<sup>-1</sup>, respectively. Of particular note was the different mechanistic considerations, computed or postulated for each of the catalytic systems, depending on the hydrogen source. For the best performing catalytic system, which involved the HCOOH/*Et*<sub>3</sub>N azeotrope, ion-pair decarboxylation results in iridium hydride

**Scheme 31** Proton responsive nonclassical carbene coordinated iridium complex towards amine preparation from aldehydes.

formation, with subsequent outer-sphere hydride transfer to the protonated imine leading to product formation, as supported by calculations. For the transfer hydrogenation exploiting the <sup>t</sup>PrOH/KO<sup>t</sup>Bu combination, Bera et al. proposed the formation of the solvated complex 241 from the cationic active species 240 (Scheme 31), with the anionic form of the ligand stabilized by a solvated potassium ion (241, Scheme 31).<sup>236</sup> This is followed by formation of the metal hydride 242, via an outer-sphere mechanism. Finally, amine formation is speculated to occur through both hydride and proton transfer from the iridium hydride and a proton from a solvent molecule, respectively. Direct hydrogenation was postulated and supported by computational calculations to ensue from the cationic active species 240, first via H<sub>2</sub> coordination yielding intermediate 244 (Scheme 31). Successive heterolytic H<sub>2</sub> cleavage across the metal and the lactam oxygen of 245 leads to ligand aromatization and subsequent lactim and iridium hydride formation, yielding intermediate 246. A synchronous process, involving hydride and proton transfer to the imine substrate, achieves product formation and regeneration of the catalytically active species via the imine H-bonded intermediate 247. The complex is therefore proposed to be able to mediate the catalytic reductive amination through three distinct mechanisms, with the ligand either being inert or facilitating the catalytic reaction via two discrete ligand cooperative pathways.

Albrecht et al. harnessed the electron donating contribution imparted by trz and combined it with an oxygen containing fragment, towards multifunctional ligand design featuring a basic oxygen hemilabile donor.<sup>237</sup> Ruthenation of an ester containing bidentate ligand 248 resulted to C,O-chelation via loss of the methyl group with formation of 249, presumed to have occurred through ester hydrolysis under the basic reaction conditions (Scheme 32, i). The catalytic alcohol dehydrogenation and transfer hydrogenation activity of the C,O-chelated ruthenium complexes were also investigated, and determined to be lower compared against the analogous trz-pyridyl complexes<sup>237</sup> (see Fig. 3). Additionally, gold(I) complexes 252 and 253 coordinated by either an alcohol or an acetate tethered trz carbene, respectively, was also reported by the same group (Scheme 32, ii).<sup>238</sup> It is well-known that coordination compounds of gold(I) generally results in linear complex formation,<sup>218,219</sup> which was also the case with the C,O-functionalized ligands.<sup>238</sup> Further development of the oxygen-tethered trz class of ligands involved coordination of a trz-containing C,O-bidentate ligand to nickel, leading to the isolation of the nickel complex 254 (Scheme 32, iii).<sup>239</sup> The nickel complex catalyzes the hydrosilylation of C=O bonds with a catalytic efficiency comparable to some of the best hydrosilylation catalysts reported to date. Moreover, the nonclassical carbene coordinated nickel complex 254 outperformed the classical NHC supported complex derivatives. The O-pendant introduced cooperativity to the complex, as PhSiH<sub>3</sub> reacted with 254 across the nickel-oxygen bond (Scheme 32, iii). This resulted to cleavage of the metal oxygen bond, yielding the catalytically active nickel hydride species 255 and 256. The contribution of multiple factors, such as the incorporation of nonclassical carbenes imparting increased donor strength to the metal, the stabilizing chelate effect which limits catalyst decomposition as noted for the monodentate nickel complexes,<sup>240</sup> in addition to cooperativity leading to the catalytically active species, again evidence the importance of appropriate ligand design to access highly active catalysts.<sup>239</sup>

Iridium(I),<sup>241</sup> iridium(III)<sup>242</sup> and ruthenium(II)<sup>242</sup> complexes coordinated by C,O-bidentate ligands featuring either an alcohol tether,<sup>242</sup> or an ether pendant<sup>241,242</sup> were also disclosed. Chelation was realized through chloride substitution, either during metalation or via chloride scavenging, yielding C,O-chelated iridium complexes 259 and 260, in addition to ruthenium complex 264 (Scheme 33).<sup>242</sup> Addition of brine to the chelated ruthenium complex 264 resulted in metallacycle ring-opening and re-formation of the hydroxyl tethered complex 263, demonstrating reversible hydroxyl binding and therefore the hemilabile nature of the tether. Transfer hydrogenation catalysis utilizing the iridium complexes proved that the pendant O-donor does have a marked influence on the catalytic activity, as the unfunctionalized complex 261 demonstrated significantly reduced catalytic activity. Furthermore, the iridium complex 257 featuring a hydroxyl pendant was reported to facilitate the hydrogenation with improved catalytic activity when compared against the ether functionalized complex 258 (Scheme 33). Stoichiometric experiments of

**Scheme 32** Mono- or bidentate complex formation with oxygen tethered triazolylidene ligands.

**Scheme 33** Towards O-donor functionalized hemilabile ligands.

$\text{Cs}_2\text{CO}_3$  addition to 259 evidenced iridium-alkoxide formation. As a consequence, the impact of the hydroxyl functionality was postulated to impart increased electron density to the metal during catalysis upon metal-bound alkoxide bond formation, subsequently increasing the catalytic activity. An alternative role was also hypothesized by the authors, involving dihydrogen abstraction via an outer-sphere mechanism with concomitant hydride and proton transfer to the substrate. The analogous ruthenium complexes demonstrate superior transfer hydrogenation catalytic activity compared to the iridium complexes, with no real difference noted between the ruthenium complexes containing either the O-functionalized pendants or the unfunctionalized ligands. Accordingly, an inner-sphere monohydride mechanism was credited as the reaction mechanism at play during the ruthenium catalyzed hydrogenation reaction. Thus, generalization of ligand cooperativity should be made only with careful consideration.<sup>242</sup> Metalation of the hydroxyl and ether substituted trz proligands, in addition to an ester containing triazolium salt, was also extended to include palladium, rhodium and iridium(I).<sup>243</sup> Oxygen coordination of the ester and ether hemilabile substituent to the trz supported palladium, rhodium and iridium complexes was not reported. However, the presence of the oxygen moiety could still function as a hard-basic site, that can aid catalysis implicating the ligand as noninnocent. On the other hand, addition of  $\text{Cs}_2\text{CO}_3$  to the alcohol containing trz palladium complex 267 resulted to metal-alkoxide bond formation, yielding 270 (Scheme 33). The rhodium and iridium complexes also yielded the corresponding alkoxide products, albeit through in situ deprotonation of the ligand with  $\text{KN}[\text{Si}(\text{CH}_3)_3]$  followed by coordination to the metal precursor, differing from the silver transmetalation strategy employed towards preparation of the aforementioned palladium complexes.<sup>243</sup>

The bidentate chelation strategy towards inhibiting pendant donor coordination to the metal, was again reported by Albrecht and co-workers.<sup>178–182</sup> However, oxygen-containing pendant donor functionalities were used instead of a pyridine tethered to the trz-pyridyl chelate (Fig. 5). The ruthenium trz-pyridyl chelated complexes feature either a carboxylic acid (271), ester (272), or carboxylate (273) pendant. Catalytic transfer hydrogenation activity of these complexes surpassed that of the analogous ruthenium complexes without a pendant donor site (Fig. 5, i).<sup>179</sup> The results indicate that the pendant carboxylate contributes in catalysis, with the noninnocent role of the ligand postulated to mediate either proton shuttling or bond manipulation processes. This necessitates C,N-bidentate chelation which in turn fosters a larger yaw angle, ultimately preventing coordination of the pendant

**Fig. 5** C,N-chelated ruthenium (i, ii) and iridium (iii) complexes.

O-donor to the metal center to render it available for substrate recognition and binding. In addition to the transfer hydrogenation, C,N-chelated ruthenium complexes (**Fig. 5, ii**) featuring either an oxygen donor **274** and **275**, or an alkyl group **276** as pendant, were also successfully used towards the catalyzed dehydrogenation of amines to nitriles, using O<sub>2</sub> as terminal oxidant.<sup>182</sup> The range of coordination compounds substituted by the trz-pyridyl ligand framework featuring the oxygen pendant donor, was extended to include iridium(III) as well (**Fig. 5, iii**).<sup>180,181</sup> The complexes **277–280** were prepared towards catalytic water oxidation<sup>180</sup> and alcohol dehydration/dehydrogenation reactions.<sup>181</sup> The C,N-chelated iridium complexes could facilitate the catalytic water oxidation reaction in the presence of cerium(IV) as sacrificial oxidant, or under electrochemical conditions.<sup>180</sup> The presence or absence of HPF<sub>6</sub> allowed for switching between the alcohol dehydration or alcohol dehydrogenation catalyzed reactions, mediated by **278**.<sup>181</sup> In both reports, the remote electronic effect imparted by the presence or absence of the oxygen containing donor moieties was credited for the observed differences in catalytic activity,<sup>180,181</sup> rather than a cooperative role as was postulated for the analogous ruthenium complexes (**Fig. 5**).<sup>179</sup>

A trz ligand featuring a hydroxyl-containing hemilabile pendant was reported in another example of mild gold(I) to gold(III) oxidation, this time mediated by visible light.<sup>244</sup> The group of Mendoza-Espinosa reported on the preparation of a series of triazolium ligand salts featuring a hydroxyl hemilabile moiety with either one, two or three methylene spacer groups between the oxygen donor and the five-membered triazolium heterocycle.<sup>244–246</sup> Coordination of these hemilabile containing ligands allowed for isolation of the corresponding monodentate gold(I) complexes.<sup>244</sup> Exposure of the trz gold(I) complex **282** to visible light (23 W fluorescent light) resulted in oxidation, yielding the biscarbene gold(III) complex **283**, albeit accompanied with gold(0) and MIC-related side-products (**Scheme 34**). The gold(I) and gold(III) complexes efficiently catalyze the hydrohydrazination of terminal alkynes with hydrazine, with the gold(I) complex demonstrating enhanced catalytic activity compared to the gold(III) complex, ascribed to possible reduction of the high oxidation state gold in the presence of a reducing agent. The role of the hemilabile oxygen moiety in both the oxidation and hydrohydrazination catalyzed reactions was not reported. However, subsequent reports by the group of Mendoza-Espinosa shed light on the possible involvement of the hydroxyl hemilabile donor once coordinated to other transition metals. Ligand coordination to palladium in the presence of pyridine yielded the corresponding trz complexes **284**, with pyridine occupying the position *trans* to the carbene (**Scheme 34**). The hydroxyl pendant did not coordinate to the metal,<sup>246</sup> similar to the palladium hydroxyl-trz complexes reported by Sankararaman and co-workers.<sup>247</sup> However, initial Suzuki-Miyaura cross-coupling catalytic investigations indicated that the hydroxyl-tethered trz palladium complexes outperformed ether functionalized derivatives or a commercially available NHC-containing palladium complex (**Scheme 34**).<sup>246</sup> Moreover, it was verified that the complexes featuring either a one or two carbon spacer, respectively, between the OH pendant and the trz heterocycle have higher catalytic activity while the complex featuring three CH<sub>2</sub> moieties displayed diminished catalytic activity.

Stoichiometric investigations allowed insight into the observed differences between the hydroxyl functionalized hemilabile trz complexes.<sup>246</sup> Deprotonation of the pendant arm resulted in stable palladium alkoxide complex formation, in the case of the two complexes featuring either one (**285**) or two (**286**) -CH<sub>2</sub>- spacer groups (**Scheme 34**). The pendant arm featuring three methylene moieties resulted in decomposition after deprotonation, reported to be attributable to formation of an unstable seven-membered palladacycle. The five- and six-membered palladacycles were also found to exhibit high catalytic activity in the abovementioned catalyzed reactions. Resultantly, the hemilabile oxygen donor functionality of complexes **285** and **286** enhance the catalytic reactivity of the palladium complexes, stabilizing the catalytic intermediate and therefore mitigating catalyst decomposition.<sup>246</sup> Similarly, allyl and cinnamyl palladium complexes featuring a hydroxyl hemilabile functional group displayed higher catalytic activity in the cross-coupling catalyzed reaction of phenylboronic acid with *p*-chloroanisole, compared against an analogous palladium complex containing a phenoxy-linked pendant.<sup>245</sup> On the other hand, similar catalytic reactivity was noted when the

**Scheme 34** O-donor tethered trz gold and palladium complexes.

hydroxyl-functionalized trz was compared against a palladium complex without a hemilabile O-donor group. The observed differences in the catalytic reactivity of the complexes investigated was rather attributed to the presence of cinnamyl versus allyl substituents, with cinnamyl substituted complexes exhibiting higher catalyst activity. The hydroxyl pendant was however implicated in a proposed reaction mechanism for the catalytic reaction, stabilizing the catalytic intermediate during the formation of the catalytically active Pd<sup>0</sup> catalyst, as illustrated in **Scheme 34**.<sup>245</sup>

The group of Sierra and Torre prepared a range of triazolium salts featuring a chiral sulfoxide pendant, with subsequent coordination to gold via a silver transmetalation route.<sup>32,248</sup> Selected gold(I) complexes were investigated as enyne cycloisomerization catalysts. It was determined that both the sulfoxide moiety and the gold metal were required for catalysis, as the complex without a sulfoxide functionality or a corresponding silver analogs complex failed to catalyze the cycloisomerization reaction.<sup>248</sup> A hypothesized mechanistic scenario involved terminal alkyne coordination with subsequent cyclization dictated by the steric bulk of the nitrogen substituent, to proceed either via the 5-exo or 6-endo cyclization pathways yielding the corresponding 5-membered or 6-membered cycles (**Scheme 35**).<sup>32,248</sup> A bulkier substituent at the nitrogen favored the 5-exo pathway, and the 5-membered product could therefore be preferentially accessed through simple ligand modification. The authors theorized description of the sulfoxide's influence in the catalytic process is especially noteworthy. It is suggested that the oxygen or the sulfur lone pair coordinates and stabilizes the gold carbenic intermediate, facilitating the reaction towards completion (oxygen coordination and stabilization is depicted in **Scheme 35**, similar to the authors mechanistic proposal).<sup>32</sup> The sulfoxide containing gold catalyst was further shown to mediate the cycloisomerization-dimerization cascade of 1,6-enynes, in addition to the diastereoselective [2+2+2] cycloaddition of 1,6-enynes with benzaldehyde.<sup>249</sup>

### 1.05.2.3.2 S-donor functionalized carbenes

Nonclassical carbenes with a sulfur pendant have also been reported.<sup>250,251</sup> Compared to its oxygen analog, the 'softer' chalcogen is expected to readily dissociate from a metal coordination sphere, vacating a coordination site on the metal.<sup>95,252</sup> Not surprising then, was the introduction of sulfur as a hemilabile pendant tethered to nonclassical carbenes. However, chelation of the sulfur containing carbene ligand was not achieved in every instance, and more specifically, sulfur coordination to copper was not realized.<sup>253</sup> Fortunately, the use of arene-containing ruthenium, osmium or iridium metal precursors allowed for the preparation of the corresponding metal complexes with coordination of the sulfur pendant (**Scheme 36**).<sup>254</sup> The complexes were used as oxidation catalysts, oxidizing benzyl alcohol as well as diphenylmethanol in the presence of *N*-methylmorpholine *N*-oxide. However, catalytic activity of the trz-substituted complexes was markedly lower compared against the analogous triazole *N*-coordinated complexes.

**Scheme 35** Noninnocent ligand mediated enyne cycloisomerization.<sup>32</sup> Modified from Sierra, M. A.; De La Torre, María C. *ACS Omega* **2019**, *4*, 12983–12994.

**Scheme 36** Introducing possible hemilability through C,S-chelation.

A noticeable difference was the selectivity of the complexes in the oxidation of benzyl alcohol, with the trz-coordinated complexes displaying higher selectivity for the targeted benzaldehyde product over the benzoic acid side product.<sup>254</sup>

### 1.05.3 Redox noninnocence

The noninnocent behavior of a ligand class cannot be discussed without referral to the original definition of (redox) noninnocence as the oxidation state ambiguity arising when redox active ligands may contribute as the site of redox processes, thereby leaving the formal metal d-electron count unequivocal.<sup>255</sup> The definition has since evolved and the terminology is nowadays broadly used to refer to the cooperative role that redox active ligands play in controlling metal complex reactivity, often involving additional chemical noninnocent roles e.g. hemilability or reversible dissociation.<sup>256</sup> Categorization of redox noninnocent ligands has been done by various definitions<sup>5,256–258</sup> to describe their roles as electron reservoirs or as radical transfer agents to substrates in both stoichiometric and catalytic conversions.<sup>259,260</sup> In the case of traditional carbene complexes, carbene ligands of the Fischer-type (acyclic heteroatom-stabilized singlet carbenes) are readily reduced in a single electron transfer to yield carbene radical ligands that mediate catalytic C–C bond formation.<sup>259</sup> For redox active NHCs, noninnocent behavior has mostly included redox switchable ligands<sup>5,261–263</sup> often with accompanying structural differences between the distinct redox states. Toggling between the various states, with different activities, selectivities or solubilities, delivers redox switchable catalysts.<sup>263–267</sup> Inherent redox noninnocence of carbenes, such as the radical reactivity displayed by one-electron Fischer-type carbene ligands<sup>259</sup> or N-donor ligands,<sup>268</sup> is lesser known for NHCs.

For the non-traditional carbene ligands under review in this chapter, redox noninnocence demonstrated has mostly been focused on one area, namely the introduction of a redox active pendant group on a trz ligand scaffold, that is utilized to tailor the Lewis basicity of the transition metal bonded to the carbene towards switchable catalytic applications. This common theme is well demonstrated for traditional NHCs with ferrocenyl-appended or annulated quinone NHC scaffolds,<sup>261</sup> a strategy also used towards the preparation of chiral ligands for chiral catalysis (vide infra). The other classes of redox noninnocence (including redox switchable hemilabile ligands,<sup>256</sup> where the ligand (i) acts as an electron reservoir, or (ii) a reactive radical involved in bond making/breaking; or (iii) mediates ligand-to-substrate single or two-electron transfer, or (iv) provides for metal-ligand bifunctional homolytic substrate cleavage, as definitively categorized in recent reviews), remains predominantly unexplored.<sup>259,260</sup> The dearth of redox noninnocence reported is especially noticeable for Im4 and CAACs and examples are almost exclusively based on the ability of these nonclassical carbene ligands to stabilize radicals (see [Section 1.05.1](#)).

## 1.05.3.1 Metallocenyl-appended carbenes

In his initial report, Sarkar et al. describes the use of a trz with a pendant ferrocenyl (Fc) substituted on the C4-position of the heterocycle, to prepare the first examples of heterobimetallic trz complexes of Fe and Au, 298 and 299 (Fig. 6, i).<sup>269</sup> Ferrocene was chosen as the redox active substituent of choice not only due to its reversible one electron anodic behavior, but also because of its ease of functionalization and its known electron-donating ability,<sup>270</sup> while the oxidized ferrocenium moiety is almost as electron-withdrawing as a  $-\text{CF}_3$  substituent.<sup>271</sup> This means that the ligand donor properties can be redox modified for catalyst fine-tuning, for example in gold(I)-mediated alkyne cyclizations where the carbophilic nature of the Lewis acidic, cationic gold(I) carbene underpins the catalytic reactivity: coordination of the unsaturated substrate to the gold center is followed by  $\pi$ -activation of the substrate towards nucleophilic attack.<sup>272–275</sup> The metallocenyl-containing trz precursors were prepared via the copper-catalyzed azide-alkyne click methodology from the accessible ferrocenyl azide and/or ferrocenyl acetylene to yield respectively, the N1-substituted or the C4-substituted Fc-appended triazoles,<sup>276–286</sup> followed by N3-methylation to give the corresponding triazolium salts. In addition, bis(triazolium) salts featuring a bridging 1,1'-ferrocendiyl as a redox active spacer provides the opportunity to prepare multinuclear complexes.<sup>287–290</sup> Taking advantage of these facile modifications, Sarkar expanded his series of metalloligands to prepare gold(I) chloride complexes with the trz containing also an N1-appended Fc, 300;<sup>291</sup> or C4,N1-diferrocenylated trz complex 301,<sup>292</sup> based on a previously reported diferrocenylated complex.<sup>293</sup> The digold complexes 302, 303 with the bridging 1,1'-ferrocendiyl completes the series (Fig. 6, i).<sup>292</sup>

The electrochemical properties of the precursor triazoles, triazolium salts and the corresponding gold(I) complexes 298–303 (Fig. 6, i) were investigated by detailed cyclic voltammetry, UV-Vis-NIR and TD-DFT (time-dependent density functional theory) calculations.<sup>292</sup> As expected, reversible one-electron oxidations are observed in all cases, associated with the ferrocene/ferrocenium couples, while irreversible reductions were found to be trz-based, as confirmed by calculated spin population analyses. A direct comparison of the oxidation potentials of 298–303 to elucidate ligand donor properties is not possible, among others due to different solvents/electrolyte systems employed in the cyclic voltammetry experiments. An indication of increased ligand donor ability is seen when comparing the  $^{13}\text{C}$  NMR carbene carbon chemical shifts, with the trz carbene carbon atoms with N1-bound Fc groups consistently resonating at higher field than the C4-bound Fc-trz carbene. Synthesis of the iridium dicarbonyl chloride trz complexes 304–306 (Fig. 6, ii) containing the diferrocenyl trz with both N1- and C4-bound Fc (304), the C4-bound Fc (305) or the N1-Fc (306), provided the opportunity for using the diagnostic carbonyl ligands as probes to determine the ligand donating properties by calculating the modified Tolman Electronic Parameter (TEP).<sup>294–296</sup> IR spectroelectrochemistry allows for the measurement of the oxidized complexes' carbonyl stretching frequencies so that the TEPs of also the one-electron oxidized trz (and two-electron in the case of 304) could be calculated for comparison with the ligands in their native form. The obtained TEPs confirmed that in general, Fc-trz (TEP = 2045–2047  $\text{cm}^{-1}$ ) are better donors than imidazol-2-ylidene based NHCs, while the one-electron oxidized trz (TEP = 2052–2057  $\text{cm}^{-1}$ ) have donor properties equivalent to phosphine ligands.<sup>294–296</sup> However, no significant increase in the donor ability of the trz with electron-donating Fc substituents compared to other alkylated/arylated trz<sup>54,55,67</sup> are observed. The electron-withdrawing nature of the ferrocenium group is reflected in 7–11  $\text{cm}^{-1}$  increase of the TEPs. Unexpectedly, the highest TEP is obtained for the diferrocenylated trz ligand, and the N1-bound Fc-trz is found to be a weaker donor compared to the C4-bound Fc-trz. For the two-electron oxidized  $[304]^{2+ \bullet\bullet}$ , the corresponding decrease in ligand donor ability is reflected by an increased TEP = 2068.3  $\text{cm}^{-1}$ .<sup>292</sup>

Chemical oxidation of 299 to  $[299]^+ \bullet$  was achieved with acetylferrocenium tetrafluoroborate.<sup>292</sup> To correlate the enhanced Lewis acidity of  $[299]^+ \bullet$  with improved catalytic activity for heterocyclic compound synthesis, the benchmark intramolecular

**Fig. 6** Ferrocenyl-functionalized triazolylidene complexes for application (i) in redox-switchable gold(I) mediated oxazoline synthesis, and (ii) as probes of ligand donor strength.

**Scheme 37** Redox switchable catalysis mediated by gold(I) Fc-trz complexes for the preparation of (i) 5-methylene-2-phenyl-4,5-dihydroxazole from *N*(2-propyn-1-yl)benzamide, (ii) 4-methyl-2-phenylfuran from 2-methylene-4-phenylbut-3-yn-1-ol and (iii) 4-methyl-1,3-dihydroisobenzofuran-5-ol from 2-methyl-5-((prop-2-yn-1-yloxy)methyl)furan.

alkyne cyclisation of *N*(2-propyn-1-yl)benzamide to 5-methylene-2-phenyl-4,5-dihydroxazole (Scheme 37, i) was probed. Catalytic conditions including 1 mol% loading of 299 and 1.2 equivalents of oxidant to generate  $[299]^{+\bullet}$  in situ in  $\text{CH}_2\text{Cl}_2$  at room temperature yielded 88% yield of the oxazoline, while only 12% yield was reported in the absence of the oxidant. Notably, no silver salts or other additives were required in the reaction with redox-induced catalyst  $[299]^{+\bullet}$ , as is usually the case for gold(I) trz complexes catalyzing organic transformations.<sup>186,238,248,297–302</sup> Utilizing the same conditions, both the native and the oxidized forms of 298, 300, and 302–304 were screened as catalysts for the reaction. In all cases, the native forms gave significantly lower conversions (0–10% except for 300 where 30% conversion was obtained).<sup>269,292</sup> Full conversion was observed for N3-bound ferroceniumyl trz complex  $[300]^{+\bullet}$  in accordance with its slightly higher TEP ( $2054.3\text{ cm}^{-1}$ ), compared to the C4-bound ferroceniumyl trz  $[299]^{+\bullet}$  (TEP =  $2052.7\text{ cm}^{-1}$ ). However, diferrocenylated-trz 304 yielded significantly lower yields (30% and 40%, respectively for the one- ( $[304]^{+\bullet}$ ) and two-electron ( $[304]^{2+\bullet\bullet}$ ) oxidized complexes), despite their higher TEP values ( $2056.9\text{ cm}^{-1}$  and  $2068.3\text{ cm}^{-1}$ , respectively). This was ascribed to the varying solubility of especially the dicationic complex  $[304]^{2+\bullet\bullet}$ . For the  $[302]^{+\bullet}$ , the excellent activity observed (95% yield with a 0.5 mol% catalyst loading taking the metal molar ratio into account), was similarly accounted for by increased solubility rather than any cooperative catalytic digold effects.

True redox switchable catalysis (RSC) (rather than redox induced) was demonstrated for catalyst 300 whereby the catalytic reaction could be cycled between a ‘switched on’ catalyst (in situ generated  $[300]^{+\bullet}$ ), followed by reduction to the native form 300 (‘switched off’) with the consecutive addition of excess decamethylferrocene as reductant, or vice versa for more than one cycle, as a first in gold(I)-catalysis.<sup>291</sup> No conversion of the substrate in the presence of either the oxidant or reductant *sans* 300 was observed. To test this redox switchability in other gold-mediated cyclizations, both the formation of furan from a  $\beta$ -alkynyl alcohol (Scheme 37, ii) and intramolecular phenol formation from furan with a terminal alkyne (Scheme 37, iii) catalyzed by 300 were investigated. These processes are known to be catalyzed by either gold(I) or gold(III), and notably require activation by a silver(I) or copper(I) salt in the case of the low valent gold, even cationic gold(I) complexes.<sup>275,303</sup>

Utilizing the same reaction conditions reported for the oxazoline synthesis, 300 as catalyst in its native form did not yield any product furan after 24 h, but 40% conversion of the substrate  $\beta$ -alkynyl alcohol was observed after 45 min of addition of  $[\text{Fe}(\text{C}_5\text{H}_4\text{C}(\text{O})\text{CH}_3)\text{Cp}]\text{BF}_4$  (Scheme 37, ii).<sup>291</sup> The reaction is quenched at this point, but addition of excess oxidant restarts the reaction. Although the reasons for reaction quenching are not clear, a conversion of 90% after 24 h can be obtained in this way. The acetyl ferrocenium oxidant itself does not catalyze the reaction, and a ‘switching off’ of the reaction can also be achieved by addition of 1.2 equiv. of decamethylferrocene. The third reaction investigated involves the ring-opening of the substrate furan followed by an intramolecular oxygen migration and rearrangement to the product phenol. Catalyst 300 in its native form catalyzes the reaction but a low conversion of only 12% is observed after 24 h. A marked increase in catalyst activity is achieved by addition of  $[\text{Fe}(\text{C}_5\text{H}_4\text{C}(\text{O})\text{CH}_3)\text{Cp}]\text{BF}_4$ , with full conversion within 5 min. Remarkably, adding reductant not only switches off the reaction, but leads to the back-conversion of phenol to the starting material alkynylfuran. The phenol does not react with decamethylferrocene, nor a mixture of the oxidant/reductant or 300, and the authors ascribe the backwards and forwards switching of the reaction as being inherently linked to the total catalytic mixture. In all three reactions investigated, oxidation of the pendant Fc group on the trz ligand is the trigger to activate the gold(I) center towards catalysis.

Parallel to the efforts of Sarkar et al. in gold(I) RSC, related Fc-trz ligands coordinated to  $\text{Rh}^{\text{I}}$  were similarly investigated for their ability to offer an additional handle on catalyst fine-tuning by influencing the catalytic metal center reactivity in heterobimetallic catalysts for olefin hydroformylation.<sup>304</sup> The series of complexes feature trz with a pendant Fc bound to the trz-C4 position, and either an alkyl (ethyl) (307, 309) or aryl (Dipp = 2,6-diisopropylphenyl) (311, 312) group on the N3-ring position, in addition to the N1-Dipp group, to investigate the effect of the ring-substituent (ethyl vs Dipp). The influence exerted by the Fc in its native

**Fig. 7** Ferrocenyl-functionalized trz rhodium(I) complexes for application in tunable olefin hydroformylation.

state on the donor properties of the ligand coordinated to Rh<sup>I</sup>, was also evaluated by replacing the metallocene with a phenyl substituent (**308**, **310**, Fig. 7).

The cod complexes **307**, **308** and **311** were employed as the catalyst precursors, while the dicarbonyl substituted complexes **309**, **310** and **312** were prepared as probes for ligand donor ability.<sup>304</sup> Unexpectedly, the TEPs<sup>305</sup> calculated for **309**, **310** and **312** were found to be equivalent (2047.0 cm<sup>-1</sup>), also to that of **300**. In an effort to delineate the more subtle ligand effects, the <sup>13</sup>C NMR spectroscopic method of Huynh et al. was applied by the preparation of **313** to probe ligand donicity in terms of the Huynh Electronic Parameter (HEP).<sup>306,307</sup> A chemical shift of <sup>13</sup>C δ162.2 ppm was observed; lower field than any of the previously evaluated N3-alkylated trz (δ157.9–160.6 ppm), with no significant electron donation evident from the proximal Fc group.<sup>304</sup> Catalytic evaluation of **307**, **308** and **311** as catalysts in the hydroformylation of 1-octene was done under optimized conditions of syngas CO/H<sub>2</sub> (1:1) at 40 bar, 75 °C in toluene with 0.08 mol% catalyst loading (Scheme 38). Complex **311** yielded slightly lower conversion (96%) compared to the full conversion reported for the N3-alkylated complexes, **307** and **308**, but gave the highest *n/iso* ratio for the formation of the more desirable linear aldehyde products (2.4 compared to 1.8 for **307** and **308**). This finding is in accord with the findings of improved regioselectivity for less electron donating and sterically more demanding NHCs.<sup>308–313</sup> However, this improved regioselectivity is accompanied with a decrease in chemoselectivity and in the total yield of product aldehyde compared to internal octene formation.<sup>304</sup> In order to maintain the steric bulk of the complex but decrease the donor ability of the N3-arylated Fc-trz ligand, one-electron oxidized complexes [**311**]<sup>+</sup> and [**312**]<sup>+</sup> (Fig. 7) were prepared either by chemical oxidation of the native complexes **311** or **312** by [Fe(C<sub>5</sub>H<sub>4</sub>C(O)CH<sub>3</sub>)Cp]PF<sub>6</sub>, or by oxidation of the precursor triazolium salt, followed by in situ deprotonation of the triazolium and coordination to [Rh(cod)Cl]<sub>2</sub>, and treatment with CO (g). Oxidation to the ferrocenium moiety led to an increase of 10 cm<sup>-1</sup> in the TEP. Performing the catalytic reaction with [**311**]<sup>+</sup> under the same conditions as for the native complexes did improve the total aldehyde yield by 10%, as well as the activity of the catalysts (full conversion and a TOF of 119 h<sup>-1</sup> compared to a TOF of 100 h<sup>-1</sup> for **311**). The effects of solubility in the toluene were not considered. Unfortunately, the regioselectivity is decreased so that the lowest *n/iso* aldehyde ratio for the series of catalysts is seen. Nevertheless, this study is another example of a redox tunable ligand influencing metal-ligand reactivity.

Replacing the Fc-substituent with an isoelectronic cobaltoceniumyl group provides yet another handle on electronic modification of the metal complex as acceptor ligands, while simultaneously altering the solubility of the complex as a result of the inherent cationic charge of the cobaltoceniumyl. Continuing on their previous work of metallocenyl-functionalized trz gold(I) complexes, Sarkar et al. prepared regioisomeric cobaltoceniumyl ferrocenyl triazolium salts with the cobaltoceniumyl bound to the C4-position on the heteroaryl ring, and the Fc bound to the N1-position of the ring (**314**, Scheme 39, i), or vice versa (**316**, Scheme 39, ii).<sup>314</sup> The tricationic triazolium precursor containing cationic cobaltoceniumyl moieties on both C4 and N1-positions was prepared as a highly polar compound with two electron-withdrawing metalloceniumyl substituents (**317**, Scheme 39, iii). Deprotonation and subsequent complexation of the trz ligands were complicated both by the commonly known nucleophilic attack of nucleophilic bases on the cobaltoceniumyl group as well as the steric bulk of the two  $\alpha$ -metallocenyl substituents hindering deprotonation of the triazolium C–H proton. Coordination was therefore not successful for **316** with the least acidic triazolium precursor. In situ deprotonation with Ag<sub>2</sub>O in the presence of excess KCl yielded monocationic silver(I) chloride complex **315** from proligand **314** (Scheme 39, i), while the silver complex from precursor **317** was not isolated, but used as carbene transfer agent in the transmetalation reaction with gold(I) precursor Cs[AuCl<sub>2</sub>] to yield the dicobaltoceniumyl trz gold(I) chloride complex **318** (Scheme 39, iii).<sup>314</sup>

The difficulty associated with the coordination of the deprotonated ligands to transition metals precluded the preparation of rhodium(I) or iridium(I) dicarbonyl complexes for experimental determination of their  $\sigma$ -donor,  $\pi$ -acceptor properties from TEPs derived from their FT-IR spectra.<sup>314</sup> However, DFT calculations were employed to calculate theoretical values for the trz based on precursors **314**, **316** and **317**. The values of 2077.9 cm<sup>-1</sup> (**314**), 2077.1 cm<sup>-1</sup> (**316**) and 2108.7 cm<sup>-1</sup> (**317**), identify these

**Scheme 38** Hydroformylation of 1-octene with trz rhodium(I) complexes.

**Scheme 39** Cobaltoceniumyl-ferrocenyl and dicobaltoceniumyl triazolium ligand precursors and the corresponding triazolylidene coinage metal complexes.

carbenes as among the most electrophilic *N*-heterocyclic MICs known.<sup>315,316</sup> Electrochemical characterization of the triazolium salts confirm the expected reversible one-electron oxidation of the Fc moieties in **314** and **316**, while no oxidation processes are observed in their absence (**317**, **318**). The reduction events of the cobaltoceniumyl groups represent two successive one-electron reductions of  $\text{Co}^{\text{III}} \rightarrow \text{Co}^{\text{II}} \rightarrow \text{Co}^{\text{I}}$ . The electrophilic nature of **318** portends to its use in the beforementioned gold-catalyzed oxazoline synthesis (Scheme 40, a). The same reaction conditions were employed as previously optimized for the Fc-trz gold(I) analogs,<sup>269,292</sup> and full conversion in less than 2 h was observed.<sup>314</sup> In this case, no redox induction/additive was required in the presence of these electron-poor dicationic carbene ligands. Redox switchability was potentially demonstrated with reaction termination upon the addition of slight excess cobaltocene. However, addition of oxidant ferrocenium did not result in the back-switching on of the catalytic activity of the system.<sup>314</sup>

Further utility of this ligand in reaction selectivity was demonstrated shortly thereafter.<sup>317</sup> Oxidative chlorination of **318** was possible simply by stirring overnight in aqua regia at room temperature, to yield dicationic gold(III) trichlorido complex **319** (Scheme 39, iii), without dissociation of the dicobaltoceniumyl trz ligand. More traditional methodology for gold(III) complex formation, e.g. the use of a  $\text{Au}^{\text{III}}$  precursor or halogens as oxidants, proved intractable. Initial attempts at using **319** as catalyst for oxazoline synthesis were discouraging, with no conversion observed under similar reaction conditions even after adding a silver(I) salt. Observation of the reduced solubility of the catalyst in dichloromethane prompted the use of the more polar solvent  $\text{CD}_3\text{CN}$  at elevated temperature. Reaction optimization resulted in conversion of the substrate (more than 90% after 24 h), but notably a different product isomer, 5-methyl-2-phenyloxazole, forms exclusively (Scheme 40, b).<sup>318</sup> This different mechanistic reaction outcomes for  $\text{Au}^{\text{I}}$  vs  $\text{Au}^{\text{III}}$  catalysts are well-known, yet such facile reaction tailoring by post-complexation of a metal-ligand system is striking.

### 1.05.3.2 Nonmetal redox active moieties appended to triazolylidenes and imidazol-4-ylidenes

Reports of redox noninnocent nonclassical carbene ligands beyond these metalloligands are limited, yet new reports of other redox active nonclassical carbenes bode well for the development of further redox switchable catalysts. One such example is the preparation of a bis-phenolate mesoionic carbene ligand that is not only redox active but the dianionic pincer ligand provides excellent stabilization for high-valent early transition metal complexes, as exemplified by the isolation of the titanium (**321**), niobium (**322**) and molybdenum (bis)imido complexes (**323**) from the precursor bisphenol triazolium **320** (Scheme 41).<sup>319</sup>

**Scheme 40** Chemoselective oxazole formation catalyzed by gold(I) and gold(III) dicobaltoceniumyl trz complexes.

**Scheme 41** Bis(phenolate)trz salt as precursor to bis(phenolate)trz imido complexes of group 4–6 transition metals.

A recent report by the group of Severin details the strategy of incorporating arylazo-groups on the C2-position of Im4 to modify the electronic properties in such a way that these aNHCs become more CAAC-like.<sup>320</sup> Au<sup>I</sup>, Rh<sup>I</sup> and Pd<sup>II</sup> complexes of these azoimidazolium-based dyes were prepared (324–326, Fig. 8, i), along with a range of C2-phenyl substituted analogs for comparative purposes (327–329, Fig. 8, ii). The aim was to maintain the strong  $\sigma$ -donating ability (i.e. high-lying HOMOs) known for Im4s while increasing the  $\pi$ -acceptor ability (i.e. lowering the LUMO energy levels) to produce complexes with the small singlet-triplet gaps that are responsible for the unique reactivity of CAACs. Experimental spectroscopic methods were employed to evaluate the ligand properties. HEPs measured from 326 (181.1 ppm) and 329 (181.0 ppm) demonstrate the similar  $\sigma$ -donor ability of both Im4. However, the TEP of 324 was determined to be 2045 cm<sup>-1</sup>, both lower than what is observed for normal NHCs (2048–2053 cm<sup>-1</sup>) and higher than typical Im4 (2037–2043 cm<sup>-1</sup>) as an indication of the overall donating ability ( $\sigma$ -donor/ $\pi$ -acceptor) of the ligands.<sup>321</sup> In comparison, TEP = 2039 cm<sup>-1</sup> for 327 falls in the range typical for Im4. From these spectroscopic values it can be inferred that the energy of the LUMO of the azo-Im4 ligand is lowered in comparison to the unfunctionalized carbene, while the HOMO energy levels remain mostly unaffected. This was confirmed by DFT calculations, as well as cyclic voltammetry experiments. The reduction events of 324–326 are unambiguously linked to the presence of the arylazo substituent, and are carbene ligand-centered as a first step in the preparation of Im4 that could potentially stabilize radicals.

**Fig. 8** Azo-Im4 complexes with CAAC-like electronic properties.

## 1.05.4 Chiral noninnocence

Enantiopure chiral products, from achiral organic substrates, can be accessed via asymmetric catalytic transformations using transition metal catalysts featuring a chiral motif on their backbone.<sup>322–327</sup> Accordingly, the use of NHCs featuring a chiral motif which imparts chirality to the corresponding metal complex after metalation, has led to further developments within the field of asymmetric catalysis. The chiral motif can be introduced on the five-membered heterocycle framework, as depicted by 330 and 331 in Fig. 9. Alternatively, the N-side arm can accommodate the chiral motif, with various types of chiral functionalities possible, such as a stereogenic center (332 or 333), or an axial (334) or a planar (335) chiral group (Fig. 9). These chiral motifs impart the required chirality to the corresponding metal complex, which dictates the chirality outcome of catalyzed reaction.<sup>322–327</sup> Not surprising then, is the substitution of NHCs with the even stronger donor abnormal carbenes to access, possibly, a complex catalyst with increased catalytic activity while controlling the stereogenic outcome of the catalyzed reaction. Consequently, the ligand plays more than just a simple spectator role, as it has a direct influence on the outcome of a catalytic reaction.

Chiral trz made their introduction in 2009, with the report of Sankararaman disclosing the palladium complex 336 featuring a chiral motif on the ligand (Fig. 10), obtained from transmetalation of the intermediary silver complex.<sup>328</sup> Similarly, the group of Albrecht reported a triazolium salt with a chiral center on the ligand backbone which was subsequently coordinated to gold, also via a silver transmetalation route 337.<sup>186</sup> PEPPSI type complexes 338 and 339, where the chiral center is situated on the ligand backbone, were reported by the groups of Sankararaman<sup>329</sup> and Sarkar,<sup>330</sup> respectively. Gangwar et al. disclosed the synthesis and isolation of chiral trz-coordinated palladium complex 340, in addition to the PEPPSI-analog.<sup>331</sup> The same group very recently also reported the axially chiral bis(trz)Au(I) complex 341, obtained by means of transmetalation from the corresponding silver complex that was isolated and characterized.<sup>332</sup>

Trz complexes featuring two chiral centers could be accessed via a chirality cascade transfer approach. Hence, Sierra, Torre and co-workers utilized the triazolium ligand salt 342 containing the chiral sulfoxide moiety<sup>248</sup> to prepare the corresponding half-sandwich rhodium and iridium metal complexes with the chirality at the metal influenced by the chirality at the trz ligand (Scheme 42, i).<sup>333</sup> As evidenced in Scheme 42, trz coordination to the metal is followed by C–H-activation in the presence of NaOAc, which affects the chirality transfer leading to the chirality at the metal center being opposite to that of the sulfoxide functional group (Scheme 42, i). Of particular note is the retention of configuration observed upon preparation of either the cationic complex 345 via chloride abstraction with NaPF<sub>6</sub>, or insertion of dimethyl acetylenedicarboxylate across the M–C<sub>phenyl</sub> bond of 344, yielding 346. The authors suggested that retention of configuration at the metal center is a result of the vacant coordination site at the metal center being occupied by the sulfoxide moiety during the dissociation process,<sup>245</sup> akin to the gold carbenic intermediate stabilized by the sulfoxide substituent during the enyne cycloisomerization (vide supra, Scheme 35).<sup>32,248</sup> This implicates the sulfoxide substituted trz ligand as fulfilling both a chiral and a multifunctional ligand noninnocent role (see Scheme 35). Facile insertion of the terminal alkyne methyl propiolate was also reported, with both regioisomers 347 and 348 isolated as enantiomerically pure diastereoisomers (Scheme 42, i).<sup>333</sup> The chiral cascade transfer methodology was exploited towards the preparation of BODIPY-tagged (BODIPY = 4,4-difluoro-4-bora-3a,4a-diaza-s-indacene) luminescent complexes featuring two chiral centers, both at the sulfoxide moiety

Fig. 9 Various representative classes of chiral functionalized NHCs.

Fig. 10 Selected chiral trz complexes.

**Scheme 42** Chirality cascade leading to enantiomerically pure complexes.

and at the metal center (Scheme 42, ii).<sup>334</sup> Lack of conjugation renders the absorption and emission of the complexes similar to the BODIPY reference. Unfortunately, the circularized polarized emissions, an application of these types of complexes, was met with no avail.<sup>334</sup> However, this illustrates the significance of this synthetic process to allow for preparation of complexes with multiple chiral centers, ultimately for highly specialized applications.

Appending ferrocene to classical NHCs is well documented and predictable (335, Fig. 9), as the combination of the strong donor carbene ligand with the planar chiral ferrocene moiety can lead to chiral catalyst mimicking the expanded field of the  $C_1$ -symmetric Fc phosphine coordinated complex catalyst<sup>335</sup> in addition to its possible redox noninnocence (see Section 1.05.3). Accordingly, Štěpnička et al. prepared a series of trz coordinated  $\text{Pd}^{\text{II}}$  and  $\text{Au}^{\text{I}}$  complexes featuring phosphinoferrocene ligands.<sup>336</sup> Sierra, Torre and co-workers also used the planar chiral element, but in combination with the chirality cascade transfer methodology from their sulfoxide containing trz ligand (355, Scheme 43).<sup>337</sup> They were thus able to prepare enantiopure bimetallic complexes containing three different chiral centers (Scheme 43). The chiral centers are located at the trz sulfoxide moiety and at the metal center, with the third chiral moiety being the planar Fc or ruthenocene substituent. Catalytic applications of these chiral complexes were not disclosed but should prove exploitable in the chiral cascade transfer approach during the preparation of chiral catalyst, especially for a complex catalyst featuring multiple chiral centers for the production of highly selective catalysts.

**Scheme 43** Bimetallic complexes with three different elements of chirality.

Direct applicability of Fc-containing nonclassical carbene ligands in chiral catalysis has been demonstrated. Planar chiral ferrocene-based triazolium ligand salts, their coordination to palladium<sup>338</sup> and copper,<sup>339</sup> and consequent asymmetric catalytic activity was reported by Fukuzawa, Haraguchi and co-workers. The chirality imparted by the planar ferrocene allows for the palladium and copper catalysts to mediate the transformation reactions selectively. Thus, the Fc-containing complex **361** was prepared starting from (*S*)-Ugi's amine **360** (Scheme 44, i).<sup>338</sup> It was found that catalyst **361** could furnish the asymmetric Suzuki-Miyaura cross-coupling reaction with good enantioselectivity and appreciable TONs (Scheme 44, ii). Similarly, copper complexes coordinated by a Fc-substituted trz ligand was prepared (Scheme 44, iii) towards the asymmetric borylation of an  $\alpha,\beta$ -unsaturated ester (Scheme 44, iv).<sup>339</sup> Complexes **362**, **363** and **364** catalyzed the borylation of methyl cinnamate with bis(pinacolato)diboron yielding the borylated complex, which further underwent oxidation in the presence of  $\text{NaBO}_3 \cdot 4\text{H}_2\text{O}$  to afford 3-hydroxy-3-phenylpropanoate (Scheme 44, iv).

Metalloocene incorporation is not the only method towards introducing planar chirality to a targeted complex featuring a nonclassical carbene, as demonstrated by Sankararaman and co-workers. Catalytic chemoselective olefin hydrogenation as well as enantioselective hydrogenation of prochiral alkenes under ambient conditions and 1 atm of  $\text{H}_2$ , was mediated by the chiral trz palladium complex **367** (Scheme 45, i).<sup>340</sup> The triazolium ligand **365** is substituted with a [2.2]paracyclophane wingtip moiety, which imparts planar chirality to the palladium complex **367**, obtained after transmetalation from the silver complex **366**. Ligand substitution yields the phosphine analog **368** from the acetonitrile complex **367**, accompanied by a *trans* to *cis* isomerization of the chlorido ligands (Scheme 45, i). Olefin hydrogenation catalyzed with 2 mol% **367** yielded the corresponding alkanes with moderate to high enantioselectivities and appreciable yields of the targeted product (Scheme 45, ii and iii). Contrary to this, **368** was determined to be catalytically inactive, attributed to the substitution of the labile acetonitrile ligand for the  $\text{PPh}_3$  donor (Scheme 45, i). Furthermore, it was found that **367** could catalyze the hydrogenation of stilbene, retaining its catalytic activity for 13 consecutive cycles, to reach a TON of 640. The combination of a catalytically active metal and a chiral ligand therefore allows for the realization of a hydrogenation catalyst that selectively hydrogenates olefins at mild conditions.

The 2,2'-diamino-1,1'-binaphthalene (BINAM) motif has been used as the backbone from which bis-triazoles could be prepared, followed by alkylation of the N3 nitrogen.<sup>341,342</sup> This resulted in the preparation of the corresponding bis(triazolium) ligand salts, with axial chirality induced by the ligand backbone. Subsequent metalation of the chiral ligand allowed for the preparation of the corresponding Pd (**370**), Ir (**371**) and Rh (**372**, **373** and **374**) complexes (Scheme 46, i), with the Rh complex **372** found to be catalytically active in the hydrosilylation of aryl ketones, yielding the alcohols with good yield and moderate enantioselectivity (Scheme 46, ii).<sup>341</sup> Similarly, the group of Chen prepared the corresponding gold complexes through coordination of the

**Scheme 44** Fc-trz complexes for asymmetric catalytic applications.

**Scheme 45** [2.2]paracyclophane Pd<sup>II</sup> complex towards selective hydrogenation of various olefins.

bis(triazolium)-BINAM ligand salt **369** to silver yielding **375**, followed by transmetalation with Me<sub>2</sub>SAuCl leading to the coinage metal complex **376** (Scheme 46, i).<sup>342</sup> The chiral gold(I) complex was prepared towards the enantioselective [2+2] cycloaddition of alleneamides with olefins, yielding chiral cyclobutanes (Scheme 46, iii). Moderate to high enantioselectivities could be obtained with **376** as catalyst in the presence of AgSbF<sub>6</sub>, at a reaction temperature of -50 °C in CH<sub>2</sub>Cl<sub>2</sub>. Furthermore, it was shown that the indole functionalized cycloadduct could be obtained with good enantioselectivity when starting from the corresponding indole and the alleneamide (Scheme 46, iv),<sup>342</sup> in an expansion of the structural analogs available of this biologically relevant class of heterocyclic compounds.<sup>343–346</sup>

Suginome et al. described the cyclopropanation of styrene with propargylic ester, yielding the cyclopropane with a 6:1 *cis:trans* ratio (Scheme 47).<sup>347</sup> The reaction was catalyzed by gold(I) complexes **378** or **380** (Scheme 47), prepared via two different strategies. The ligand used towards preparation of gold(I) complex **378** could be obtained either by the copolymerization of a triazole-containing monomer or the post-polymerization CuAAC across an alkyne-functionalized PQX [PQX = poly(quinoxaline-2,3-diyl)s] to yield the precursor **377**. Positive signals obtained in the circular dichroism (CD) spectra indicated the induction of *P*-helical structures via chirality transfer from the triazole group to the polymer main chain. Conversion of the pendant 1,2,3-triazole precursors to trz-Au-Cl complexes **378** as catalyst precursors were achieved by alkylation to yield the triazolium pendants, followed by treatment with silver(I) oxide and transmetalation to AuCl at room temperature (Scheme 47, i). Alternatively, the gold(I) complex **380** was also prepared starting from the monomer triazolium salt **379**, with the bis(trz)-Au<sup>I</sup> complex obtained due to the absence of a rigid polymer chain (Scheme 47, ii). As a proof of concept, **378** and **380** were employed as catalysts after activation with AgSbF<sub>6</sub> to prepare cyclopropane from the reaction of propargylic pivalate with styrene (Scheme 47, iii). Higher yields were obtained for the polymer-supported **378** compared to **380**, but the most notable benefit of the use of **378** vs **380** is the ability to recover **378** from the reaction by precipitating it out with solvent pentane, whereafter it could be reused at least eight times without any loss of catalytic activity.<sup>347</sup>

Within the realm of luminescence, circularly polarized light is advantageous towards various optical applications.<sup>348</sup> As mentioned earlier, the BODIPY-tagged trz iridium complexes (Scheme 42, ii) were subjected to circularly polarized light emission studies, albeit without success.<sup>334</sup> However, symmetrical CAAC-CuCl complexes **381** and **382** accessed starting from either (-)-L-Menthol or (+)-D-Menthol, respectively, were described to exhibit circularly polarized luminescence (Scheme 48, i).<sup>348</sup> Photophysical characterization, and more specifically, electronic circular dichroism (ECD) and circularly polarized light experiments, confirmed that **381** and **382** have preferential emission of light in one direction over the other. This could be achieved due to the presence of the simple chiral CAAC ligand inducing the light emission in the left or right direction. Also, of particular importance, is the short timescale coupled with excitation and subsequent emission. Upon application as catalyst, no chiral induction in the catalyzed reaction could be observed. The lack of chirality transfer during the catalytic reaction mediated by **381**, was reported by Bertrand, Jazzar, Mauduit and co-workers to be a result of conformational inversion (Scheme 48, ii).<sup>349</sup> The chiral CAAC-CuCl complex **381** was used to mediate the asymmetric conjugate borylation reaction to prepare the corresponding chiral organoboron products (Scheme 48, iv). However, it was reported that **381** catalyzed the reaction with diminished selectivity, albeit with high catalytic activity. The lack of control over the selectivity outcome was traced back to the energetically accessible conformer of **381**, being **383** (Scheme 48, ii). Conformational inversion leads to the existence of two conformers in solution, hence the lack of selectivity. The authors addressed this problem by introducing increased steric bulk at the quaternary carbon in question, in the form of a 5 $\alpha$ -cholestan-3-one group. The more rigid CAAC would resist conformational changes, ensuring the presence of one conformer in solution. Accordingly, the copper complex **385** could be isolated after deprotonation of the ligand salt **384** with KHMDS followed by metalation with CuCl, with X-ray analysis confirming the absolute stereochemistry of the complex (Scheme 48, iii). Catalyzing the asymmetric conjugate borylation reaction using **385** delivered the chiral organoboron product

**Scheme 46** BINAM-based axially chiral bis(trz) complexes towards enantioselective catalyzed reactions.

with a marked improvement in the enantioselectivities of the targeted product, while retaining the high catalytic activity (**Scheme 48**, iv).

A serendipitous cascade cyclization-rearrangement resulted in a chiral CAAC-gold(I) complex (**387**, **Scheme 49**, i), further established to selectively catalyze the cycloisomerization of allenol, yielding the substituted dihydrofuran as a single diastereomer (**Scheme 49**, iii).<sup>350</sup> The chance synthetic protocol was subsequently utilized to prepare a range of different chiral containing CAAC-gold(I) complexes. From this, a proposed mechanism towards the formation of the gold complexes was elucidated, with the formation of the zwitterionic vinyl-gold complex **390** from the  $\pi$ -coordinated gold intermediate **389** postulated (**Scheme 49**, ii). A [3,3]-sigmatropic rearrangement ensues, leading to iminium **391** which ultimately undergoes a 1,2-silicon migration, resulting in the observed gold complex **393**. An alternative mechanism was also considered, involving the high energy carbene intermediate **394**, from the alkylation on the  $\beta$ -carbon of the vinyl system. The high energy carbene **394** isomerizes via carbon and silicon migrations, yielding the thermodynamically favored product **393** (**Scheme 49**, ii). An independent theoretical investigation confirmed that the pathway following the [3,3]-sigmatropic rearrangement towards **393** is feasible, and also lower in energy compared against the pathway via the high energy carbene intermediate **394** (**Scheme 49**, ii).<sup>351</sup> The gold complex **387** was also

**Scheme 47** Preparation of (i) polymer PQX-supported and (ii) monomer triazolylidene Au<sup>I</sup> complexes as (iii) cyclopropanation catalyst precursors.

found to efficiently catalyze the intramolecular hydroamination of *N*-methyl-2-(2-phenylethynyl)aniline yielding the corresponding indole (**Scheme 49**, iv), in addition to the cycloisomerization (**Scheme 49**, iii).<sup>350</sup> It was further evidenced that the chiral gold complexes exhibited biological properties, with the complexes successfully screened against various cancer cell lines. Hence, the unique cascade cyclization-rearrangement reaction allows for the preparation of chiral containing CAAC-gold(I) complexes, finding application in multiple disciplines.

The advancements made in olefin metathesis catalyzed by CAAC coordinate ruthenium complexes was very recently extensively covered in the perspective by Bertrand and co-workers.<sup>352</sup> Only selected milestones are mentioned, of which the recent report by Bertrand et al.<sup>353</sup> regarding a chiral catalyst mediating the metathesis reaction with induced chiral control, is of particular relevance to the current topic. The proliferation of CAAC-Ru complexes for olefin metathesis can be attributed to their exceptional catalytic activity, as opposed to their NHC counterparts.<sup>352</sup> This difference was already noted in 2007 with the first example of a CAAC coordinated ruthenium complex 396 catalyzing the ring-closing metathesis reaction (**Scheme 50**, i).<sup>354</sup> Bertrand, Grubbs and co-workers continued their research, expanding the family of CAAC coordinated ruthenium metathesis complexes to include catalysts with exceptional metathesis catalytic activity.<sup>355</sup> This included the CAAC ruthenium complex 397, catalyzing the ethenolysis of methyl oleate with a TON of 340,000 when using ethylene with a purity of 99.995% at a catalyst loading of 1 ppm, while ethylene with a slightly lower purity gave TONs of 180,000 (**Scheme 50**, ii). Similar olefin metathesis activity could also be achieved with bis(-CAAC)Ru indenylidene complexes of the type 398 (**Scheme 50**, ii), which could catalyze the formation of both terminal and internal olefins.<sup>356</sup> The properties of the CAAC ruthenium complexes allowing for the high metathesis catalytic reactivity was investigated.<sup>357</sup> It was determined that the CAAC-Ru complexes are susceptible to bimolecular coupling but resist  $\beta$ -elimination due to stabilization imparted by the stronger  $\sigma$ -donor carbenes (**Scheme 50**, iii). Decreased complex decomposition through  $\beta$ -elimination allows for lower catalyst loading, which also decreases the propensity towards decomposition via bimolecular coupling. The high

**Scheme 48** Chiral containing CAAC-CuCl complexes towards (i) circularly polarized light emission and (iv) asymmetric conjugate borylation reaction.

catalytic activity and low catalyst loading render these metathesis catalysts industrially applicable,<sup>355</sup> and even more so, with the realization of these catalyzed reactions in continuous flow processes<sup>358,359</sup> or the preparation of the complex catalyst via mechanochemical techniques circumventing the use of solvents (Scheme 50, iv).<sup>360</sup>

Optically pure CAAC ruthenium complexes for asymmetric olefin metathesis was reported by the group of Bertrand, Jazzar and Maduit.<sup>353</sup> The (+)-(R)-Ru 406 and (-)-(S)-Ru 407 could be isolated, obtained through the separation of (*rac*)-Ru 405 with preparative high-performance liquid chromatographic techniques (<sup>Prep</sup>HPLC) (Scheme 51, i). The method allowed for the isolation of the two enantiomers with excellent yields and optical purities, with ECD and XRD characterization confirming the absolute configuration of the complexes. The asymmetric ring-opening cross-metathesis of styrene with norbornenes catalyzed by the chiral ruthenium complexes was investigated. The reaction yielded the products of metathesis with excellent enantiomeric purity. It was further demonstrated that the catalyst (-)-(S)-Ru 407 and the (+)-(R)-Ru 406 yielded the metathesis product with an *S,R*- or *R,S*-configuration, respectively. Both enantiopure catalyst also showed excellent *E/Z* ratios, with the ratio increasing from an *E/Z* ratio of 80:20 to an *E/Z* ratio of 95:5. The authors proposed a preliminary reaction mechanism by which the ruthenium catalyst selectively mediates the metathesis reaction (Scheme 51, ii).<sup>353</sup> A 14 electron-propagating Ru-benzylidene species 409 was suggested, accessed after the addition of excess styrene resulting to the dissociation of the *p*-nitro styrenylether ligand. The *anti*-conformer 409 (calculated 9.9 kcal/mol in energy compared to 407 at 0.0 kcal/mol) is formed that is less stable due to the quaternary chiral center being above the benzylidene fragment (i.e. the benzylidene is apical or *trans* to the *N*-Dipp moiety), resulting to increased steric congestion. Accordingly, calculations support direct rotation of the CAAC ligand around the metal-carbon bond, leading to the more stable *syn*-conformer 410 (calculated 7.2 kcal/mol in energy compared to 407 at 0.0 kcal/mol), with the *N*-Dipp moiety being above the benzylidene fragment (i.e. the benzylidene is apical or *syn* to the quaternary chiral substituent). This results in decreased steric congestion, favoring 410 as the 14e-propagating species (Scheme 51, ii). Subsequent coordination of norbornene was considered to occur *trans* to the carbene carbon and on its *exo* face, leading to 411 and 412 as possible conformers. Coordination of norbornene at 412 positions the phenyl substituent of the chiral carbon at a calculated distance of 3.64 Å and 3.38 Å from the norbornene substituents, which results in an increase in the energy of 412 due to the steric clash between the mentioned substituents. Alternatively, coordination of norbornene at 411 positions the norbornene substituents away from the phenyl substituent, which results in the energy of 411 increasing to 23.6 kcal/mol from 410, calculated to be 7.2 kcal/mol. This results towards formation of the metallacyclobutane 413, while the unfavored pathway leads to formation of metallacyclobutane 414, which ultimately yields 418, the

**Scheme 49** Cascade cyclization-rearrangement leads to chiral CAAC-gold(I) complexes via a [3,3]-sigmatropic shift.

minor product of the reaction. Calculations confirmed that 411 formation is favored, being 4.1 kcal/mol lower in energy compared to 412. This was attributed to a lack of steric clash noted in 411, while 412 experienced steric repulsion. Hence, the chiral center at the CAAC ligand ensures the selectivity transfer from the top down, first dictating the formation of either the *syn* or *anti*-isomer of the propagating species, which subsequently controls the product of insertion, preferentially leading to a single isomer via a lower reaction energy barrier controlled by steric congestion or lack thereof. Subsequent norbornene ring-opening at 415 followed by styrene insertion leads to the targeted product 417 and the catalytically active species 410, via intermediate 416.

### 1.05.5 Multinuclear cooperativity

The multinuclearity effect, or cooperative effect, is a term used to describe the synergistic properties, function amplification or integrated multifunctionality attained for metal complexes containing two or more metal atoms/ions within a designated framework to provision for direct metal-metal bonds, or electronically discrete metal centers.<sup>361–363</sup> The approach to design such multinuclear systems are often inspired by metalloenzymes with proximal active sites,<sup>364,365</sup> where the posing of the active metal centers within an effective relevant distance to achieve their desired functions are accomplished by using appropriate ligand scaffolds, i.e. rigid or flexible, allowing for  $\pi$ -communication along the aromatic framework,<sup>366</sup> or enhanced probability of interaction with catalytic substrates due to the three dimensional structural arrangement of metals with appropriate intermetallic distances.<sup>367</sup>

The metal centers employed may be the same, rendering enhanced catalytic performance (more than summative improvement in activity and selectivity) for the homobi- or -multimetallic catalysts compared to the monometallic species or as building blocks for supramolecular assemblies. Incorporation of different transition metals opens up pathways toward multifunctional, tandem or cascade catalysis.<sup>368</sup>

#### 1.05.5.1 Homonuclear cooperativity

Considering the modularity of the 1,2,3-triazol-5-ylidene (trz) backbone via ‘click’-chemistry approaches, it is perhaps not surprising that the examples of bi- to tetranuclear homometallic complexes of this class of non-classical carbenes (vi)–(xii)

**Scheme 50** CAAC-coordinated ruthenium olefin metathesis catalyst.

outnumber those of Im4 (i) and (xiii) and CAACs (ii)–(v), **Fig. 11**. The bonding modes of homobimetallic complexes of the trz include incorporation of a spacer- or linker group bound to the N1-positions of the two bridged trz rings (vi),<sup>369–372</sup> or the C4-position (viii–xii)<sup>204,300,373,374</sup> to link two trz metal moieties that can accommodate interaction between the homonuclear metal centers. This approach is also the first step for the preparation of cyclometalated complexes where C4-trz substitution with a phenylene linker leads to *ortho* C–H activation (**Fig. 11**, x).<sup>375</sup> Direct coupling of the C4-positions of two trz in the so-called i-bitz (bis(1,2,3-triazol-5-ylidene)) ligands<sup>376</sup> (vii),<sup>377</sup> or introduction of a P-donor site on C4 (**Fig. 11**, ix)<sup>378</sup> yields dinuclear complexes with enforced proximity of the metals leading to direct metal-metal bonds.

In the case of Im4, bimetallic complexes are formed almost exclusively from the bridging of two metal centers by a single ditopic anionic NHC or NHDC (N-heterocyclic dicarbene),<sup>379,380</sup> and very few homonuclear examples are known (**Fig. 11**, i).<sup>118,381–383</sup> For example, the dimetallic palladium(II) complex **421** was prepared by sequential metalation.<sup>381</sup> The C2-imidazolium position of precursor **419** is metalated first via transmetalation from silver(I) to yield monometallic **420**, followed by oxidative addition of the iodide-functionalized C4-imidazolylidene to a different Pd<sup>0</sup> precursor (**Scheme 52**). Although both C2- and C4-ring positions are occupied by Pd<sup>II</sup> in **421**, the asymmetry of the ditopic NHDC leads to electronic inequivalence for potential exploitation of site-specific reactivity and redox activity.<sup>381</sup>

Both directed synthetic routes and serendipitous findings have yielded homobimetallic complexes with a NHDC ligand coordinated to the two metal centers. Transmetalation of an NHDC complex **422** with coordinated Na on the C2- and Zn coordinated on the C4-imidazole to gold(I) with 2 equiv. of (PPh<sub>3</sub>)AuCl yields the neutral digold(I) NHDC complex **423** (**Scheme 53**, i) as an example of targeted homonuclear complex preparation.<sup>382</sup> A PNC-pincer NHC complex of Co<sup>I</sup> (**424**) with a dearomatized phosphine-picoline tethered to the NHC, is unexpectedly converted to a dinuclear dicobalt(I) complex **425** with coordinated N<sub>2</sub> and a second PNC-Co moiety bound to the C4-imidazolylidene group upon reduction with KC<sub>8</sub> in a non-saturated N<sub>2</sub> atmosphere (**Scheme 53**, ii).<sup>383</sup>

If the main group cluster adducts (Si, P, Al, Ga, Ge, Se, etc.) of CAACs are excluded, the number of reported multimetal CAAC complexes are unexpectedly small. Homonuclear bimetallic complexes that feature direct metal-metal bonds (**Fig. 11**, ii),<sup>384</sup> (iii)<sup>385,386</sup> and (iv)<sup>387</sup> or doubly-bridged metal centers (**Fig. 11**, v)<sup>135,388–393</sup> are representative examples. In all cases, the inherent noninnocent behavior of the CAAC ligands (vide supra) stabilize the metals in varying oxidation states, including radical centers,<sup>135</sup>

**Scheme 51**  $C_1$ -Symmetric CAAC ruthenium complexes towards asymmetric olefin metathesis.

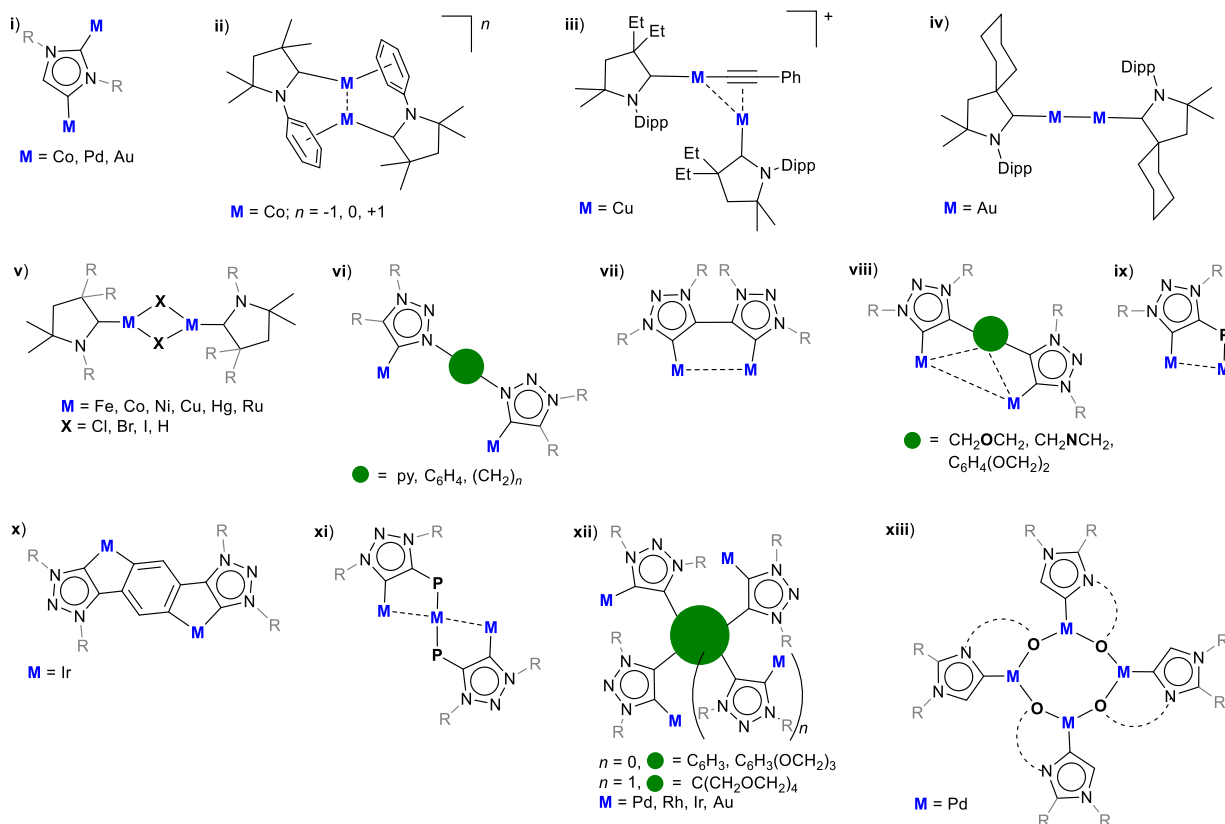

Fig. 11 Common bonding modes for homonuclear multimetallic complexes of the non-classical heteroatom stabilized carbenes.

Scheme 52 Stepwise preparation of homobimetallic NHDC complex of Pd<sup>II</sup>.

Scheme 53 Targeted and unanticipated homobimetallic NHDC complex formation.

**Scheme 54** (i) Synthesis and application of the Ru(CAAC)(indenylidene) dimer as RCM (ii and iii) and (iv) ethenolysis catalyst precursor.

or maintain proximity of the metals by facilitating metal- $\pi$ -aryl interactions of CAAC-substituent to the transition metal,<sup>384,385</sup> or dimerization with labile bridging halides or hydride X-type ligands.

Catalytic applications of the homobimetallic CAAC complexes are limited. One example is the Ru<sup>II</sup> indenylidene CAAC dimer 426 (Scheme 54, i),<sup>389</sup> employed as a Grubbs type olefin metathesis catalyst (see Section 1.05.4 above).<sup>352</sup> The dimer 426 could outperform the monomeric analogs at a very low catalyst loading (0.005%) in the RCM of diallyl malonate (Scheme 54, ii), while excellent selectivity was seen in macro-RCM to yield the exaltolide precursor with no trace of oligomerization (Scheme 54, iii). The increased initiation rate and productivity of these reactions were ascribed to the lability of the bridging chloride, while the stability of the catalyst towards oxygen in these processes was simultaneously attributed to the lack of vacant coordination sites in the dimer.<sup>388</sup> Similarly, the dimer compared favorably with monometallic catalysts for the ethenolysis reaction (Scheme 54, iv), although catalytic activity was demonstrated as being predominantly reliant on ethylene pressure.<sup>389</sup>

Considering the widespread utility of the copper-catalyzed azide-alkyne cycloaddition (CuAAC)<sup>394,395</sup> as the premier example of a 'click' chemistry reaction,<sup>396,397</sup> it is not surprising that copper(I) NHC complexes were explored early on as click catalysts.<sup>398–401</sup> Mechanistic studies by Fokin et al. identified cationic  $\pi,\sigma$ -bis(copper) acetylide complexes as the catalytically active species,<sup>402</sup> but it was not until the group of Bertrand employed a stabilizing CAAC ligand that the isolation of this reactive dinuclear species 430 could be realized from the reaction of the monomeric CAAC-copper(I) acetylide 428 with the related CAAC-copper(I) triflate 429 (Scheme 55, i).<sup>385</sup> They went on to demonstrate that although both monomeric 428 and dinuclear 430 are active in the dipolar cycloaddition catalytic cycle, the 430 cycle is the kinetically favored pathway (Scheme 55, ii). Importantly, though, it was found that the use of the weakly coordinating triflate ligand is key to the observation of the bis(copper) 430 as well as the newly elucidated bis(copper) triazole complex 431 as catalyst resting state (Scheme 55, ii). Incoming substrate alkyne protodemetalates 431 to regenerate 430, as the step in the catalytic cycle that excludes 428 from the preferred pathway.

**Scheme 55** (i) Preparation of active click catalysts **428** and **430**, and (ii) mechanistic pathway elucidated with the isolation of intermediate **431**.

Copper(I) complexes of other nonclassical carbenes, especially  $\text{Cu}^{\text{I}}$  bis(trz) complexes have been increasingly reported for application in molecular catalysis, with the prevalence of metal cooperativity for this coinage metal on the rise. The catalytic applications range widely, extending from catalytic hydroboration of styrene with commercial boranes<sup>373</sup> to the development of new click catalysts.<sup>370,372,377</sup> Synthetic approaches include bonding motifs (vi)–(viii) as shown in Fig. 11. The bistriazolium salt **432** with a bridging 2,6-pyridylene linker attached to the respective C4-positions of the triazoles could be metalated with  $\text{Ag}_2\text{O}$  to yield the homoleptic dinuclear silver(I) dimer **433** (Scheme 56, i).<sup>373</sup> Following transmetalation from the silver(I) complex as carbene transfer agent, the dinuclear dicopper(I) complex **434** could be isolated. Stepwise copper-based oxidation events were observed during cyclic voltammetry experiments as an indication of an expanded  $\pi$ -conjugated triazolylidene ring system of the pyridine-bridged ligand. Utilizing this complex **434** as catalyst in the hydroboration of *trans*- $\beta$ -methylstyrene with bis(pinacolato)diborane allowed for the  $\beta$ -selective formation of 1-methyl-2-phenylethylboronate (Scheme 56, ii), while the reaction with the corresponding *cis*-styrene substrate did not occur. However, despite the electrochemical suggestion of metal-interaction, no evidence for multi-nuclear cooperativity was evidenced in the catalytic reaction.

**Scheme 56** (i) Preparation of pyridyl-bridged bistriazolylidene dicopper **434**, and (ii) its application as catalyst for styrene hydroboration.

Exploitation of Cu<sup>I</sup> trz complexes as click catalysts progressed a couple of years after the development of the NHC catalysts with comparative activity for the mesoionic carbene catalyst precursors.<sup>253,403–405</sup> However the initial reports focused mostly on mononuclear catalysts and examples of well-defined dicopper catalysts are scarce in the literature, despite the highlighted role played by dinuclear catalytic intermediates.<sup>406</sup> This lack was addressed by Sarkar et al. in preparing a dicopper bis(*i*-bitz) complex **437** for direct comparison with the catalytic activity of the monomeric catalyst precursors, the neutral halido-substituted complex trz-Cu<sup>I</sup> **435** or the cationic bis(trz)-Cu<sup>I</sup> **436** (Scheme 57, i).<sup>377</sup> The use of the *i*-bitz ligand, directly linking the C4-positions of two trz, positions the two copper metal centers in close proximity (2.8–2.9 Å) in the 10-membered metallacycle formed by the bridging of two *i*-bitz ligands. Substrates phenyl azide and phenyl acetylene were employed in the benchmark click reaction to prepare 1,4-diphenyl-1*H*-1,2,3-triazole and the less sterically hindered *N*-benzyl substituted **437** proved to be the most active of the series of dicopper complexes (Scheme 57, ii). Comparison of this catalyst precursor with the monomeric catalysts **435** and **436** under the same conditions (room temperature, neat, with a total metal mol% catalyst loading of 0.50%) demonstrated significantly improved activity, with a TOF of 89 h<sup>-1</sup> for the dicopper **437** after 135 min reaction time, compared to TOF = 25 h<sup>-1</sup> for **435** and 64 h<sup>-1</sup> for **436**. Kinetic NMR experiments were conducted to investigate the indicated metal cooperativity. A reaction order of 1 with respect to the catalyst points to the involvement of a dinuclear species in the catalytic cycle, while the disappearance of the acetylene C–H, and the appearance of the bis(triazolium) acidic C–H proton chemical resonances lead to the hypotheses of Cu–C<sub>carbene</sub> bond breaking for two of the Cu–trz bonds (of the same *i*-bitz ligand), to generate the ligand precursor. The postulated catalytically active species therefore still contains one bridging *i*-bitz ligand linking the two copper(I) metal centers, while the demetalated *i*-bitz acted as an internal base to deprotonate the alkyne to yield the expected Cu-acetylide, in accordance with the known mechanism. The catalytic reaction is efficient for the cycloaddition of a wide range of alkene and azide substrates, with even the most sterically hindered substrates showing improved conversions compared to the known monomeric copper-catalyzed reactions.<sup>404,405</sup>

With the knowledge in hand that Cu–trz bond breaking (× 2) is likely for the cationic dicopper complexes containing two bridging bis(trz) ligands (**437**), as well as the importance of a weakly coordinating acetate ligand for the formation of the proved dicopper catalytic intermediates,<sup>386,406</sup> the group of Sarkar continued their investigations by preparing another trz-supported dicopper click catalyst (Scheme 58, i).<sup>372</sup> A bis(trz) ligand containing an N1-methylene linker (**438**) binds to two copper(I) metal centers, supporting the bridging of the labile acetate ligand that can act as an internal base in complex **439** (Scheme 58, i). The μ-OAc forces the copper metal centers into a spatial arrangement such that the Cu–Cu distance of 2.76 Å is smaller than the sum of the Van der Waals radii of two copper centers, thus the short distance is not necessarily an indication of cuprophilic interactions. The benchmark reaction in this case employs substrate phenyl acetylene again, alongside the less bulky benzyl azide. The complex is a very active catalyst with complete conversion (and 95% isolated yield for the triazole product) in 30 min with 1 mol% catalyst loading. Kinetic experiments for full mechanistic elucidation also indicated the catalyst efficiency, with complete conversion observed with a catalyst loading of 0.15 mol%, and 80% completion within 110 min as tribute to unprecedented efficiency for dilute click reactions. The kinetic NMR measurements demonstrated an overall first order reaction, but yielded an estimated catalyst order of 0.87. Subunity reaction orders are usually attributed to fast and reversible formation of an inactive catalytic intermediate.<sup>407–409</sup> In addition, it was determined that the azide substrate participates in the slowest step of the catalytic cycle, but not the alkyne – contrary to some literature reports.<sup>385,410,411</sup> A modified catalytic cycle was therefore postulated, with equilibration of the σ,π-dicopper acetylide key

**Scheme 57** (i) Synthesis and (ii) benchmark activity of neutral mononuclear, and cationic mono- and dinuclear copper(I) trz complexes as click catalysts for triazole preparation.

**Scheme 58** (i) Synthesis, (ii) catalytic performance and (iii) postulated mechanism for bis(triazolylidene) dicopper acetate click catalyst precursor.<sup>372</sup> Modified from Beerhues, J.; Fauché, K.; Cisnetti, F.; Sarkar, B.; Gautier, A. *Dalton Trans.* **2019**, *48*, 8931–8936.

intermediate to an inactive  $\sigma,\pi$ -bis(dicopper acetylide) dimer **440** (Scheme 58, iii). The rate-determining step in this cycle is the formation of the copper-triazolide before the final step of protodemetalation by the acetic acid. Further developments in the click methodology by the same group, namely (di)copper trz complex catalysts for halo-click reactions that utilize halo-alkynes, have on the other hand, been shown not to demonstrate any observable benefit for the incorporation of two metal centers compared to the mononuclear catalyst precursors for this modified click reaction.<sup>370</sup>

The success of cyclometalated trz-Ir complexes as WOCs (see Section 1.05.2) prompted investigation of other catalytic reactions. A C,C-dicyclopentylated Ir<sup>III</sup> complex (**442**) of a bis(trz) ligand featuring a C4,C4-phenylene group was published, together with its mononuclear analog **441** (Scheme 59, i).<sup>375</sup> The central phenylene in **442** both connects the two Ir<sup>III</sup> moieties as a spacer group and facilitates *ortho*-cyclometalation on each iridium center with the addition of sodium acetate during the transmetalation reaction from the Ag<sup>I</sup> precursor to Ir<sup>III</sup> (unlike the bis-C4-phenyl-trz Ir<sup>III</sup> WOC catalysts prepared in the absence of base).<sup>371</sup> The related bis-triazole complex **443** with C,N-dicyclopentylated Ir<sup>III</sup> metal centra was prepared for comparative reasons. Potential cooperativity was investigated in the catalytic transfer hydrogenation of benzaldehyde and acetophenone with sacrificial hydrogen donor isopropanol. For both reactions, the dinuclear C,N-dicyclopentylated complex **443** displayed higher activity than the mononuclear complex **441**, and even higher conversions for the reactions were obtained for the C,C-dimetalated phenylenebis(trz) complex **442** (Scheme 59, ii).

A series of mono- and dinuclear Rh<sup>I</sup> complexes were prepared from a COC- and a CNC-pincer proligand, containing either an ether or amine-linker, respectively. The latter serves as both spacer group and heteroatom-donor in the case of the CNC-bis(trz) ligand (Scheme 60, ii).<sup>204</sup> The complexes displayed diverse coordination modes, ranging from bridged dinuclear (**444**) to chelated dinuclear (**445**) complex geometry for the bidentate COC-ligand, while versatility of the CNC-ligand yielded a mononuclear pincer complex of Rh<sup>I</sup> with a tridentate ligand (**446**), a bischelated dinuclear complex with a tetradentate ligand (**447**), or a pincer Rh<sup>I</sup>

**Scheme 59** (i) Mono- and dinuclear C,C-dicyclopentylated Ir<sup>III</sup> complexes for (ii) transfer hydrogenation of acetophenone.

**Scheme 60** Preparation of mono- and homobimetallic Rh<sup>I</sup> complexes with (i) COC- and (ii) CNC-bistriazolylidene ligands, as (iii) selective alkyne hydrothiolation catalysts.

complex bridging a second metal center (**448**). The role of the mono- vs dinuclear complexes, N- vs O-functionalized triazolylidene and chelating vs bridging ligands were investigated for selective alkyne hydrothiolation.<sup>374</sup> In all cases, excellent selectivity (> 95%) for the α-vinyl sulfide product was obtained in the benchmark reaction of thiophenol with 1-hexyne (**Scheme 60**, iii). For the same catalyst (metal) loading, increased conversion was observed for the homobimetallic **444** with an ether-bridge, compared to its chelated mononuclear analog **445**. **444** also outperformed all the CNC-complexes **446–448**, even in the absence of a hemilabile, basic N-donor group that can assist with substrate thiol deprotonation/activation. This result, coupled with the observation that a decrease in selectivity for the α-isomer was observed when the ancillary cod-ligands were substituted with π-acid carbonyls, points to an alternative catalytic mechanism for these complexes as compared to the non-oxidative route (**Scheme 26**, vide supra).<sup>187</sup>

The inclusion of another donor group, namely a phosphino group on the C4-trz position, has also recently been utilized for the preparation of not only homobi- but also heterobi- and trimetallic metal complexes (**Fig. 11**, xi).<sup>378</sup> The 4-phosphino-1,2,3-triazolylidene ligand was found to be thermally stable and could be isolated as the free carbene **449** (**Scheme 61**), in contrast to its normal N-phosphinoimidazol-2-ylidene<sup>412–414</sup> and abnormal imidazol-5-ylidene counterparts.<sup>415</sup> Coordination to the coinage metals (Cu, Ag, Au) afforded not only the formation of the expected head-to-head homobimetallic complexes **450**, but transmetalation to gold(I) from the Ag<sup>I</sup> **450** yielded a heterodinuclear Ag<sup>I</sup>–Au<sup>I</sup> complex **451** or a head-to-tail homobimetallic Au<sup>I</sup> complex **452**, while the corresponding transmetalation from Cu<sup>I</sup> **450** gave rise to trinuclear Au<sup>I</sup> complexes **453** and **454**.<sup>378</sup> In addition, computational studies indicated increased nucleophilicity for both the carbon and the phosphorous atoms of the free carbene ligand **449** by way of increased energy of the occupied frontier orbitals, although this feature is yet to be exploited in catalytic reactions.

The N3-alkylated analog **456** of **449** was prepared by using a bottom-up approach in building a triazole **455** functionalized with the same phosphino group (**Scheme 62**).<sup>416</sup> Metalation with gold(I) led to formation of homobimetallic **457** as analog of **452**, displaying the same supported aurophilic interactions as enforced by the rigid scaffold and spatial proximity of the donor sites,<sup>417</sup> accompanied by yellow phosphorescence that was tentatively assigned to free (or delocalized) excitons related to molecular chain formation in the solid state.

Utilization of a central phenylene-linker as strategy to develop trimetallic complexes is a common alternative to the use of heteroatom-donor to increase complex nuclearity (**Fig. 11**, xii). This route has been followed with success to prepare tris(triazolium)phenyl ligand salts where the triazole is bound to the phenyl spacer on the C4-ring position either directly<sup>418,419</sup> (**Scheme 63**, i and ii), or connected by a methyleneoxy-bridge (**Scheme 64**, i).<sup>300,420,421</sup> The first methodology has been followed to prepare Ir<sup>III</sup> complex **459** for catalytic transfer hydrogenation (**Scheme 63**, i), where di- or trimetallic complexation is dependent on the base employed during synthesis and metalation.<sup>418</sup> However the steric bulk surrounding the central benzene ring precludes the possibility of *ortho*-cyclometalation as seen for the dinuclear derivative **442** (**Scheme 59**, i),<sup>375</sup> and the lack of cooperativity observed in the catalytic reactions was ascribed to the corresponding reduction of electronic interaction of the non-cyclometalated Ir<sup>III</sup> centra of

**Scheme 61** Synthesis and versatile coordination of a phosphino-trz for the preparation of di- and trinuclear group 11 metal complexes.

**Scheme 62** Preparation of phosphino-trz gold(I) derivative from a phosphino-alkyne click-precursor.

**Scheme 63** Preparation of trinuclear metal complexes from a tris(triazolium)benzene ligand precursor.

**Scheme 64** (i) Mono- to tetrametallic trz complexes and their comparative catalytic performance in palladium-catalyzed coupling reactions (ii and iii), gold-mediated intramolecular enyne cyclization (iv and v) alkyne hydrohydrazination.

459. Tris(triazolium) salts of this type has also been investigated as potential anion receptors, while reaction with a silver(I) precursor (and subsequent transmetalation with Au<sup>I</sup>) forms a prismatic trinuclear cage with the metal cations sandwiched between two tridentate tris(trz) ligand scaffolds (460, **Scheme 63**, ii).<sup>419</sup> The coordination occurs via a metal-controlled self-assembly to yield exclusively the cylindrical coordination cages 460 as reaction products. The phenoxy-linked trz ligands (**Scheme 64**, i) could be modified by including either one, two or three O-methylene triazolium groups on the phenyl-spacer to prepare the corresponding mono- (461), di- (462) or trinuclear complexes (463) of group 9–11 transition metals.<sup>300</sup> NMR studies indicated complete symmetry for the trinuclear complexes. Synergistic multinuclear effects in catalytic reactions were probed for both palladium-catalyzed carbon-carbon bond formation ( $\alpha$ -arylation of propiophenone with aryl bromides, **Scheme 64** (ii) and Suzuki-Miyaura coupling of aryl bromides and boronic acids, **Scheme 64**, iii), as well as intramolecular alkyne cyclization catalyzed by gold(I) (enyne methoxycyclization, **Scheme 64**, iv). In all cases, enhanced catalytic performance was seen, increasing successively from the mono- to di- to trinuclear catalysts. Replacement of the central rigid aromatic linker with a flexible aliphatic group (central quaternary carbon with four methyleneoxy-connected triazolium rings derived from a pentaerythritol scaffold) provides for extension to tetranuclear complexes 464 (**Scheme 64**, i) to be exploited in Rh<sup>I</sup><sup>422</sup> or Au<sup>I</sup>-mediated catalysis.<sup>423</sup> As for the trinuclear complexes, improved catalyst performance suggestive of cooperative effects was evident for both the rhodium(I) and gold(I) tetrametallic complexes, in benchmark catalytic reactions, e.g. Rh<sup>I</sup>-catalyzed alkyne hydrosilylation or Au<sup>I</sup>-catalyzed alkyne hydrohydrazination (**Scheme 64**, v).

A combination of the preceding construction motifs can be employed to prepare bi- and trimetallic gold(I) or silver(I) steroid-derived trz, or even a tetrametallic trz steroid macrocycle.<sup>424</sup> Click-reaction of 3-O-propargylestrone 465 with a di- or tri-azidomethylene-functionalized benzene followed by triazole alkylation (466) and metalation yield the corresponding symmetrical gold complexes with the central phenylene linker 467 and 468, while biscarbene formation with silver delivers the metallacyclic compounds 469 and 470 (**Scheme 65**). If a functionalized phenylene is not employed as the core but rather a macrocyclic tetrakis-triazolium salt containing four steroidal spacers linked by a dialkyne, then incorporation of four gold carbene functionalities in the framework producing the stereoidal cavity is possible (471, **Fig. 12**) for potential biological and chiral catalytic activity.

Tridentate CNO-pincer ligands were prepared from imidazolium salts as precursors to Im<sub>4</sub> C-donors, with an N-CH<sub>2</sub>C(O)NHPh-OH substituent to provide the pendant N- and O-donor moieties.<sup>227</sup> For the imidazolium salts containing a C2-phenyl substituent, deprotonation and coordination to PdCl<sub>2</sub> proceeded smoothly to yield the unprecedented tetranuclear complexes

**Scheme 65** Polymetallic complexes of steroid-appended trz.<sup>424</sup> Modified from Frutos, M.; de la Torre, María C; Sierra, M. A. *Inorg. Chem.* **2015**, *54*, 11174–11185.

**Fig. 12** Gold trz embedded in a tetrametallic macrocyclic steroidal cavity containing four estrone nuclei.

472 (Scheme 66, route i), as a first for Im4 palladium complexes (Fig. 11, xiii). In contrast, for the imidazolium salt containing a C2-Me group, only the mononuclear derivatives 473 were isolated (Scheme 66, route ii). The strongly electron-donating ability of the CNO-ligand is exemplified by the short Pd–C<sub>carbene</sub> bond distance observed (1.9308(8) Å), one of the shortest of those reported for palladium Im4 complexes (ranging from 1.951–2.022 Å).<sup>425,426</sup> Moreover, the  $\mu$ -phenoxide bridge was found to be stable even in the presence of PPh<sub>3</sub>, pyridine or at elevated temperatures.<sup>227</sup> The catalytic activity of the tetra- vs mononuclear complexes was evaluated in the Mizoroki-Heck reaction in ionic liquid medium. Only at very low catalyst loadings (0.1 mol% Pd and lower), did the multinuclear complexes demonstrate superior catalytic activity compared to the mononuclear analogs (Scheme 66, iii).

### 1.05.5.2 Heterobimetallic cooperativity

NHC ligands are an attractive choice as scaffold for the design of multinuclear architectures due to the ability to link not only two or more carbenes as C-donors to different metals separated by a spacer group, but also the ease of introduction of other donor functionalities tethered to either the ring-N or backbone-C to yield so-called hybrid ligands.<sup>427</sup> For imidazol-based heterocycles, these methodologies are very widely explored pertaining to traditional N-heterocyclic carbenes. For nonclassical Im4, incorporation of two different transition metals in a heteronuclear complex most often is based on the backbone metalation of an NHC to yield the formally anionic, ditopic NHDCs.<sup>380,428</sup> Reports detailing coordination of the C4- or C2-imidazolylidene position with non-transition metals (i.e. s- or p-block elements) are relatively common,<sup>429–439</sup> often displaying unpredictable reactivity.<sup>440,441</sup> However, NHDC complexes metalated with only d-block metals are less common, and only the reports by Kühn and Baratta et al. disclose coordination of two different metals.<sup>137,442,443</sup> Such an assembly of two distinct metal centers with varying functionality in electronic contact is of particular interest in cooperative catalysis, but this application is currently limited by the synthetic scope. The complexes are obtained by consecutive reaction of a Ru<sup>II</sup> precursor with two P-functionalized imidazolium salts (474), to coordinate first as an P,C-chelated NHC 475, and then as a P,C-chelated Im4 476 (Scheme 67). Subsequent metalation and transmetalation of the Im4 with silver(I) and then gold(I) precursors, yield the first example of complexes 477 and 478 bearing anionic dicarbene ligands connecting different transition metals (Scheme 67, route i).<sup>442</sup> The Ag/Ru bimetallic derivative 477 could be employed as precursor for transmetalation to iridium(I)<sup>137</sup> or palladium(II)<sup>443</sup> to yield complexes of the type 479 (Scheme 67, route ii) and 480 (Scheme 67, route iii), respectively. Electrochemical studies indicated pronounced metal interactions affecting

**Scheme 66** (i) Synthesis of tetra- and (ii) monopalladium(II) aNHC complexes and (iii) comparative catalytic performance in the Mizoroki-Heck coupling reaction.

**Scheme 67** Preparation (routes i–iii) and application (iv) of heteronuclear NHDC complexes in tandem Suzuki-Miyaura/transfer hydrogenation catalysis.

the redox behavior of the  $\text{Ru}^{\text{II}}/\text{Ru}^{\text{III}}$  for  $\text{Ru}/\text{Ir}$  479, however this did not translate to cooperative effects in the catalytic transfer hydrogenation reaction investigated for this heteronuclear complex. Dimeric complex  $\text{Pd}/\text{Ru}$  480, on the other hand, could be employed as a tandem Suzuki-Miyaura/transfer hydrogenation catalyst for bromoacetophenones and boronic acids to yield biphenyl alcohols (Scheme 67, iv). Moreover, 480 demonstrated enhanced catalytic performance compared to a combination of the related mononuclear ruthenium complex 476 and benchmark  $[\text{Pd}(\text{IMes})_2\text{Cl}_2]$  in the tandem catalytic reactions.<sup>443</sup>

Hybrid (multifunctional) ligands incorporating trz are accessible from click-chemistry approaches in a metal coordination sphere, whereby the cycloaddition of *coordinated* alkynes and azides give coordinated triazoles as precursor to the corresponding triazolylidene metal complex,<sup>444,445</sup> and can be extended to bimetallic complexes containing different metals connected to the C4- or N1-positions of the trz.<sup>446</sup> Alternatively, click reactions on functionalized scaffolds of ligand motifs such as salens, well known in homogeneous catalysis, can similarly produce hybrid ligands via consecutive metalations.<sup>447–450</sup> The group of Peters prepared hybrid salen-bis(triazolium) ligand precursors from a benzylic azide 481 and alkyne CuAAC reaction, followed by Schiff base condensation of reaction product 482 to yield proligand 483 (Scheme 68, i).<sup>451</sup> Selective metalation of the  $\text{N}_2\text{O}_2$  salen core (484) followed by sequential carbene metalation can be employed to yield either homo- or hetero- or trinuclear complexes 485–487 (Scheme 68, i). The catalytic 1,4-addition of an oxindole to a nitroolefin was studied in a preliminary investigation of the catalytic application of the hybrid complexes (Scheme 68, ii). The palladium complexes fared better, especially the heterodinuclear  $\text{Pd}/\text{Ag}$  complex 485, but decomposition of the trinuclear complexes 486 and 487 was observed under the given reaction conditions.

Hybrid NHC-trz ligands with a methylene linker for heterobimetallic complexes with unsymmetrical dicarbene ligands were developed not long after the first reports of trz as MICs, yet surprisingly few examples of these ligands bridging two different metals are known.<sup>452–454</sup> The first of these were reported in 2012 by Cowie et al. utilizing sequential metalations to form first the NHC-anchored/pendant-triazolium complex, after which a second metal center could be coordinated to the trz C4-position to give the  $\text{Pd}/\text{Rh}$  heterobimetallic complexes 488<sup>455</sup> or a more recent example, 489,<sup>456</sup> in addition to the known symmetrical dicarbene bis(trz) ligands that function as heterodinuclear bridge 490 (Fig. 13).<sup>457</sup>

### 1.05.5.3 Metal carbene complex heterogenization

Immobilization and other heterogenization strategies related to multinuclear cooperativity have been increasingly utilized over the past two decades in pushing the boundary of NHC transition metal complex application to heterogeneous catalysis and other material science applications.<sup>458–464</sup> For CAACs, Im4 and trz, these developments have been in the making only during the past 10 years, but interest is surging. The non-classical NHCs here play a role in furnishing a functional metal complex while also providing unique access to immobilization strategies. An example of remarkably improved catalytic performance by abnormal carbene ligand modification is observed when changing a peripheral N1-bound methyl in 170 to an N1-octyl group in 175, for the  $\text{Cp}^*\text{Ir}$

**Scheme 68** (i) Preparation of hybrid bis(trz)-salen mono- to trinuclear complexes and (ii) catalytic application in the 1,4-addition of oxindoles to nitroolefins.

**Fig. 13** Bridging dicarbene ligands for heterobimetallic complexes.

complexes with C,N-cyclometalated trz-pyridyl WOCs (vide infra, Fig. 3).<sup>465</sup> The methyl-substituted complex 170 displays comparative activity in water oxidation to the most active known iridium-based WOCs with a  $\text{TOF}_{\text{max}} = 16\text{--}19 \text{ min}^{-1}$  and rate independence of the catalyst concentration and the nature and concentration of the sacrificial oxidant.<sup>466,467</sup> However, if CAN is employed as sacrificial oxidant with 175, the catalytic activity rate increases up to 10 times that of 170, and is reliant on both concentration of catalyst and oxidant. Kinetic studies revealed a bifurcation time where the activity of 175 increases substantially compared to 170, producing oxygen at a constant rate. Initially, this was presumed to indicate associated processes such as micelle formation facilitated by the amphiphilic nature of the octyl-substituted 175 inducing metal proximity for the rate-limiting O–O bond formation step. Diffusion NMR experiments showed that 175 exhibits only marginally higher self-aggregation tendency than 170, with an equilibrium between monomeric and dimeric species implicated from the measured aggregation numbers  $N = 1.4\text{--}2$ , with 175 having the higher  $N$ -value. If the self-aggregation studies were performed in the presence of the sacrificial oxidant CAN, oxidation of the Cp\* ligand is observed but the C,N-cyclometalated pyridyl-trz ligand remains bound to the iridium, presumably with bridging oxo or hydroxo-moieties as proposed by Crabtree.<sup>468</sup> In this case, larger aggregation numbers are obtained, but the absence of any particles in the 3–500 nm hydrodynamic radius supports the formation of oligomeric aggregates rather than any micellar assemblies. Thus, oxidative transformation of 175 with its longer alkyl chain leads to self-aggregation to yield a catalyst with uncommonly high activity.

In the case of heterogeneous catalysis effected by immobilization methodologies, water-solubilization strategies for biphasic catalysis or solvent precipitation/recyclability has often been implicated,<sup>469–472</sup> or immobilization of the complex metal atom/ion via coordination to a tethered, anchored carbene ligand,<sup>462,464,473,474</sup> or stabilization of elemental allotropes or small metal clusters to metal surfaces with carbene ligands.<sup>459,460,475</sup> The developments are discussed in this section based on the nature of the metal carbene ligand interaction – from molecular complexes with tethered ligands to surface stabilization of infinite metal atom arrays (Fig. 14). However, the carbene ligand commonly serves a stabilizing rather than a noninnocent role, and thus only some striking developments are highlighted here.

#### 1.05.5.3.1 Tethered nonclassical metal carbene complexes

Surprisingly few reports of the nonclassical carbenes under review describe the inclusion of charged polar groups like sulfonates or carbonates as pendant water-solubilizing moieties for catalytic activity in aqueous media.<sup>476</sup> One such report details the preparation of a CAAC ruthenium complex as biphasic olefin metathesis catalyst.<sup>477</sup> Unlike other CAAC ruthenium olefin metathesis catalysts like 396 and 398 (Scheme 50, i), CAAC salt 491 (Scheme 69, i) was tagged with an electrophilic amino substituent on the backbone. Thus, addition of MeOTf to the CAAC coordinated ruthenium complexes resulted in alkylation of the amino groups and formation of 493 and 495, from 492 and 494, respectively (Scheme 69, i). The highly polar functional groups render the ruthenium catalyst soluble in environmentally benign polar protic solvents, such as methanol, isopropanol, water and a mixture of methanol and water. It was further demonstrated that the ruthenium complexes were stable under atmospheric conditions and could catalyze various metathesis reactions. In the mentioned protic solvents, catalyst 493 and 495 could also furnish the metathesis reactions. Therefore, the synthetic methodology imparts high solubility to catalyst of industrial relevance,<sup>477</sup> and 493 and 495 were even determined to be active in the environmentally significant ammonia borane hydrolytic dehydrogenation yielding hydrogen in neat water.<sup>478</sup> The ammonia borane dehydrogenation reaction was catalyzed with a TON of 86,100, which equates to 1.70 kg H<sub>2</sub> released per 1 g ruthenium metal used (Scheme 69, ii).

**Fig. 14** Immobilization strategies for nonclassical carbenes: (i) Tethering to macromolecules e.g. polymers or solid support, stabilization of (ii) clusters, (iii) nanoparticles and (iv) surfaces.

**Scheme 69** Polar functionalized tagged CAAC ruthenium complexes.

Functionalization of the nonclassical carbene ligand framework with (larger) molecular moieties also comprising ancillary applications is a well-known catalyst design strategy, and have included such diverse substituents as chrysin and coumarin<sup>479</sup> and carboranes.<sup>480–482</sup> Trz ligands that render catalytically active metal complexes are especially popular in this heterogenization methodology, as covalent linking facilitated by click-reactions to different support is facile. Tethering of carbene complexes to polymer supports is attractive as an immobilization strategy for scaffolds that are homogeneous in reactions but heterogeneous for recovery.<sup>483–485</sup> Such phase reversibility is mediated by polymers with switchable solubility, as observed for poly(quinoxaline-2,3-diyl)s (PQXs).<sup>486</sup> Moreover, the rigid helical rod-structure of the PQX polymer provides for a highly enantioselective chiral catalyst.<sup>487</sup> These advantages were combined with the ease of preparation and post-polymerization functionalization of macromolecules by CuAAC methodologies to yield macromolecular 1,2,3-triazole precursors to supported triazolydene metal complexes for chiral gold catalysis (see 378 and 380, **Scheme 47**).<sup>347</sup>

Exploitation of the facile CuAAC click reaction was similarly employed in the synthesis of N-doped carbon boxes from microporous organic polymers (MOPs).<sup>488</sup> Microporous organic network (MON) layers are formed on the surface of Cu<sub>2</sub>O nanocubes<sup>489</sup> by click reaction of tetra(4-ethynyl)methane (1 equiv.) with 1,4-diazidobenzene (2 equiv.), utilizing the copper surface of the nanocube as catalyst. The copper is etched out by treatment with hydrochloric acid to form hollow MON boxes 496 bearing triazole rings, which can then be alkylated to yield the corresponding triazolium species H-CMOPs (hollow click-based MOP) 497 (**Scheme 70**). Successive incorporation of rhodium is achieved by metalation of 497 with [Rh(cod)Cl]<sub>2</sub> in the presence of base NaH and KI, to generate H-CMOP-Rh 498 featuring trz coordinated rhodium(I) (2.2 mmol/g trz), as confirmed by NMR and X-ray photoelectron spectroscopy (XPS).<sup>490</sup> N<sub>2</sub> sorption studies showed that the surface area of 498 increases to 310 m<sup>2</sup>/g from 167 m<sup>2</sup>/g for 497, with a pore size volume of 0.55 cm<sup>3</sup>/g. Complex 498 can then be used as heterogeneous catalyst for the stereoselective synthesis of poly(-arylacetylene)s, in a rare example of a Rh-based heterogeneous catalytic system.<sup>491–495</sup> Utilizing an optimized catalyst load of 0.60 mol% 498, yields of 96% (*cis-trans* content 98%) was achieved.<sup>490</sup> If the conventional nonhollow spherical CMOP-Rh was employed, significantly impaired catalytic efficiency is observed due to reduced diffusion pathways of the reagents. The recyclability of 498 was illustrated in catalytic activity maintained for five cycles and is a good indicator for the usefulness of Rh-containing H-CMOPs in other catalytic reactions.

Covalent tethering of a catalytically active metal complex to a graphene material is a heterogenization strategy for designing hybrid catalysts, but is contingent on a simple method of covalent attachment. For nonclassical carbenes based on triazoles, CuAAC click-chemistry presents yet again a facile route towards anchoring triazolium groups on the carbonaceous surface of thermally reduced graphene oxide (TRGO) materials 499 via the abundant epoxy groups situated at the basal planes, as an alternative to functionalization of surface hydroxyl groups.<sup>496</sup> The 1,2-epoxide ring opening is mediated with sodium azide to give the azide-functionalized graphene material 500 which can then be treated with phenylacetylene in the presence of sodium ascorbate and copper(II) sulfate catalyst for the click-reaction (**Scheme 71**, i). The resultant 1,2,3-triazole surface can be reacted with methyl iodide to quaternize the triazol-N1 atoms to yield surface 501 decorated with triazolium groups, in addition to free hydroxyl groups. The amount of ligand introduced in the graphene sheet was quantified as 5.8 wt% by means of TGA. If 501 was directly reacted with

**Scheme 70** Preparation of heterogeneous Rh<sup>I</sup> polymerization catalysts from templated Cu<sub>2</sub>O nanocubes to give hollow click-based microporous organic polymers (H-CMOP-Rh).<sup>490</sup> Modified from Cho, K.; Yang, H.; Lee, I.; Lee, S. M.; Kim, H. J.; Son, S. U. *J. Am. Chem. Soc.* **2021**, *143*, 4100–4105.

[Rh( $\mu$ -OMe)(cod)<sub>2</sub>], the coordinated methoxy group does not deprotonate the triazolium moieties but rather the rhodium coordinates to the remaining surface hydroxyl groups in metal-functionalized TRGO 502. To circumvent Rh–O bond formation, the hydroxyl groups can be first protected to yield the TRGO material with triazolium and -OTMS surface pendant groups 503. If 503 is treated with [Rh( $\mu$ -OMe)(cod)<sub>2</sub>], then trz coordination is achieved to give anchored 504 Rh(cod)(trz)-complexes on TRGO with 2.6 wt% Rh as determined by means of ICP-MS measurements, with a homogenous distribution of the metal. A reference molecular complex 506 (Scheme 71, ii) as analog to the anchored complexes was also prepared.

Catalytic alkyne hydrosilylation reactions employing 1-octyne and HSiMe<sub>2</sub>Ph or HSiEt<sub>3</sub> as substrates were evaluated with 502, 504, and 506 (Scheme 71, iii). The homogeneous catalysts 506 displayed excellent catalytic performance both in terms of selectivity (for the thermodynamically less stable  $\beta$ -Z vinylsilane isomer),<sup>497</sup> while the hybrid 502 and 504 are active at 60 °C in solvent CDCl<sub>3</sub>, although decreased selectivity is seen for 504 when the more active silane HSiEt<sub>3</sub> is employed as substrate.<sup>496</sup> However the labile Rh–O linkages for hybrid 502 lead to the loss of activity over successive catalytic cycles whereas the heterogeneous 504 with robust Rh–C(trz) covalent bonds can be reused at least six times, even under atmospheric conditions, without loss of activity. Heterogenization of a molecular catalyst utilizing instead of Rh<sup>I</sup> a C,C-cyclometalated Rh<sup>III</sup> anchored to the TRGO material, was probed next as a more  $\beta$ -Z vinylsilane selective hydrosilylation complex catalyst.<sup>498</sup> The Rh<sup>III</sup> complex 507 was prepared containing a C4-phenyl trz ligand (Scheme 71, ii), and proved highly active even at room temperature (Scheme 71, iii). DFT calculated mechanistic routes pointed to a metal-ligand bifunctional mechanism for 507 involving a reversible cyclometalation of the C4-phenyl-trz ligand that is competitive with a noncooperative pathway. The triazolium moiety with a C4-phenyl group was bound to the TRGO surface through a similar strategy as used for 504, whereafter metalation with [RhCp\*Cl<sub>2</sub>]<sub>2</sub> (Cp\* = pentamethylcyclopentadienyl) in the presence of sodium *tert*-butoxide as base yielded the hybrid 505 as immobilized version of the molecular rhodium(III) catalyst 507 (Scheme 71, ii), with the iodo-ligands replaced by Rh–O bonds from the O-functionalities on the carbon wall. 505 only proved active at 60 °C but the hybrid again showed excellent recyclability with exclusive selectivity for the  $\beta$ -Z vinylsilane formation (Scheme 71, iii).

**Scheme 71** (i) Click-preparation of hybrid hydrosilylation catalysts on thermally reduced graphene oxide surfaces<sup>496</sup> and (ii) molecular catalysts for (iii)  $\beta$ -Z selective alkyne hydrosilylation. Modified from Sánchez-Page, B.; Jiménez, M. V.; Pérez-Torrente, J. J.; Passarelli, V.; Blasco, J.; Subias, G.; Granda, M.; Álvarez, P. *ACS Appl. Nano Mater.* **2020**, *3*, 1640–1655.

Click-based covalent connection of trz to nanoparticles is equally attainable, to prepare for example, nanomagnetic catalysts that can be readily recycled with magnetic work-up.<sup>499</sup> Hydroxyl-surface functionalized magnetic nanoparticles (MNPs) prepared via coprecipitation of Fe<sup>III</sup> and Fe<sup>II</sup> at high pH was reacted with 3-azidopropyltriethoxysilane that could be subjected to CuAAC-reaction with phenylacetylene to yield the triazole-functionalized MNPs **508** (Scheme 72). Alkylation followed by metalation with Pd(OAc)<sub>2</sub> result in Pd<sup>II</sup> trz-functionalized MNPs **509** that proved efficient in Suzuki-Miyaura and Mizoroki-Heck cross-coupling reactions under mild conditions. The benefit of the heterogenization was illustrated in catalyst recycling and reuse of up to 10 times without appreciable loss of catalytic activity.

### 1.05.5.3.2 Nonclassical carbene stabilized metal clusters

The uncommon stabilizing effect attained from the unique bonding between polymetallic and organic species in organometallic clusters are well-documented, although the cooperative effects of carbon-multimetal bonds in catalytic reactions remain obscure.<sup>500</sup> Especially for carbenes, this can be ascribed to the fact that the exact nature of the carbon-metal bond in clusters is ambiguous, and the redox behavior of the multimetal centers may differ from single metal compounds. The inherent noninnocence of CAACs exemplified by their radical-stabilization capabilities (Section 1.05.1, vide supra) make these nonclassical carbenes the most-explored of the series under review in this work, extended to the stabilization of the p-block elements, allotropes and radicals,<sup>501–505</sup> monomers;<sup>506,507</sup> dimers<sup>508–510</sup> to small molecules<sup>511</sup> and clusters.<sup>512–516</sup> Examples of small metal clusters stabilized by the other monoheteroatom-stabilized carbenes (Im4 and trz) are exceedingly rare and adventitious.<sup>517</sup>

For atomically precise *transition metal* clusters that are ligand-protected (Fig. 14, ii), precedents utilizing nonclassical NHCs are scarce and exclusively implicated for the coinage metals and CAACs, as metal and carbene partners, respectively.<sup>71,518</sup> The interest in these types of cluster compounds lies in their potential to act as mimics for heterogeneous catalysts while maintaining the advantage of possible catalytic reaction intermediate characterization. The initial study of Bertrand et al. detailing the stabilization of electron-rich mono- and dinuclear gold(0) complexes with CAACs<sup>387</sup> was followed by a straightforward synthesis of small gold(I)/gold(0) triangular clusters ligated by three CAACs.<sup>518</sup> The corresponding cyclohexyl-substituted CAAC-gold(I) chloride **510** can be treated with Ag<sub>2</sub>O in the presence of NaBF<sub>4</sub> to yield the μ<sup>3</sup>-oxo **511**, which can be reduced with carbon monoxide to the mixed valent cluster **512** (Scheme 73). Alternatively the readily available phosphine μ<sup>3</sup>-oxo complex **513** can be used as a precursor for reaction of the

**Scheme 73** (i) CAAC-stabilized Au<sub>2</sub>Au<sup>I</sup> clusters utilized in (ii) catalytic amine carbonylation.

diethyl-substituted CAAC **514** in a ligand substitution reaction to give trinuclear oxo complex **515** before reduction to the characterized  $\text{Au}_2^0\text{Au}^{\text{I}}$  cluster **516**. **516** was shown to be an active catalyst for the catalytic carbonylation of cyclohexylamine to a urea derivative, but not under anaerobic conditions (Scheme 73, ii). Only if the reaction was performed in the air was product formation observed, with a significant improvement under a 10 psi  $\text{O}_2$  atmosphere at  $90^\circ\text{C}$ , while a CAAC- $\text{Au}^{\text{I}}$ -Cl remained inactive and the  $\mu^3$ -oxo bridged **515** much less efficient. Identification of the different reaction steps were possible by the isolation of the reaction intermediates. First, cyclohexylamine reaction with **516** leads to an oxidized dinuclear gold(I)-gold(I) complex **517** with bond distances typical for  $\text{Au}^{\text{I}}-\text{Au}^{\text{I}}$  aurophilic interactions (Scheme 73, i). The requirement for an oxygen atmosphere was presumed to be necessary for the scavenging of the hydrogen atoms. Treatment of **517** with CO (g) reduces the two gold(I) atoms to the recovered **516** and the carbon monoxide is oxidized by two electrons. Trace amounts of cyclohexyl isocyanate and urea formation was also noted in this step.

Preparation of the copper-derivative of the  $\text{M}_2^0\text{M}^{\text{I}}$  cluster via reduction of the  $\mu^3$ -oxo complex **519** with carbon monoxide did not proceed as for the gold congener **516**.<sup>71</sup> However, if bis(neopentyl glycolato)diboron was employed as the reducing agent, the corresponding trinuclear  $\text{Cu}_2^0\text{Cu}^{\text{I}}$  cluster **520** was accessible in high yield (Scheme 74). The availability of the copper variant of these trinuclear coinage metal clusters stabilized by the ambiphilic CAACs meant that the concept of galvanic exchange, the redox process between a sacrificial metal template and metal ions in solution to deposit the replacement metal ions on the surface of the template,<sup>519</sup> could be utilized for absolute templating.<sup>71</sup> For copper as the least electronegative of the three coinage metals, the exchange of all the copper in a sacrificial template with silver or gold should be possible. DFT calculations confirmed that the exchange of copper by gold should be exergonic ( $+27.6\text{ kcal mol}^{-1}$ ). Thus **520** could be employed as a template for the clean preparation of **516** from the complex **514-Au-Cl**. Using **514-Ag-OPh** as silver precursor analog, the increased oxophilicity of copper compared to silver could be exploited as driving force of the reaction to prepare also the mixed valent  $\text{Ag}_2^0\text{Ag}^{\text{I}}$  cluster **521**, which in turn could be used as template for **516** preparation from **514-Au-Cl** in a synthetic route that describes the first examples of mixed-valent trinuclear clusters also for silver and copper (Scheme 74).

Computational analyses suggested that the galvanic replacement does not occur through an outer sphere reduction pathway, but rather via an associative addition-elimination. This observation is rationalized by the isolobal analogy of **516** with the triatomic hydrogen cation  $[\text{H}_3]^+$  as  $\sigma$ -aromatic compound.<sup>520</sup> Lewis base reactivity where the delocalized metal-metal bonds mimic the  $\pi$ -aromatic interactions is therefore implicated to form tetranuclear 4-center-2-electron clusters with Lewis acid metals.<sup>521</sup> From these presumptions, it was proposed that galvanic templating occurs incrementally via a transient tetranuclear dicationic alloy cluster to form intermediated trinuclear alloys.<sup>71</sup> The similarity of the spatial arrangements of **516**, **520** and **521** to a M(111) metal surface (see Scheme 75, i), and the M-M bond distances of the clusters that closely resemble the distances observed in the free-standing 2D monolayers, lead to the hypothesis that these clusters could be used as a molecular model for understanding the interaction of small molecule substrates with M(111) metal surfaces. Specifically, for carbon dioxide reduction, surface interaction takes place via charge transfer from the surface to the antibonding orbital of  $\text{CO}_2$ . Formation of a bent radical is then disputed to either dissociate into CO and O, or to facilitate transient carboxyl (COOH) or formate (HCOO) formation.<sup>522</sup> **516** and **521** do not react with  $\text{CO}_2$ , in accordance with computational studies,<sup>523</sup> but **520** reacts cleanly to form **519** with CO formation (Scheme 75, ii).<sup>71</sup>

**Scheme 74** Mixed-valent trinuclear coinage metal cluster formation via absolute templating by galvanic exchange.

**Scheme 75** Using  $\text{M}_2^0\text{M}^{\text{I}}$  clusters as (i) M(111) molecular model for understanding of (ii)  $\text{CO}_2$  reduction on M(111) surfaces.<sup>71</sup> Modified from Peltier, J. L.; Soleilhavoup, M.; Martin, D.; Jazzar, R.; Bertrand, G. *J. Am. Chem. Soc.* **2020**, *142*, 16479–16485.

With the introduction of a reducing agent to regenerate 520, a TON of 1000 could be obtained without optimization. The use of 520 as a surrogate for Cu(111) means that the hypothesis of reductive  $\text{CO}_2$  dissociation to  $\text{CO} + \text{O}$  by copper surfaces could be supported at the molecular level. The electronic properties of CAACs are also excellently suited to the control of cluster size and composition of coinage metal/chalcogen clusters.<sup>524</sup> This translates to a tunability of the functionality of the clusters in terms of their photophysical properties as the increased  $\sigma$ -donicity and  $\pi$ -acceptor ability lower the metal/chalcogenide-to-ligand charge transfer excited states to impact on the observed photoluminescence.

### 1.05.5.3.3 Metal nanoparticles and surfaces stabilized by nonclassical carbenes

Although the value of metal carbenes in heterogeneous catalysis is well-recognized, the influence of carbene surface attachment has been barely explored.<sup>525–527</sup> Carbene stabilized nanoparticles (NPs) are commonly prepared by ligand exchange of L-NP with NHC, or by controlled selective degradation of the corresponding metal complexes using reducing agents.<sup>528</sup> For classic NHCs, robust self-assembled monolayers on Au(111) surface and nanoparticles (NPs) have been reported as a consequence of the strong, substitutionally inert metal-carbon bond formed.<sup>529</sup> The bonding mode for CAACs on heterogeneous surfaces has been implicated to differ from the single carbene-metal bond found in CAAC complexes.<sup>530</sup> In other, independent studies, it could be shown that Rh-NP formation occurred as a result of Rh-CAAC complex decomposition, as shown independently by the groups of Bullock<sup>531</sup> and Glorius<sup>532</sup> for Rh-catalyzed arene hydrogenations. In both cases, the formed Rh-NPs are stabilized by protonated CAAC species, albeit that these non-carbene CAAC derivatives did play a key role in determining the chemoselectivity of fluorinated arene hydrogenation.<sup>532</sup> Even more recently, a systematic investigation of CAACs on coinage M(111) (M = Cu, Ag, Au) surfaces has been conducted.<sup>533</sup> The dimethyl-CAAC- $\text{CO}_2$  adduct 522 was used as precursor for free carbene 68 formation which could be vacuum-deposited on M(111) surfaces to form 523 (Scheme 76). Confirmation and characterization of the intact-deposited carbene and surface-interaction was achieved with scanning tunneling microscopy (STM), X-ray photoelectron spectroscopy (XPS) and DFT calculations. The 2,6-diisopropylphenyl group is orientated perpendicular to the CAAC ring and parallel to the surface, while the two methyl groups adjacent to the ring-N points upward to minimize steric hindrance. At high coverage, molecular islands with short-range order were observed. The asymmetry and bulk of the substituents flanking the carbene carbon atom prevents self-assembly to a well-ordered, close-packed structure. STM images showed that the CAACs are mobile on the metal surfaces at lower coverage.

**Scheme 76** Deposition of CAACs generated from  $\text{CO}_2$ -adducts on M(111) surface.<sup>533</sup> Modified from Bakker, A.; Freitag, M.; Kolodzeiski, E.; Bellotti, P.; Timmer, A.; Ren, J.; Lammers, B. S.; Moock, D.; Roesky, H. W.; Mönig, H.; Amirjalayer, S.; Fuchs, H.; Glorius, F. *Angew. Chem. Int. Ed.* **2020**, *59*, 13643–13646.

This pioneering study on the coinage metal surfaces paves the way for studies of other nonclassical carbenes on (different) metal surfaces.<sup>525–527</sup>

### 1.05.6 Emerging applications of nonclassical carbenes

In the different categories of ligand noninnocence highlighted in this work, the applications of the metal complexes developed have been predominantly in the arena of molecular catalysis. The nonclassical carbenes are increasingly used also in non-catalytic applications including supramolecular and material chemistry<sup>458–461</sup> (see Section 1.05.5), and in light emitting or harvesting,<sup>458,534–538</sup> and biological or medicinal applications<sup>458,534,539–542</sup> of these carbon-donor ligands. Of relevance to the current work is especially the demonstration of a participatory role of the ligand in the targeted application extending beyond the inherent electronic properties of the ligand, to facilitate the photophysical or biological applications.

#### 1.05.6.1 Light-harvesting and -emitting applications

Transition metal complexes of Pt<sup>II</sup>, Ir<sup>III</sup> and Ru<sup>II</sup> are well-known as triplet emitters for OLED (Organic Light Emitting Diode) applications, as a result of the spin-orbit coupling (SOC) induced by the heavy metal central atom,<sup>543</sup> or as photosensitizer dyes for solar energy conversion based on electrochemiluminescence.<sup>544,545</sup> Cost and availability factors mean that less expensive complexes based on iron, copper, osmium, etc. are attractive alternatives, but the role of the ligand on the photophysical and -chemical properties is an important consideration here. The interest in the photoactivity of the nonclassical carbene complexes is on the rise as a consequence of the stereoelectronic properties of these ligands. Robust metal-carbon bonds that can facilitate stressed geometries are preventative to distortions in the excited state to disfavor nonradiative decay for improved emission.<sup>546</sup> Secondly, strong  $\sigma$ -donor ligands increase the energy levels of the empty d-orbitals as an additional strategy for emissive complex design that avoid the nonradiative metal-centered d-d transitions. The bonding motif of cyclometalated bi- or tridentate C- and/or N-donor luminophores is the most explored one to achieve the objectives above. Based on the success of polypyridine complexes of ruthenium(II) as photosensitizer dyes for dye sensitized solar cells (DSSCs),<sup>545,547,548</sup> this has also been the starting point for research using the nonclassical carbenes as C,N- (or C,C)-cyclometalated  $\sigma$ -donors substituting one or more pyridine sites.

##### 1.05.6.1.1 Photoactive nonclassical carbene complexes of group 8 transition metals

Accordingly, several examples of triazolylidene Ru<sup>II</sup> complexes have been investigated (Fig. 15). The first of these were reported by Albrecht in a series of NHC-py and one trz-py (524) complex,<sup>549</sup> in an improvement to emissionless picolyl-tethered NHC complexes without the CH<sub>2</sub>-spacer.<sup>550</sup> The bidentate i-bitz ligand as C,C- analogs in 528 was compared also to the trz-py C,N-bidentate ligands where the pyridine was linked to either N1 (525) or C4-ring triazol-ring position (527). The significant effect of trz incorporation on ground and excited state redox potentials was demonstrated when comparing emission band positions and excited state lifetimes of the benchmark [Ru(bpy)<sub>3</sub>]<sup>2+</sup> complex emitting from the long-lived triplet metal-to-ligand charge transfer (<sup>3</sup>MLCT) state.<sup>551</sup> Moreover, this was also the first report of Os<sup>II</sup> trz complexes (526, 529, Fig. 15) for photosensitizer applications. Alternatively, C,C-cyclometalating ligands were used to prepare monocationic derivatives 530.<sup>552</sup> Proceeding from the

Fig. 15 Photoluminescent tris(bidentate) and bis(tridentate) ruthenium(II) complexes with triazolylidene donor ligands.

tris-bidentate ligand arrangement to a bis-tridentate octahedral Ru<sup>II</sup> was accomplished with CNN-pincer trz-py-py (531, Fig. 15) or CNC-pincer trz-py-trz (532 and 533, Fig. 15) ligands as analogs to the well-known bis(terpyridine) (terpy = 2,2':6',2''-terpyridine) ruthenium(II) complexes.<sup>206–208</sup> The advantages of high stability and isomer-free functionalization of terpy complexes are often offset by short-lived excited states, due to rapid deactivation via energetically low-lying triplet metal-centered (<sup>3</sup>MC) excited state. This is a result of weaker  $\sigma$ -donation of the pyridyl-based ligands with strained bond-angles deviating from ideal octahedral geometry in [Ru(terpy)<sub>2</sub>]<sup>2+</sup>. For the Ru<sup>II</sup> trz complexes listed in Fig. 15, destabilization of the <sup>3</sup>MC state relative to the <sup>3</sup>MLCT state occurs with the introduction of the trz donors, in addition to the expected more positive redox potentials which should facilitate charge separation in the excited state.<sup>550</sup> Radiationless deactivation via <sup>3</sup>MC is thereby suppressed. Also the weaker  $\pi$ -donation from trz ligands facilitates a <sup>3</sup>MLCT–<sup>3</sup>MC separation as well as an increase in the ground state (GS)–<sup>3</sup>MLCT gap to yield complexes displaying photoluminescence emission with longer lived excited states and higher emission quantum yields. The practical functionality of the Ru<sup>II</sup> dyes in DSSCs is proven with the cooperative binding of the complexes to TiO<sub>2</sub> surfaces through the carboxylate- or phosphonate-functionalized terpy-ligands (533). This anchoring method robustly anchors the complex while maintaining charge transfer from the dye into the semiconductor.<sup>208,553</sup>

For the first-row transition metal analog of [Ru(bpy)<sub>3</sub>]<sup>2+</sup> and its polyimine derivatives, the smaller ligand-field splitting of Fe<sup>II</sup> results in high-spin electronic configurations that are characterized by low-lying MC states (quintet <sup>5</sup>MC and triplet <sup>3</sup>MC).<sup>554</sup> The <sup>5</sup>MC state is commonly regarded as the main deactivating state for the photochemically pertinent <sup>3</sup>MLCT state, leading to extremely short excited state lifetimes in the femtosecond range.<sup>555</sup> The use of ligands with higher field strength and  $\sigma$ -donation can effectively destabilize the <sup>5</sup>MC state so that the <sup>3</sup>MLCT state is first intercepted by the <sup>3</sup>MC before the <sup>5</sup>MC surface crosses the <sup>3</sup>MLCT potential energy surface.<sup>556</sup> Employment of the strongly donating bidentate bis(triazolylidene) i-bitz ligand in the heteroleptic complex Fe<sup>II</sup> 534 (Fig. 16), destabilizes both the <sup>5</sup>MC and the <sup>3</sup>MC states so that a long-lived <sup>3</sup>MLCT state (13 ps compared to the 130 fs of [Fe(bpy)<sub>3</sub>]<sup>2+</sup>) is accessible with photophysical behavior resembling that of Ru<sup>II</sup>.<sup>557</sup> The strategy of using the i-bitz ligands to realize longer-lived excited state lifetimes for iron complexes were extended by the same group, to a homoleptic tris(bidentate) complex 535 (Fig. 16) featuring a low-spin Fe<sup>III</sup>.<sup>558</sup> The unique combination of the ground state doublet iron(III) metal center and the three i-bitz ligands promotes the reversal of the charge-transfer excitation direction.<sup>559</sup> A ligand-to-metal charge-transfer (<sup>2</sup>LMCT) excited state is generated, with a groundbreaking lifetime of 100 ps emitting at room temperature. The complex in the double <sup>2</sup>LMCT state retains its ground state geometry so that little energy is lost to molecular rearrangements during the light-induced charge transfer process. Thus the <sup>2</sup>LMCT state provides for spin-allowed fluorescence as it relaxes to the ground state with conservation of electron spin.

Chemical reduction of Fe<sup>III</sup> in 535 by dithionite to Fe<sup>II</sup> yields dicationic 536 (Fig. 16), that displays the expected MLCT as the lowest-energy charge transfer process as observed for 534.<sup>560</sup> However, the homoleptic ligand environment furnishes an unusually strong ligand field for the Fe<sup>II</sup> complex that provides for an unprecedented lifetime of 528 ps for the <sup>3</sup>MLCT state, with a deactivation pathway that excludes energetic access to the <sup>5</sup>MC state.<sup>561</sup> Resonant photoelectron spectroscopy (RPES) provides direct spectroscopic evidence to corroborate the density theory calculations revealing pronounced mixing of the frontier orbitals as MO interactions between the iron(III) 3d-levels and the i-bitz frontier  $\sigma$ - and  $\pi$ -orbitals of 535.<sup>562</sup>

### 1.05.6.1.2 Photoactive nonclassical carbene complexes of group 9 transition metals

The high SOC of the heavy platinum-group metal ions means that rapid intersystem crossing (ISC) takes place in the excited state, so that high quantum efficiencies are reached for the photoluminescent emissions of these triplet emitters in OLED applications.<sup>563</sup> Also in the case of photoluminescent iridium(III) and platinum(II) complexes, the structural motif of bidentate N,N-, N,C- or C,C- ligands employing neutral pyridyl or anionic pyrazolyl derivatives as N-donors and anionic phenyls or neutral NHCs as C-donors for cyclometalation, has been the most common approach. In the case of Ir<sup>III</sup> complexes, these metal-ligand combinations deliver mostly blue and near-UV phosphorescence.<sup>535,564</sup> As for the group 8 metal complexes discussed above, only the trz class of the nonclassical carbenes under review has been explored as even stronger donating C-donors for Ir<sup>III</sup> complexes for OLED applications.

Fig. 16 Photoluminescent iron bis(triazolylidene) complexes.

The use of two trz-pyridyl (C,N) (537),<sup>565</sup> trz-triazolide (C,C) (538),<sup>566</sup> trz-phenyl (C,C) (539),<sup>121</sup> and trz-imidazolylidene (C,C) (540 and 541)<sup>567</sup> bidentate ligands yield phosphorescent Ir<sup>III</sup> complexes emitting in the blue region with microsecond lifetimes ranging from 0.4–3.8  $\mu$ s at room temperature (Fig. 17). Variable quantum efficiencies of 3.1–28.0% for 539,<sup>121</sup> 9–12% for 537,<sup>565</sup> 538<sup>566</sup> and 541,<sup>567</sup> and 50.0–57.4% for 540<sup>567</sup> are achieved, and depend on the ancillary ligands present in the coordination sphere.<sup>568</sup> The expected <sup>3</sup>MLCT state is the major emitting state, although for 537 it was found that ligand-centered (LC) transitions between the two trz present occur. Nevertheless, the moderate  $\pi$ -acceptor and strong  $\sigma$ -donor abilities of the trz are again responsible for stabilizing the emissive complexes due to more stable Ir–C bonds<sup>566</sup> to lower access to the nonradiative deactivation pathway involving low-lying <sup>3</sup>MC states.<sup>568</sup>

### 1.05.6.1.3 Photoactive nonclassical carbene complexes of group 10 transition metals

A series of C,C-cyclometalated platinum(II) complexes featuring phenyl-Im4 (543, Fig. 18)<sup>569</sup> or -trz (544<sup>570</sup> and 545,<sup>571</sup> Fig. 18) with  $\beta$ -diketonate acac (acetylacetonato) auxiliary ligands were reported by Strassner et al. They propose a strongly metal-perturbed intraligand/metal-to-ligand charge transfer (ILCT/MLCT) for the long-lived (27–57  $\mu$ s) room temperature phosphorescence ( $\phi$  = 40–69%) observed for the cyclometalated Im4 complexes 543.<sup>569</sup> Improved quantum yields ( $\phi$  = 67–78% and 70–84%, respectively for 545 and 544) in poly(methyl methacrylate) (PMMA) matrices are paired with shorter excited state lifetimes (18–21  $\mu$ s and 11–15  $\mu$ s, respectively) upon introduction of the trz ring instead of Im4. Modification of the cyclometalating phenyl in 544 to the annulated dibenzofuranyl shifts emission to significantly lower energy,<sup>571</sup> while variation of the N3-aryl from phenyl to mesityl or duryl in 544 (Fig. 18) also affects emission color. The sterically unencumbered N3-phenyl rotates into the molecular plane to enlarge the conjugated system as predicted by theoretical calculations to stabilize the excited state. In contrast, planarization of the mesityl ligand is hindered due to steric demand such that its contribution to the conjugated system is reduced which leads to a blue shift of the emission.<sup>570</sup>

A tridentate CNC-ligand comprising a central pyridine flanked by two trz was used to chelate a platinum(II) metal to give the square planar complexes 542 with variable ancillary ligands (chloride, acetonitrile or cyanido) that only slightly influences emission wavelengths and lifetimes (Fig. 18).<sup>211,572</sup> Only weak green emission was observed ( $\phi$  = 3%) arising from mixed LC and MLCT transitions.<sup>572</sup> If a CNC-pincer like 2,6-di(*p*-tolyl)pyridine is rather used as ancillary chromophoric ligand, cyclometalation of a trz with a phenyl substituent on the N1-position yields complexes 546 and 547, consecutively, with the CNC ligand either acting as a bidentate or tridentate ligand in the octahedral coordination sphere (Fig. 18).<sup>573</sup> Complexes 546 and 547 represent the first examples of Pt<sup>IV</sup> with mesoionic carbenes. At room temperature, weak emission from <sup>3</sup>LC states is observed, but in PMMA matrices quantum efficiencies increase to 71% and 61%, respectively, for 546 and 547. An increase in the energy of deactivating LMCT excited states is ascribed to the aryl-carbene ligand. Fine-tuning of emission color from blue to yellow is accessible by introduction of variable C,N-chelating chromophores into the Pt<sup>IV</sup> coordination sphere (548–549, Fig. 18), with exceptional efficiency reported for the first time for platinum(IV) complexes ( $\phi$  = 97% for 549 and  $\phi$  = 93% for 550).<sup>574</sup> The role of the trz is that of supporting ligand that leads to significantly lower nonradiative decay rates and higher quantum efficiencies, compared to the homologous C2-symmetrical [PtCl<sub>2</sub>(C,N)trz-Ph]. Computational calculations substantiate the effect of the carbene ligands in raising the energies

Fig. 17 Phosphorescent iridium(III) trz complexes.

**Fig. 18** Photoluminescent platinum bis(trz) complexes.

of the nonemissive deactivating <sup>3</sup>LMCT states for the OC-6-54 isomers 548–552 shown in Fig. 18. In contrast, the OC-6-42 isomers are not luminescent as they present a <sup>3</sup>LMCT state with long excited state lifetimes.

#### 1.05.6.1.4 Photoactive nonclassical carbene complexes of group 11 transition metals

The linear geometry of the coinage metals in oxidation state +1 coordinated by NHC ligands are well-known to produce photoluminescent complexes.<sup>458,535,575,576</sup> The large SOC of the 4d<sup>10</sup> and 5d<sup>10</sup> metals, enhanced by relativistic effects in the case of gold and underscored by aurophilic interactions, facilitates the access to emissive triplet excited states via intersystem crossing.<sup>576</sup> Using simple monodentate trz, either neutral monocarbene Au<sup>I</sup> complex 553 or cationic biscarbene Au<sup>I</sup> complex 554 were prepared, or the dinuclear 555 with a bidentate i-bitz ligand enforcing short Au–Au bond distances (Fig. 19).<sup>577</sup> MLCT and intraligand π–π\* transitions led to the identification of two excited states – a singlet state with weak fluorescence as well as an intense and long-lived phosphorescent triplet state.

For 3d<sup>10</sup> Cu, metal-centered d–d\* transitions are absent to preclude excited state deactivation but SOC is small in comparison to its heavier congeners. High radiative rate constants can nevertheless be achieved by using π-accepting carbenes as monodentate chromophoric ligands that lead to the formation of excited states with large MLCT or LLCT.<sup>578–581</sup> Especially the molecular design strategy of the combination of a donor amide and an acceptor carbene ligand bridged by a d<sup>10</sup> metal (CMA = carbene metal amide) mediates interligand charge transfer (LLCT). In this way, thermally activated reverse intersystem crossing (rISC) from nonemissive triplet states to fluorescent singlet states can be achieved for thermally activated delayed fluorescence (TADF) emitters (vide infra Cu CAAC complexes).<sup>582–584</sup> Fu and Yan et al. utilized the CMA motif in the preparation of linear gold(I) (556) and copper(I) complexes (557, Fig. 19) containing pyridine-fused trz ligands *trans* to either an unfunctionalized carbazolidide or a di(*tert*-butyl)-substituted carbazolidide to hinder π–π interactions.<sup>585</sup> In both cases, head-to-tail intermolecular self-assembly between the carbazolidide and pyridine-fused trz of adjacent molecules also facilitate intermolecular CT. In the absence of triplet-quenching oxygen, a delayed photoluminescent component in both solution and in the solid state is indicative of TADF emitters. Evidence for the existence of a monomer-dimer equilibrium in solution presents dual-emission bands which displays single component multicolor emission. Moreover, emission color could be tuned by variation of excitation wavelength, temperature, degree of concentration and complex concentration.

Photoluminescence is also dependent on the coordination geometry of the d<sup>10</sup> coinage metals, with three coordinate trigonal planar copper(I) complexes demonstrating tunable behavior from pure phosphorescence to TADF depending on the CMA dihedral angles.<sup>582</sup> Limited ligand scaffold possibilities are available for photophysical tuning of the triplet-singlet gap by modification of three coordinate geometries to ground state Jahn Teller-distorted T-shapes.<sup>586</sup> The combination of a carbazolidide with two flanking

**Fig. 19** Photoactive trz complexes of Au<sup>I</sup> and Cu<sup>I</sup> with linear geometries.

trz yields such T-shape geometries for all three the coinage metals Cu<sup>I</sup> (558),<sup>210</sup> Ag<sup>I</sup> (559, Fig. 20)<sup>217</sup> and Au<sup>I</sup> (206, Scheme 28).<sup>216</sup> The unique reactivity of 206 with electrophiles provides the opportunity to modify the gold(I) complex post-complexation by electrophilic attack either at the amide to yield the cationic linear Au<sup>I</sup> complex 209, or at the nucleophilic metal to furnish the Au<sup>III</sup>-F square planar complex 213 (Scheme 28, Section 1.05.2.2.1).<sup>217</sup> Emissions extending from the blue (copper) to green (gold) to orange (silver) spectrum originate from metal-perturbed  $\pi(\text{carbazolide})-\pi^*(\text{carbene})$  <sup>3</sup>ILCT excited states. The highest quantum yield ( $\phi = 14\%$ ) is observed for the linear Au<sup>I</sup> complex 209. rISC is prohibited by a larger triplet-singlet gap to suppress TADF, with greater phosphorescence contributions to the photoluminescence leading to longer decay times in THF at room temperature. On the other hand, the lifetime of Cu<sup>I</sup> complex 558 is too short (sub-nanosecond) to be determined with certainty, and emission may be fluorescent in nature. For the Ag<sup>I</sup> 559 and Au<sup>I</sup> 206 analogs, decay lifetimes in the microsecond range, increases to millisecond lifetimes upon cooling to 77 K. This increase is in line with the assignment of a change in emission origin from <sup>3</sup>ILCT to <sup>3</sup>IL excited state and may suggest TADF.

Modification of the bis(trz)carbazolide scaffold can be effected by means of the carbazolide-trz connection via the N1-trz atoms instead of the C4-trz atoms, as well as utilization of an intramolecular cyclization as N-alkylation strategy.<sup>587</sup> Employing (earth) alkali metals prevents ligand distortion following excitation to avoid nonradiative deactivation. A lithium dimeric structure bridged by iodo- and lithium iodide adducts (560, Fig. 20) is used also as a precursor for the preparation of the mononuclear magnesium bromide complex 561. Blue-green and intense lime-green luminescence in solution were observed for 560 and 561 ( $\phi = 16\%$  and 14%, respectively) at room temperature.

The recent seminal developments of highly emissive coinage metal complexes of CAACs were initiated by the photophysical investigation of linear copper(I) halido complexes 562, 563 and 564 in Fig. 21, by the groups of Credgington and Bochmann,<sup>588</sup> Steffen,<sup>589</sup> and Bertrand and Thompson,<sup>590</sup> respectively, utilizing adamantyl (AdCAAC) 600, dimethyl (Me<sub>2</sub>CAAC) 68 or diethyl (Et<sub>2</sub>CAAC) 514 substituted CAAC ligands. In contrast to analogous NHC complexes that are almost non-emissive,<sup>589</sup> these complexes displayed excellent quantum efficiencies with values for  $\phi$  of up to 96% achieved for 562 with AdCAAC ligand 600.<sup>588,590</sup> Disproportionation of the neutral linear complexes yield cationic bisCAAC complexes 566. Both these, and the 3- and 4-coordinate Cu<sup>I</sup>-AdCAAC complexes (567, 568, Fig. 21) accommodating bi- or tridentate trispyrazolylborate (Tp) ligands

**Fig. 20** Bis(trz)carbazolide complexes of the coinage and the s-block metals.

**Fig. 21** Photoactive CAAC complexes of the coinage metals.

were found to display much lower quantum yields, associated with radiationless energy loss involving excited structural rearrangements for coordination numbers exceeding two.<sup>590</sup> The complexes are phosphorescent with decay lifetimes ranging from 1 to 32  $\mu$ s and radiative rate constants ( $k_r = 2.6\text{--}3.9 \times 10^4 \text{ s}^{-1}$ ), indicating emission from the triplet  $^3\text{MLCT}$  state, with evidence for aggregation that leads to a red-shift in the emission wavelengths as compared to NHC  $\text{Cu}^I$  complexes.<sup>589,590</sup> The improved  $\sigma$ -donor/ $\pi$ -acceptor properties of the CAACs, compared to the NHCs, allow for participation of the copper d-orbitals in several HOMOs. This yields exceptionally strong SOC mixing of the  $^1\text{MLCT}$  and  $^3\text{MLCT}$  states to ensure efficient ISC, CT and radiative recombination in commercially available OLED host-guest systems.<sup>589</sup>

Copper(I) CAAC complexes with nanosecond photoemissions could be achieved with the incorporation of aryloxy- (569), thiophenol (571) or arylamido- (573) ligands as the second coordinating moiety (Fig. 21).<sup>591</sup> The heavier gold(I) analogs 570, 572 and 574, respectively, were similarly shown to present decay lifetimes varying from 2 to 275 ns. Emission color ranged from blue to yellow, depending on the ancillary ligand, while luminescence intensity was shown to increase with increasing steric bulk of the CAAC employed, as well as the  $M\text{--}O\text{--}C\text{--}C$  torsion angles for 569 and 570. Notably, more than one emission mechanism were found to operate for both the first and third row metals: both a prompt fluorescence emission in the nanosecond range, and a minor component with (sub)microsecond lifetime, depending on the ligand *trans* to the carbene in LMLCT-type delayed emissions. Silver(I) CAAC complexes 575 and 576 similarly displayed such dual emission mechanisms.<sup>592</sup>

Employment of potentially bidentate S,S or N,S-ligands to prepare 3-coordinate copper(I) complexes 577 and 578, as well as linear 579 (Fig. 21) was reported next by Bochmann et al.<sup>593</sup> The two-coordinate 579 proved to be a particularly efficient white phosphorescent emitter, with solid state quantum yield exceeding 96%. On the other hand, the tridentate 577 proved nonemissive, but the complex was found to decompose at 180  $^\circ\text{C}$  with the loss of the coordinating  $\text{CS}_2$  molecule, yielding the first example of a CAAC- $\text{Cu}^I$ -carbazolidene with the CMA-motif (vide supra). The same group also demonstrated the use of *malon*NHCs as anionic 6-membered NHC ligands based on a malonate unit to prepare zwitterionic  $\text{Cu}^I$  (580),  $\text{Ag}^I$  (581) and  $\text{Au}^I$  (582) mixed-carbene complexes (Fig. 21).<sup>579</sup> The two carbene ligands are co-planar which allows LUMO delocalization across the carbene carbon atom of both carbenes. This results in overlap between the HOMO and LUMO, and the large HOMO-LUMO energy gap (as

established electrochemically), gives rise to blue-white phosphorescence with excited state lifetimes (of 50–400  $\mu\text{s}$ ) increasing from the first row to the third row metal, in line with the SOC constants. For these compounds, and the preceding complexes, no strong intermolecular interactions were observed. Ultimately, however, the CMA bonding motif yielded the most successful photoemitters. Both copper (583) and gold (584) AdCAAC carbazolidine (Cbz) complexes were prepared, as well as substituted Cbz-gold(I) 585 and diphenylamide 586 (Fig. 21) for incorporation into OLED devices.<sup>594</sup> Rapid ISC from the triplet state is required to enable higher efficiencies for phosphorescent OLEDs not based on heavy atoms like platinum or iridium, or TADF OLEDs with low exchange energies. In the case of these CMAs 583–585, molecular configurations (depending on the relative dihedral angle of the CAAC (acceptor) and Cbz (donor) planes) that achieve low exchange energies exist. This means that internal quantum efficiencies of near-100% are obtained for the solution-processed OLEDs. Optimization of the Cu<sup>I</sup> CAAC OLED by fine-tuning of the CAAC steric encumbrance (CAAC variation between AdCAAC 600 in complex 583, MenthCAAC 41 in complex 587, Et<sub>2</sub>CAAC 514 in complex 588 and Me<sub>2</sub>CAAC 68 in complex 589, Fig. 21) and electronic properties of substituted Cbz (cyano-substituted 591, methoxy-substituted 592 or methyl-substituted 590) in addition to diphenylamide 593, Fig. 21 demonstrate the requirement of coplanar conformation of the ligands to suppress nonradiative decay associated with structural reorganization to achieve photoluminescence efficiencies > 99% from microsecond lifetime interligand charge transfer (ICT) transition between carbene and amide, and SOC through the metal d orbitals.<sup>595</sup>

In a further investigation of the photophysical properties of linear CAAC coinage metal CMAs (comparing Cu<sup>I</sup> 587, Ag<sup>I</sup> 594 and Au<sup>I</sup> 595, Fig. 21), it was found that the metals are redox innocent in contrast to other d<sup>10</sup> metal centers that emit from MLCT excited states.<sup>580</sup> Instead, the metal modulates electron coupling as a monoatomic electrical conduit between donor Cbz and acceptor CAAC. Delayed fluorescence resulting from thermally promoted rapid ISC arises from long-lived T<sub>1</sub> transition to the S<sub>1</sub> state. The fastest radiative rate is achieved for the silver complex, inversely related to the metal-ligand bond distances of the complexes. Exploitation of the success of the CAAC-based CMA photoemitters is evident from the rapid development of analogous coinage metal photoemitters utilizing e.g. first (596, 597, Fig. 21) and second generation carbazolidine dendrimers (598, 599, Fig. 21),<sup>581,596</sup> or modified CAACs such as the cyclic (aryl)(amino)carbenes (CAArCs)<sup>597</sup> or bicyclic CAACs,<sup>581</sup> with new or improved photophysical properties.

#### 1.05.6.2 Biological and medicinal applications of the nonclassical carbenes

The precedent of NHC metal complexes as chemotherapeutic agents<sup>458,539–542,598</sup> for anticancer, antimicrobial and antibacterial applications, or for biomedical applications<sup>458,540,599,600</sup> like chemosensing, photodynamic therapeutics or cell imaging, is underpinned by the strong metal carbon bond formed, as well as the ease of substituent variation and high functional group tolerance for biological property tuning. For the nonclassical carbene complexes under review, biological applications are being reported with increasing frequency, but remains an area where development is still in its infancy.

Coinage metal carbene complexes are being developed in attempts to minimize the significant side effects of Auranofin, the leading phosphine gold(I) thiolate complex with antitumor activity used clinically. Auranofin, and other gold(I)-based drugs, are thought to operate via a mode of action that includes binding to selenocysteine groups of the Thioredoxin Reductase (TrxR) enzyme active site, which is involved in cell death pathways mediated by Reactive Oxygen Species (ROS).<sup>601</sup> The stronger metal-ligand bond granted by coinage metal CAAC complexes of the type CAAC–M–Cl (562–565, 575; Fig. 21) was therefore thought to be potential cytotoxic agents capable of inhibiting TrxR with improved selectivity, while the cationic biscarbene complexes of the type CAAC–M<sup>+</sup>–CAAC (566, 576; Fig. 21) (M = Cu, Ag, Au) as delocalized lipophilic cations have the potential to target the mitochondria of cancer cells by compounds characterized by elevated partition coefficient values to readily pass lipid membranes.<sup>602</sup> The neutral and cationic CAAC coinage metal complexes were screened against a panel of human cancer cell lines of varying degrees of cisplatin resistance by O'Connell and Bochmann et al., with high cytotoxicity exhibited (the half maximal inhibitory concentration ( $\mu\text{M}$ ) required to inhibit the growth of 50% of cells in the culture, or IC<sub>50</sub> values, are in submicromolar – 100 nanomolar range). Especially the CAAC–M<sup>+</sup>–CAAC complexes proved effective against the cisplatin-insensitive cell lines. The mode-of-action of these complexes could not be unambiguously assigned, but TrxR inhibition and ROS formation were ruled out as primary pathways. A closer inspection of the apparently metal-dependent mode-of-action<sup>602</sup> was done by preparing the Et<sub>2</sub>CAAC–Au<sup>+</sup>–Et<sub>2</sub>CAAC 601 and the CAAC-bound Auranofin analog 602 containing the gluco-pyranosyl-1-thiolate ligand (Fig. 22), and evaluating TrxR and bovine serum albumin (BSA) protein binding.<sup>603</sup> 601 proved even more cytotoxic than Auranofin and is also the least lipophilic of the series but showed the highest cellular uptake. No mitochondrial delocalization occurred and thus the cytotoxicity of 601 is likely cell-based but independent of the mitochondria or the inhibition of related proteins.

The anticancer activity of trz coordinated complexes has also been explored for similar reasons, namely the robust metal-carbon bond that is stable under physiological conditions, while examples of Im4 complexes explored for their cytotoxic activity are exceedingly rare.<sup>202</sup> Ruthenium, osmium (193 and 194, Fig. 4 and 603, Fig. 23),<sup>600,604</sup> and iridium trz complexes (604, Fig. 23)<sup>604</sup> have been reported. All the complexes showed in vitro cytotoxicity for human ovarian cancer cells (e.g. for 603, human ovarian cancer cell lines A2780 and A2780R IC<sub>50</sub> < 50  $\mu\text{M}$ ; or for 604, for ovarian cancer cell line MES\_OV IC<sub>50</sub> = 4.08 ± 0.5  $\mu\text{M}$ ), with a high degree of selectivity towards normal cell lines. No metal dissociation under physiological conditions occurred. Linear coinage metal metallocenyl-trz complexes 315 and 318 (see Scheme 39, i and iii, respectively) have also displayed varying degrees of cytotoxicity but proved non-selective.<sup>314</sup> If Fc-functionalized trz complexes containing C5-alkyl chains (605 and 606, Fig. 23) were prepared, good antibacterial activity against the resistant Gram-negative bacterial *Salmonella* strain was obtained, although higher concentrations were required for the inhibition of *E. coli*.<sup>605</sup> The requirement of both the metal centers (Fe and Au) as well as the cationic

Fig. 22 Cytotoxic CAAC Au<sup>I</sup> complexes.

Fig. 23 Trz metal complexes with medicinal or bio-photophysical applications.

charge for cytotoxicity towards lung cancer cell lines A549 and H1975 (with limited cytotoxicity for human embryonic kidney cells HEK-293 as a normal cell model), could be unambiguously proved for a Fc-trz gold(I) phosphine 607 (Fig. 23), although preliminary mode-of-action studies only confirmed apoptotic cell death pathways.<sup>606</sup>

Different cellular targets are available to the harder Au<sup>III</sup> complexes for antitumor activities based on different mechanisms than TrxR inhibition, as viable alternatives to isoelectronic platinum(II)-based drugs. However, the kinetic lability, light sensitivity and the tendency for the Au<sup>III</sup> to reduce to Au<sup>I</sup> or Au<sup>0</sup> under physiological conditions limit the usefulness of Au<sup>III</sup> metal complexes as anticancer agents.<sup>607,608</sup> Modification of the bis(trz)carbazolide ligand scaffold known to favor gold(I) oxidation,<sup>216</sup> yielded a proligand containing an 'unsubstituted' aromatic planar carbazole moiety for potential DNA intercalation. Metalation and subsequent chemical oxidation resulted in a redox stable Au<sup>III</sup> complex 608 (Fig. 23) containing a labile chloride ligand available for covalent DNA-bonding, as a multi-pronged approach to targeting cancer DNA.<sup>609</sup> The complex was found to be notably cytotoxic toward the breast cancer cell line MDA-MB-231 (IC<sub>50</sub> = 2.3 ± 0.8 μM) and behaves as a partial DNA intercalator that can target DNA three-way junctions with good specificity, several other B-DNA forms and Z-DNA *in silico*. Both the redox stability (and inertia towards reaction with intracellular reductant glutathione GSH) and the DNA affinity of 608 might be key factors underlying its cytotoxicity *in vitro*.

One further area of application is the combination of photoactivity in the biological field for cell imaging possibilities. The principle was recently demonstrated by a fluorescent Pd<sup>II</sup> trz complex 609 (Fig. 23) as a non-toxic probe for selectively labelling the

endoplasmic reticulum in live cells,<sup>610</sup> and Ir<sup>III</sup> trz complexes 541 (Fig. 17) as luminescent probes for cell imaging of lung cancer cells.<sup>567</sup> The developments in biological and photophysical applications have been in line with the tunable electronic, steric and stabilizing properties associated with these carbene ligands. The applications are therefore mostly based on the inherent electronic properties of these ligands, rather than specific noninnocent behavior (ligand-based cooperative or multifunctional), with the notable exception of 608.<sup>609</sup>

### 1.05.7 Perspective

In little more than a decade, the deployment of nonclassical carbenes Im4, CAACs and trz as ligands has seen the boundaries of metal-mediated (re)activity pushed to new limits. The distinct (stereo)electronic properties of the different nonclassical carbenes have led to remarkable inherent noninnocent ligand behavior of the heterocycles when compared to classical NHCs and other donor ligands. Exploitation of this feature during ligand design leads to tailored ligands for highly specialized applications, particularly when coupled with the incorporation of a functional group furnishing a multifunctional role for the nonclassical carbene heterocycle in (chiral) catalysis. The potential of switchable carbene ligands that can adopt more than two electronic states, or the combination of two different switchable states, e.g., redox and light switchable, especially warrants future interest. The ancillary roles accessible from these ligands pave the way to multimodal functional compounds. As an illustrative example, the development of theranostic compounds or multitarget therapeutic agents can be anticipated from the preparation of ligands that are cytotoxic, redox- and photoactive. Applications extending beyond the molecular level are still rare, but scaling up to functional macromolecular materials is the next step.

### Abstract

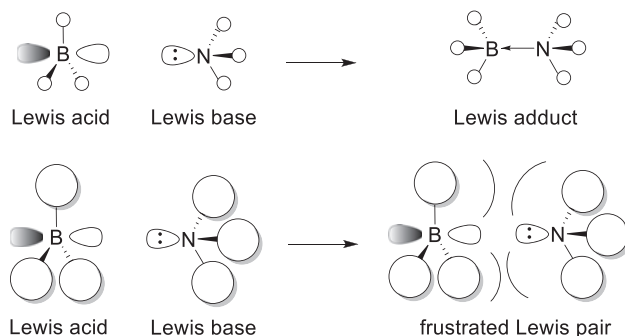

Since frustrated Lewis pairs were first defined in 2006, they have become one of the most exciting areas of main group chemistry. In just 15 years, these systems have gone from chemical curiosities to commonplace catalysts, and many research groups are now exploring their ability to supersede conventional transition metal catalysts. This article aims to discuss the catalytic applicability of frustrated Lewis pairs, with a discussion on hydrogenation catalysis, 1,2-hydrofunctionalization catalysis, cyclization catalysis, and CO<sub>2</sub> reduction catalysis.

### 1.06.1 Introduction to frustrated Lewis pairs (FLPs)

When a Lewis acid and a Lewis base combine, the lone pair of electrons on the base are donated into the empty *p*-orbital of the acid to form a Lewis adduct. In cases where there is segregation between the Lewis acidic and basic sites, an adduct is unable to form and instead a frustrated Lewis pair (FLP) is formed (Fig. 1). FLPs retain the reactivity of the individual Lewis acid and base centers and are thus able to partake in reactions which Lewis adducts are recalcitrant toward.<sup>1</sup>

Whilst the first frustrated Lewis pair was not identified until 2006, unexpected reactivity by Lewis acids and bases that could retrospectively be described as FLP-like in nature can be found as early as 1942.<sup>2–4</sup> In 1996, Piers observed that tris(pentafluorophenyl)borane [B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>] was an efficient catalyst toward the hydrosilylation of carbonyls with triphenylsilane, but it was not for a further 12 years that the mechanism was fully elucidated.<sup>5,6</sup> Stephan coined the term ‘frustrated Lewis pair’ following the

**Fig. 1** Formation of Lewis adducts and frustrated Lewis pairs.<sup>1</sup>

seminal discovery of 2006, which reported the first metal-free reversible activation of dihydrogen (**Scheme 1**).<sup>7</sup> The described phosphinoborane exhibited a large steric bulk around the Lewis acidic and basic sites and was able to reversibly activate dihydrogen under mild conditions.<sup>7</sup>

The simplicity of hydrogen activation by frustrated Lewis pairs led to a plethora of interest in their application toward further small molecule activation, and more recently catalysis. Since 2006, the scope of small molecules amenable to activation by FLPs has expanded toward CO<sub>2</sub>, NO<sub>2</sub>, SO<sub>2</sub>, alkenes and N<sub>2</sub>.<sup>8–11</sup> This article aims to explore the catalytic aspect of frustrated Lewis pairs.

### 1.06.2 FLP-mediated catalytic hydrogenation

The catalytic reduction of unsaturated compounds with dihydrogen is one of the most widely applied processes in industrial and academic settings. In fact, it is estimated that up to 20% of all synthesized chemicals have been subjected to one form of catalytic hydrogenation at one point in development<sup>12</sup>; however, the majority of catalysts used in the hydrogenation transformation contain a transition-metal center, which facilitates the reduction of dihydrogen with its *d*-orbitals. Herein, the filled  $\sigma$  orbital of dihydrogen is able to donate into an empty *d*-orbital of the metal, whilst simultaneously a filled *d*-orbital is able to donate electron density into the dihydrogen's empty  $\sigma^*$  orbital (**Fig. 2**, left).

A different process occurs in the activation of hydrogen by FLPs, wherein the basic component is able to donate electron density into the empty  $\sigma^*$  orbital of dihydrogen, whilst the acidic component is able to accept electron density from the filled  $\sigma$  orbital of dihydrogen (**Fig. 2**, right). For many years transition metals dominated the field of hydrogen reduction, with reports of main-group metals utilized in the field significantly rarer.<sup>13</sup> Thus, upon the seminal discovery of frustrated Lewis pairs an exciting new article in metal-free catalytic hydrogenations was launched.

#### 1.06.2.1 FLP-mediated catalytic hydrogenation of polar substrates

The serendipitous discovery by Stephan that a phosphinoborane could reversibly activate H<sub>2</sub> launched an exciting new article within the field of metal-free catalysis.<sup>7</sup> In quick succession, Stephan and other researchers observed that an FLP's ability to mediate reversible dihydrogen activation also granted it the ability to reduce catalytically a range of polar substrates. C–N multiple bonds and silyl

**Scheme 1** First example of reversible activation of dihydrogen by a non-metal complex.<sup>7</sup>

**Fig. 2** Activation of H<sub>2</sub> by metals (left) and FLPs (right).

enol ethers were the first to be reduced; however, it was not long before a more diverse scope of amides, phosphine oxides, and carbonyls were observed to be amenable to FLP-catalyzed hydrogenation.

### 1.06.2.1.1 Reduction of C–N multiple bonds and silyl enols

Stephan's seminal work on stoichiometric H<sub>2</sub> activation was swiftly followed with the first example of FLP catalyzed hydrogenation (Scheme 2).<sup>14</sup> Two intramolecular FLPs, **1** and **2**, were demonstrated to catalyze the reduction of a range of eleven sterically demanding unsaturated substrates including imines, protected nitriles and unactivated aziridines into their respective amines **3**, in poor to excellent yield.<sup>14</sup>

Shortly afterwards, Erker reported that phosphonium borate **4** could be employed as an intramolecular FLP toward the reduction of bulky imines. Unlike in previous examples,<sup>14</sup> where elevated temperatures were required for efficient reduction, FLP **4** was capable of reducing five imines under ambient conditions in good to excellent yield. Furthermore, this system also gave the first report of enamine reduction at room temperature (Scheme 3).<sup>15</sup>

A linked amine-borane FLP **5** termed a 'molecular tweezer' was later developed by Repo (Fig. 3).<sup>16</sup> This new system was reported to reduce imines that the previously known phosphine/borane FLPs had been recalcitrant toward.<sup>14,15</sup> For example, when catalyst **1** was investigated in this reduction, the imine substrate formed a strong amine-borate adduct **6**. The strength of this B–N interaction resulted in inhibition of the boron center, thus only allowing for stoichiometric reductions to occur.<sup>16</sup>

FLP **5** was found to catalyze the reduction of imines at low loadings under relatively ambient conditions, reflux in toluene under 2 bar of hydrogen (Scheme 4). Eight examples were reported, with almost quantitative NMR yields observed for most substrates; however, less sterically demanding imines (**7** and **8**) remained a limitation for this catalytic system, generating their corresponding amine products in a mere 4% yield.<sup>16</sup>

An intermolecular FLP composed of 1,8-bis(diphenylphosphino)naphthalene **9** and B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> was reported to catalyze the reduction of five silyl enol ethers into silanes (Scheme 5).<sup>17</sup> Whilst a relatively high catalyst loading was required, very mild conditions and low H<sub>2</sub> pressure was sufficient to catalyze the reduction, forming the desired silanes in high yields; however, for the less sterically demanding enol silyl ether **10**, a much harsher pressure of H<sub>2</sub> was required for the reduction to proceed.<sup>17</sup>

**Scheme 2** The first report of FLP catalyzed hydrogenation with intramolecular FLPs **1** and **2**.<sup>14</sup>

**Scheme 3** FLP catalyzed reduction of imines.<sup>15</sup>

**Fig. 3** Intramolecular FLP **5** for imine reduction (left); amine-borate adduct **6** formed when catalyst **1** used in imine reduction (right).<sup>16</sup>

**Scheme 4** Imine reduction catalyzed by FLP **5**.<sup>16</sup>

**Scheme 5** Silyl enol ether reduction catalyzed with a **9**/ $\text{B}(\text{C}_6\text{F}_5)_3$  FLP.<sup>17</sup>

In effort to improve the functional group tolerability for catalytic reduction, novel FLP systems were designed by Soós (**Scheme 6**). A simple modification to the archetypal  $\text{B}(\text{C}_6\text{F}_5)_3$  was employed, wherein a single perfluorinated aryl group on the borane was replaced with a mesitylene substituent. This had the effect of increasing congestion around the boron center, thus preventing the FLP from unwanted reactivity with the olefin functionalities in most cases. With the Lewis acid  $\text{B}(\text{C}_6\text{F}_5)_2\text{Mes}$  in hand, a screening with

**Scheme 6** Catalytic reduction by  $\text{B}(\text{C}_6\text{F}_5)_2\text{Mes}/\mathbf{11}$  and  $\text{B}(\text{C}_6\text{F}_5)_2\text{Mes}/\mathbf{12}$  FLP systems.<sup>18</sup>

various commercially available nitrogen-based Lewis bases was performed toward the reduction of an imine. Here DABCO (1,4-diazabicyclo[2.2.2]octane) **11** and quinuclidine **12** were found to perform the best when combined with  $B(C_6F_5)_2Mes$ , with the DABCO **11** system operating efficiently under ambient conditions.

The novel FLPs comprised of  $B(C_6F_5)_2Mes$  and **11** or **12** were applied toward the reduction of seven imines, with poor to excellent yields observed. Notably, challenging substrates **13** and **14** were also reduced by these FLP systems. In the case of allyloxy derivative **13**, the FLP systems tolerated the allyl and unactivated olefin groups, with only reduction of the imine observed; however, when subjecting the crotyl imine **14** toward the reduction, both the imine and olefin groups were hydrogenated. Finally, carvone **15** was investigated and the  $B(C_6F_5)_2Mes/11$  FLP was observed to reduce selectively the activated olefin within the six-membered ring in the presence of a terminal alkene, whereas the  $B(C_6F_5)_2Mes/12$  FLP was unable to promote any reactivity.<sup>18</sup>

An alternative approach to conventional FLP chemistry was demonstrated by Ashley, who used the softer *p*-block element, tin, rather than boron (Scheme 7).<sup>19</sup> Stannylum salt  ${}^iPr_3SnOTf$  **16** was prepared, of which the ion,  ${}^iPr_3Sn^+$ , can be considered as an isolobal equivalent to a triarylborane. The bulky alkyl groups around the tin center prevent the triflate counterion from interacting with its empty *p*-orbital, thus generating a shielded electrophilic moiety acidic enough to participate in FLP-type reactivity. Here, in combination with various bases, **16** was employed in the reduction of carbonyls and imines under mild conditions in 1,2-dichlorobenzene (DCB), and without the requirement for air sensitive techniques. Four carbonyls and six imines were readily reduced, with product yields strongly dependent on the identity of the base; in most cases the reaction proceeded best with 2,4,6-trimethylpyridine (collidine).<sup>19</sup>

### 1.06.2.1.2 Reduction of amides and phosphine oxides

The one-pot reduction of tertiary amides was achieved with a catalytic amount of the weakly Lewis acidic  $B(2,6-F_2C_6H_3)_3$  **17** in combination with an excess of oxalyl chloride  $(COCl)_2$ .<sup>20</sup> Oxalyl chloride served as a deoxygenating agent for the amide, forming chloroiminium chloride **18** in situ. Further reduction yielded the desired amine, which was formed as hydrochloride salt **19** and could be obtained readily by filtration. Through  $H_2/D_2$  isotope scrambling between **17** and tetraphenylphosphonium chloride, it was revealed that the chloride **18** formed in situ served as the Lewis base in the FLP, in what was noted as the first example of a halide acting as a Lewis base in FLP chemistry (Scheme 8).<sup>20</sup>

The reduction protocol with **17** was observed to be versatile across a range of functionalities, with benzoyl, formyl and cyclohexyl derived amides amenable to reduction in good to excellent yield. Moreover, acid-sensitive amides derived from proline **20** or containing a *tert*-butyloxycarbonyl (Boc) group **21** were also reduced adequately; however, acetyl derived amides performed poorly and highly reactive aromatic *N*-heterocycles such as diphenylamine and indole simply decomposed (Scheme 9).<sup>20</sup>

A combination of **17** and oxalyl chloride was also used in the reduction of triaryl phosphine oxides.<sup>21</sup> Here, 2,6-lutidine **22** was initially applied as the Lewis basic component of the FLP. While an optimization found the reduction would work efficiently, forming the desired phosphine in 93% yield, the hydrogen chloride by-product was observed to protonate **22**, thereby deactivating the catalyst. The reduction was also noted to occur quantitatively in the absence of **22**, wherein the phosphine oxide itself served as the Lewis basic component of the FLP (Scheme 10).<sup>21</sup> Further examples of substrates which act as a Lewis base in FLP chemistry can be found in the next section.

Scheme 7  ${}^iPr_3SnOTf$  **16** catalyzed reduction of carbonyls and imines.<sup>19</sup>

Scheme 8  $H_2/D_2$  isotope scrambling between  $B(2,6-F_2C_6H_3)_3$  **17** and tetraphenylphosphonium chloride.<sup>20</sup>

**Scheme 9** FLP mediated reduction of tertiary amides.<sup>20</sup>

**Scheme 10** FLP mediated reduction of phosphine oxides.<sup>21</sup>

Interestingly, by applying a higher pressure of hydrogen, the reduction of triaryl phosphine oxides could be observed to occur in the absence of the borane altogether, forming the phosphine in 93% yield. Computational studies suggested that this reaction proceeded via  $H_2$  activation by the phosphine oxide and a chlorophosphonium ion **23** (generated *in situ* by reaction between the phosphine oxide and the  $(COCl)_2$  additive) which served as the Lewis basic and Lewis acidic components of a new FLP respectively (Scheme 10).<sup>21</sup>

### 1.06.2.1.3 Substrates which also serve as the Lewis basic components of FLPs

Just 2 years after the discovery of frustrated Lewis pairs, it was recognized that basic substrates could also act as a component in a FLP, negating the use of an external base in the reaction. This was demonstrated simultaneously by Klankermayer and Stephan through the reduction of bulky imines by  $B(C_6F_5)_3$  (Scheme 11).<sup>22,23</sup> Stephan investigated a short scope of six imines, exploring the functional group tolerance with a set of optimized conditions.<sup>23</sup> Meanwhile, Klankermayer optimized the reduction of three imines, optimizing time,  $H_2$  pressure, catalyst loading and temperature.<sup>22</sup>

Stephan further expanded this methodology toward a protected aziridine, forming the corresponding amine in 95% yield (Scheme 12). Nitrile reduction was also attempted; however, it was observed that protected nitriles were not basic enough to extract the proton from the activated  $H_2$  without external assistance. Nonetheless, the addition of an external base, such as  $P(C_6H_2Me_3)_3$ , proved to be sufficient to catalyze the reduction of protected nitriles.<sup>23</sup>

A subsequent report further increased the scope of this system, with the reduction of five *N*-heterocycles such as acridine and substituted quinolines (Scheme 13). Whilst some quinolines required elevated temperatures to undergo reduction, good to excellent yields were observed throughout.<sup>24</sup>

Stephan later detailed that  $B(C_6F_5)_3$  could also catalyze the reduction of indole derivatives into their corresponding dihydroindoles.<sup>25</sup> Whilst the imines and *N*-heterocycles investigated previously were reducible under relatively ambient conditions,<sup>23,24</sup> the indole derivatives required harsher temperatures and pressures (80 °C; 103 bar  $H_2$ ) for sufficient reactivity. High temperatures were

**Scheme 11** Catalytic reduction of imines where the imine acts as both substrate and the basic component of the FLP.<sup>22,23</sup>

**Scheme 12** Catalytic reduction of aziridine and nitriles with B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>.<sup>23</sup>

**Scheme 13** Catalytic reduction of *M*-heterocycles with B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>.<sup>24</sup>

also required for the reduction of pyridines and diimines, although only 4 bar of H<sub>2</sub> was required. Notably, upon the reduction of pyridine derivatives, the FLP system selectively reduced the imine functionality and not the aromatic pyridine ring (**Scheme 14**).<sup>25</sup>

In 2009, Berke introduced a modified Lewis acid with two acidic centers, 1,8-bis(dipentafluorophenylboryl)naphthalene **24**, which was able to form a FLP with the substrates it was designed to reduce. Seven bulky imines were subjected toward the reduction with this FLP system with 10 mol% loading of **24** (**Scheme 15**). Most substrates were reduced into their respective amines in 99%

**Scheme 14** Catalytic reduction of indoles, pyridine derivatives and diimines.<sup>25</sup>

**Scheme 15** Catalytic reduction of imines with bisborane **24**.<sup>26</sup>

yield in as little as 6 h; however, a limitation was noted upon the attempted reduction of *N*-benzyl-1-phenylmethanimine **25**, which was resistant toward reaction.<sup>26</sup>

Moreover, the reduction of protected oximes into their corresponding protected hydroxylamines was observed by Oestreich, whilst using a catalytic amount of B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> (**Scheme 16**). Good to excellent yields were reported over 14 examples, though the reduction was found to be unsuccessful with unprotected oximes or when the oxime protecting group was not sufficiently bulky. The stable boron-oxime adduct intermediate was observed when a *t*Bu or Si<sup>*i*</sup>Pr<sub>3</sub> protecting group was installed on the oxime; however, the Si<sup>*i*</sup>Pr<sub>3</sub> protecting group was preferred as the free hydroxylamine was obtainable through a simple treatment with

**Scheme 16** Chemoselective reduction of protected oximes with catalytic  $\text{B}(\text{C}_6\text{F}_5)_3$ .<sup>27</sup>

$\text{HF}\cdot\text{pyridine}$ .<sup>27</sup> Moreover, the reduction was observed to be chemoselective, with exclusive reduction of the  $\text{C}=\text{N}$  bond and no  $\text{N}-\text{O}$  bond scission.<sup>27</sup>

Du targeted the direct reduction of pyridines with the use of a borane catalyst formed in situ through the hydroboration of Piers borane  $[\text{HB}(\text{C}_6\text{F}_5)_2]$  with alkene **26** (Scheme 17). A broad range of 21 piperidines were formed through reduction of their corresponding pyridines with excellent *cis* stereoselectivities (up to 99:1 d.r.) and isolated yields (up to 99%). This methodology was also applied toward the synthesis of isosolenopsin A, an anti-HIV drug.<sup>28</sup>

#### 1.06.2.1.4 Enantioselective reduction of C–N multiple bonds and silyl enols

Enantioselective reductions are of high importance to the synthetic chemist. With many biologically active molecules active only as a single enantiomer, there is a great deal of interest in the enantioselective synthesis of compounds. Many enantioselective catalysts are based upon transition metals due to the ease of installing chiral ligands onto the metal center; however, there have been an increasing number of frustrated Lewis pair systems that are viable alternatives for enantioselective reductions.

The first report of a FLP-mediated enantioselective reduction came in 2008, where Klankermayer prepared a chiral borane catalyst capable of reducing imines asymmetrically. This chiral borane was derived from the natural product (+)- $\alpha$ -pinene, which upon hydroboration with Piers borane formed borane **27**. By applying 10 mol% of **27**, heating to 65 °C and applying 20 bar of hydrogen pressure, full conversion of an imine substrate could be observed with 13% *e.e.* (Scheme 18).<sup>22</sup>

**Scheme 17** Catalytic reduction of pyridines with Piers borane and **26**.<sup>28</sup>

**Scheme 18** First report of FLP-mediated enantioselective reduction of imines.<sup>22</sup>

This system was significantly improved just 2 years later with the introduction of a borane derived from a different natural product, (1R)-(+)-camphor. Again, Piers borane was employed to undergo a hydroboration reaction with the natural product to form a chiral borane, which when in the presence of  $P^tBu_3$  would form FLP system **28**. This novel chiral intermolecular FLP system was investigated in a series of pro-chiral ketimine reductions (Scheme 19). Indeed, higher enantioselective reductions of up to 83% *e.e.* were achieved with just 5 mol% catalytic loading of **28**.<sup>29</sup>

An intramolecular version of intermolecular FLP **28** was developed in 2012 (Scheme 20). Here, (1R)-(+)-camphor was initially installed with a phosphine moiety before hydroboration with Piers borane to form the desired chiral borane **29**. **29** was then subjected toward a scope of imines with variously substituted aryl groups, promoting highly enantioselective reductions (up to 76% *e.e.*). Moreover, recyclability of the catalyst was also investigated. It was found that **29** could give reproducible results (>99% conversion, 76% *e.e.*) over four consecutive experiments, confirming the catalyst's effectiveness and stability.<sup>30</sup>

Diastereoselective reduction of chiral ketimines was attempted with  $B(C_6F_5)_3$  to mixed success (Scheme 21). Whilst yields were observed to be satisfactory over nine examples, the success of diastereoselectivity was found to correlate with the distance between the chiral center of the imine and the unsaturated carbon center. For example, the camphor **30** and menthone **31** derived imines performed well under the conditions investigated, whilst phenethylamine **32** did not.<sup>31</sup>

In 2011, Repo prepared a chiral variant **33** of the 'molecular tweezer' FLP **5**,<sup>16</sup> and probed the capability of this novel catalyst in the enantioselective reduction of imines (Fig. 4).<sup>32</sup> However whilst *ansa*-ammonium borate **33** displayed high air and moisture stability it did not show satisfactory results in enantioselective reductions, with a maximum reported *e.e.* of 37%.<sup>32</sup>

Du established an alternate strategy for asymmetric reduction with catalytically active bisboranes, generated through reaction of chiral dienes or diyenes with Piers borane. Here the chirality imparted upon the catalytic reduction originated from the ligand

**Scheme 19** Enantioselective reduction of imines with an intermolecular FLP system containing a camphor-based borane.<sup>29</sup>

**Scheme 20** Enantioselective reduction of imines with an intermolecular FLP system containing a camphor-based borane.<sup>30</sup>

**Scheme 21** Diastereoselective reduction of chiral ketimines with  $\text{B(C}_6\text{F}_5\text{)}_3$ .<sup>31</sup>

**Fig. 4** Chiral variant of FLP 'molecular tweezers'.<sup>32</sup>

attached to the boron based catalyst.<sup>33–36</sup> The first attempt toward asymmetric reduction was performed with diene **34** (Scheme 22), which when reacted with Piers borane formed a catalytically active chiral bisborane in situ. Various ketimines were subjected toward reduction by this bisborane, with high yields and enantioselectivities observed at room temperature (63–99%, 74–89% *e.e.*). Moreover, various functional groups on the phenyl substituent were tolerated, including an alkyne moiety.<sup>33</sup>

A related chiral diene with modified aryl rings **35** was later developed into a chiral bisborane through hydroboration with Piers borane (Scheme 23). Here, equimolar  $\text{P}^t\text{Bu}_3$  was employed to assist in the asymmetric reduction of silyl enol ethers in excellent yields (up to 99%) and high *e.e.* (up to 99%).<sup>34</sup>

**Scheme 22** Chiral reduction of ketimines with bisborane based upon diene **34**.<sup>33</sup>

**Scheme 23** Chiral reduction of silyl enol ethers with bisborane based upon diene **35**.<sup>34</sup>

A further, more electron deficient chiral diene **36** was employed in the preparation of a different in situ chiral diphenyl bisborane through reaction with Piers borane for the asymmetric reduction of quinoxalines (**Scheme 24**). Here the quinoxaline was able to act as the Lewis base of the frustrated Lewis pair, leading to 14 enantioselective reductions at room temperature. The formed tetrahydroquinoxalines were highly *cis*-selective (up to 99:1 *d.r.*) and highly enantioselective (67–96% *e.e.*).<sup>35</sup>

The most recent development by Du in chiral reduction was based upon a naphthyl-derived diyne ligand **37** (**Scheme 25**). Such structural change made the chiral borane formed upon hydroboration with Piers borane more rigid, as well as susceptible to electronic tuning upon modification to the naphthyl ring. The chiral bisborane and P<sup>t</sup>Bu<sub>3</sub> were employed in the catalytic reduction of a range of silyl enol ethers, employing the optimized conditions used with the bisborane based upon **35**.<sup>34</sup> The reactions proceeded smoothly, yielding optically active alcohols in up to 99% isolated yields and up to 99% *e.e.*<sup>36</sup>

Further effort in imparting chirality by using a binaphthyl scaffold within an FLP was reported with binaphthyl-linked amino-borane **38** (**Scheme 26**). This intramolecular FLP was utilized in the asymmetric reductions of six imines and notably, in the first reported asymmetric reduction of enamines. Under mild conditions, the chiral catalyst was able to reduce various *N*-aryl and *N*-alkyl imines, including imines with non-bulky *N*-substituents such as **39**. Smaller imines tend to be problematic for FLP systems, as they often form strong B–N adducts, thus promoting irreversible catalyst deactivation. The reductions of bulkier imines proceeded with good to excellent yields and *e.e.s* (up to 92% and 83% respectively); however, the *e.e.* was significantly reduced when *N*-alkyl imines were investigated (34% *e.e.*). Symmetric and asymmetric enamines also showed excellent results, displaying up to 99% isolated yields and up to 99% *e.e.s* following reduction.<sup>37</sup>

#### 1.06.2.1.5 Reduction of carbonyls

As many FLP systems contain boron-based compounds as their acidic component, the FLP mediated hydrogenation of carbonyl substrates posed a difficult problem for many researchers. Attempts to perform catalytic carbonyl reduction often resulted in the

**Scheme 24** Chiral reduction of ketimines with bisborane based upon diene **36**.<sup>35</sup>

**Scheme 25** Chiral reduction of silyl enol ethers with bisborane based upon diene **37**.<sup>36</sup>

**Scheme 26** Chiral reduction of imines and enamines.<sup>37</sup>

formation of boronic acids rather than the desired alcohols due to the high oxophilicity of the Lewis acids. Despite this complication, the FLP mediated reduction of carbonyls was achieved independently by Stephan and Ashley in 2014, who both utilized  $\text{B}(\text{C}_6\text{F}_5)_3$  as a catalyst in a Lewis basic ethereal solvent (**Scheme 27**).<sup>38,39</sup> Stephan reported the reduction of 18 carbonyls in  $\text{Et}_2\text{O}$ , using a high  $\text{H}_2$  pressure,<sup>38</sup> whereas Ashley reported the reduction of 14 carbonyls in 1,4-dioxane using a milder  $\text{H}_2$  pressure but longer reaction times and higher temperatures.<sup>39</sup>

Mechanistic probes indicated that the reduction of carbonyls bore many similarities to the reduction of imines (**Scheme 28**).<sup>38</sup> The catalytic cycle was initiated upon the co-ordination of the ethereal solvent (depicted below as  $\text{Et}_2\text{O}$ ) to  $\text{B}(\text{C}_6\text{F}_5)_3$ , thereby forming the active FLP catalyst in situ (**Scheme 28, I**). This catalyst was able to activate  $\text{H}_2$  (**Scheme 28, II**), facilitating its heterolytic cleavage between the acidic and basic centers. The resulting protonated solvent was then able to form a hydrogen-bond with the oxygen atom on the carbonyl substrate, thus making the carbonyl carbon more susceptible to attack by the hydride from the  $[\text{HB}(\text{C}_6\text{F}_5)_3]^-$  anion (**Scheme 28, III**). Upon protonation, the alcohol was released and the active FLP catalyst regenerated, closing the catalytic cycle.<sup>38</sup>

The reduction of ketones and aldehydes was later demonstrated in the non-ethereal solvent toluene, but only in the presence of 4 Å molecular sieves (4 Å MS) or alpha-cyclodextrin ( $\alpha\text{-CD}$ ) (**Scheme 29**). Using these insoluble Lewis bases, a heterogeneous FLP system could be formed upon exposure to  $\text{B}(\text{C}_6\text{F}_5)_3$ . The reduction of 25 carbonyl containing complexes was observed with excellent yields, in up to 99% with both Lewis bases.<sup>40</sup>

**Scheme 27** First reports of FLP mediated reduction of carbonyls.<sup>38,39</sup>

**Scheme 28** Mechanism of carbonyl reduction by  $\text{B(C}_6\text{F}_5)_3$  in an ether solvent.<sup>38</sup>

**Scheme 29** Reduction of carbonyl containing complexes with an FLP comprised of  $\text{B(C}_6\text{F}_5)_3$  and alpha-cyclodextrin ( $\alpha\text{-CD}$ ) or 4 Å molecular sieves (4 Å MS).<sup>40</sup>

When acetophenone was subjected to reduction, two products were observed. One was the expected phenylethanol, and the other styrene, a product of reductive deoxygenation (Scheme 30). Whilst reductive deoxygenation of carbonyls had previously been reported with stoichiometric  $B(C_6F_5)_3$ ,<sup>41</sup> this was the first FLP catalyzed reaction of its type. Further investigation uncovered a range of aryl ketones, including bicyclic and diaryl ketones, that were amenable toward catalytic reductive deoxygenation, resulting in the formation of their corresponding alkanes or alkenes.<sup>40</sup>

The mechanism was proposed to be analogous to the reduction of carbonyls using ethereal solvents, with the key difference being the identity of the Lewis basic oxygen: whereas previously the oxygen was situated on a basic solvent, forming a homogeneous system, the present system incorporated Lewis basic oxygens on the surface of  $\alpha$ -cyclodextrin or molecular sieves, thereby forming a heterogeneous FLP catalyst (Scheme 31).<sup>40</sup>

The catalytic cycle initiated when dihydrogen was heterolytically split by the FLP. The protonated basic surface was then able to form a hydrogen bond with the carbonyl's oxygen atom. The activated carbonyl was then susceptible to nucleophilic attack from the borohydride (Scheme 31, I). The generated basic alkoxide anion then accepted the proton from the Lewis basic surface, forming the alcohol product and regenerating the borane catalyst (Scheme 31, II). For most carbonyl compounds, the catalytic cycle terminated at this point; however, in the case of benzylic alcohols, an autocatalytic amount of ketone was able to promote FLP-mediated reductive deoxygenation. Here, an FLP was formed between the ketone and the borane, which heterolytically split  $H_2$ . The protonated ketone then proceeded to activate the C–O bond of the alcohol, leading it to be susceptible to hydride delivery from  $[HB(C_6F_5)_3]^-$  (Scheme 31, III). Subsequent C–O bond cleavage and water liberation formed the alkane or alkene with concomitant loss of  $H_2$ .<sup>40</sup> Molecular sieves served a dual purpose in this mechanism. Not only were they used for the initial reduction, but they also absorbed the water by-product from the reductive deoxygenation, thereby promoting the reaction further.

One inherent problem of using  $B(C_6F_5)_3$  is its moisture sensitivity. Upon exposure to water, the oxophilic boron atom will form a strong adduct, which fills its empty  $p$ -orbital and ultimately prevents the borane's ability to act as a catalyst irreversibly.<sup>42</sup> One method to overcome this is to replace the fluorinated aryl rings of the borane with heavier halogens, which impart more steric shielding around the boron's acidic center, thus shielding it from any water molecules; however, altering the halogen substitution pattern around the triarylborane can cause remarkable effects upon its Lewis acidity and consequentially its catalytic activity.<sup>43</sup>

Soós aimed to develop a moisture tolerant, bench stable, and functional group tolerant FLP catalyst in order to make the reduction of carbonyls more accessible through the design of novel triarylboranes 40 and 41 which incorporated chlorine atoms at the *ortho* position of a single aryl ring (Scheme 32). This had the effect of increasing the steric effect around the boron center but also did

**Scheme 30** Reductive deoxygenation of carbonyl containing complexes with an FLP comprised of  $B(C_6F_5)_3$  and 4 Å molecular sieves (4 Å MS).<sup>40</sup>

**Scheme 31** Mechanism of reductive deoxygenation of carbonyl containing complexes with an FLP comprised of  $B(C_6F_5)_3$  and  $\alpha$ -cyclodextrin ( $\alpha$ -CD) or 4 Å molecular sieves (4 Å MS).<sup>40</sup>

**Scheme 32** Moisture tolerant FLPs **40** and **41** for carbonyl reduction.<sup>44</sup>

not decrease the Lewis acidity significantly enough to prevent it from activating dihydrogen. The choice of the water tolerant Lewis base was also important, as strong Lewis bases were known to inhibit hydrogenation through forming hydrogen bonds with water. Thus tetrahydrofuran (THF), a weakly coordinating ethereal solvent was chosen to complete the moisture tolerant FLP design. The reductions were then performed without the use of air sensitive techniques. A scope of 10 carbonyls were readily reduced using this moisture tolerant FLP system. Electron-deficient and electron-rich benzaldehydes were readily tolerated, and chemoselective reactivity was noted upon reduction of cinnamaldehyde **42**, wherein the alkene functional group remained intact.<sup>44</sup>

#### 1.06.2.1.6 Reductive etherification of carbonyls

Further investigation by Soós found that water tolerant borane **40** could also be employed in the reductive etherification of acetals, aldehydes and ketones without the use of air-sensitive techniques (Scheme 33).<sup>45</sup> Initially, the reduction of acetals into ethers was probed, with THF acting as both the reaction medium and the basic component of the FLP. The lower oxophilicity of borane **40** compared to  $B(C_6F_5)_3$  was observed to be important, as neither the alcohol by-product nor the ethereal product were observed to hinder the catalytic activity through binding irreversibly to the boron center. Fifteen examples were given, with good to excellent yields throughout. High functional group tolerance was noted, with satisfactory reactivity even when unactivated olefin **43** or ester moieties were present in the substrate. The protocol was expanded through the reductive etherification of aldehydes and ketones. Here, three equivalents of an alcohol or an *ortho*-ester were required to act as an alkylating agent for the transformation. A wide variety of carbonyls were converted into their corresponding ethers with varying yields. When alcohols were used as the alkylating agent, the resultant ether yields were significantly reduced, due to the competing reduction of the carbonyl reagents into alcohols.<sup>45</sup>

This reductive etherification of carbonyls was termed to operate under 'auto-tandem' catalysis, wherein FLP catalyzed hydrogenation and FLP-assisted Brønsted-Lowry acid catalysis worked synchronously (Scheme 34).<sup>45</sup> The proposed mechanism began with the formation of a FLP between the borane and the THF solvent, followed by FLP-mediated  $H_2$  activation to generate  $H[THF]^+$  and borohydride  $H[BAr_3]^-$  (Scheme 34, I). The carbonyl's oxygen could then be protonated by the Brønsted-Lowry acidic  $H-THF^+$  (Scheme 34, II), thereby activating the carbonyl and making it susceptible to attack by the alkylating agent ( $R^3OH$ ). Upon loss of water and a proton, this generated the acetal intermediate (Scheme 34, III), which was accompanied by release of water. The released proton was then able to acidify another THF molecule, which in turn protonated the acetal (Scheme 34, IV). Expulsion of one  $R^3OH$  group generated the oxocarbenium cation (Scheme 34, V), which was readily reduced into the ether product (Scheme 34, VI) by the previously generated borohydride  $H[BAr_3]^-$ .<sup>45</sup>

#### 1.06.2.1.7 Reductive alkylation of amines with carbonyls

The exceptional moisture tolerance of Soós' boranes **40** and **41** in the reductive etherification of carbonyls inspired Ogoshi to apply borane **41** toward the reductive alkylation of amines with carbonyls and dihydrogen (Scheme 35).<sup>46</sup> The presented system operated under a tandem catalytic procedure, wherein FLP-mediated reductive alkylation and Lewis acid catalyzed intramolecular amidation occurred concurrently. Moisture tolerant borane **41** was crucial to the success of the reaction as water was the sole by-product of secondary amine formation. Whilst other boranes such as  $B(C_6F_5)_3$  were investigated, only the imine intermediate could be isolated as the FLP-mediated reductive alkylation was inhibited, presumably due to the generated water promoting catalyst deactivation.

The presented FLP system operated with 5 mol% of borane **41** and was able to exploit THF as both a solvent and the Lewis basic component of the FLP. 4 Å molecular sieves were inserted into the reaction vessel to absorb the water by-product. Whilst borane **41** was moisture tolerant, the inclusion of molecular sieves reduced reaction time and increased product yields significantly.<sup>46</sup> 34 secondary amines were successfully prepared in good to excellent yields, with functional group tolerance of bulky, carboxyl, and

**Scheme 33** FLP catalyzed reductive etherification of acetals, aldehydes and ketones.<sup>45</sup>

**Scheme 34** Mechanism of reductive etherification of acetals, aldehydes and ketones.<sup>45</sup>

**Scheme 35** FLP catalyzed reductive alkylation of amines with carbonyls to form secondary amines, isoindolinones, and 3-aminophthalic anhydrides.<sup>46</sup>

hydroxyl groups (Scheme 35); however, a limitation was noted upon the attempted reductive alkylation of aniline with 4-(dimethylamino)benzaldehyde, wherein the presence of a secondary amino group promoted FLP-mediated-hydrogenation followed by reduction to instead form *N,N*-dimethyl-*p*-toluidine. Moreover, by careful choice of reagents and by applying slightly harsher reaction conditions, the FLP system could catalyze intramolecular cyclizations to form isoindolinones and 3-aminophthalic anhydrides in good to excellent yields (Scheme 35).<sup>46</sup>

A mechanism which was comprised of two tandem catalytic cycles was proposed (Scheme 36). It was suggested that the first catalytic cycle comprised solely of Lewis acid catalysis, wherein the borane initially coordinated to and activated the carbonyl substrate (Scheme 36, I). The activated carbonyl was then susceptible toward nucleophilic attack from the amine, resulting in the formation of the imine intermediate and H<sub>2</sub>O as a by-product (Scheme 36, II). The second catalytic cycle involved FLP-mediated reduction, wherein the THF solvent acted as the Lewis basic component of the FLP. First, the FLP performed heterolytic cleavage of H<sub>2</sub>, which could then be used to reduce the imine (Scheme 36, III) to generate the desired amine (Scheme 36, IV).<sup>46</sup>

Motivated by previous investigation into the <sup>i</sup>Pr<sub>3</sub>SnOTf 16 catalyzed reduction of carbonyls and imines (Scheme 7),<sup>19</sup> Ashley extended the use of <sup>i</sup>Pr<sub>3</sub>SnOTf toward the reductive amination of carbonyls (Scheme 37). 17 secondary amines were formed in good to excellent yields, with tolerance toward bulky, electron-donating and electron-withdrawing groups. In most cases, the substrates were able to act as the Lewis basic FLP component, but collidine 44 was added to assist reactivity for more difficult substrates. For substrates with lower amine yields, this was attributed to a competing reaction wherein the carbonyl was directly reduced into its corresponding alcohol.<sup>47</sup>

### 1.06.2.2 FLP-mediated catalytic hydrogenation of non-polar substrates

The reduction of unsaturated non-polar substrates such as alkenes, allenes and alkynes presented a large challenge for FLP-based catalysts for many years. The primary factor behind this difficulty was that the generated Brønsted acid from the H<sub>2</sub> activated

**Scheme 36** Mechanism of FLP catalyzed reductive alkylation of amines with carbonyls to form secondary amines.<sup>46</sup>

**Scheme 37**  $t\text{Pr}_3\text{SnOTf}$  catalyzed reductive alkylation of amines with carbonyls to form secondary amines.<sup>47</sup>

FLP complex needed to be acidic enough to protonate the substrate to form a carbocation, whilst the base needed to be able to release its hydride so that it could attack this carbocation. Traditional bases used in FLP systems were too strong for effective reduction of non-polar substrates. Hence, modified FLP systems were introduced by increasing the Brønsted acidity of the formed conjugate acid by using a weak Lewis base in the FLP.

#### 1.06.2.2.1 Reduction of alkenes and allenes

The first recorded FLP-mediated reduction of alkenes was reported by Stephan in 2012, who used a system comprised of  $\text{B}(\text{C}_6\text{F}_5)_3$  and the weakly basic phosphine  $\text{Ph}_2\text{P}(\text{C}_6\text{F}_5)$ . Initial evidence that this FLP could activate dihydrogen came from low temperature  $^{31}\text{P}$  NMR studies, wherein a signal at  $\delta = 12.5$  ppm indicated that  $[\text{HP}(\text{C}_6\text{F}_5)_2\text{Ph}]^+$  was generated at  $-80$  °C when mixed with  $\text{B}(\text{C}_6\text{F}_5)_3$  under a dihydrogen atmosphere. A slight increase of temperature to  $-50$  °C revealed that the phosphine could liberate its proton to reform  $\text{H}_2$ , indicating that this FLP system required a very low energy barrier for the reversible activation of  $\text{H}_2$  and confirming that weak bases could participate in FLP reductions.<sup>48</sup> Encouraged by this observation, ten olefins which were capable of forming stable carbocations were subjected toward reduction using gaseous hydrogen and a catalytic amount of FLP, consisting of  $\text{B}(\text{C}_6\text{F}_5)_3$  with various weak phosphine Lewis bases (Scheme 38). Generally, reductions proceeded smoothly; however, the poorest conversions were observed when electron-deficient olefins were subjected to the reaction conditions. This suggested that the FLP's ability to reduce an olefin was strongly dependent on its ability to stabilize the formed carbocation upon the initial protonation by the phosphonium cation. Additionally, methoxy substituted olefin 45 resulted predominantly in the formation of a dimerized

**Scheme 38** First reported example of FLP-mediated olefin reduction.<sup>48</sup>

product. This was attributed to the inefficiency of the hydride transfer step and competing Brønsted acid-catalyzed Friedel-Crafts dimerization. This dimerization could be avoided by applying a diphosphine (GemPhos) as a Lewis base.<sup>48</sup>

Combined experimental and computational probes were undertaken in order to elucidate the reaction mechanism (**Scheme 39**). It was suggested that the FLP initially activated dihydrogen (**Scheme 39, I**). The conjugate acid  $[\text{HPR}_3]^+$  then attacked the olefin to form a transient carbocation (**Scheme 39, II**). Hydride attack from  $[\text{HB}(\text{C}_6\text{F}_5)_3]^-$  toward this carbocation resulted in the saturated product and regeneration of the FLP.<sup>48</sup>

Further investigation by Stephan found that  $\text{Et}_2\text{O}$  could serve as the Lewis base in an FLP with  $\text{B}(\text{C}_6\text{F}_5)_3$  for the reduction of 1,1-diphenylethene **46** (**Scheme 40**). Notably in this case,  $\text{Et}_2\text{O}$  was added in a catalytic amount to a chlorinated solvent, instead of being used as the reaction medium. Without  $\text{Et}_2\text{O}$  present, the olefin would undergo Friedel-Crafts dimerization in the chlorinated solvent.<sup>49</sup>

Moreover, the partial reduction of five polycyclic aromatic hydrocarbons was demonstrated with a FLP comprised of  $\text{P}(\text{C}_6\text{F}_5)_2$  and  $\text{B}(\text{C}_6\text{F}_5)_3$ . Harsh conditions were required, but reduction occurred in good to excellent yield (**Scheme 41**).<sup>50</sup> DFT calculations suggested that the mechanism for 1,4-hydrogenation of polycyclic aromatic hydrocarbons operated in a similar fashion to the 1,2-hydrogenation of olefins, through  $\text{H}_2$  activation (**Scheme 41, I**), followed by substrate protonation and subsequent hydride attack (**Scheme 41, II**).<sup>50</sup>

**Scheme 39** Mechanism of FLP-mediated olefin reduction.<sup>48</sup>

**Scheme 40** Reaction of 1,1-diphenylethene **46** with  $\text{B}(\text{C}_6\text{F}_5)_3$  in the presence and absence of  $\text{Et}_2\text{O}$ .<sup>49</sup>

**Scheme 41** FLP-mediated reduction of polycyclic aromatic hydrocarbons.<sup>50</sup>

By using a weakly Lewis acidic borane  $B(2,6-F_2C_6H_3)_3$  **17**, the functional group tolerance of FLP-mediated hydrogenation was observed to increase. This was attributed to a greater nucleophilicity of the generated borohydride upon hydrogen activation, thus promoting the hydride attack in olefin reduction. Indeed, when the **17**·THF adduct was combined with the weak Lewis base, 2,6-lutidine **22**, the catalytic reduction of nitro substituted olefins proceeded under mild conditions (Scheme 42). Further substitution to the nitroolefins through the installation of various electron withdrawing and donating groups was not observed to hinder reactivity, with excellent isolated yields of eleven alkanes. Moreover, the scope of reactivity was widened toward  $\alpha,\beta$ -unsaturated esters and acrylates, with collidine **44** used as a Lewis base instead of 2,6-lutidine **22**.<sup>51</sup>

The FLP-mediated diastereoselective hydrogenation of Morita-Baylis-Hillman adducts was also observed with a weak borane, in this instance  $B(2,4,6-F_3C_6H_2)_3$  **47** in combination with DABCO **11**. Over 28 examples, excellent reactivity was noted with good to excellent yields (80–97%) and diastereoselective ratios (up to 89:11 *d.r.*) (Scheme 43). Inspired by these results, the authors explored sequential organo-FLP catalysis for the preparation of  $\beta$ -aminoacid derivatives from readily available starting materials. The first step of this reaction involved a DABCO-catalyzed aza-Morita-Baylis-Hillman reaction of *N*-sulfonyl aldimines with  $\alpha,\beta$ -unsaturated ketones. Sequential addition of the borane and a continuation of reaction under a hydrogen atmosphere allowed for various  $\beta$ -aminoacid derivatives to be obtained in good yields (52–66%) and good diastereoselective ratios (80:20–85:5 *d.r.*).<sup>52</sup>

The scope of FLP-mediated reductions was also expanded toward electron-deficient allenes using catalytic DABCO **11** and  $B(C_6F_5)_3$  (Scheme 44). Five variously substituted diethyl 2-vinylidenemalonates were transformed into their respective olefinic products in good to excellent yield (43–94%) using this system; however, deviation from the optimized conditions was observed to lead to Friedel-Crafts alkylation, affording cyclized products. Interestingly, reductions occurred exclusively on the  $C=C$  double bond directly attached to the ester functional group. To study whether the allene moiety was indeed crucial for reductions, alkylidene malonates were also subjected toward the optimized conditions. These substrates were also well tolerated, with reductions operating at a faster rate and lower catalytic loadings of FLP compared to the allenes.<sup>53</sup>

Deuterium labelling studies suggested that instead of a direct protonation of the olefinic moiety, the reaction proceeded through hydrogen bonding between  $[HDABCO]^+$  and the carbonyl moiety of one of the esters (Scheme 45, I). The borohydride could then perform nucleophilic attack on the activated substrate (Scheme 45, II). Protonation by  $[HDABCO]^+$  could then regenerate the unactivated FLP and yield the desired product (Scheme 45).<sup>53</sup>

**Scheme 42** B(2,6-F<sub>2</sub>C<sub>6</sub>H<sub>3</sub>)<sub>3</sub> **17·THF** mediated reduction of nitroolefins,  $\alpha,\beta$ -unsaturated esters and acrylates.<sup>51</sup>

**Scheme 43** FLP-mediated diastereoselective hydrogenation of Morita-Baylis-Hillman adducts (left) and sequential organo-FLP catalysis for the preparation of  $\beta$ -aminoacid derivatives (right).<sup>52</sup>

### 1.06.2.2.2 Reduction of alkynes

The first FLP-mediated reduction of unactivated internal alkynes was reported in 2013, with the use of intramolecular FLP *ansa*-aminohydroborane **48** as a catalyst. This active hydroborane catalyst was formed in situ via H<sub>2</sub> activation by aminoborane **49** and a subsequent B–C<sub>6</sub>F<sub>5</sub> hydrogenolysis. Various dialkyl-, diaryl-, and arylalkyl-acetylenes were successfully stereoselectively reduced into their respective *cis*-alkenes under mild conditions with no overreduction toward the alkane products (**Scheme 46**). Moreover,

**Scheme 44** FLP mediated reduction of allenes and alkylidene malonates.<sup>53</sup>

**Scheme 45** Deuterium label studies on the FLP mediated reduction of alkylidene malonates.<sup>53</sup>

**Scheme 46** FLP-mediated reduction of unactivated internal alkynes.<sup>54</sup>

silyl-protected ynols, esters, and enynes were also observed to undergo chemoselective reductions. Contrarily, terminal alkynes were inert toward the transformation.<sup>54</sup>

Various experimental and computational mechanistic studies were conducted in order to propose a catalytic cycle (**Scheme 47**). First, aminoborane pre-catalyst **49** was exposed to a hydrogen atmosphere to form a borohydride (**Scheme 47, I**), which subsequently performed B–C<sub>6</sub>F<sub>5</sub> protonative cleavage at 80 °C to form the active hydroborane catalyst **48**. The alkyne substrate was then activated via hydroboration with the catalyst, forming a vinylborane (**Scheme 47, II**). The vinylborane then activated H<sub>2</sub>, resulting in the formation of a zwitterionic intermediate (**Scheme 47, III**), which upon intramolecular protonation of the vinyl carbon resulted in the elimination of the *cis*-alkene and a regeneration of the active catalyst.<sup>54</sup>

The stereoselective reduction of alkynes to *Z*-alkenes was later achieved by applying a heterogenous, silica-supported intermolecular borane/phosphine FLP. Importantly, it was demonstrated that the supported catalyst could be recycled by adding one equivalent of the Lewis acid up to a maximum of five times.<sup>55</sup>

**Scheme 47** Mechanism of FLP-mediated reduction of unactivated internal alkynes.<sup>54</sup>

Although the successful reduction of alkynes was a milestone in the continued expansion of FLP-mediated reactivity, terminal alkynes were thought recalcitrant for many years. Rather than reduction, FLPs were observed to react with terminal alkynes via deprotonative borylation through irreversible  $C_{sp}-H$  cleavage. Instead of liberation of an alkene, this yielded alkynylborate adduct 50 thus deactivating the catalyst (**Scheme 48**).<sup>56</sup>

In 2020, the FLP-mediated reduction of terminal alkynes was achieved with intramolecular FLP 51. This novel FLP system exhibited unique behavior after  $H_2$  activation. Following initial formation of the expected  $H_2$ -activated pyridone borane 52, the complex dissociated, resulting in the formation of Piers borane and 6-*tert*-butylpyridone 53. The active catalyst 52 was thus generated in situ, through the coordination of  $HB(C_6F_5)_2$  and 53 under a hydrogen atmosphere. Combined experimental and computational studies revealed that unlike conventional FLP systems, 51 was able to undergo reversible  $C_{sp}-H$  cleavage, allowing for the catalytic reduction of terminal alkynes. Indeed, six terminal alkynes were stereoselectively reduced to their corresponding *cis*-alkenes under mild conditions, with isolated yields of 47–76%. Six internal alkynes were also reduced into their corresponding *cis*-alkenes, displaying the versatility of the catalyst (**Scheme 49**).<sup>57</sup>

A proposed catalytic cycle suggested that the reduction process initiated with the hydroboration of the terminal alkyne by  $HB(C_6F_5)_2$ , resulting in the formation of alkenyl borane 54. 6-*tert*-butylpyridone 53 then coordinated toward the alkenyl borane (**Scheme 50**, I), which initiated protodeborylation to form the desired *cis*-alkene and boroxypyridine 51. 51, an intramolecular FLP, then activated  $H_2$ , resulting in the formation of the pyridine complex 52, which finally underwent ligand dissociation (53) to regenerate the Piers borane catalyst (**Scheme 50**).<sup>57</sup>

### 1.06.2.3 FLP-mediated transfer hydrogenation

An alternative to the reduction of unsaturated bonds using molecular hydrogen is the use of a surrogate  $H_2$  source, in what is termed as ‘transfer hydrogenation’. The primary advantage of transfer hydrogenation is that it negates the inherent safety risks of working with gaseous  $H_2$ ; however, large quantities of waste are produced from the surrogate, which can reduce the economic benefit and increase the environmental impact of the reaction. The idea of FLP-mediated transfer hydrogenation was initiated from the observation that  $B(C_6F_5)_3$  was able to abstract a hydride from the  $\alpha$ -carbon of secondary or tertiary amines.<sup>58,59</sup> For example: reaction of  $B(C_6F_5)_3$  with  $Et_2NPh$  would form an equilibrium between salt 55 and zwitterion 56 (**Scheme 51**).<sup>58</sup>

**Scheme 48** Irreversible catalyst deactivation upon attempted terminal alkyne reduction.<sup>56</sup>

A catalytic example of transfer hydrogenation with FLPs was the reduction of  $C=N$  bond, as part of the catalytic racemization of chiral imines.<sup>60</sup> By applying diisopropylamine **57** as a  $H_2$  surrogate, imines, enamines and  $N$ -heterocycles could be readily reduced (**Scheme 52**). Most imines and enamines were reduced almost quantitatively, whilst  $N$ -heterocycles, such as aziridine and quino-line, were reduced to form amines in lower yields.<sup>60</sup>

Mechanistic studies found that  $B(C_6F_5)_3$  would not interact with the substrate at first, but instead would abstract a proton from the  $\alpha$  carbon from the diisopropylamine **57**. The formed salt (**Scheme 53**, **I**) was then able to undergo proton transfer with the

**Scheme 51** Ability of  $B(C_6F_5)_3$  to abstract a hydride from the  $\alpha$ -carbon of  $Et_2PhN$ .<sup>58</sup>

**Scheme 52** An example of catalytic transfer hydrogenation.<sup>60</sup>

**Scheme 53** Mechanism of catalytic transfer hydrogenation.<sup>60</sup>

chosen substrate to form a second salt consisting of the borohydride and the protonated imine product (**Scheme 53, II**). Upon relinquishing its hydride toward the imine, the desired amine (**Scheme 53, III**) could be formed and the  $B(C_6F_5)_3$  catalyst could be regenerated.<sup>60</sup>

Cyclohexa-1,4-diene **58** was also exploited as a  $H_2$  source in the catalytic hydrogenation of imines and heteroarenes (**Scheme 54**).<sup>61</sup> Whilst good to excellent yields were observed, bulky protecting groups such as Ph or  $SO_2Tol$  were required on the imine substrates in order to be successfully reduced. On the other hand, all heteroarenes probed in the study were reduced almost quantitatively (up to 94%).<sup>61</sup>

Similarly, Hantzsch ester **59** was explored as a  $H_2$  surrogate toward the  $B(C_6F_5)_3$  catalyzed hydrogenation of imines (**Scheme 55**). Under the conditions probed, a notably low catalytic loading of 0.1 mol%  $B(C_6F_5)_3$  proved sufficient to transform 16 imines into their respective amines.<sup>62</sup> Further investigation found that this system could be adapted toward asymmetric imine transfer hydrogenation. The chirality was imparted via chiral diene ligand **35**, which upon hydroboration with Piers borane would form a chiral bisborane in situ. This bisborane was also used for the reduction of silyl enol ethers (**Scheme 23**).<sup>34</sup> This asymmetric variant

**Scheme 54** Transfer hydrogenation with cyclohexa-1,4-diene **58** as a H<sub>2</sub> surrogate.<sup>61</sup>

**Scheme 55** Symmetric and asymmetric imine transfer hydrogenation using Hantzsch ester **59** as a H<sub>2</sub> surrogate.<sup>62</sup>

of transfer hydrogenation required higher catalytic loadings; however, excellent yields of amine were reported, along with moderate *e.e.s* of 16–38%.<sup>62</sup>

One significant disadvantage to transfer hydrogenation is the amount of waste generated from the H<sub>2</sub> surrogate. In 2016, Du demonstrated the use of ammonia borane **60** as a hydrogen source in the B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> catalyzed reduction of pyridines (**Scheme 56**), wasting significantly fewer atoms than the amines, dienes and Hantzsch ester employed previously. Here, 17 *N*-heterocycles were generated in moderate to excellent yields (44–88%) with great *cis*-selectivities (up to 99:1). Reductions were tolerated with a wide variety of diaryl pyridines, although electron donating groups gave slightly reduced yields. 2-Aryl-6-methyl pyridines were also well tolerated; however, limited conversion and lower *cis*-selectivity was observed with 2,3-disubstituted pyridines.<sup>63</sup>

The use of ammonia borane as a hydrogen surrogate was further incorporated into the enantioselective transfer hydrogenation of imines (**Scheme 57**). Here, Piers borane and (*R*)-*tert*-butylsulfonamide **61** were employed, wherein the sulfonamide served as both the Lewis basic component of the FLP catalyst and as the source of chirality. A pyridine additive was also included to trap any unreacted Piers borane, which would otherwise promote a racemic imine reduction. This system was found to reduce 17 imines in good to excellent yields, and excellent enantioselectivities of up to 95% *e.e.*<sup>64</sup>

**Scheme 56** Transfer hydrogenation employing ammonia borane as the  $H_2$  surrogate.<sup>63</sup>

**Scheme 57** Enantioselective transfer hydrogenation of imines.<sup>64</sup>

The intermolecular FLP system composed of **61** and Piers borane, coupled with an ammonia borane as a hydrogen surrogate was subsequently employed in the reduction of 2-alkyl-3-arylquinoxalines and 2,3-dialkylquinoxalines (**Scheme 58**).<sup>65</sup> These substrates were initially subjected to the conditions presented in **Scheme 24**, wherein molecular hydrogen was used in an attempt to promote reduction, however no reactivity was observed.<sup>35</sup> Conversely, using a combination of **61** and Piers borane was observed to reduce 25 quinoxalines successfully in up to 99% *e.e.* *Cis*-tetrahydroquinoxalines were generally the predominant isomers formed upon 2-alkyl-3-arylquinoxaline reduction, whilst *trans*-tetrahydroquinoxalines were formed when 2,3-dialkylquinoxalines were used.<sup>65</sup>

The first reported transfer hydrogenation of silyl enol ethers was observed with the use of a FLP system composed of 2,2,6,6-tetramethylpiperidine (TMP) **62** and  $B(C_6F_5)_3$ , and with the widely available  $\gamma$ -terpinene **63** as a source of  $H_2$  (**Scheme 59**). 10 mol% of FLP catalyst was employed with a slight excess of  $\gamma$ -terpinene to mediate the reduction of 29 silyl enol ethers with a wide variety of substituents in excellent yield.<sup>66</sup>

#### 1.06.2.4 FLP-mediated dehydrogenation

As highlighted in the previous section on FLP-mediated transfer hydrogenation, Lewis acidic triarylboranes are capable of  $C_{sp^3}-H$  bond activation via hydride abstraction. This allows for the use of a hydrogen surrogate in catalytic reduction, rather than molecular  $H_2$ . Until 2016, hydride abstraction by boranes was exploited only for transfer hydrogenation; however, simultaneous reports by Paradies and Kanai proved it was possible to reverse the protocol, through the FLP catalyzed dehydrogenation of heterocycles.<sup>67,68</sup>

Paradies developed a protocol toward the  $B(C_6F_5)_3$ -catalyzed acceptor-less dehydrogenation of 21 *N*-protected indolines (**Scheme 60**). The resultant indoles were obtained in good to excellent yields; however, when the sterically demanding indoline with a neopentyl *N*-protecting group was subjected toward the reaction conditions, it was not oxidized, indicating that hydride abstraction or transfer can be sterically blocked by the *N*-substituent. Moreover, the protocol was expanded toward other

**Scheme 58** Chiral transfer hydrogenation of 2-alkyl-3-arylquinoxalines and 2,3-dialkylquinoxalines.<sup>65</sup>

**Scheme 59** Transfer hydrogenation of silyl enol ethers.<sup>66</sup>

**Scheme 60**  $B(C_6F_5)_3$ -catalyzed dehydrogenations of *N*-protected indolines.<sup>67</sup>

heterocycles including 1,4-dihydropyridines and thiazoline. Some heterocycles required more forcing conditions to undergo dehydrogenation, but the oxidized product could be isolated in good to excellent yield.<sup>67</sup>

Meanwhile, Kanai reported the  $B(C_6F_5)_3$ -catalyzed dehydrogenation of 23 *N*-heterocycles, with a range of steric and electronic variations (Scheme 61). 5 mol% of  $B(C_6F_5)_3$  catalyst was applied for most substrates; however, a slightly higher temperature of 150 °C was required for efficient dehydrogenation. Notably, the protocol was extended toward the preparation of biologically active pyrazoles, displaying a metal-free alternative toward a precursor to celecoxib, a nonsteroidal painkiller. Good to excellent yield of the oxidized product was noted in all cases.<sup>68</sup>

Paradies further explored the mechanism of this dehydrogenation through a combination of kinetic and DFT probes. The reaction was observed to proceed via an initial borane-induced hydride abstraction at the  $C_2$  position of the indole **64**, resulting in the formation of a 3*H*-indolium ion intermediate (Scheme 62, I). A rapid intermolecular proton transfer at the  $C_3$  position of the 3*H*-indolium ion to a second indoline nitrogen atom generated the first equivalent of indole product **65** and an ammonium hydridoborate intermediate (Scheme 62, II). In the rate-determining step, proton-hydride recombination occurred, releasing  $H_2$ , a second equivalent of indole product **65** and regenerating the borane catalyst. Interestingly, the reaction could be accelerated by incorporating an additional 5 mol% of the less Lewis acidic borane  $B(2,4,6-F_3C_6H_2)_3$  **47**, which served as a hydride shuttle. Thus, in the proton-hydride recombination step,  $B(2,4,6-F_3C_6H_2)_3$  **47** generated a stronger hydride donor than  $B(C_6F_5)_3$ , accelerating the final  $H_2$  liberation.<sup>67</sup>

### 1.06.2.5 Unusual FLP systems for catalytic hydrogenation

Since the ground-breaking discovery of a phosphinoborane capable of activating dihydrogen, many types of FLPs that are alternate to the conventional phosphinoborane or triarylborane/bulky Lewis base FLPs have been described. Selected examples include: FLPs containing transition metals as the Lewis acidic or Lewis basic component; FLPs based upon polymers and nanoparticles, and FLPs with cationic Lewis acidic centers.<sup>69</sup> This section aims to discuss the less common FLP systems which have been reported to partake in catalytic reductions.

#### 1.06.2.5.1 Borenium cations

Borenium cations are a class of cationic boron compound  $[L \rightarrow BR_2]^+$  which contain only two  $\sigma$ -bound substituents (R) and are partially stabilized by one dative interaction with a ligand (L). This results in a highly electropositive species which acts as a potent

**Scheme 61**  $B(C_6F_5)_3$ -catalyzed dehydrogenations of *N*-protected heterocycles.<sup>68</sup>

**Scheme 62** Mechanism of FLP-mediated dehydrogenation of indoles.<sup>67</sup>

Lewis acid. In 2012, Stephan reported the first use of these highly acidic species in FLP-mediated reductions, citing them as an attractive smaller alternative to bulky triarylboranes such as  $B(C_6F_5)_3$ . Such borocations are readily available through hydride abstraction with trityl tetrakis(pentafluorophenyl)borate  $[Ph_3C][B(C_6F_5)_4]$  from the appropriate air-stable adduct. Here, Stephan prepared an FLP comprised of the *N*-heterocyclic carbene (NHC) adduct of 9-borabicyclo[3.3.1]nonane (9-BBN) (**Scheme 63**). Initial probes found that this could activate  $H_2$  in the presence of  $P^tBu_3$ .<sup>70</sup>

Further investigation showed the Lewis acid **66** to be highly active toward the catalytic reduction of imines through an FLP mechanism (**Scheme 64**). Catalytic loadings as low as 1 mol% were found to be sufficient to mediate the reduction of seven imines at room temperature, yielding the corresponding amines in good to excellent isolated yields. Whilst the reactions were performed at room temperature, a high dihydrogen pressure of 102 bar was required.<sup>70</sup>

**Scheme 63** Preparation of FLP containing a borenium cation.<sup>70</sup>

**Scheme 64** Catalytic reduction of imines with a borenium cation **66**.<sup>70</sup>

Crudden later expanded the scope of cationic Lewis acids for hydrogenation catalysis toward mesoionic carbene-stabilized boronium ions. A series of 1,2,3-triazolylidene-based mesoionic carbene boranes were prepared from their respective 1,2,3-triazolium salts, a base, and a borane. They were then subjected toward the reduction of *N*,1-diphenylethanamine, wherein catalyst **67** was observed to be most active. Catalyst **67** was then applied toward the reduction of 11 sterically hindered *N*-heterocycles, with only mild conditions required for efficient transformation (Scheme 65).<sup>71</sup>

### 1.06.2.5.2 Electrophilic phosphonium cations

A further type of FLP system consisting of electrophilic phosphonium cation (EPC)  $[\text{FP}(\text{C}_6\text{F}_5)_3][\text{B}(\text{C}_6\text{F}_5)_4]$  **68** in combination with bulky silylamine *p*-Tol<sub>2</sub>NSiEt<sub>3</sub> **69** was reported by Stephan for the reduction of alkenes (Scheme 66). EPCs are highly Lewis acidic species, in which reactivity arises from a low lying  $\sigma^*$  orbital. This can be contrasted to traditional Lewis acids, wherein the reactivity originates from an empty *p*-orbital. The formation of an FLP between **68** and **69** which was capable of reversible H<sub>2</sub> activation was proven through H/D isotope scrambling.<sup>72</sup>

Before a scope of catalytic reductions was performed, a screening of suitable Lewis bases was investigated, which revealed that increased steric hindrance around the Lewis base had an adverse effect upon catalytic efficiency. *p*-Tol<sub>2</sub>NSiEt<sub>3</sub> **69** and *p*-Tol<sub>2</sub>NSi(*i*Pr)<sub>3</sub> were eventually chosen as the most suitable Lewis bases for the catalytic reduction. Previous research by the group on EPCs had found that **68** was capable of catalyzing the dehydrocoupling of *p*-Tol<sub>2</sub>NH with HSiEt<sub>3</sub> to form **69**,<sup>73</sup> and thus the combination of the amine and silane or the silylamine was used interchangeably. With EPC **68** and a choice of silylamine in hand, twelve olefins were reduced to their corresponding alkanes in good to excellent conversion (Scheme 67). A limitation was noted upon the reduction of bulky olefins, which resulted in lower conversions to their respective alkanes.<sup>72</sup>

**Scheme 65** Catalytic reduction of sterically hindered *N*-heterocycles using a 1,2,3-triazolylidene-based mesoionic carbene borane catalyst **67**.<sup>71</sup>

**Scheme 66** Activation of H<sub>2</sub> by an FLP composed of an electrophilic phosphonium cation **68** (EPC) and a bulky silylamine **69**.<sup>72</sup>

**Scheme 67** Catalytic reduction of olefins by an FLP composed of an electrophilic phosphonium cation (EPC) and a bulky silylamine.<sup>72</sup>

A proposed mechanism was based upon DFT calculations and experimental isotope labelling studies (**Scheme 68**). Initially, the EPC and silylamine activated  $H_2$  to form hydridophosphorane [FP(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>H] and ammonium cation [*p*-Tol<sub>2</sub>N(H)SiEt<sub>3</sub>]<sup>+</sup> (**Scheme 68, I**). The ammonium cation was then able to protonate the olefin to form a carbocation (**Scheme 68, II**). Subsequent hydride delivery from the hydridophosphorane liberated the alkane product and regenerated the unactivated FLP.<sup>72</sup>

### 1.06.2.5.3 Inverse FLPs

A conventional frustrated Lewis pair is composed of a strong Lewis acid that is unable to form an adduct with a weak-to-medium strength Lewis base, often due to unfavorable steric interactions between the acidic and basic centers. Conversely, an inverse FLP is composed of a bulky Lewis superbase that is unable to form an adduct with weak-to-medium strength Lewis acids.

Krempner has extensively focused upon the use of inverse FLPs toward dihydrogen cleavage and substrate reduction. The first report of an inverse FLP occurred in 2013, inspired by a search to use more readily available and stable Lewis acids for FLP chemistry rather than the expensive triarylborane B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>.<sup>74</sup> Initial computational studies suggested that  $H_2$  could be cleaved by a weak Lewis acid in situations where a strong and bulky base was present. Indeed, experimental evidence demonstrated that strongly basic zwitterionic organosodium compound **70** was able to activate  $H_2$  in the presence of weaker Lewis acids, such as BPh<sub>3</sub> or HBMe<sub>2</sub> (**Fig. 5**).<sup>74</sup>

The catalytic potential of inverse FLPs was first demonstrated in the reduction of *N*-benzylidenaniline. Various inverse FLP systems were studied, comprised of phosphazene **71** or Verkade's superbase **72** in combination with a weak Lewis acid. From these observations, it was demonstrated that inverse FLPs **71**/BPh<sub>3</sub> and **72**/9-Hex-BBN were able to catalytically reduce the imine in

**Scheme 68** Mechanism of olefin reduction by an FLP composed of an electrophilic phosphonium cation (EPC) and a bulky silylamine.<sup>72</sup>

**Fig. 5** First example of a superbases capable of activating  $H_2$  as part of an inverse FLP.<sup>74</sup>

quantitative yields at only 5 mol% loading (**Scheme 69**). However, harsh conditions were required to maximize conversion (60–80 °C, 50–100 bar  $H_2$ ).<sup>75</sup>

Inverse FLPs were later demonstrated to be active toward the catalytic reduction of ketones. The bulky base phosphazene **71** was used in combination with aryl substituted derivatives of 9-BBN (9-(4-X-C<sub>6</sub>H<sub>4</sub>)-BBN) where X could be designated an electron donating or withdrawing group. Both donating and withdrawing groups on the substituted boranes could be used in combination with **71** to perform the selective catalytic reduction of acetophenone with no formation of side products.

Optimal yields were obtained when 9-(4-(F<sub>3</sub>C)-C<sub>6</sub>H<sub>4</sub>)-BBN **73** was used as a Lewis acid, wherein diphenylethanol could be quantitatively prepared from its corresponding ketone after just 5 h. As with the reduction of imines, harsh reaction conditions were required for the reaction to proceed efficiently. Moreover, the speed of reduction was significantly improved when two equivalents of Lewis acid was used per equivalent of base. The presented inverse FLP was observed to be more tolerant toward functional groups than classical FLPs. 26 aliphatic and aromatic ketones, some bearing sensitive amide, amine, thioether, or ester groups were all successfully reduced in excellent yield (**Scheme 70**). Limitation was noted upon the reduction of isopropyl ketone, which

**Scheme 69** First examples of catalytic reduction by inverse FLPs.<sup>75</sup>

**Scheme 70** Catalytic reduction of ketones by an inverse FLP.<sup>76</sup>

proceeded poorly and formed the alcohol in just 15% yield after 40 h, whilst 4-nitroacetophenone and 4-cyanoacetophenone could not be reduced.<sup>76</sup>

Combined DFT and experimental deuteration studies justified the requirement of two acid equivalents per base. A proposed mechanism showed that a highly reactive borohydride species was initially formed via H<sub>2</sub> activation by the inverse FLP (**Scheme 71, I**). This borohydride was then able to react with an additional equivalent of Lewis acid **73** to form a stable, bridged borohydride (**Scheme 71, II**). A subsequent hydride transfer with the carbonyl substrate then yielded alkoxide anion (**Scheme 71, III**), which was then readily protonated by the conjugate acid, releasing the alcohol product and regenerating the inverse FLP. A secondary minor pathway was also suggested, in which the alkoxy anion intermediate (**Scheme 71, III**) acted as the Lewis base in an FLP in combination with Lewis acid **73**. Upon activating H<sub>2</sub>, this FLP formed the bridged borohydride salt (**Scheme 71, II**) upon the release of the alcohol product.<sup>76</sup>

### 1.06.3 Hydrosilylation

Hydrosilylation is a well-known method of installing synthetically useful silanes onto unsaturated bonds (**Scheme 72**).<sup>77</sup> Classically, this process was performed with platinum based catalysts, such as Speier's catalyst or Karstedt's catalyst; however, with a focus toward sustainable chemistry many research groups have elected to pursue viable alternatives based upon earth abundant metals and main group elements.<sup>77</sup> Recent advances have found that FLP systems can also be used for the process.

#### 1.06.3.1 FLP-mediated hydrosilylation

Whilst the term frustrated Lewis pair was not coined until 2006, a decade earlier Piers observed unusual activity during the B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> catalyzed hydrosilylation of aromatic aldehydes, ketones and esters with triphenylsilane.<sup>5</sup> Extensive mechanistic probes revealed that the borane did not activate the carbonyl moiety as was the expected reactivity at the time, and instead coordinated to the silane's hydride. A further result that preceded the discovery of frustrated Lewis pairs was that the substrate was required to be sufficiently basic to undergo hydrosilylation.<sup>5</sup>

Twelve years later, Oestreich performed a concerted mechanistic study to reveal conclusively that FLP-type reactivity was present in B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>-catalyzed hydrosilylation (**Scheme 73**). It was proved that the hydride abstraction from the silane occurred simultaneously with the coordination of the carbonyl moiety toward the silicon atom to enable hydride abstraction by the borane.<sup>6</sup>

The metal-free hydrosilylation protocol with a B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> catalyst was further extended toward imines (**Scheme 74**).<sup>78</sup> Twelve amines were obtained after a base promoted desulfonylation, resulting in moderate to excellent yields (57–97%). In the reaction,

**Scheme 71** Mechanism of reduction of ketones by an inverse FLP.<sup>76</sup>

**Scheme 72** Hydrosilylation of a carbonyl.<sup>77</sup>

**Scheme 73** Mechanism of  $B(C_6F_5)_3$  catalyzed hydrosilylation.<sup>5,6</sup>

**Scheme 74**  $B(C_6F_5)_3$  mediated hydrosilylation of imines.<sup>78</sup>

a silyliminium ion pair intermediate **74** was identified spectroscopically, which suggested that the imine hydrosilylation mechanism was indeed FLP-like in nature.<sup>78</sup>

Enones and silyl enol ethers have also been observed to undergo  $B(C_6F_5)_3$ -catalyzed hydrosilylation.<sup>79</sup> Whilst not described as a frustrated Lewis pair as the term had not yet been coined, FLP-like activation was noted in a similar vein to the  $B(C_6F_5)_3$ -catalyzed hydrosilylation of carbonyls.<sup>5</sup> Both cyclic and acyclic enones were observed to participate in 1,4-hydrosilylation in good to high yields (**Scheme 75**); however, certain substrates such as 3-methyl-2-cyclopentenone **75** and methyl vinyl ketone **76** gave complicated mixtures, presumably by participating in competing 1,2-hydrosilylation and oligomerization reactions. Further investigation found that a wide range of silanes could be employed in the hydrosilylation, with only triisopropylsilane recalcitrant toward the reaction with enones.<sup>79</sup>

When the silane was used in excess, the silyl enol ether product from initial hydrosilylation was observed to undergo a secondary hydrosilylation reaction (**Scheme 76**). Such  $\beta$ -silylalkoxy functionalities are known to be susceptible to elimination under acidic or basic conditions, revealing how the hydrosilylation catalysis protocol could transform an enone into an alkene with a vinylic group.<sup>79</sup>

In 2005, the  $B(C_6F_5)_3$ -catalyzed hydrosilylation of thiobenzophenones was reported as a novel synthetic route toward a silicon-sulfur bond (**Scheme 77**). A combination of sterically accessible tertiary hydrosilanes and dihydrosilanes was crucial for such transformation, as when two equivalents of thiobenzophenone were reacted with the more sterically hindered  $(H^tPr_2Si)_2$ , no reactivity was observed after 48 h. Over six examples, the reactions gave quantitative conversions toward the corresponding silyl thioethers with catalytic loadings of  $B(C_6F_5)_3$  as low as 0.004 mol%.<sup>80</sup>

A further observation of a borane-silane adduct which was able to engage in FLP-mediated hydrosilylation was demonstrated with a combination of a boraindene **77** and triethylsilane. Initially the formation of the adduct could not be spectroscopically observed at room temperature; however, variable-temperature  $^{19}F$  and  $^1H$  NMR experiments (following the boraindene and the

**Scheme 75** Hydrosilylation of enones.<sup>79</sup>

**Scheme 76** Hydrosilylation of silyl enol ethers.<sup>79</sup>

silane respectively) clearly revealed the formation of adduct **78**. Subsequently, adduct **78** was further reacted with the nucleophile  $(\text{Ph}_3\text{PNPPH}_3)\text{Cl}$  to form hydridoborate salt **79** and  $\text{Et}_3\text{SiCl}$ . This analogy toward carbonyl nucleophiles once again confirmed the generally accepted FLP mechanism in the process of borane-catalyzed hydrosilylation (**Scheme 78**).<sup>81</sup>

The FLP-mediated hydrosilylation of pentafulvenes into allyl silanes was observed in excellent yield and regioselectivity.<sup>82</sup> Whilst standard Lewis acid catalysis by  $\text{B}(\text{C}_6\text{F}_5)_3$  was observed to promote both hydrosilylation and fulvene oligomerization, the introduction of a sterically hindered base suppressed any oligomerization from occurring. When tris(1-naphthyl)phosphine **80** was employed as the base, the reactions proceeded at room temperature and regioselectively catalyzed 1,2-hydrosilylation at the  $\text{C}_2$  carbon in excellent yields (**Scheme 79**).

The hydrosilylation of unsymmetrical fulvenes, such as 6-phenyl-6-methylfulvene **81**, yielded two isomers at the  $\text{C}_2$  carbon (*E*) and (*Z*) in a 1.6:1 ratio. Moreover, regioselectivity was drastically decreased when 6,6-dimethylbenzofulvene was subjected toward hydrosilylation, where the formation of two regioisomers **82** and **83** was observed in a 1.2:1 ratio, a result of both Markovnikov and anti-Markovnikov addition (**Scheme 79**).<sup>82</sup>

Electrophilic phosphonium cations have also been observed to partake in FLP-style reactivity during hydrosilylation catalysis. The first example was shown through the hydrosilylation of olefins and alkynes with two EPCs, **68** and **84** (**Scheme 80**).<sup>83</sup> EPC **68** differed from **84** by the replacement of one pentafluorophenyl ring with one phenyl ring, a modification that reduced its electrophilicity substantially. This was reflected in its slower performance when catalyzing the hydrosilylation of hexene with triethylsilane. Nevertheless, good to excellent isolated yields were obtained by employing both **68** and **84** as catalysts for the hydrosilylation of 14 unsaturated C–C bond containing substrates.<sup>83</sup>

Combined mechanistic and DFT studies suggested that initially the EPC catalyst **68** activated the silane, in a fashion similar to borane catalysts (**Scheme 81, I**). Introduction of the olefin resulted in a polarization of the olefin bond by the electropositive silicon atom (**Scheme 81, II**). 1,2-addition then occurred, whereupon the hydride from the silicon attacked the olefin carbocation in an anti-fashion, leading to addition to the free silane cation (**Scheme 81, III**). This liberated the silylated product and regenerated the EPC catalyst **68** (**Scheme 81**).<sup>83</sup>

The substrate scope, amenable toward hydrosilylation by EPC catalyst **68** was later extended toward ketones, imines, and nitriles (**Scheme 82**).<sup>84</sup> Whilst the ketones and imines formed their corresponding silyl enol ethers and *N*-silylamines respectively, the

## Silanes

## Disilanes

**Scheme 77**  $B(C_6F_5)_3$ -catalyzed hydrosilylation of thiobenzophenones.<sup>80</sup>

**Scheme 78** Further evidence of a borane-silane adduct participating in FLP-type reactivity.<sup>81</sup>

hydrosilylation of nitriles would either form *N*-silylimines or *N,N*-disilylamines depending on the identity of the substrate. All substrates underwent hydrosilylation in excellent conversion, with the exception of *N*-benzyl-1-phenylmethanimine **25**, presumably as a result of steric hindrance around the basic nitrogen atom precluding reactivity. Competition reactions found that **68** would preferentially catalyze the groups in the order ketone > nitrile > imine > olefin in substrates where multiple functional groups were present.<sup>84</sup>

The mechanism of reaction was proposed to be common for ketones, imines and nitriles. DFT and experimental probes suggested that the EPC catalyst **68** initially activated the silane (**Scheme 83, I**). Introduction of the ketone led to an interaction between the basic carbonyl oxygen and the electropositive silicon (**Scheme 83, II**). The carbonyl then attacked the silane, thereby forming a carbocation and forcing the silane hydride to transfer onto the EPC (**Scheme 83, III**). Hydride attack from the EPC to the carbocation liberated the silyl enol ether and thus regenerated the free EPC **68** (**Scheme 83**).<sup>84</sup>

### 1.06.3.2 Asymmetric FLP-mediated hydrosilylation

The first example of asymmetric hydrosilylation was demonstrated with chiral silane (<sup>Si</sup>*R*)-**85** and  $B(C_6F_5)_3$ , as part of the mechanistic study which confirmed the FLP-type reactivity of the hydrosilylation reaction.<sup>6</sup> It was observed that a mixture of (<sup>Si</sup>*R*)-**85** and 5 mol% of  $B(C_6F_5)_3$  would hydrosilylate acetophenone to form hydrosilane (<sup>Si</sup>*R*, *R*) **86** as a scalemic mixture with a *d.r.* ratio of

**Scheme 79** FLP-mediated hydrosilylation of pentafulvenes.<sup>82</sup>

**Scheme 80** Hydrosilylation of olefins and alkynes with an EPC catalyst.<sup>83</sup>

74:26. Following a racemization-free reductive cleavage of (<sup>Si</sup>R, R) **86**, the alcohol **87** was isolated in good yield (68%) and *e.e.* (38%) (**Scheme 84**).<sup>6</sup>

A series of six acyclic methyl ketones were subsequently hydrosilylated in an asymmetric fashion with a racemic mixture of silane **85** (**Scheme 85**).<sup>85</sup> The reactions proceeded at room temperature, with excellent conversions and good diastereoselective ratios (up to 81:19). Unexpectedly, when cyclic ketones (**88**, **89**) were subjected toward the asymmetric hydrosilylation, the reactions were sluggish, and the obtained diastereoselective ratios were low. Additionally, when the same conditions were applied toward the hydrosilylation of imines, good conversions of racemic mixtures were obtained.<sup>85</sup>

It was suggested that such discrepancy in stereochemical outcome was a result of different hydride transfer pathways (**Fig. 6**). Whilst hydride transfer was able to impart chirality at the silylated carbonyl (**Fig. 6, I**) during the hydrosilylation of carbonyls, when imines were hydrosilylated, hydride transfer would instead occur at the borane-activated imine (**Fig. 6, II**) during a different

**Scheme 81** Mechanism of hydrosilylation of olefins with an EPC catalyst.<sup>83</sup>

**Scheme 82** Hydrosilylation of ketones, imines and nitriles by an EPC catalyst **68**.<sup>84</sup>

**Scheme 83** Mechanism of hydrosilylation of ketones by an EPC catalyst.<sup>84</sup>

**Scheme 84** First example of FLP-mediated asymmetric hydrosilylation.<sup>6</sup>

stage of the reaction due to the steric encumbrance around the silylated iminium ion intermediate (**Fig. 6, III**) where it had no effect upon stereoselectivity.<sup>85</sup>

The first highly enantioselective hydrosilylation of imines was achieved by Klankermayer with the use of chiral camphor-derived boranes **28** and **90** (**Scheme 86**). With low catalytic FLP loadings, a range of six acyclic *N*-aryl imines were hydrosilylated and reduced in good to excellent yields and high enantioselective ratios. Limitations were noted upon the attempted reduction of more sterically hindered imines such as 2-methyl-*N*-(1-phenylethylidene)aniline, which gave negligible conversions and imines which contained electron withdrawing groups on the *para* position of their aryl rings, which were formed in low yield but high *e.e.*<sup>86</sup>

The THF adduct of a chiral analogue of  $B(C_6F_5)_3$ , (*S*)-**91**·THF, was developed to probe further asymmetric hydrosilylation reactions. This borane had a lower Lewis acidity when compared to  $B(C_6F_5)_3$ , a result of fewer pentafluorophenyl groups, but the incorporation of a BINOL-like ligand imparted axial chirality upon the molecule (**Scheme 87**). Initially, a series of four imines were asymmetrically hydrosilylated and reduced using  $Me_2PhSiH$  as a hydride source. The (*S*)-borane preferentially catalyzed the formation of (*S*)-amines, resulting in overall moderate *e.e.s* (30–41%). Interestingly, further investigations revealed that when axially chiral silanes (*S*-**92** or *R*-**92**) were used as the hydride source, the amine product would preferentially be the same enantiomer of the chiral silane used rather than the (*S*)-amine that was formed when (*S*)-**91**·THF was employed as a catalyst with a racemic silane.<sup>87</sup>

**Scheme 85** Asymmetric hydrosilylation of prochiral ketones.<sup>85</sup>

**Fig. 6** Origin of stereochemical outcomes in the hydrosilylation of ketones and imines.<sup>85</sup>

**Scheme 86** First FLP-mediated enantioselective reduction of imines.<sup>86</sup>

**Scheme 87** Tuneable FLP-mediated asymmetric hydrosilylation.<sup>87</sup>

The hydride transfer pathway for (S)-91·THF catalyzed imine hydrosilylation was later identified using in situ <sup>1</sup>H-NMR studies. An equimolar ratio of the free amine 93 and silylated enamine 94 intermediates were observed during the hydrosilylation process (Fig. 7), along with the expected silylated iminium ion intermediate 95. The presence of these unexpected intermediates suggested that there were competing reaction pathways that introduced further enantioselectivity-determining steps, thus increasing the likelihood that a racemic silyl imine would be formed despite the use of a chiral borane.<sup>88</sup>

The proposed mechanism suggested that the hydrosilane was initially activated by the borane catalyst (Scheme 88, I). A subsequent reaction of an imine with this activated complex formed a silyliminium ion and its ion pair borohydride (Scheme 88, (E)-II or (Z)-II), with the inverted stereochemistry of the silyliminium ion when compared to the imine reagent used. Both silyliminium ions (Scheme 88, (E)-II and (Z)-II) were then susceptible toward the hydride attack from the borohydride, forming their respective

**Fig. 7** Intermediates observed during the (S)-91·THF catalyzed imine hydrosilylation reaction.<sup>88</sup>

**Scheme 88** Mechanism of imine hydrosilylation catalyzed by (*S*)-**91**·THF.<sup>88</sup>

silylamine product (**Scheme 88**, **III**) through loss of the borane. Furthermore, two other mechanisms were also observed to occur. The silyliminium ion (**Scheme 88**, (*E*)-**II** and (*Z*)-**II**) could also be deprotonated by unreacted imines to form a silylated enamine **94**, which was one of the intermediates detected by the initial <sup>1</sup>H NMR study. The silylated enamines were then able to interconvert through C–N bond rotation (**Scheme 88**, **IV**), which resulted in the racemized silylamine product (**Scheme 88**, **III**). The second possible mechanism involved silyliminium ion (**Scheme 88**, (*Z*)-**II**; note, this mechanism could also involve (*E*)-**II**; however, only (*Z*)-**II** is explicitly drawn for clarity), being attacked at the  $\alpha$ -position by a second equivalent of (*E*)-imine to form an ion pair (**Scheme 88**, (*E*)-**V**) through a loss of hydrosilane. Reduction of the iminium cation (**Scheme 88**, (*E*)-**V**) formed the free amine **93**, the other intermediate detected by the initial <sup>1</sup>H NMR study. Upon re-exposure to an equivalent of hydrosilane, an ion pair composed of an ammonium ion and a borohydride was formed (**Scheme 88**, **VI**). Deprotonation of the ammonium cation (**Scheme 88**, **VI**) by the silylated enamine **94** resulted in the formation of silyliminium ion (**Scheme 88**, (*E*)-**II**), which upon hydride attack from the borohydride subsequently resulted in the formation of silylamine (**Scheme 88**, **III**).<sup>88</sup>

A further analogue of (*S*)-**91**·THF was later developed by Oestreich for the enantioselective hydrosilylation of carbonyls. (*S*)-**96**·DMS also contained axial chirality, but it contained extra steric congestion around the boron center from the installation of phenyl groups at the 3 and 3' positions on its binaphthyl rings. Such modification found that THF was too large to co-ordinate to the boron, thus dimethyl sulfide (DMS) was instead employed.<sup>89</sup> With catalyst (*S*)-**96**·DMS in hand, the hydrosilylation of acetophenone was optimized against a range of hydrosilanes. In general, larger monohydrosilanes were more unreactive, which was attributed to their steric hindrance; however, more compact trihydrosilanes such as PhSiH<sub>3</sub> and MeSiH<sub>3</sub>, showed quantitative conversions in up to 87% *e.e.*<sup>89</sup> 16 acetophenone derivatives were then subjected toward hydrosilylation with PhSiH<sub>3</sub> using a catalytic amount of (*S*)-**96**·DMS (**Scheme 89**). Acetophenones containing strongly electron withdrawing groups on the aryl rings caused the reactions to proceed significantly slower, yielding the corresponding alcohols in moderate yields, albeit good *e.e.* Conversely, acetophenones with electron donating groups on the aryl ring underwent full conversion more rapidly, although the resultant *e.e.s* were significantly lower. Additionally, sterically hindered acetophenone derivatives displayed both low reactivity and enantioselectivity.<sup>89</sup>

Chiral bisboranes formed through the hydroboration of binaphthyl-based dienes by Piers borane have already been discussed for their activity in catalytic asymmetric hydrogenations.<sup>33–36</sup> Further studies found that such catalysts could also be extended toward asymmetric hydrosilylations (**Scheme 90**).<sup>90</sup> A range of chiral bisboranes were evaluated for their capability toward imine hydrosilylation, with the bisborane formed from diene **35** being chosen as optimal. The chiral borane was employed in the successful enantioselective hydrosilylation of 18 imines, with excellent yields and *e.e.s* of the corresponding amine observed following reduction. Interestingly, this system did not require an external Lewis base, in contrast to Klankermayer's chiral boranes (**28**, **90**), which racemically reduced the imines in the absence of a Lewis base.<sup>86,90</sup>

**Scheme 89** (S)-96.DMS-mediated hydrosilylation of acetophenones.<sup>89</sup>

**Scheme 90** Asymmetric hydrosilylation catalyzed by a chiral bisborane.<sup>90</sup>

The bisborane formed from hydroboration of **35** with Piers borane was later employed in the asymmetric hydrosilylation of acetophenone derivatives when part of an FLP with P<sup>t</sup>Bu<sub>3</sub>. Employing 5 mol% of the chiral FLP catalyst enabled the hydrosilylation of simple ketones in excellent yields and *e.e.* (**Scheme 91**).<sup>91</sup>

The first example of FLP-mediated diastereoselective hydrosilylation was presented through the B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>-catalyzed hydrosilylation and bishydrosilylation of  $\alpha$ -diketones. Interestingly, the relative stereochemistry of the products was determined by the steric bulk of the hydrosilane reagent. When smaller hydrosilanes such as Me<sub>3</sub>SiH were employed, *meso* products were preferentially formed (up to 96 *d.e.*). Conversely, larger silanes such as Ph<sub>3</sub>SiH provided *dl* products preferentially (up to 92 *d.e.*) (**Scheme 92**).<sup>92</sup>

Further diastereoselective hydrosilylation of 1,2-dicarbonyls was demonstrated using a bisborane formed by the hydroboration of diyne **97** with Piers borane.<sup>93</sup> The bisborane was subjected toward the hydrosilylation of a range of 1,2-dicarbonyl compounds to form optically active  $\alpha$ -hydroxy ketones and  $\alpha$ -hydroxy esters in good to excellent isolated yields and *e.e.s* following reduction (**Scheme 93**). A limitation upon the system was noted upon the reduction of smaller substrates; when acetophenone was hydrosilylated and subsequently reduced, 1-phenylethanol was obtained in 95% yield with a mediocre *e.e.* of 42%.<sup>93</sup>

### 1.06.3.3 FLP-mediated reduction of amides to amines via hydrosilylation

Metal-free amide reduction was classically a challenging transformation; previously, metal-free approaches employed stoichiometric boron hydrides, but a common problem was over-reduction and the resultant formation of unwanted by-products. These issues made the reactions less economically viable and made product purification a more challenging task.<sup>94</sup>

**Scheme 91** FLP-mediated asymmetric hydrosilylation of acetophenones by a chiral bisborane.<sup>91</sup>

**Scheme 92** FLP-mediated diastereoselective hydrosilylation of  $\alpha$ -diketones.<sup>92</sup>

**Scheme 93** FLP-mediated enantioselective hydrosilylation of 1,2-dicarbonyl compounds.<sup>93</sup>

In 2016, it was found that EPC systems could be employed to reduce amides into amines via a hydrosilylated intermediate.<sup>95</sup> Two EPCs **68** and **98** were observed to readily catalyze amide reduction with low catalytic loadings, although harsh reaction conditions and long reaction times were required for quantitative conversions. Moreover, the silane reagent also played a crucial role in the effectiveness of the reaction. Silanes with lower hydricity such as  $\text{HSiMe}_3$  or  $\text{HSiPh}_3$  promoted no reduction of *N,N*-dimethylbenzamide, whereas the more hydridic  $\text{PhSiH}_3$  gave almost quantitative conversion. A wide scope of aliphatic and aromatic amides was subsequently reduced to their corresponding amines in up to 99% conversion with concomitant loss of siloxane (**Scheme 94**). A series of 2,2,2-trifluoroacetamides were also chemoselectively reduced into their respective 2,2,2-trifluoroethyl amines in good to excellent isolated yield; however, limitations on the efficiency of the protocol were observed with highly basic amides, which were recalcitrant toward reduction. This was attributed to irreversible binding of the EPC to the substrate, thus poisoning the catalyst.<sup>95</sup>

The reaction mechanism of the EPC catalyzed amide reductions was based upon previous FLP-like EPC catalyzed hydrosilylations.<sup>83,84,95</sup> It was proposed that upon addition of the silane to the EPC **68**, the Si–H bond was weakened through co-ordination of the hydride with the Lewis acidic phosphorus atom (**Scheme 95, I**). Nucleophilic attack of the amide toward the activated silane

**Scheme 94** FLP-mediated reduction of amides into amines via a hydrosilylated intermediate.<sup>95</sup>

**Scheme 95** Proposed mechanism of FLP-mediated reduction of amides into amines.<sup>95</sup>

then occurred (Scheme 95, II) which formed a silylated intermediate 99. This intermediate further reacted with another equivalent of activated silane (Scheme 95, I) to liberate the amine, the silylether, and the EPC catalyst 68 (Scheme 95).<sup>95</sup>

#### 1.06.4 FLP-mediated hydroamination

$B(C_6F_5)_3$  was first adapted for use as a hydroamination catalyst by Stephan in 2013. 14 enamines were formed in good to excellent yield as the Markovnikov addition product, following the  $B(C_6F_5)_3$ -mediated 1,2-addition of a secondary amine to an alkyne. For efficient reactivity, slow addition of the alkyne into the reaction mixture was necessary and low temperatures were required to enhance product yield in certain circumstances (Scheme 96). Inspired by the FLP-like nature of the hydroamination catalysis and the well-established reduction catalysis mediated by FLPs, two examples of one-pot tandem hydroamination/hydrogenation reactions were also demonstrated to directly form tertiary amines in good yield (Scheme 96).<sup>96</sup>

The observed enamine products from Markovnikov addition suggested the reaction to be FLP-like in nature, with the amine substrate also acting as the FLP's Lewis basic component (Scheme 97, I). It was proposed that the alkyne initially coordinated to  $B(C_6F_5)_3$  resulting in an adduct between the terminal alkyne carbon and the Lewis acidic boron atom. Nucleophilic attack by the amine then resulted in the formation of a zwitterionic intermediate (Scheme 97, II) wherein the alkyne was activated between

**Scheme 96**  $B(C_6F_5)_3$  mediated hydroamination of terminal alkynes and  $B(C_6F_5)_3$  mediated tandem hydroamination/hydrogenation of alkynes.<sup>96</sup>

**Scheme 97** Mechanism of  $B(C_6F_5)_3$  mediated hydroamination of terminal alkynes.<sup>96</sup>

the Lewis acidic and basic centers. A subsequent 1,3-proton transfer furnished the enamine product **100**, whilst regenerating the Lewis acid catalyst (**Scheme 97**).<sup>96</sup>

The  $B(C_6F_5)_3$  catalyzed hydroamination protocol was later extended toward tandem intramolecular hydroamination/hydrogenation reactions for the preparation of cyclic amines.<sup>97</sup> Seven substrates were reported to form their respective *N*-heterocycles in good to high yields using similar conditions reported for the intermolecular reaction.<sup>96</sup> Whilst the preparation of five, six and seven-membered heterocycles was successful, the attempted cyclization of *N*-propynyl-substituted anilines into their respective aziridines could not be achieved under the explored conditions (**Scheme 98**).<sup>97</sup>

Paradies later applied Lewis acidic boranes toward the synthesis of indoles via intramolecular hydroamination; however, only  $B(C_6F_5)_3$  was able to promote the reaction while neither of weakly Lewis acidic boranes such  $B(2,6-F_2C_6H_3)_3$  **17** or  $B(2,4,6-F_3C_6H_2)_3$  **47** could do so. Six indoles were successfully synthesized in good to excellent yield through 5-*endo*-dig cyclizations (**Scheme 99**). Limitation to the protocol was noted when the nucleophilicity of the nitrogen atom was reduced whereupon no reactivity was observed. Additionally, some substrates were able to form adducts with  $B(C_6F_5)_3$  but decomposed under elevated temperatures without forming the desired indole.<sup>98</sup>

### 1.06.5 FLP-mediated C–H borylation

In 2015, Fontaine demonstrated the C–H activation and subsequent borylation of heteroarenes with the use of intramolecular FLP **101** (**Scheme 100**). The intramolecular catalyst was designed specifically for this reaction: the position of the Lewis acidic boron

**Scheme 98**  $B(C_6F_5)_3$  mediated tandem hydroamination/hydrogenation of alkynes.<sup>97</sup>

**Scheme 99**  $B(C_6F_5)_3$  catalyzed indole synthesis through intramolecular hydroamination.<sup>98</sup>

**Scheme 100** FLP-mediated borylation of heteroarenes.<sup>99</sup>

atom was constructed to be in close proximity to the heteroarene's nucleophilic carbon, whilst the base was designed to be bulky in order to prevent any possible dimerization which could occur following proton abstraction of the heteroarene. In solution, **101** was observed to be in equilibrium between a monomeric and dimeric form. Catalyst **101** was observed to catalyze the borylation of 13 oxygen, nitrogen and sulfur containing heterocycles in high conversions. The position of borylation was dependent upon the substrate. Initially 1-methylpyrrole was investigated toward borylation, which formed two regioisomers: 2-borylated **102** and 3-borylated **103** in a 93:7 ratio. Bulkier *N*-protecting groups on pyrrole such as triisopropyl silyl ether (TIPS) **104** and trimethylsilyl (TMS) enabled the pyrroles to undergo the borylation specifically at the 3 position, whilst protection with a benzyl group reduced selectivity significantly toward a 3:2 ratio. Electron-rich furan derivatives generally underwent borylation with exclusive selectivity at the C<sub>2</sub> position in high to excellent conversion. Notably, 3-bromofuran required harsher conditions (increased temperature, time and catalytic loading) to undergo borylation. Although selectivity was heavily decreased, yielding **105** and **106** in a 10:9 ratio, 90% overall conversion was observed. Only electrophilic thiophene derivatives were amenable to reaction. 3,4-Ethylenedioxythiophene in particular was observed to form either monoborylated **107** or diborylated products in 87% and 99% yield respectively, depending upon the stoichiometry of HBPin applied.<sup>99</sup>

With the aid of DFT and kinetic studies, a mechanism was proposed for the borylation of 1-methylpyrrole. Initial dissociation of the FLP dimer **101** resulted in the formation of the monomeric active catalyst **108**. In the rate determining step of the cycle, **108** proceeded to activate the C–H bond of the 1-methylpyrrole via a four-membered transition state (**Scheme 101, I**), generating zwitterionic species (**Scheme 101, II**). A subsequent rapid H<sub>2</sub> release from this zwitterionic species formed a borohydride intermediate

**Scheme 101** Mechanism of FLP-mediated borylation of heteroarenes.<sup>99</sup>

(**Scheme 101, III**), from which product **102** was obtained via a four-center sigma bond metathesis with HBPIn (**Scheme 101, IV**). Activation at the C<sub>2</sub> position was found to require only 0.4 kcal mol<sup>-1</sup> less energy compared to the C<sub>3</sub> position, thus accounting for the formation of two regioisomers.<sup>99</sup>

One year later, Fontaine improved this protocol with the introduction of an oxygen and moisture stable precatalyst **109**, thus precluding the necessity for Schlenk techniques or glove boxes for the catalytic borylation transformation (**Scheme 102**). Precatalyst **109** differed only by the installation of a fluoroborate salt in favor of the dihydroborane group in **101**. Deprotection of **109** to the active dihydroborane catalyst **101** was mediated by the borylating agent HBPIn, thus no other additive was required for the reaction. A brief substrate scope of six heteroarenes found that the catalytic activity of **109** was comparable to **101**, despite the bench-stable nature of the precatalyst.<sup>100</sup>

Repo later discovered that 2-aminophenylboranes were able to catalyze the C–H activation of heteroarenes, as the rigid phenyl bridge between the acidic and basic sites provided an optimal geometry for efficient reactivity. It was demonstrated that the catalyst's reactivity was more affected by steric factors and the Lewis acidity and basicity of its boron and nitrogen atoms, rather than being sensitive to the substituents situated upon the acidic and basic sites.<sup>101</sup>

With these observations in hand, Fontaine subsequently investigated modifications to the amine moiety of catalyst **101**, citing low yields and expensive synthesis as motivation to replace the TMP unit. Thus, smaller and more readily available amine

**Scheme 102** FLP-mediated borylation of heteroarenes with a bench stable pre-catalyst.<sup>100</sup>

derivatives such as piperidine, diethylamine and dimethylamine were installed onto the intramolecular FLP catalyst. Moreover, it was observed that these smaller FLPs were up to 15 times more reactive than **101**. DFT and kinetic studies revealed this increase in activity was due to the change in the rate determining step; in the presence of smaller amines the rate determining step became the initial dimer dissociation, rather than the C–H activation step observed for **101**.<sup>102</sup>

### 1.06.6 FLP-mediated cyclization reactions

Stoichiometric cyclization reactions involving FLPs are well documented. Examples include: intramolecular additions of amines to unsaturated C–C bonds to form zwitterionic nitrogen containing heterocycles (**Scheme 103, I**)<sup>103</sup>; three-component cyclizations of phosphines, boranes and olefins to form zwitterionic phosphorus containing heterocycles (**Scheme 103, II**)<sup>104</sup>; and B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> mediated cyclization of propargyl amides to form methylene-oxazolines (**Scheme 103, III**).<sup>105</sup>

Notably, when B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> mediated cyclization was performed on N–H propargyl amides with an aryl substituent, the methylene-oxazoline products were observed to isomerize into oxazoles, an important heterocyclic moiety found in anti-bacterial and anti-fungal agents.<sup>105,106</sup> Unfortunately, whilst 16 examples of B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> mediated propargyl amide cyclizations into their respective methylene-oxazoline products were reported, only four isomerizations were observed (**Scheme 104**). This isomerization required gentle heating over 4 days, and only one oxazole was isolated out of the four prepared. This reaction was

**Scheme 103** Examples of stoichiometric FLP-mediated cyclizations.<sup>103–105</sup>

**Scheme 104** B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> mediated cyclization and subsequent isomerization of propargyl amides.<sup>105</sup>

initially perceived to be incapable of catalysis as the dative bond  $N \rightarrow B$  in the isolated compound was too strong to permit the release of  $B(C_6F_5)_3$ <sup>105</sup>; however, when the propargyl amide was installed with an adamantyl group, steric frustration was induced in the dative  $N \rightarrow B$  bond prompting the release of the Lewis acid. The formation of oxazole **110** in 83% yield was thus observed from its corresponding propargyl amide when 10 mol% catalytic loading of  $B(C_6F_5)_3$  was applied. Harsh conditions were essential (100 °C, 240 h), but this was the first example of catalytic transition metal-free cyclization of propargyl amides.<sup>105</sup>

FLPs were later observed to catalyze the cycloisomerization of 1,5-enynes.<sup>107</sup> Initial stoichiometric reactions between 1,5-enyne and  $B(C_6F_5)_3$  resulted in the formation of 5-*endo*-dig cyclized product **111** (Scheme 105). DFT probes suggested that the borane initially activated the alkyne, to form a reactive carbocation. Addition of the olefinic bond to this carbocation resulted in a cyclization and the formation of zwitterionic intermediate **112**. The formed reactive carbocation subsequently rearranged via a 1,1-carbaboration and a 1,2-hydride shift to form intermediate **113**, which upon a final 1,3-borane shift, furnished the stable borane product **111**.<sup>107</sup>

When a phosphine Lewis base was included in the cycloisomerization reaction, the 1,1-carbaboration was prevented. Instead, the phosphine was observed to promote proton abstraction from carbocation intermediate **112**, forming the stable onium borate intermediate **114**, which existed in equilibrium with its addition product **115**. Heating to 90 °C promoted protodeborylation, furnishing the cycloisomerized product **116** and liberating the FLP (Scheme 106).<sup>107</sup>

With proof of catalytic cycloisomerization, the protocol was developed further to variously substituted enynes using 20 mol% catalytic loading of  $B(C_6F_5)_3$  and  $PPh_3$ . Overall, 7 examples were presented with NMR yields ranging from 50% to 98%. Electron

**Scheme 105** Synthesis of 5-*endo*-dig cyclized product **82** from 1,5-enyne and  $B(C_6F_5)_3$ .<sup>107</sup>

**Scheme 106** Mechanism of FLP-mediated cycloisomerization of 1,5-enynes.<sup>107</sup>

donating substitutions on the alkyne moiety provided better results whereas electron withdrawing and thiophenyl substitutions decreased the yields. Moreover, exchanging the core phenyl ring with heterocyclic furanyl or thiophenyl groups caused the catalytic cyclization to completely cease, presumably due to the increased distance between alkene and alkyne functional groups (**Scheme 107**).<sup>107</sup>

$B(C_6F_5)_3$  was also observed to act as a dual-role catalyst in the preparation of 3,4,5-triaryl-1,2,4-triazoles from *N*-tosylhydrazones and anilines (**Scheme 108**). 3,4,5-triaryl-1,2,4-triazole motifs are found in a range of pharmaceutical drugs, pesticides, and organic photovoltaic cells; however, many of their preparations are restricted by large excesses of reagents or narrow functional group tolerance, thus this one-pot metal-free system was shown to be particularly useful.<sup>108</sup> Symmetrical 1,2,4-triazoles were obtained in good to excellent yield after 48 h, using two equivalents of hydrazone and one equivalent of amine. Additionally, the protocol was extended to asymmetrical 1,2,4-triazoles by using two different hydrazones, yielding the asymmetrical triazole in excellent yield. Due to the potential low selectivity, the two different *N*-tosylhydrazone reagents were required to possess different electronic properties on their aryl groups, otherwise a 1:1:1 ratio between the symmetrical and asymmetrical products was observed.<sup>108</sup>

A combined experimental and computational approach allowed for the elucidation of the catalytic cycle, wherein  $B(C_6F_5)_3$  acted as both a Lewis acid catalyst and as the Lewis acidic component of an FLP at different stages. The cycle commenced with the formation of an adduct between  $B(C_6F_5)_3$  and *N*-tosylhydrazone, in which the boron coordinated toward the  $sp^2$ -hybridized nitrogen atom (**Scheme 109, I**). The aniline **117** then coordinated to this adduct, forming a zwitterionic complex which performed a rate-determining intramolecular hydride transfer from  $N^3$  to  $N^1$ , thus furnishing an adduct intermediate (**Scheme 109, II**), which upon reaction with a second equivalent of *N*-tosylhydrazone, resulted in the formation of an unstable intermediate (**Scheme 109, III**) through loss of a  $NH_2Ts$  fragment. Intermediate (**Scheme 109, III**) then rapidly cyclized to form a heterocycle (**Scheme 109, IV**).

**Scheme 107** FLP-mediated cycloisomerization of 1,5-enynes.<sup>107</sup>

**Scheme 108**  $B(C_6F_5)_3$ -mediated synthesis of 3,4,5-triaryl-1,2,4-triazoles.<sup>108</sup>

**Scheme 109** Mechanism of FLP-mediated synthesis of 3,4,5-triaryl-1,2,4-triazoles.<sup>108</sup>

via initial dissociation of the borane from  $N^1$  and subsequent protonation of  $N^4$ , resulting in an intramolecular nucleophilic attack of  $N^2$  to  $N^1$  to form the new N–N bond with concomitant loss of another  $NH_2Ts$  fragment. At this stage  $B(C_6F_5)_3$  switched role from a Lewis acid catalyst to be part of an FLP catalyst, facilitating dehydrogenative aromatization to liberate the triazole product **118** and the zwitterionic FLP (Scheme 109, V). Finally, release of  $H_2$  from this FLP liberated aniline and regenerated the borane catalyst for further turnovers (Scheme 109).<sup>108</sup>

### 1.06.7 FLP-mediated reduction of $CO_2$

It is well known that increasing levels of carbon dioxide in the Earth's atmosphere is one of the main contributing factors toward global warming. One method to reduce the levels of this greenhouse gas in our atmosphere is to use it as a chemical feedstock. For example,  $CO_2$  can be reduced to form methanol, which can be used for electricity generation in fuel cells and can serve as a precursor for many organic molecules. Such utilization of  $CO_2$  is a challenging task due to its high thermodynamic and kinetic stability, thus harsh conditions and transition-metal catalysts are generally required for the direct reduction of  $CO_2$  into methanol with molecular  $H_2$ .<sup>109</sup> As a result of this, the application of metal-free catalysts toward  $CO_2$  reduction has become an up-and-coming field of research.<sup>110</sup>

Following Stephan and Erker's discovery that an FLP comprised of  $B(C_6F_5)_3$  and  $P^tBu_3$  could reversibly bind to  $CO_2$  under mild conditions,<sup>111</sup> the search for FLPs which are able to promote  $CO_2$  reduction has become a target for main-group chemists worldwide. The first examples of FLP-mediated reduction of  $CO_2$  with gaseous  $H_2$  were stoichiometric. An FLP comprised of TMP **62** and  $B(C_6F_5)_3$  was observed to quantitatively reduce  $CO_2$  into  $CH_3OB(C_6F_5)_2$ , from which methanol could be obtained by vacuum distillation, albeit in low yields of 17–25%.<sup>112</sup> A subsequent report found that stoichiometric FLP-mediated  $CO_2$  reduction into methanol could occur at room temperature when  $BH_3 \cdot NH_3$  was employed as a hydrogen source.<sup>113</sup> A joint publication from the groups of Stephan and Fontaine found an aminoborane FLP capable of activating both  $H_2$  and  $CO_2$ ; however, this system was unable to release the reduced products.<sup>114</sup> The first successful catalytic reduction of  $CO_2$  into methane was reported by Piers; however, catalytic efficiency was low. The intermolecular FLP caused an unfavorably high entropy within the system and 18 equivalents of triethylsilane reductant were required for efficient reaction.<sup>115</sup> A proposed mechanism suggested that  $B(C_6F_5)_3$  would form an FLP with both TMP **62** and an adduct with triethylsilane at different stages in the reaction. Initially, the  $B(C_6F_5)_3 \cdot TMP$  adduct activated hydrogen **119**. This activated complex could then go on to activate  $CO_2$  to form formatoborate intermediate **120**. Meanwhile, the  $B(C_6F_5)_3 \cdot HSiEt_3$  **121** adduct was formed, which was able to hydrosilate formatoborate **120** to form a formatosilane **122**.

Sequential hydrosilylation of the formatosilane by the adduct **121** resulted in bis(triethylsilyl)acetal **123**, followed by silylether **124** and finally methane through the loss of disiloxane **125** (Scheme 110).<sup>115</sup>

The first highly efficient FLP-catalyzed reduction of CO<sub>2</sub> was reported by Fontaine in 2013, with the use of an air-stable aryl-bridged phosphinoborane FLP **126**. Reaction of catecholborane with CO<sub>2</sub> in the presence of a catalytic amount of **126** was observed to form methoxyborane **127** with concomitant loss of a B–O–B dimer. Hydrolysis of **127** liberated methanol readily. This transformation proceeded under mild conditions, with low CO<sub>2</sub> pressures and catalytic loading, albeit with large amounts of waste per methanol generated (Scheme 111).<sup>116</sup> A recent computational study by Grimme observed that Fontaine's catalytic system was more active than the ensuant systems reported by Stephan,<sup>117</sup> and Cantat.<sup>118,119</sup>

An extensive combined experimental and DFT study elucidated the mechanism of this reaction, revealing that the phosphinoborane did not adhere to conventional FLP-style small molecule activation. Instead, it was observed that the Lewis basic center activated the HBCat reducing agent, whilst the Lewis acidic/basic centers promoted catalysis through assisting the release of the reaction products. It was suggested that the Lewis basic center of the phosphinoborane initially activated the catecholborane, thereby forming an adduct. This resulted in a hydride transfer from the borane to the carbon of CO<sub>2</sub>, thereby forming a formate anion which could co-ordinate to the Lewis acidic center of the phosphinoborane to form intermediate **120**. This intermediate existed in equilibrium with **129**, wherein the nucleophilic catecholborane co-ordinated to the CO<sub>2</sub> rather than the Lewis basic component of the phosphinoborane. Reaction with a second equivalent of catecholborane resulted in intermediate **130**, which was subsequently reduced to form the formaldehyde phosphinoborane adduct **131**. Finally, this species was reduced by another equivalent of catecholborane to form the methoxyborane product **132** (Scheme 112).<sup>120</sup>

Scheme 110 FLP-mediated reduction of CO<sub>2</sub> into methane.<sup>115</sup>

Scheme 111 FLP-mediated reduction of CO<sub>2</sub> into methanol via a methoxyborane intermediate.<sup>116</sup>

**Scheme 112** Proposed mechanism of FLP-mediated reduction of CO<sub>2</sub> into methanol via a methoxyborane intermediate.<sup>120</sup>

Subsequent spectroscopic and computational mechanistic studies identified that phosphinoborane **126** was a precatalyst and rather, the formaldehyde phosphinoborane adduct **133** (**Fig. 8**) acted as the active catalyst in the reaction. Experimental comparisons and deuteration studies confirmed that adduct **133** was more active toward CO<sub>2</sub> reduction than the phosphinoborane **126** alone.<sup>121</sup>

In 2014, Stephan reported a different intramolecular FLP catalyst **134** for CO<sub>2</sub> reduction (**Scheme 113**). This FLP was generated from reaction of two equivalents of 9-BBN with an *N*-phosphorylated NHC. Catalytic amounts of **134** were observed to promote the reduction of CO<sub>2</sub> by catecholborane under relatively mild conditions to form the corresponding methoxyborane. Notably, the identity of the reductant had a significant effect upon the product or products observed. If HBpin was used, a mixture of HCO<sub>2</sub>Bpin, CH<sub>2</sub>(OBpin)<sub>2</sub> and MeOBpin was formed, whilst when BH<sub>3</sub>·SMe<sub>2</sub> was used as the reductant, exclusively (MeOBO)<sub>3</sub> was generated.<sup>117</sup>

**Fig. 8** Identity of active catalyst in **Schemes 111 and 112**.<sup>121</sup>

**Scheme 113** Reduction of CO<sub>2</sub> with an NHC-borane FLP **134**.<sup>117</sup>

It was proposed that **134** would initially activate  $\text{CO}_2$  between the boron and one of the phosphorus centers (**Scheme 114, I**). Subsequent reaction with the borane reductant formed cyclic intermediate (**Scheme 114, II**), which liberated the boron formate **135** to regenerate the FLP catalyst. The liberated boron formate could then be further reduced by additional borane reductants to afford the observed mixture of products depending upon which reductant was used.<sup>117</sup>

Shortly afterwards, Stephan also probed intermolecular FLP systems comprised of 9-BBN and bulky Lewis basic phosphines for  $\text{CO}_2$  reduction. Here, 9-BBN was used as a reductant, to form its corresponding methoxide product **136** upon  $\text{CO}_2$  reduction. Of the bases probed,  $\text{P}^t\text{Bu}_3$  was observed to be most selective, with other bases promoting the formation of other  $\text{CO}_2$ -reduced products such as boron-bound formate species **137** or diolate-linked compounds **138** (**Scheme 115**).<sup>122</sup>

Silylium cations are isoelectronic to boranes, thus can also be used as the Lewis acidic component of FLPs. Stephan first discussed the application of silylium cation FLPs for  $\text{CO}_2$  activation in 2015; however, these were stoichiometric reactions and formed simple adducts rather than promoting reduction.<sup>123</sup>

Cantat later introduced a base-stabilized silylium species **139**, which was able to readily react with  $\text{CO}_2$  to yield the corresponding FLP· $\text{CO}_2$  adduct salt **140** quantitatively (**Fig. 9**).<sup>118</sup> Salt **140** exhibited a greater stability compared to Stephan's silylium-based

**Scheme 114** Mechanism of  $\text{CO}_2$  reduction with an NHC-borane FLP **134**.<sup>117</sup>

**Scheme 115** Reduction of  $\text{CO}_2$  with 9-BBN.<sup>122</sup>

Fig. 9 Silylium cation FLPs for CO<sub>2</sub> activation.<sup>118</sup>

FLP-CO<sub>2</sub> adducts, which had been observed to decompose at room temperature.<sup>123</sup> Moreover, it was demonstrated that steric crowding around the Si<sup>+</sup> center was essential in determining whether the CO<sub>2</sub> adduct could be formed, as <sup>i</sup>Pr 141 and Ph 142 substituted silylium cations were unable to bind to CO<sub>2</sub>. Thus, it was suggested that the FLP·CO<sub>2</sub> adduct was not thermodynamically favorable and therefore could be potentially suitable for catalytic CO<sub>2</sub> reduction.<sup>118</sup> Indeed, a series of base stabilized silylium cation FLPs and their CO<sub>2</sub> adducts were observed to catalytically hydroborate CO<sub>2</sub>, yielding the corresponding methoxide quantitatively.<sup>118</sup>

### 1.06.8 Summary and outlook

In this article, the catalytic applications of frustrated Lewis pairs have been considered. From simple catalytic reduction of substrates with dihydrogen, to complex enantioselective reduction and 1,2-functionalizations, FLPs have been demonstrated to act as excellent alternatives to precious metal catalysts. With such exponential interest in the field over the past decade and a half we predict many more exciting catalytic reactions to be performed by FLPs.

### Abstract

Fluorinated alkoxyaluminates  $[\text{Al}(\text{OR}^{\text{F}})_4]^-$ ,  $[(^{\text{F}}\text{RO})_3\text{Al}-\text{F}-\text{Al}(\text{OR}^{\text{F}})_3]^-$  and the related borates  $[\text{B}(\text{OR}^{\text{F}})_4]^-$  ( $\text{R}^{\text{F}}$  stands for a poly- or perfluorinated organic alkyl residue) belong to the class of Weakly Coordinating Anions (WCAs) that made their way over the past decades from a means to stabilize unusual cationic systems of fundamental interest to a well-developed class of materials that help to prepare problem case model compounds similarly to being useful in applied research, e.g.,

\*All authors contributed equally.

for Ionic Liquids (ILs). In this review we briefly sketch the range of known WCAs, before turning mainly to the aluminate class of materials, but, where relevant, also to the related borates. We highlight the synthesis of starting materials, ways to introduce the WCAs to the system, the physical properties they induce and report on their performance in fundamental as well as applied chemistry, i.e. in catalysis, polymerization, electrochemistry, as electrolyte salts for supercaps and secondary batteries.

### 1.07.1 Introduction

Fluorinated alkoxyaluminates  $[\text{Al}(\text{OR}^{\text{F}})_4]^-$  belong to the class of Weakly Coordinating Anions (WCAs) that made their way over the past decades from a means to stabilize unusual cationic systems of fundamental interest to a well-developed class of materials that help to prepare problem case model compounds similarly to being useful in applied research, e.g., for Ionic Liquids (ILs), catalysis, polymerizations, electrochemistry and electrolytes (Fig. 1). In this article  $\text{R}^{\text{F}}$  stands for any poly- or perfluorinated organic residue. The specific abbreviations used for the most common WCAs are delineated in Fig. 2. In the following we briefly sketch the range of known WCAs, before turning mainly to the aluminate  $[\text{Al}(\text{OR}^{\text{F}})_4]^-$  class of materials, but, where relevant, also to the related borates  $[\text{B}(\text{OR}^{\text{F}})_4]^-$ . We highlight the synthesis of starting materials, their physical properties, typical routes to introduce them into a system and report on their performance in fundamental as well as applied chemistry.

This chapter is an update on our 2013 review in this book<sup>1</sup> and covers the literature until end of 2021/beginning of 2022.

#### 1.07.1.1 A brief introduction to weakly coordinating anions

The prime role of WCAs is to suppress strong cation-anion interactions and to replace the few strong electrostatic interactions in classical salts by a multitude of weak interactions. To achieve this goal, the majority of more recent WCAs are rather large and exhibit diameters in the nanometer range; moreover their “surfaces” are often covered by poorly polarizable fluorine atoms that produce a “Teflon”-type coating additionally dampening the efficiency of ion pairing and increasing the (kinetic) inertness and (thermodynamic) stability of these anions against ligand coordination or abstraction as well as oxidation. Overall this leads to improved solubilities of WCA-salts in less or even non-polar solvents, reduces ion pairing in these solvents and ultimately also leads to electric conductivity in these media. Clearly these are favorable properties for a range of applications and accordingly a large group of different WCAs has been prepared over the years. Those were recently reviewed<sup>2,3</sup> and shall not be detailed here, other than mentioning that they are typically built from a very Lewis acidic central atom M that usually bears a range of mainly univalent, chemically robust and often fluorinated ligands L giving the normally univalent ate-complexes  $[\text{M}(\text{L}_{n+1})]^-$  ( $n$  = valency of M) as WCAs. Examples are the classical fluorometallates like  $[\text{BF}_4]^-$  or  $[\text{MF}_6]^-$  and their aggregates like  $[\text{M}_2\text{F}_{11}]^-$  ( $\text{M} = \text{As}, \text{Sb}$ ), poly-fluorinated tetraaryl- or tetraalkylborates  $[\text{B}(\text{R}^{\text{F}})_4]^-$  ( $\text{R}^{\text{F}} = \text{CF}_3, \text{C}_6\text{F}_5, \text{C}_6\text{H}_3(\text{CF}_3)_2$  and others), dimeric borates  $[\text{X}(\text{B}(\text{C}_6\text{F}_5)_3)_2]^-$  ( $\text{X} = \text{CN}, \text{NH}_2$  and others), tetra- or hexateflatometallates  $[\text{M}(\text{OTeF}_5)_n]^-$  ( $n = 4, 6, \text{M} = \text{B}, \text{Al}, \text{Ga}$ ;  $n = 6, \text{M} = \text{As}, \text{Sb}, \text{Bi}, \text{Nb}$ ) but also bis(trifluoromethane-sulfonyl)imides  $[(\text{R}^{\text{F}}\text{SO}_2)_2\text{N}]^-$  or tris(trifluoromethane-sulfonyl)methanides  $[(\text{R}^{\text{F}}\text{SO}_2)_3\text{C}]^-$  and many others. Alternatively, also chemically robust *closo*-clusters may replace the central Lewis acidic atom M. When the periphery of these clusters is halogenated or trifluoromethylated, this leads to the important and chemically very stable, but difficult to prepare class of

Fig. 1 Overview to common WCAs excluding the simple anions that are common knowledge like  $[\text{ClO}_4]^-$ ,  $[\text{CF}_3\text{SO}_3]^-$ ,  $[\text{BF}_4]^-$ ,  $[\text{MF}_6]^-$  and more.

**Fig. 2** Definitions of the acronyms of the most commonly used fluorinated residues and WCAs used in this article.

carborane based WCAs  $[CB_{11}X_nH_{12-n}]^-$  ( $n = 0-12$ ,  $X = F, Cl, Br, I, CH_3, CF_3$ ), which was augmented by the synthetically in larger scale accessible *closo*-dodecaborates  $[B_{12}X_{12}]^{2-}$  ( $X = F, Cl, Br, I$ ). Recent additions include the WCAs  $[M(OTeF_5)_4]^-$  ( $M = Al, Ga$ ), introduced by the Riedel group,<sup>4,5</sup> and  $[Ga(C_2F_5)_4]^-$  prepared by the Hoge group.<sup>6</sup> Fig. 1 shows a personally selected overview on currently used WCAs.

### 1.07.1.2 Fluorinated alkoxyaluminates as WCAs: A comparison to competitors

Among the above mentioned WCAs, the fluorinated alkoxyaluminates  $[Al(OR^F)_4]^-$  are a newer addition that were first published by S. Strauss<sup>7</sup> in 1996 and were complemented by our group since 1999.<sup>8-12</sup> Also several of the related borates  $[B(OR^F)_4]^-$  came into the focus,<sup>13-15</sup> mainly for use in ionic liquids or as electrolyte salts for various batteries. Currently we are aware of about 100 groups worldwide that use the favorable properties of this chemically robust and easily in large scale or even commercially at [www.iolitec.de](http://www.iolitec.de) available WCA class. Importantly, a simple and straight-forward large scale access to the least coordinating fluoride-bridged anion  $[(^{PF}RO)_3Al-F-Al(OR^{PF})_3]^-$  was published<sup>12</sup>; the synthesis routes delineated therein override the ones published in 2004.<sup>16</sup> The simplified nomenclature used to address the most frequent aluminate and borate WCAs described with this work is included with Fig. 2.

With Respect to Coordinating Ability: Since the major purpose of a WCA is to reduce the overall cation-anion interaction, the performance of the coordination ability of the  $[pfo]^-$  and  $[alfal]^-$  aluminate in comparison to other well-known WCAs may best be visualized by from a projection of the BP86/def2-TZVP calculated electrostatic potential onto a  $0.005 e^- \text{ Bohr}^{-3}$  isodensity surface of the aluminate WCA in comparison to classical WCAs (Fig. 3; red coloration indicates high accumulation of negative charge).

**Fig. 3** Projection of the BP86/def2-TZVP calculated electrostatic potential map onto a  $0.005 e^- \text{ Bohr}^{-3}$  isodensity surface of  $[hfo]^-$ ,  $[pfo]^-$  and  $[alfal]^-$  in comparison to classical WCAs.

When comparing with the often employed fluorinated tetraarylborates (Fig. 4), one also realizes the favorable performance of the aluminates. From this projection also follows that the weak coordination ability of the  $[pf]^-$  and  $[alfal]^-$  aluminates is a result of two effects: electronic deactivation of the most basic oxygen alkoxide atoms by the fluorination (see low  $pK_a$  value of  $\text{HO}-\text{C}(\text{CF}_3)_3$  of 5.4 if compared to non-fluorinated  $\text{HO}-\text{C}(\text{CH}_3)_3$  of 19.3)<sup>8,17</sup> and the steric hindrance introduced by the umbrella effect of the bulky  $\text{C}(\text{CF}_3)_3$  group preventing electrophiles/cations to attack these most basic/negatively charged sites.

The final Fig. 5 of this series, compares the  $[pf]^-$  and  $[alfal]^-$  aluminates with the difficult to synthesize, but chemically extraordinary robust carborane based WCAs. One realizes from this Fig. 5, that only the most advanced mixed fluorinated-/trifluoromethylated carborane WCAs reach the potential of the  $[pf]^-$  and  $[alfal]^-$  aluminates in terms of for coordination available negatively charged sites. The more common only partially chlorinated carborane based anions exhibit higher and accessible surface charges. In agreement with this, these carborane ions tend to get easily coordinated, but can sustain extreme electrophilicity in such a coordinated state (e.g., they tolerate a coordinated  $\text{AlMe}_2^+$  cation).<sup>18</sup>

In Terms of Thermodynamic WCA-Stability: Little quantitative data is available here, and apart from comparisons on a chemical basis ("This WCA is compatible with this reactive cation, while another WCA does not tolerate this...!"), which may on a personal basis be concluded from the next sections, only few comparative studies on the basis of quantum chemical calculations exist. Larger parts of the following section were adapted from Refs.<sup>2,19</sup> and later addenda.<sup>3,20,21</sup> However, as recently the use of the very reliable DSD-PBEP86(D3BJ)/def2-QZVPP//pbeh3-c/def2-mSVP level of theory as described by Greb et al.<sup>22</sup> was recommended, we have recalculated all data collected in Table 1 at this reliable D3BJ-dispersion corrected double hybrid functional level. With the calculated data, the thermodynamic stability of the WCA's as collected in Table 1 was established based on the following considerations:

- (i) The *Fluoride Ion Affinity FIA*: All anions that are based on Lewis acidic central atoms, are prone to ligand abstraction as a decomposition reaction. A measure for the intrinsic stability of a given WCA is the Lewis acidity of the parent Lewis acid A, i.e., the acid  $\text{B}(\text{C}_6\text{F}_5)_3$  for the anion  $[\text{B}(\text{C}_6\text{F}_5)_4]^-$ . A firmly established measure for Lewis acidity is the fluoride ion affinity *FIA*.<sup>21</sup> The higher the *FIA*-value of the parent Lewis acid A, the more stable is the WCA against ligand abstraction. For recent systematic work by Greb et al. see.<sup>23–25</sup>
- (ii) The *Ligand Affinity LA* of the WCAs. The *LA* is the enthalpy of reaction necessary to remove the anionic ligand  $[\text{L}]^-$  from the anion  $[\text{M}(\text{L})_n]^-$  (Eq. 1):

**Fig. 4** Projection of the BP86/def2-TZVP calculated electrostatic potential onto a  $0.005 \text{ e}^- \text{ Bohr}^{-3}$  isodensity surface of  $[pf]^-$  and  $[alfal]^-$  in comparison to fluorinated tetraarylborates.

**Fig. 5** The  $[\rho f]^-$  aluminates in comparison with the difficult to synthesize, but chemically extraordinary robust carborane based WCAs. Projection of the BP86/def2-TZVP calculated electrostatic potential onto a  $0.005 e^- \text{ Bohr}^{-3}$  isodensity surface.

**Table 1** Calculated properties of WCAs: The *FIA* of the parent Lewis acid, the *LA*, *PD* and *CuD* of the WCA, the position of the HOMO of the WCA in eV and the HOMO-LUMO gap of the WCA in eV.

<sup>a</sup>The HOMO-LUMO gaps were calculated with TD-DFT as the first singlet excitation energy at the DSD-PBEP86(D3BJ)/def2-QZVPP level.<sup>26</sup>

<sup>b</sup>LA and FIA are identical.

<sup>c</sup>FIA vs. 2  $\text{Al}(\text{OR})_3$ .

<sup>d</sup>For size restrictions, we had to use the DSD-PBEP86(D3BJ)/def2-TZVP level of theory, which gave for  $[\rho f]^-$  very similar values (i.e., 7.15 (def2-TZVP) vs. 7.06 eV (def2-QZVPP)). Note, the WCAs were selected based on Ref.<sup>2,3,19-21</sup> and the values recalculated at the DSD-PBEP86(D3BJ)/def2-QZVPP//pbeh3-c/def2-mSVP level of theory as described by Greb et al.<sup>22</sup>

The *LA* is always endothermic and the higher the positive *LA*-value in **Table 1**, the more stable is the WCA versus a ligand abstraction. However, a word of caution is needed here: The *LA* also reflects the intrinsic stability of the generated  $[L]^-$  anion. Thus, if  $[L]^-$  is stable such as  $[L]^- = [OC(CF_3)_3]^-$  or  $[OTeF_5]^-$  the *LA* is relatively low compared to less stable anionic ligands such as  $[L]^- = [C_6H_5]^-$  or  $[C_6H_3(CF_3)_2]^-$ .

- (iii) To assess the stability of a WCA towards attack of a hard or soft electrophile and to eliminate the contribution of the intrinsic stability of  $[L]^-$  in (ii), the decomposition reactions of  $[M(L)_n]^-$  with the hard  $H^+$  (Eq. 2) and soft  $Cu^+$  (Eq. 3) electrophiles were calculated:

*PD* stands for *Proton-Decomposition* (Eq. 2) and *CuD* for *Copper-Decomposition* (Eq. 3). Since a gaseous anion and a gaseous cation react giving two neutral species, *PD* and *CuD* are both exothermic. The less negative *PD*- and *CuD*-values in **Table 1** are, the more stable is the WCA against electrophilic attack.

- (iv) The energy of the HOMO of a WCA relates to its resistance towards oxidation. The lower the HOMO energy, the more difficult it is to remove an electron and thus oxidize the WCA.
- (v) The HOMO-LUMO gap in **Table 1** can be associated with the resistance of an anion towards reduction and the larger the gap, the more stable is the anion with respect to reduction. Small gaps in combination with very low HOMOs such as those for  $[Sb_4F_{21}]^-$  or  $[As(OTeF_5)_6]^-$  are an indication of the potentially oxidizing character of these anions that may interfere with counter cations sensitive towards oxidation.

Ligand abstraction and hydrolysis are frequently observed decomposition pathways for WCAs and, therefore, the computational approach to calculate *LA*, *PD* and *CuD* mimics experimental observations (see<sup>2,3</sup>).

However, by calculations only the underlying thermodynamics can be assessed, kinetic barriers against decomposition may additionally stabilize a given WCA. The data included in **Table 1** may not be taken absolute. Yet, since the same methods were used for all computations relative trends will definitely be correct.

## 1.07.2 Chemistry with fluorinated alkoxy-aluminates and -borates

One of the major advantages of these aluminates is their simple access on a preparative scale: they can be prepared with little synthetic effort on a large scale with high yield within 2 days in common inorganic/organometallic laboratories; many  $[pf]^-$  salts are also commercially available at [www.iolitec.de](http://www.iolitec.de).

### 1.07.2.1 Starting materials to introduce $[M(OR^F)_4]^-$ aluminates and borates

Over the past decade new and optimized syntheses of a wide range of starting materials to introduce the  $[pf]^-$  aluminates into a given system were developed.

*Homoleptic Anions:* The syntheses of all  $[Al(OR^F)_4]^-$  starting materials begin with the preparation of the  $Li^+$ -salts using carefully purified  $LiAlH_4$  and the appropriate commercially available alcohols in heptane (Eq. 4).

Explicit details for the preparation of these Li-salts were published; we recommend to check the fine details.<sup>11</sup> The related borates work either with  $LiBH_4$ <sup>27</sup> or  $NaBH_4$ <sup>13,14</sup> instead of  $LiAlH_4$ . The alcohols  $(HOC(H)(CF_3)_2)$ ,  $HOC(CH_3)(CF_3)_2$  and  $HOC(CF_3)_3$  were purchased from Apollo Scientific, Fluorochem or ABCR (at 0.1–3 € per gram) and were first degassed, then distilled prior to use. The synthesis of the  $Li[pf]$  salts is done in our group in well over 99% yield within 2 days in scales of up to 250 g.

Most other salts can then be prepared in high yield via metathesis reactions with precipitation of  $LiX$  ( $X = F, Cl, Br, BF_4$ ) or by protonation with e.g., protonated ethers.<sup>28</sup> In addition, the more recent access to (synergistic or innocent) oxidants like  $Ag^+$ ,  $Ag^+$ /

0.5 X<sub>2</sub> (X = Cl, Br, I), NO<sup>+</sup>, NO<sub>2</sub><sup>+</sup> or Phenazin<sup>F+</sup> (cf. sections below) did allow for access to many new materials on deelectronation<sup>a</sup> routes.

The borates may be obtained from both, the Li as well as Na borohydride salts as in Eq. (5):

*Routes to the [alfal]<sup>-</sup> Anion:* The converged and best preps available in multigram scale start from Me<sub>3</sub>Si-F-Al(OR<sup>F</sup>)<sub>3</sub>, including the ion-like bound SiMe<sub>3</sub><sup>+</sup> cation.<sup>12</sup> Its optimized large-scale ‘best synthesis’ is described here, before we turn to the [alfal]<sup>-</sup> preparation. AlEt<sub>3</sub> (15.0 mL, 109 mmol, 93% purity) was dissolved in heptane (120 mL) and cooled to -40 °C. Under vigorous (!) stirring, the first two equivalents of HOR<sup>F</sup> (30.0 mL, 215 mmol, 2.0 eq.) were added dropwise to the reaction mixture, while keeping the cooling bath between -40 °C and -20 °C. During the addition of HOR<sup>F</sup>, gas evolution (C<sub>2</sub>H<sub>6</sub>) was observed, the viscosity of the solution increased and small amounts of precipitate formed. After complete addition of the first HOR<sup>F</sup> portion (typically within 1 h), Me<sub>3</sub>SiF (12.5 g, 136 mmol, 1.2 eq.) was condensed onto the reaction mixture at -40 °C. The solution was stirred for 10 min, and then the third equivalent of HOR<sup>F</sup> (20.0 mL, 143 mmol, 1.3 eq.) was added within 5 min. The cooling bath was removed and the reaction mixture was allowed to reach r.t., which led to dissolution of the precipitate. After 30 min, more HOR<sup>F</sup> (5.0 mL, 36 mmol, 0.3 eq.) was added and the solution was stirred overnight. From the clear solution, slowly a white powder crystallized. For product isolation, simply the solvent and excess alcohol was removed *in vacuo* yielding a white crystalline powder (85.4 g, 103 mmol, 94%). Note: One needs the excess of the fluorinated alcohol, as it is very volatile (b.p. = +45 °C) and the continuous stream of evolving ethane removes the part of the alcohol through the bubbler.

The synthesis of the [alfal]<sup>-</sup> WCA then uses the reaction with many [PF<sub>6</sub>]<sup>-</sup> salts,<sup>12</sup> as the PF<sub>5</sub> is the much weaker Lewis acid if compared to Me<sub>3</sub>Si-F-Al(OR<sup>F</sup>)<sub>3</sub>. Hence, in general Cat<sup>+</sup>[alfal]<sup>-</sup> forms by reaction with Cat[PF<sub>6</sub>] and Cat<sup>+</sup> being K<sup>+</sup>, Ag<sup>+</sup>, NO<sup>+</sup>, NO<sub>2</sub><sup>+</sup>, CPh<sub>3</sub><sup>+</sup> etc. (Fig. 6).

Also the smaller [fal]<sup>-</sup> anion (= F-Al(OC(CF<sub>3</sub>)<sub>3</sub>)<sub>3</sub><sup>-</sup>) can be synthesized in this way. Yet, this includes one coordinating fluoride-tooth. Table 2 gives an overview on useful materials, for which good synthesis routes have been developed.

It should be noted that in contrast to the normally easily hydrolyzed alkoxyaluminates, the [pff]<sup>-</sup> anion is stable in 6 N nitric acid.<sup>8</sup> This stability towards hydrolysis was attributed to steric shielding of the oxygen atoms, provided by the bulky C(CF<sub>3</sub>)<sub>3</sub> groups, as well as to electronic stabilization due to perfluorination. The electron withdrawing effect of the fluorinated ligand can be demonstrated by the increased acidity of the fluorinated HOC(H)(CF<sub>3</sub>)<sub>2</sub> (pK<sub>a</sub> = 9.5) and HOC(CF<sub>3</sub>)<sub>3</sub> (pK<sub>a</sub> = 5.5) alcohols in comparison to the non-fluorinated HOC(CH<sub>3</sub>)<sub>3</sub> (pK<sub>a</sub> = 19.3).<sup>8,17</sup> Thus, perfluoro<sup>b</sup>butanol is 14 orders of magnitude more acidic than non-fluorinated <sup>b</sup>butanol. Therefore, the [pff]<sup>-</sup> anion may be viewed as the complex anion of the H[pff] super acid. This H[pff] acid can be prepared and is capable of directly protonating mesitylene 1,3,5-Me<sub>3</sub>C<sub>6</sub>H<sub>3</sub>.<sup>61</sup> In addition, the redox stability of both, the [pff]<sup>-</sup> and [alfal]<sup>-</sup> anions towards high deelectronation potentials is large and they sustain reversible redox processes in published work<sup>63</sup> that may reach +1.42 V vs. Fc<sup>+</sup>/Fc, but in unpublished work we see that one may even reach +1.9 V vs. Fc<sup>+</sup>/Fc in suitable polar, but weakly basic solvents like 1,2,3,4-F<sub>4</sub>C<sub>6</sub>H<sub>2</sub> (= 4FB). This complies with the reported<sup>64</sup> stability of the [pff]<sup>-</sup> anion in Li<sup>+</sup> ion battery electrolytes of up to 5.5 V vs. Li<sup>+</sup>/Li.

### 1.07.2.2 Reactive cations stabilized by [pff]<sup>-</sup> aluminates

The best choices to stabilize really electrophilic reactive cations with aluminate WCAs, are the [pff]<sup>-</sup> and [alfal]<sup>-</sup> WCAs with the perfluorinated residue OC(CF<sub>3</sub>)<sub>3</sub>; the latter often forms as a decomposition product of the first. Electrophilic limits for anion stability are cations like [CCl<sub>3</sub>]<sup>+</sup> or [P<sub>2</sub>Cl<sub>5</sub>]<sup>+</sup> that are stable in solution at about -20 °C, but have a half-life at RT of about 1–2 h. Small truly

**Fig. 6** Optimized preparation towards Cat<sup>+</sup>[alfal]<sup>-</sup> salts. Frequently used Cat<sup>+</sup> include K<sup>+</sup>, Ag<sup>+</sup>, NO<sup>+</sup>, NO<sub>2</sub><sup>+</sup>, CPh<sub>3</sub><sup>+</sup> etc. Scale is typically done in the 5–10 g product range, the typical solvents include CH<sub>2</sub>Cl<sub>2</sub>, oDFB or SO<sub>2</sub>. Also the smaller [fal]<sup>-</sup> anion (= F-Al(OC(CF<sub>3</sub>)<sub>3</sub>)<sub>3</sub><sup>-</sup>) including one clearly coordinating (Al–)F tooth can be synthesized in this way.

<sup>a</sup>We use the elementary steps *electronation* and *deelectronation* in their strict sense, i.e., addition or removal of e<sup>-</sup>. Thus, a classically termed ‘oxidant’ is addressed as a ‘deelectronator’ and a ‘reductant’ as an ‘electronator’, if only a single electron transfer as the elementary step takes place. This particle-based terminology is related to the acid-base picture, where the terms deprotonation and protonation describe the transfer of a proton between two partners, i.e., deelectronation is the electron-based equivalent to a deprotonation. This terminology has been discussed in ref.<sup>29</sup> and ref.<sup>30</sup> from our work on the protoelectric potential map and is transferred to describe these types of reactions more accurately.

tricoordinate silylium ions like  $[Me_3Si]^+$  are not compatible at room temperature with these WCAs, but still have a reasonable lifetime at lower temperatures. In addition, the coordination of a silane to the silane stabilized  $[R_3Si-H-SiR_3]^+$  ions greatly increases stability.<sup>65,66</sup> Moreover, subvalent silicocenium ions like  $[Cp^*Si]^{+67}$  as well as silylium ions with larger residues like pentamethylphenyl,  $[Si(C_6Me_5)_3]^+$ , are stable with the  $[pf]^-$  WCA.<sup>68</sup> Favorably, it was shown that the  $[pf]^-$  WCA also enables very rapid silylium

**Fig. 7** Different decomposition pathways of the  $[pf]^-$  anion depending on the nature of the electrophilic cation  $E^+$ .

ion based catalysis with in part unprecedented turn over frequencies (hydrosilylation, hydrodefluorination) even if small silane stabilized  $\text{SiR}_3^+$  residues such as  $\text{R} = \text{Me}, \text{Et}$  were used.<sup>65</sup>

**Decomposition Pathways of the  $[pf]^-$  Anion:** To show the (moderate) limitations of these aluminates upfront, we initially sketch repeatedly observed decomposition reactions of  $[pf]^-$ . Larger parts of this section were taken from ref.<sup>10</sup> Generally, two different possibilities exist: the electrophilic cation attacks either the oxygen atom, the most basic site of the anion, or one of the 36 peripheral fluorine atoms (Fig. 7).

Small oxophilic cations such as  $[\text{P}_2\text{Cl}_5]^+$ , or eventually it's dissociation product  $\text{PCl}_2^+$ , initially attack one of the 4 O atoms and abstract an alkoxy group. The resulting  $^{\text{PF}}\text{RO}-\text{PCl}_2$  has been detected in low temperature  $^{31}\text{P}$  NMR studies as a decet.<sup>16</sup> The generated  $\text{Al}(\text{OR}^{\text{F}})_3$  Lewis acid, which can be prepared independently and later was shown to be Lewis superacidic,<sup>20,21,69</sup> then abstracts an  $\text{F}^-$  ion from the  $^{\text{PF}}\text{RO}-\text{PCl}_2$  that is in close proximity. The formed  $[\text{F}-\text{Al}(\text{OR}^{\text{F}})_3]^-$  and  $\text{Al}(\text{OR}^{\text{F}})_3$  then combine to the fluoride bridged anion.

More fluorophilic cations such as  $[\text{SiMe}_3]^+$ ,  $[\text{BX}_2]^+$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ) abstract one of the peripheral fluorine atoms. This attack is followed by a rearrangement of the alkoxy group and formation of a Lewis acid-base adduct of  $\text{Al}(\text{OR}^{\text{F}})_3$  and the epoxide  $\text{C}_4\text{F}_8\text{O}$ . In the following step the epoxide is replaced by another abstracted fluoride ion from another  $[pf]^-$  anion forming the (known<sup>12</sup>)  $[fal]^-$  anion ( $= [\text{FAl}(\text{OR}^{\text{PF}})_3]^-$ ). This anion may now react with the just formed  $\text{Al}(\text{OR}^{\text{PF}})_3$  by complexation to the stable fluoride bridged  $[alfal]^-$  anion. Alternatively, fluorophilic cations  $\text{E}^+$  like  $\text{SiMe}_3^+$  may prefer direct coordination to the fluoride tooth of  $[\text{FAl}(\text{OR}^{\text{PF}})_3]^-$  and hence give  $\text{Me}_3\text{Si}-\text{F}-\text{Al}(\text{OR}^{\text{PF}})_3$ .<sup>12</sup> Thus, the decomposition may proceed by

- (i) Ligand ( $\text{R}^{\text{PF}}\text{O}^-$ ) abstraction or
- (ii) Fluoride ion abstraction.

The thermodynamic stability of the  $[pf]^-$  and  $[alfal]^-$  anion with respect to (i) and (ii) are compared in Table 3.

Note that the decomposition reactions were assessed through isodesmic reactions and should therefore be reliable.<sup>10</sup> Which of the two mechanisms proceeds, depends on the steric bulk of the attacking electrophile  $\text{E}^+$ , the bond enthalpies of the formed  $\text{E}-\text{F}$  or  $\text{E}-\text{OR}$  compounds and the strengths of the  $\text{Al}-\text{O}$  or  $\text{C}-\text{F}$  bonds in the  $[pf]^-$  anion.

We note that the formation of the epoxide  $\text{C}_4\text{F}_8\text{O}$  or related ones is a general decomposition pathway of all  $[\text{Al}(\text{OR}^{\text{F}})_4]^-$  anions observed upon thermal treatments<sup>31,70</sup> of the salts or upon collisions<sup>57</sup> inside a mass spectrometer with sufficiently high energies.

Nevertheless, the following sections show that these aluminate WCAs tolerate considerably high electrophilicity and allow the preparation of a wealth of unusual reactive cation salts. For the revision, we have chosen a structure following the position of the reactive cations first in the respective main group, next according to the ligand class in the respective transition metal systems.

**Fig. 8** Examples for known siloxane complexes of group 1 metal cations ( $= (\text{Me}_2\text{SiO})_x$  with  $x = 5-8$ ) generated via reaction of the respective  $\text{M}^+[\text{pf}]^-$  ( $\text{M} = \text{Li}, \text{K}, \text{Cs}$ ) with the siloxane.

### 1.07.2.2.1 Unusual group 1 M<sup>+</sup>-complexes

As a consequence of the very weakly coordinating character, also rather nontypical ligands complex to the M<sup>+</sup> cation of the [pfl]<sup>-</sup> anion, in part only discovered by serendipity.

**Almost Planar Li-Siloxane Complexes:** In a reaction designed to give Se<sub>6</sub>Ph<sub>2</sub>([pfl])<sub>2</sub> from Se<sub>4</sub>[AsF<sub>6</sub>]<sub>2</sub>, 2 Li[pfl], and Se<sub>2</sub>Ph<sub>2</sub>, unexpectedly the crystals of Li(D<sub>6</sub>)<sup>+</sup>[pfl]<sup>-</sup> were obtained in the presence of silicone grease. Subsequently, Li(D<sub>5</sub>)<sup>+</sup>[pfl]<sup>-</sup> and Li(D<sub>6</sub>)<sup>+</sup>[pfl]<sup>-</sup> were prepared in high yield by the reaction of Li[pfl] with D<sub>5</sub> or D<sub>6</sub> in CH<sub>2</sub>Cl<sub>2</sub> solution (Fig. 8).<sup>71</sup>

The syntheses of the Li(D<sub>5</sub>)<sup>+</sup>[pfl]<sup>-</sup> and Li(D<sub>6</sub>)<sup>+</sup>[pfl]<sup>-</sup> salts are the first examples of the preparation of host-guest complexes directly from cyclic dimethylsiloxanes, alkali-metal ions, and WCAs. Their structures imply that the cyclic dimethylsiloxanes (D<sub>5</sub> and D<sub>6</sub>) act as pseudo crown ethers and provide rare examples of silicon ethers behaving as Lewis bases.<sup>71</sup> The counterpoise-corrected binding energies for the alkali-metal complexes [MD<sub>6</sub>]<sup>+</sup> exhibit a remarkable similarity to that for [18]crown-6 for both sets of complexes (in the gas phase). The binding energies become less negative with increasing size of the alkali-metal cation. However, the binding affinity of D<sub>6</sub> calculated at the HF/3-21G\* level is approximately 100 kJ mol<sup>-1</sup> less than that of [18]crown-6, reflecting the lower basicity of the siloxanes.

Recently, Hänisch and co-workers (re-)investigated alkali cation-siloxane complex salts. They discovered that while a [Ga<sub>4</sub>]<sup>-</sup> anion is sufficient to prepare respective Li-Rb<sup>+</sup> siloxane complexes, the preparation of novel Rb<sup>+</sup> and Cs<sup>+</sup>-siloxane complexes as well as 2:1 complexes demanded a good WCA, in this case [pfl]<sup>-</sup>.<sup>72</sup> Here, the synthesis of the Cs(D<sub>8</sub>)<sup>+</sup>[pfl]<sup>-</sup>, K(D<sub>7</sub>)<sup>+</sup>[pfl]<sup>-</sup> and Rb(D<sub>8</sub>)<sup>+</sup>[pfl]<sup>-</sup> were reported. Moreover, the synthesis of the first sandwich-type complexes with cyclosiloxane ligands could be isolated in the form of the 2:1 complexes Cs(D<sub>6</sub>)<sub>2</sub><sup>+</sup>[pfl]<sup>-</sup> and K(D<sub>5</sub>)<sub>2</sub><sup>+</sup>[pfl]<sup>-</sup>.

**Lithium-Siloxane-Phosphane-Complex:** The lithium-siloxane-phosphane-complex<sup>73,74</sup> shown in Fig. 8 is related to the siloxane complex in the preceding section: These results showed that cyclosiloxanes can be considered as inorganic analogs of the well-established crown ether ligands. In this respect the cage [P<sub>2</sub>{(Si<sup>i</sup>Pr<sub>2</sub>)<sub>2</sub>O}<sub>2</sub>{Me<sub>2</sub>Si(OSiMe<sub>2</sub>)<sub>2</sub>}] (A) corresponds to a cryptand. This analogy could be confirmed by the synthesis of the lithium complex [Li@A]<sup>+</sup>[pfl]<sup>-</sup> (R<sup>F</sup> = C(CF<sub>3</sub>)<sub>3</sub>; Fig. 9).

**Lithium Phosphane Complexes:** According to HSAB, the small and hard group 1 cations prefer ionic interactions to hard, electro-negative Lewis bases such as water, alkoxides etc. However, homoleptic neutral Li<sup>+</sup>-phosphane complexes could be prepared by simply mixing the phosphane ligands with Li<sup>+</sup>[pfl]<sup>-</sup> in toluene.<sup>75</sup> Structural analysis as well as solid state and solution multinuclear NMR studies, confirm a distorted octahedral coordination at the Lithium cation. The analogous sodium complexes could be synthesized by using Na<sup>+</sup>[B{3,5-(CF<sub>3</sub>)<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>}<sub>4</sub>]<sup>-</sup> as "naked" cation source.

### 1.07.2.2.2 Reactive group 2 and related group 12 cations

#### 1.07.2.2.2.1 Alkaline earth metals

**On the Way to [Cp\*Be]<sup>+</sup>:** Due to the extreme Lewis acidity of the hard Be<sup>2+</sup> cation, the Be<sup>2+</sup> cation in known cationic complexes is stabilized by strong N- or O-donors. Aiming for the isolation of a [Cp\*Be]<sup>+</sup> cation, Ag<sup>+</sup>[pfl]<sup>-</sup> was reacted with Cp\*Be-Br in PhF or 1,2-DFB (Fig. 10).<sup>76</sup> Although AgBr precipitation showed the successful bromide-abstraction, the in situ generated highly Lewis-acidic [Cp\*Be]<sup>+</sup> cation induced the decomposition of the [pfl]<sup>-</sup> anion to form the [fal]<sup>-</sup> adduct Cp\*Be-F-Al(OR<sup>F</sup>)<sub>3</sub>. An ionic dissociation into [Cp\*Be]<sup>+</sup> and [fal]<sup>-</sup> was postulated to be feasible in polar solvents.

**Group 2 cations stabilized by β-diketiminato ligands:** To study interactions of the highly Lewis acidic group 2 cations with various mostly soft nucleophiles, a stabilization of the metal cation by β-diketiminato ligands has proven feasible (Fig. 11). Here, Hill and co-workers reported the synthesis of complexes of [(<sup>Me</sup>BDI)Ae]<sup>+</sup> and [(<sup>tBu</sup>BDI)Ae]<sup>+</sup> (<sup>Me</sup>BDI = HC{(Me)CN-2,6-*i*Pr<sub>2</sub>C<sub>6</sub>H<sub>3</sub>}<sub>2</sub>; <sup>tBu</sup>BDI = HC{(tBu)CN-2,6-*i*Pr<sub>2</sub>C<sub>6</sub>H<sub>3</sub>}<sub>2</sub>) with Ae = Mg or Ca to benzene or toluene.<sup>77</sup> The usage of the weakly-coordinating [pfl]<sup>-</sup> anion precluded ion-pair formation and an η<sup>6</sup>-coordination of Mg and Ca to the aromatic systems could be observed. In contrast, ion

Fig. 9 Reactions of Li<sup>+</sup>[pfl]<sup>-</sup> with the siloxane-phosphane A: Formation of the lithium complex [Li@A]<sup>+</sup>[pfl]<sup>-</sup> (R<sup>F</sup> = C(CF<sub>3</sub>)<sub>3</sub>).

Fig. 10 Preparation of the [fal]<sup>-</sup> adduct of [Cp\*Be]<sup>+</sup> via decomposition of a [pfl]<sup>-</sup> anion.

**Fig. 11** Examples for complexes containing  $[(^{\text{Me}}\text{BDI})\text{Ae}]^+$  ( $^{\text{Me}}\text{BDI} = \text{HC}(\text{Me})\text{CN-2,6-}i\text{Pr}_2\text{C}_6\text{H}_3_2$ ) cations and  $[\text{pf}]^-$  anions.

pairs were reported for the analogous complexes with the  $[\text{B}(\text{C}_6\text{F}_5)_4]^-$  anion, allowing only for an  $\eta^3$ -coordination of benzene in the respective Mg complex.<sup>78</sup> Similar observations have been made for Cp and norbornadiene complexes of  $[(^{\text{Me}}\text{BDI})\text{Mg}]^+$ .<sup>79</sup> Moreover, Hill and co-workers observed formation of the first  $\text{Mg-PPh}_3$  complexes by addition of  $\text{PPh}_3$  to  $[(^{\text{Me}}\text{BDI})\text{Ae}(\text{C}_7\text{H}_8)]^+[\text{pf}]^-$  or  $[(^{\text{tBu}}\text{BDI})\text{Ae}(\text{C}_7\text{H}_8)]^+[\text{pf}]^-$ .<sup>77</sup> In a recent publication, multimetallic hydride derivatives could be obtained via reaction of  $[(^{\text{Me}}\text{BDI})\text{Mg}]^+[\text{pf}]^-$  with  $[(^{\text{Me}}\text{BDI})\text{MgH}]_2$  or  $[(^{\text{Me}}\text{BDI})\text{CaH}]_2$ .<sup>80</sup>

**Dicationic Group 2 Arene Complexes:** Inspired by the reported cationic group 2 arene complexes, we aimed for the isolation of dicationic and highly Lewis acidic group 2 arene complexes. Here, the synthesis of the first unsupported dicationic arene complexes of calcium and strontium could be achieved by reaction of the hexamethylbenzene radical cation  $[\text{HMB}]^+[\text{alfal}]^-$  (*vide infra*) with the elemental metals in 1,2-difluorobenzene.<sup>48</sup> In these complexes, an  $\eta^6$ -HMB coordination to  $\text{Ca}^{2+}$  and  $\text{Sr}^{2+}$  is observed as well as a  $\kappa^2$ -F-coordination of four 1,2-DFB solvent molecules. Unfortunately, in all cases partial decomposition of the  $[\text{alfal}]^-$  anion yielded *fal*-adducts  $[\text{M}(\text{HMB})(1,2\text{-DFB})_n\{\text{fal}\}]^+[\text{alfal}]^-$  ( $n = 2$  for  $\text{M} = \text{Ca}$ ,  $n = 3$  for  $\text{M} = \text{Sr}$ ,  $\text{Ba}$ ). While the *fal*-adduct represented only a minor impurity for the strontium complex, the respective complexes of calcium and barium were the major products in the oxidation reactions.

The reactions of  $[\text{HMB}]^+[\text{alfal}]^-$  with magnesium metal did only proceed after addition of acetonitrile to yield the complex salts  $[\text{Mg}(\text{MeCN})_6]^{2+}([\text{WCA}]^-)_2$  ( $\text{WCA} = [\text{pf}]^-$  or  $[\text{alfal}]^-$ ).

The application of group 2 cations demanded for clean starting materials. Hence, we developed a simple route to a “naked”  $\text{Sr}^{2+}$  synthon  $[\text{Sr}(\text{pf})]^+[\text{pf}]^-$  via salt metathesis between  $\text{Ag}[\text{pf}]$  and  $\text{SrI}_2$  in 1,2-DFB.<sup>36</sup> Here, the strontium dication is coordinated closely by the three oxygen atoms of one *pf*-unit, while the other  $[\text{pf}]^-$  anion only coordinates loosely via the fluorine atoms. Addition of dixylylethylene (DXE) to solutions of  $[\text{Sr}(\text{pf})]^+[\text{pf}]^-$  allowed for the isolation of the dicationic  $\text{Sr}^{2+}$ -ansa-arene complex  $[\text{Sr}(\text{DXE})(1,2\text{-DFB})_2]^{2+}([\text{pf}]^-)_2$  in **Fig. 12**. The high Lewis-acidity of this complex could be unambiguously shown by catalysis of the hydrosilylation of  $\text{CO}_2$  to methane and successful initiation of a controlled isobutene polymerization at high temperatures ( $-12^\circ\text{C}$  and  $0^\circ\text{C}$ ), yielding polyisobutylene with narrow dispersities and high molecular weights.

#### 1.07.2.2.2 Group 12 metals

**Divalent  $\text{Zn}^{\text{II}}$ -Compounds.** Attempts to prepare previously unknown simple and very Lewis acidic  $[\text{RZn}]^+[\text{pf}]^-$  salts from  $\text{ZnR}_2$ ,  $\text{AlR}_3$ , and  $\text{HO-R}^{\text{F}}$  delivered the *ion-like*  $\text{R-Zn}(\text{pf})$  ( $\text{R} = \text{Me}$ ,  $\text{Et}$ ) with a coordinated counterion, but never the ionic compound.<sup>81,82</sup> They were synthesized in a one-pot reaction and fully characterized by single-crystal X-ray diffraction, NMR and vibrational spectroscopy, and by quantum chemical calculations.<sup>81,82</sup> Increasing the steric bulk in  $\text{RZn}^+$  to  $\text{R} = \text{CH}_2\text{CMe}_3$ ,  $\text{CH}_2\text{SiMe}_3$ , or  $\text{Cp}^*$ , thus attempting to induce ionization, failed and led only to reaction mixtures including anion decomposition.

The catalytic activity of *ion-like*  $\text{Et-Zn}(\text{pf})$  in intermolecular hydroamination and in the unusual double hydroamination of anilines and alkynes was investigated.<sup>81</sup> Favorable performance was also found in comparison to the  $\text{Et}_2\text{Zn}/[\text{PhNMe}_2\text{H}]^+[\text{B}(\text{C}_6\text{F}_5)_4]^-$  system generated in situ at lower catalyst loadings of 2.5 mol%.<sup>81</sup>

From these *ion-like* ethylzinc aluminates, the arene complexes  $[\text{EtZn}(\text{arene})_2]^+[\text{pf}]^-$  were accessible as well soluble salts. Ionization yielded the salts with arene = toluene, mesitylene, or *o*-difluorobenzene (*o*DFB)/toluene. In contrast to the known<sup>83</sup> *ion-like*  $\text{EtZn}(\eta^3\text{-C}_6\text{H}_6)(\text{CHB}_{11}\text{Cl}_{11})$  with coordinated counterion, which co-crystallizes with one benzene molecule, the less coordinating nature of the  $[\text{pf}]^-$  anion allowed the ionization and preparation of the purely organometallic  $[\text{EtZn}(\text{arene})_2]^+$  cation (**Fig. 13**).

**Fig. 12** Literature-known dicationic Group 2 arene complexes. DXE = Dixylylethylene.

**Fig. 13** Molecular structures of *ion-like* Et–Zn[*pf*] (top) and [EtZn(toluenes)<sub>2</sub>]<sup>+</sup>[*pf*]<sup>–</sup> (bottom) and synthesis of the second from the first.

These stable *ion-like* organozinc aluminate materials were shown to have further applications, for example, as initiators of isobutene polymerization.<sup>82</sup> DFT calculations to compare the Lewis acidities of the zinc cations to those of a large number of organometallic cations were performed on the basis of the fluoride ion affinity. The complexation energetics of EtZn<sup>+</sup> with arenes and THF was assessed and related to the experiments.<sup>82</sup>

**Univalent Base-stabilized Zn<sub>2</sub><sup>2+</sup> Dication:** A base-stabilized [Zn<sub>2</sub>]<sup>2+</sup> dication, namely [(dmap)<sub>3</sub>Zn–Zn(dmap)<sub>3</sub>]<sup>2+</sup>, was obtained from the reaction of [Cp\*<sub>2</sub>Zn<sub>2</sub>(dmap)<sub>2</sub>] (dmap = 4-dimethylaminopyridine) with two equivalents of [H(OEt<sub>2</sub>)<sub>2</sub>][*pf*] and was structurally characterized for the first time as its [*pf*]<sup>–</sup> salt. It exhibits a Zn–Zn bond lengths of 2.419(1) Å.<sup>84</sup> The low stability of the [Zn<sub>2</sub>]<sup>2+</sup> cation is in marked contrast to that of the intensively studied [Hg<sub>2</sub>]<sup>2+</sup> and [Cd<sub>2</sub>]<sup>2+</sup> cations, which are long-known also with very simple ligands or even in the absence of ligands in Lewis acidic salt melts.

### 1.07.2.2.3 Reactive group 13 cations: Normal valency and subvalent

#### 1.07.2.2.3.1 Reactions leading to trivalent group 13 cations

**Cationic Phosphonioborane Lewis Acid:** From a zwitterionic, chloro-substituted phosphonioborate, the Cl atom could be heterolytically cleaved by reaction with Ag[*pf*] giving the cationic Lewis acid shown in Fig. 14.<sup>85</sup>

Only when using the silver salt of the good WCA [*pf*]<sup>–</sup>, the free cationic Lewis acid could be generated and was studied also at RT in CH<sub>2</sub>Cl<sub>2</sub> solution. With [PF<sub>6</sub>]<sup>–</sup> as counterion, decomposition through fluoride ion abstraction and formation of the fluoro-substituted phosphonioborate was observed. The more coordinating [CF<sub>3</sub>SO<sub>3</sub>]<sup>–</sup> and [CF<sub>3</sub>COO]<sup>–</sup> anions were bound by the boron atom of the cationic Lewis acid.<sup>85</sup>

**Cationic Borole:** Halide abstraction from a NHC-chloroborole precursor with Li[*pf*] yielded the first cationic borole featuring a high boron-centered Lewis-acidity.<sup>86</sup> The cation is formally antiaromatic, since the boron atom is part of a cyclic 4π electron system. With CO, it reversibly reacts under formation of an extremely rare example of a main group metal carbonyl complex. The C–O stretching frequency at 2128 cm<sup>–1</sup> suggests that backbonding plays a role in this cationic CO complex.<sup>86</sup>

**Chloroborane Masked Chiral Borenium Ion:** Chloroborane masked borenium ions, featuring a symmetrical [B–Cl–B]<sup>+</sup> linkage have been prepared and employed as catalysts in enantioselective Diels-Alder cycloaddition reactions.<sup>87</sup> These cationic complexes

**Fig. 14** Structure of the Cationic Phosphonioborane Lewis Acid.

**Fig. 15** Molecular structure of a chiral chloroborane masked borenium ion. The  $[pf]^-$  counter anions are not shown for clarity.

are available after chloride abstraction with one equivalent  $\text{Li}[pf]$  from  $C_2$ -symmetric cyclic chiral diboron complexes. The substituents of the chiral oxazolidinone ligand (see Fig. 15) control the stereoselectivity, which can be improved by adding  $\text{SnCl}_4$ .<sup>87</sup>

**Chloroborenium Ion:** After chloride abstraction from  $\text{Cp}^*\text{BCl}_2(\text{cAAC})$ , a tricoordinated chloroborenium ion with one  $[\text{Cp}^*]^-$  and one cAAC ligand could be synthesized.<sup>88</sup>  $\text{Ag}[pf]$  had to be employed as the chloride abstracting reagent, since attempts to isolate the product in the analogous reaction with  $\text{TMSOTf}$ , other silver salts or  $\text{AlCl}_3$  were futile.<sup>88</sup>

**Ferrocene-Based Planar-Chiral Borenium Cation:** The first planar chiral, enantiomerically pure ferrocenylborenium cation was obtained as its  $[pf]^-$  salt after halide abstraction from the respective chloroborane adduct using either  $[\text{Ag}(\text{CH}_2\text{Cl}_2)][pf]$  or  $\text{Li}[pf]$ .<sup>89</sup> With acetophenone, the borenium ion forms a Lewis acid-base adduct, which can be isolated and readily reacts with  $\text{HSiEt}_3$ , resulting in the hydrosilylation of acetophenone.<sup>89</sup> This ferrocenylborenium ion catalyzes the stereoselective hydrosilylation of acetophenone, however, with modest enantiomeric excess.<sup>89</sup>

**Borinium Cation:** The synthesis of a highly Lewis acidic borinium cation was recently achieved by chloride-abstraction from  $\text{Cl}(\text{Mes})\text{B-TMP}$  (TMP = tetramethylpiperidine) with  $\text{Ag}[pf]$ . The  $[\text{Mes-B-TMP}]^+$  cation was reported to initiate cyanosilylation and catalyze hydrosilylation of ketones and aldehydes.<sup>90</sup>

**Diazadiborinine Radical Cation:** One-electron oxidation of a neutral 1,4,2,5-diazadiborinine with  $\text{Ag}[pf]$  afforded the respective diazadiborinine radical cation as its  $[pf]^-$  salt.<sup>91</sup> The spin density mainly resides on the B centers, accounting for a boron-centered radical reactivity. This was confirmed by the reactions of the radical cation with *p*-benzoquinone and  $\text{Ph}_3\text{SnH}$ , which furnished a non-radical dicationic complex after B–O bond formation, and a non-radical monocationic species featuring a B–H bond, respectively.<sup>91</sup> The molecular structures of the diazadiborinine radical cation and of the reaction products are shown in Fig. 16.

**Borazine Radical Cation:** The radical cation  $[1,2\text{-B}_2\{1,2\text{-(MeN)}_2\text{C}_6\text{H}_4\}_2]^{\bullet+}$  has been synthesized by deelectronation of the neutral, methylated 1,2-bis(diaminobenzene)diborane precursor with  $\text{Ag}[pf]$ .<sup>92</sup> However, unlike in the diazadiborinine radical cation,<sup>91</sup> only a minor contribution of boron-based orbitals to the spin density is observed. Instead, the radical is centered primarily on the two N-heterocycles joined by a  $\text{B}_2$  moiety.<sup>92</sup>

**A boron<sup>III</sup>/oxido-phenalenone Complex:** The isolation of a monocationic complex featuring a central  $\text{B}^{\text{III}}$ , coordinated in a nearly tetrahedral fashion by two chelating 9-oxido-1-phenalenone ligands, has recently been reported.<sup>93</sup>

**Multinuclear, Mixed Boron/Transition Metal Clusters:** The cationic  $[\text{Rh}_2(\kappa^2\text{-P,P-DPEphos})_2(\sigma,\mu\text{-(H}_2\text{B)}_2\text{NHMe})]^+$  complex, which has been shown to act as a catalyst in the dehydropolymerization reaction of  $\text{H}_3\text{B}\cdot\text{NMeH}_2$ , could not be crystallized with borate anion  $[\text{BAR}^{\text{F}}_4]^-$ , but with the  $[pf]^-$  anion (structure A) in Fig. 17.<sup>94</sup> Another unusual cation was obtained from the reaction of a platinum(II)-bis(tricyclohexylphosphine)-bromo-oxoboryl complex with the bromide abstraction agent  $\text{Ag}[pf]$  giving the dinuclear and dicationic platinum(II)-bis(tricyclohexylphosphine) with an unprecedented 1,3,2,4-dioxodiboretane ligand that bridges two cationic bis(tricyclohexylphosphine)platinum(II)-fragments, which have a distorted T-shaped geometry (structure B) in (Fig. 17).<sup>95</sup> The observed cyclodimerization reaction indicates the influence the platinum fragment exerts on the oxoboryl moiety.<sup>95</sup>

**Fig. 16** Reactivity of a diazadiborinine radical cation towards *p*-benzoquinone and  $\text{Ph}_3\text{SnH}$ . The  $[pf]^-$  counter anions are not shown for clarity.

**Fig. 17** Molecular structures of three mixed boron/transition metal complexes. The  $[pf]^-$  counter anions are not shown for clarity.

Additionally, the fluoroarene complex  $[\text{Rh}(\text{dcpm})(\eta^6\text{-1,2,3-F}_3\text{C}_6\text{H}_3)][pf]^-$  (dcpm = *bis*(dicyclohexylphosphino)methane) does not act as an efficient hydrodefluorination catalyst towards  $\text{H}_3\text{B}\cdot\text{NMe}_2\text{H}$ , but instead forms the bimetallic aminoborylene complex  $\{[\text{RhH}(\mu\text{-dcpm})]_2(\mu\text{-H})(\mu\text{-BNMe}_2)\}^+$  (structure c) in Fig. 17.<sup>96</sup> In this cation, a hydride and a borylene moiety act as bridging units (structure C) in Fig. 17).

**Aluminocenium Cation:** The reaction of the protonated ether salt  $[\text{H}(\text{OEt}_2)_2]^+ [pf]^-$  with  $\text{AlCp}_2$  in ether solution leads to the  $[\text{AlCp}_2]^+$ -cation, which is stabilized by the weakly coordinating anion  $[pf]^-$ .<sup>97</sup> In an equilibrium reaction, the aluminocenium cation is coordinated in solution by two diethylether molecules. Depending on the conditions, from this solution crystallize either the free  $[\text{AlCp}_2]^+$ -cation (Fig. 18), characterized for the first time by single crystal XRD, or the coordinated  $[\text{AlCp}_2\cdot 2\text{Et}_2\text{O}]^+$  species.

Furthermore, the influence of the counterions  $[pf]^-$  and  $[\text{MeB}(\text{C}_6\text{F}_5)_3]^-$  on the activity of  $[\text{AlCp}_2]^+$  as initiators for the polymerization of isobutene<sup>97,98</sup> was investigated: It appears that the  $[pf]^-$  salt is more active as initiator.

**Chiral Tetra-coordinate Aluminum Cation:** An  $\text{Al}^{\text{III}}$  cation can also be stabilized by chiral amino-alcoholate ligands.<sup>99</sup> It was shown experimentally that the Lewis acidity of this species exceeds that of  $\text{B}(\text{C}_6\text{F}_5)_3$ . As suggested by preliminary catalytic activity studies, the tetra-coordinate aluminum cation is an effective catalyst for hydroboration of ketones, Diels-Alder reactions, and Michael additions. However, the enantioselectivity of these reactions is limited due to the presence of the labile  $\text{N}-\text{Al}$  bond.<sup>99</sup>

**Cationic Aluminum Carboxylate:** The Lewis acidic trityl cation in  $[\text{Ph}_3\text{C}][pf]^-$  can be used to abstract a formate ligand from a dimeric, N-heterocyclic imino-supported aluminum carboxylate complex.<sup>100</sup> Formate abstraction can also be performed with two equivalents of  $\text{B}(\text{C}_6\text{F}_5)_3$  and yields a dinuclear cationic aluminum complex with one bridging carboxylate ligand.<sup>100</sup>

**Two-coordinate Gallium Cations:**  $[(2,6\text{-Mes}_2\text{C}_6\text{H}_3)_2\text{Ga}]^+ [\text{Li}[hf]_2]^-$  containing a linear two-coordinate gallium cation, was obtained by metathesis reaction of  $(2,6\text{-Mes}_2\text{C}_6\text{H}_3)_2\text{Ga}-\text{Cl}$  with dimeric  $\text{Li}[hf]$  in  $\text{C}_6\text{H}_5-\text{Cl}$  solution at room temperature (Fig. 19).<sup>101,102</sup>

The compound consists of isolated  $[(2,6\text{-Mes}_2\text{C}_6\text{H}_3)_2\text{Ga}]^+$  cations and Lithium-bridged  $[\text{Li}[hf]_2]^-$  anions,<sup>101,102</sup> that were initially observed as the  $[\text{EMIM}]^+$ <sup>17</sup> and  $[\text{CPh}_3]^+$ <sup>9</sup> salts. The  $\text{C}-\text{Ga}-\text{C}$  angle is  $175.69(7)^\circ$  and the  $\text{Ga}-\text{C}$  distances are 191.3(1) and 191.5(2) pm. The compound is remarkably stable and is only a weak Lewis acid that polymerizes cyclohexene oxide. This behavior indicates that in non-basic solvents like  $\text{CH}_2\text{Cl}_2$  or  $\text{C}_6\text{H}_5\text{Cl}$ , only one  $\text{Li}^+$  cation from the dimeric  $\text{Li}[hf]$  that exists in

**Fig. 18** The unsubstituted aluminocenium cation in  $[\text{AlCp}_2]^+ [pf]^-$ .

**Fig. 19** Synthesis of the almost linear  $[\text{Ga}(\text{Ar})_2]^+$  cation.

the solid phase<sup>17</sup> is available and that the Li-bridged  $[\text{Li}(\text{hf})_2]^-$  anion is remarkably more stable<sup>9</sup> than the simple homoleptic  $[\text{hf}]^-$  anion that decomposes with similarly electrophilic cations.

Upon chloride abstraction from  $(^t\text{Bu}_3\text{Si})_2\text{GaCl}$  with  $\text{Ag}[\text{pff}]$ , the salt  $[(^t\text{Bu}_3\text{Si-Ga-Si}^t\text{Bu}_3)[\text{pff}]$  was isolated quantitatively.<sup>103</sup> The highly reactive  $[(^t\text{Bu}_3\text{Si-Ga-Si}^t\text{Bu}_3)^+$  cation features a perfectly linear Si–Ga–Si unit<sup>103</sup> and is isostructural and isoelectronic with neutral  $[(^t\text{Bu}_3\text{Si-Zn-Si}^t\text{Bu}_3)]^{104}$  and anionic  $[(^t\text{Bu}_3\text{Si-Cu-Si}^t\text{Bu}_3)]^{-105}$ .

**A Bridged, Dinuclear Ga<sup>III</sup> Complex:** Reaction of  $\text{IPr-GaCl}_3$  with  $[\text{Ag}(\text{CH}_2\text{Cl}_2)_3][\text{pff}]$  yielded, in the presence of adventitious water, the salt  $\{[\text{IPrGaCl}(\mu\text{-OH})_2]_2 \cdot \text{H}_2\text{O}\}[\text{pff}]_2$  with a dinuclear cationic gallium dihydroxide.<sup>106</sup>

**Disproportionation Reactions of Ga<sup>+</sup> yielding Ga(III)-Complexes:** Subvalent Ga<sup>+</sup> is rather stable as  $[\text{pff}]^-$  salt, as long as weakly basic ligands and solvents are present. Yet, Ga<sup>+</sup> cations disproportionate in the presence of non-innocent reducible ligands, e.g., 2,2'-bipyridine (bipy) and a substituted derivative, 4,4'-(<sup>t</sup>Bu)<sub>2</sub>-bipy (D'Bbipy). Hence, mixing the Ga<sup>I</sup> source  $[\text{Ga}(\text{PhF})_x][\text{pff}]$  with these ligands yielded Ga<sup>0</sup> as well as  $[\text{Ga}^{\text{III}}(\text{D}'\text{Bbipy})_3]^{3+107}$  and  $[\text{Ga}^{\text{III}}\{(\text{bipy})_3\}]^{2+108}$  respectively. The latter includes one radical anionic  $[\text{bipy}]^-$  ligand.

A disproportionation reaction was also observed when mixing  $[\text{Ga}(\text{HMB})][\text{pff}]$ ,  $\text{SbCl}_3$  and a non-innocent bisiminopyridine  $\text{dimpyr}^{\text{dipp}}$ , since, among other products,  $[\text{Ga}^{\text{III}}\text{Cl}_2(\text{dimpyr}^{\text{dipp}})][\text{pff}]$  was isolated.<sup>62</sup>

**Functionalization of a pentaphosphaferrocene:** The reaction of two equivalents of  $[\text{Cp}^*\text{Fe}(\eta^5\text{-P}_5)]$  with  $\text{Ti}[\text{pff}]$  and  $\text{GaI}_3$  afforded the bimetallic compound  $\{[\text{Cp}^*\text{Fe}]_2\{\mu, \eta^{5:5}\text{-}(\text{P}_5)_2\text{GaI}_2\}\}[\text{pff}]$  with the unprecedented  $\{(\text{cycloP}_5)_2\text{GaI}_2\}$  ligand and thus resulted in functionalization of pentaphosphaferrocene.<sup>109</sup> Employing  $\text{BBr}_3$  instead of  $\text{GaI}_3$  furnished  $\{[\text{Cp}^*\text{Fe}]_2\{\mu, \eta^{5:5}\text{-}(\text{P}_5)_2\text{BBr}_2\}\}[\text{pff}]$ , with a structurally analogous cation.<sup>109</sup> However, calculations suggest that the BBr<sub>2</sub>-linker is better described as a borate-bridge, since the B atom shows negative charge accumulation.<sup>109</sup> In contrast to this, the P–Ga bonds in the GaI<sub>2</sub>-bridged cation have a more polar character, accounting for the small positive charge on the Ga atom.<sup>109</sup>

**A Dicationic [H-Ga(PPh<sub>3</sub>)<sub>3</sub>]<sup>2+</sup> Salt:** The dissolved  $[\text{Ga}(\text{HMB})][\text{pff}]^-$  salt reacts with  $[\text{H-PPh}_3]^+$  under formation of the unprecedented dicationic gallium hydride complex  $[\text{H-Ga}(\text{PPh}_3)_3][\text{pff}]_2$ , which may either proceed via a direct oxidative addition of Ga<sup>I</sup> into the H–P bond or via initial protonation of Ga<sup>I</sup>, followed by the subsequent addition of the deprotonated, Lewis basic  $\text{PPh}_3$  (Fig. 20).<sup>62</sup>

**Gallylene Transition-Metal Cations:** The Aldridge group described the syntheses of a series of cationic transition metal complexes with gallylene ligands of the type  $(\text{NacNac})^{\text{dipp}}\text{Ga}$ , underlining the carbene-like character of subvalent gallium.<sup>110,111</sup>

**Gallylene Main Group-Metal Cations:** Halide abstraction of the carbene-coordinated pnictinidenes  $(^{\text{Me}}\text{cAAC})\text{EGa}(\text{Cl})\text{L}$  ( $\text{E} = \text{P},^{112} \text{As}, \text{Sb}$ ,  $^{\text{Me}}\text{cAAC} = [\text{H}_2\text{C}(\text{CMe}_2)_2\text{Ndipp}]\text{C}$ ;  $\text{L} = \text{HC}[\text{C}(\text{Me})\text{Ndipp}]_2$ ) yielded the cationic group 15 compounds  $[(^{\text{Me}}\text{cAAC})\text{EGaL}][\text{pff}]$  ( $\text{E} = \text{P},^{112} \text{As}, \text{Sb}$ ). Quantum chemical calculations suggest that the central pnictogen atom determines the electronic nature of the cations  $[(^{\text{Me}}\text{cAAC})\text{EGaL}]^+$ . In these structures, the heavier pnictogen atoms serve as a trap for the positive charge, resulting in carbene-stabilized heterovinyl-type structures.<sup>113</sup> The cation containing the lighter congener P reacts with ethyl isocyanate under C–C bond formation.<sup>112</sup>

**An In<sup>III</sup>-Crown Ether Complex:** In addition to the [18]crown-6 ether complex of univalent indium<sup>114</sup> (*vide infra*), the isolation of  $[\text{InCl}_2(\{18\}\text{crown-6 ether})][\text{pff}]$  with a linear  $[\text{Cl-In}^{\text{III}}-\text{Cl}]^+$  chain has been reported.<sup>115</sup>

#### 1.07.2.2.3.2 Subvalent group 13 cations: From coordination compounds to clusters

The stability of group 13 elements in their +1 oxidation state increases with increasing atom number, due to the stabilizing “inert pair effect” of the  $ns^2$  electrons.<sup>116,117</sup> Consequently, no successful isolation of cationic B<sup>I</sup> or Al<sup>I</sup> complexes has been reported so far, while cationic Ga<sup>I</sup>, In<sup>I</sup> and Tl<sup>I</sup> compounds are well known.

**Gallium.** Even though subvalent gallium is more stable than subvalent boron or aluminum, classical Ga<sup>I</sup>-sources like “GaI”<sup>118,119</sup> or “GaX<sub>2</sub>”<sup>120–122</sup> still tend to undergo redox reactions like dis- or comproportionation with  $\sigma$ -donating ligands, which hampered systematic studies on the coordination chemistry.<sup>123,124</sup> The susceptibility of Ga<sup>I</sup> to redox chemistry upon the interaction with electron donating ligands or the counter anion is reduced by employing WCAs and  $\pi$ -donating ligands, e.g., arenes.<sup>124</sup> When  $[\text{Ga}[\text{GaX}_4]]$  ( $\text{X} = \text{Cl}, \text{Br}$ ) is dissolved in the presence of chelating arene ligands like cyclophanes, a similar interaction of the weakly accepting Ga<sup>+</sup> ion with three arene ligands may be realized. However, if the chelating cyclophane is replaced by individual arenes, only coordination of up to two arenes per Ga<sup>+</sup> ion was hitherto possible,<sup>125</sup> likely due to the weak complexation of the third arene that competes with stronger interactions with the  $[\text{GaCl}_4]^-$  counterion at 310–370 pm in the  $[\text{Ga}(\text{C}_6\text{H}_6)_2][\text{GaCl}_4]^-$  salt<sup>125</sup> (sum of Ga + Cl van der Waals radii: 370 pm).<sup>126</sup> If the more coordinating  $[\text{GaCl}_4]^-$  counterion is replaced by the less coordinating  $[\text{pff}]^-$  anion, this competition is negligible and the entropically and enthalpically normally disfavored coordination of a third arene becomes now possible, underlining the weakly coordinating nature of the  $[\text{pff}]^-$  anion.<sup>33</sup>

Notably, salts of the type  $[\text{Ga}(\text{arene})_x][\text{pff}]$  (arene = e.g., toluene,<sup>33</sup> *p*-xylene,<sup>127</sup> mesitylene,<sup>128</sup> HMB<sup>127</sup> or oDFB,<sup>33</sup> in most cases  $\text{PhF}^{33,128}$ ,  $x = 2\text{--}3$  and  $x = 1$  for *ansa*-arene ligands<sup>127</sup>) are well-defined and nowadays established starting materials for Ga<sup>I</sup> chemistry, since they are room temperature stable and easily synthesized by oxidizing elemental gallium with the silver salt  $\text{Ag}[\text{pff}]$  in an

Fig. 20 Oxidative addition of a P–H bond at a subvalent gallium cation.<sup>62</sup>

aromatic solvent by using ultrasound.<sup>33</sup> With the particularly electron rich HMB, isolation of a mono-arene complex has been reported from the HMB radical cation.<sup>54</sup> Consequently, the introduction of  $[\text{Ga}(\text{arene})_x][\text{pf}]$  has allowed for the synthesis of several unusual cationic, subvalent gallium compounds and has led to a better understanding of  $\text{Ga}^{\text{I}}$  chemistry, which was recently reviewed<sup>124</sup> and from which part of the descriptions here are taken. Isolated mononuclear  $\text{Ga}^{\text{I}}$  (and  $\text{In}^{\text{I}}$ ) complexes with the  $[\text{pf}]^-$  counter anion are shown in Fig. 21.

The central  $\text{Ga}^+$  ion may interact with a variety of ligands, ranging from soft (e.g., phosphines, carbenes) to hard (e.g., pyrazine, crown ethers). The steric bulk and denticity of the ligands determine the coordination numbers. Reaction of sterically less demanding  $\text{PPh}_3$ <sup>33</sup> and pyrazine ligands<sup>129</sup> with  $[\text{Ga}(\text{PhF})_x][\text{pf}]$  yielded the respective trigonal-pyramidal gallium complexes (Fig. 21). The coordination mode reflects the electron donation of the ligands in the three empty  $4p$  orbitals at gallium and its formally stereochemical active lone pair. It is interesting to note that each  $\text{Ga}^+$  cation is coordinated in a trigonal-pyramidal fashion by three  $\eta^1$ -donating pyrazine ligands, and that the ligands are not  $\pi$ -coordinated, which would likewise be conceivable.<sup>129</sup> This coordination mode is also observed in 1D coordination polymers of  $[\text{Ga}(\mu\text{-pyrazine})_2(\eta^1\text{-pyrazine})]_n[\text{pf}]_n$  which clearly implies that  $\text{Ga}^+$  cations favor  $\sigma$ - over  $\pi$ -coordination.<sup>129</sup> A  $\text{Ga}^{\text{I}}$  complex with the tridentate, chelating pentamethyldiethylenetriamine (PMDTA) has also been described (Fig. 21).<sup>130</sup> The  $\pi$ -Lewis-acidity of the  $\text{Ga}^+$  cation is significantly diminished upon saturation of all three  $4p$ -orbitals by the ligands.<sup>124</sup> In contrast, the steric bulk of a  $\text{P}(\text{tBu})_3$  ligand allowed only for coordination of two phosphines to the gallium atom (Fig. 21).<sup>34</sup> With  $N$ -heterocyclic carbenes (NHC = IMes, IPr), structurally similar dicoordinate complex cations were isolated and characterized (Fig. 21).<sup>131</sup> An analysis of the crystal structure and of the bonding situation reveals a  $\sigma$ -backdonation of the  $4s^2$  lone pair into the LUMO of the NHCs.<sup>131</sup> Thus, since the Lewis acidity of  $\text{Ga}^+$  is not quenched by the coordination of only two ligands, such dicoordinate gallium complexes may potentially show a metal-centered, ambiphilic, transition-metal like reactivity with a low-valent and low-coordinate main-group cation.<sup>124</sup> With sterically highly demanding 2,6-di-*tert*-butyl-4-methylpyridine (DTBMP), a nonchelated mixed  $\sigma$ - and  $\pi$ -bound complex was obtained, i.e.,  $[\text{Ga}(\text{C}_6\text{H}_5\text{F})_2(\text{DTBMP})]^+$ . As with pyrazine, the aromatic nitrogen base exclusively interacts through its nitrogen lone pair. However, the steric bulk of the DTBMP ligand only allows for one ligand to coordinate to  $\text{Ga}^+$ , while the PhF ligands display their usual  $\pi$ -coordination mode.<sup>129</sup> Moreover, the  $\text{pf}$  salt of a  $[\text{Ga}^{\text{I}}(\text{18crown-6})]^+$  complex with one arene ligand above and below the  $\text{Ga}$ -[18]crown-6 plane, respectively, was reported (Fig. 21).<sup>114</sup> In this complex cation, one arene ring is bound in  $\eta^6$ -fashion to  $\text{Ga}^+$ , while the second arene ligand shows only a  $\eta^1$ -coordination.<sup>114</sup> The  $\eta^6$ -coordination for the second arene ligand is probably prevented by the  $4s^2$  lone pair residing on  $\text{Ga}^{\text{I}}$ , which likely exerts a stereochemical effect.

The mono-arene complex  $[\text{Ga}(\text{HMB})]^+$  can also serve as a starting point for  $\text{Ga}^{\text{I}}$  chemistry. The aromatic HMB ligand can be replaced by the electron rich, chelating and non-innocent *bis*iminopyridine *dimpyr*<sup>dipp</sup> ligand, allowing for the isolation of  $[\text{Ga}(\text{dimpyr}^{\text{dipp}})][\text{pf}]$ .<sup>62</sup>

**A Homoleptic Olefin Main Group Metal Complex:** Employing the very weakly coordinating  $[\text{pf}]^-$  anion also allowed the isolation of the first homoleptic olefin complex of any main-group metal accessible as a bulk compound, i.e.,  $[\text{Ga}^{\text{I}}(\text{COD})_2][\text{pf}]$  ( $\text{COD} = 1,5$ -

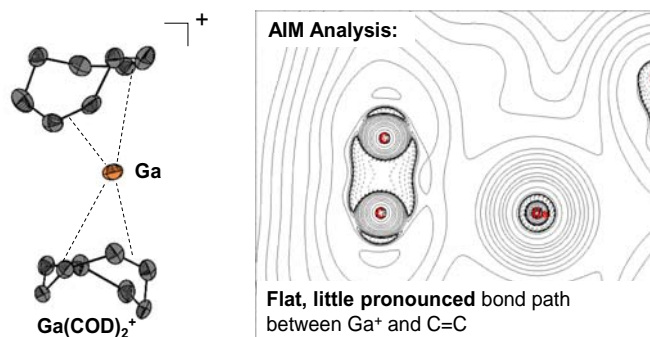

**Fig. 21** Synthesis of cationic  $\text{M}^{\text{I}}$  complexes starting from  $[\text{M}(\text{PhF})_{2-3}][\text{pf}]$  ( $\text{M} = \text{Ga, In}$ ) and  $\sigma$ -donating ligands (mesityl = 2,4,6-( $\text{CH}_3$ )<sub>3</sub> $\text{C}_6\text{H}_2$ ; dipp = 2,6- $\text{Pr}_2\text{C}_6\text{H}_3$ ).<sup>124</sup>

cyclooctadiene).<sup>132</sup> It constitutes an olefin complex of a main-group metal that may adopt different oxidation states, again showing parallels to transition metals and opening potential applications in catalysis. The highly unusual bonding between an olefin and a main-group metal was analyzed in detail and was shown to be a weak bond with mostly electrostatic character.<sup>132</sup> The crystal structure of the cation as well as the Laplacian of the electron density of the bonding interactions between Ga and a carbon-carbon double bond is shown in Fig. 22.

**Indium.** The chemistry of univalent indium is akin to the chemistry of univalent gallium and for this reason included with Fig. 21.<sup>124</sup> In analogy to the  $[pf]^-$  salt of the lighter counterpart,  $[\text{In}(\text{PhF})_x][pf]$  ( $x = 2-3$ ) has proven to be a useful source of  $\text{In}^+$  as it is easily synthesized by oxidizing elemental indium with the silver salt  $\text{Ag}[pf]$  in PhF by using ultrasound.<sup>34,35</sup> Additionally, the *o*DFB complex  $[\text{In}(\text{oDFB})_2]^{+35}$  has also been isolated. With electron rich aromatic ligands, monoarene complexes of the type  $[\text{In}(\text{arene})_1]^+$  (arene = mesitylene, HMB) were prepared after in situ generation of the radical cations with  $\text{I}_2$  and  $\text{Ag}[pf]$ .<sup>54</sup> Starting from  $[\text{In}(\text{PhF})_x][pf]$  ( $x = 2-3$ ), mononuclear  $\text{In}^1$  complexes with PMDTA,<sup>130</sup> IPr,<sup>131</sup> [18]crown-6 ether<sup>114</sup> and  $\text{P}^t\text{Bu}_3$ <sup>34</sup> could be synthesized, as shown in Fig. 21. The molecular structures of these compounds are analogous to the respective  $\text{Ga}^1$  complexes. Employing  $\text{PPh}_3$  leads to two different  $\text{In}^1$  complexes, with the first cation being structurally similar to the  $\text{Ga}^1$  complex. In the second cation, two  $[\text{In}(\text{PPh}_3)_3]^+$  units are linked by a bridging  $\text{PPh}_3$  ligand.<sup>34</sup> However, the  $\text{In}-\text{P}$  bond lengths for the seventh phosphane ligand exceed the sum of their van-der-Waals radii, suggesting that the additional phosphane does not affect the coordination at the indium cations and is located in between the indium centers due to packing effects.<sup>34</sup>

**Binuclear  $\text{Ga}^1$  and  $\text{In}^1$  Complexes:** With  $[\text{Ga}(\text{HMB})][pf]$  and  $\text{GeCp}_2$  or  $\text{SnCp}_2$ , two isostructural binuclear complexes, i.e.,  $[\text{Ga}(\mu\text{-Cp})\text{GeCp}]^+$  and  $[\text{Ga}(\mu\text{-Cp})\text{SnCp}]^+$ , were isolated as their  $pf$  salts, respectively.<sup>133</sup> Instead of obtaining a GaGa-bonded Lewis acid-base adduct, the reaction between  $[\text{Ga}(\text{HMB})][pf]$  and  $\text{GaCp}^*$  only yielded the inverse sandwich cation  $[\text{GaCp}^*\text{Ga}][pf]$  under substitution of neutral HMB.<sup>133</sup> It was concluded that coordination by the formally negatively charged aromatic  $\text{Cp}^*$  moiety is favored over the coordination by the Lewis basic Ga atom.<sup>133</sup> The reaction between  $[\text{In}(\text{HMB})][pf]$  and  $\text{GeCp}_2$  afforded the binuclear complex  $[\text{In}(\mu\text{-Cp})\text{GeCp}]^+$  in an unselective reaction, while the reaction  $\text{SnCp}_2$  resulted in a crude mixture of products.<sup>133</sup> The different reaction outcomes are summarized in Fig. 23.

**Cationic Coordination Polymers:** Starting from  $[\text{In}(\text{HMB})][pf]$  and  $\text{SnCp}_2$  or  $\text{FeCp}_2$ , cationic coordination polymers featuring a chain motif were isolated, i.e.,  $[\{\text{In}(\text{HMB})(\mu\text{-SnCp}_2)\}_n][pf]_n$  and  $[\{\text{In}(\text{HMB})(\mu\text{-FeCp}_2)\}_n][pf]_n$ , respectively.<sup>133</sup>  $\text{FeCp}_2$  reacts

**Fig. 22** Molecular structure of the cation (left; hydrogen atoms are omitted for clarity) as well as the Laplacian of the electron density of the bonding interaction between Ga and a carbon-carbon double bond of a COD ligand (right).<sup>124,132</sup>

**Fig. 23** Reactivity of  $[\text{M}(\text{HMB})][pf]$  ( $\text{M} = \text{Ga, In}$ ) towards  $\text{M}'\text{Cp}_2$  ( $\text{M}' = \text{Sn, Ge}$ ) and  $\text{GaCp}^*$ . Note that the formation of  $[\text{In}(\mu\text{-Cp})\text{GeCp}]^+$  is unselective and accompanied by the side product  $[\text{CpGe}(\mu\text{-Cp})\text{GeCp}][\text{al}fa]$  with a decomposed anion.<sup>133</sup>

**Fig. 24** Molecular structures of the infinite ( $n = \infty$ ) coordination polymers  $\{[\text{In}(\text{HMB})(\mu\text{-SnCp}_2)]_n\}^{n+}$  (shown with  $n = 3$ ; a) and of  $\{[\text{Ga/In}(\text{HMB})(\mu\text{-FeCp}_2)]_n\}^{n+}$  (shown with  $n = 2$ ; b). Thermal displacement ellipsoids drawn at 50% probability,  $[\text{pf}]^-$  counterions are omitted for clarity.<sup>133</sup>

with  $[\text{Ga}(\text{HMB})][\text{pf}]$  under the formation of the isostructural cationic coordination polymer  $\{[\text{Ga}(\text{HMB})(\mu\text{-FeCp}_2)]_n\}^{n+}$ .<sup>133</sup> The molecular structures of these compounds are shown in Fig. 24.

**Multinuclear Complexes of  $\text{Ga}^I$ ,  $\text{In}^I$  and  $\text{Tl}^I$  with  $\text{E}_n$  ( $\text{E} = \text{Group 15}$ ) ligands:** With the sandwich complexes  $[\text{Cp}^*\text{Fe}(\eta^5\text{-E}_5)]$  ( $\text{E} = \text{P, As}$ ) and  $\text{Ga}^+$  or  $\text{In}^+$ , the Scheer group obtained one-dimensional coordination polymers  $[\text{M}(\mu, \eta^5: \eta^1\text{-E}_5\text{FeCp}^*)_3]_n[\text{pf}]_n$  ( $\text{M} = \text{In, Tl}$  for  $\text{E} = \text{As}$ <sup>134</sup>;  $\text{M} = \text{Ga, In}$  and  $\text{Tl}$  for  $\text{E} = \text{P}$ <sup>134,135</sup>). In these compounds, the  $\text{P}_5$  ligands are  $\eta^5$ -bound and show a very weak  $\sigma$ -interactions between one P atom of the ring and the neighbored subvalent group 13 cation, as shown in Fig. 25.<sup>134</sup>

Again using the  $[\text{pf}]^-$  anion, the same group reported the synthesis of a tetracationic indium aggregate including  $\text{P}_2$  ligands<sup>35</sup> as well as the synthesis of polymeric chain compounds of  $\text{In}^+$  ions, bridged by  $[\text{CpM}'(\text{CO})_2(\eta^3\text{-P}_3)]$  units ( $\text{M}' = \text{Cr}$ <sup>35</sup> or  $\text{Mo}$ ).<sup>136</sup>

The reaction of  $\text{Tl}[\text{pf}]$  and  $\{[\text{CpMo}(\text{CO})_2]_2(\text{P}_2)\}$  afforded a dimeric, dicationic  $\text{Tl}^I$  compound, with the two  $\text{Tl}^I$  ions asymmetrically bridged by two  $[\text{CpMo}(\text{CO})_2]_2(\text{P}_2)$  moieties.<sup>135</sup> One dimensional coordination polymers containing  $\text{Tl}^I$  were also obtained starting from  $\text{Tl}[\text{pf}]$  and a mixed  $\text{P}_m\text{Sn}_n$  ligand or  $[\text{CpM}'(\text{CO})_2(\eta^3\text{-P}_3)]$  ( $\text{M}' = \text{Cr, Mo}$ ).<sup>136</sup> Reacting  $[(\text{Cp}^*\text{Mo})_2(\mu, \eta^6: \eta^6\text{-P}_6)]$  with  $\text{Tl}[\text{pf}]$ <sup>137</sup> yielded a two-dimensional coordination network.<sup>138</sup>

**Miscellaneous  $\text{Tl}^I$  Complexes:** As already pointed out, the stability of subvalent Group 13 elements increases with increasing atom number due to the inert pair effect. Thus, the +1 oxidation state is rather common for Tl and relying on WCAs is usually not a prerequisite when investigating  $\text{Tl}^I$  chemistry. Due to the stability of  $\text{Tl}^I$ , it is unsurprising that the solvent-free salts  $\text{Tl}[\text{pf}]$ <sup>137</sup> and  $\text{Tl}[\text{hf}]$ <sup>139</sup> are readily available from the reaction of the respective Li salt and  $\text{TlF}$ . It was shown that, stabilized by a 2,5-bis(2-pyridyl)phosphole ligand, mono- and dimetallic  $\text{Tl}^I$  complexes are obtained with  $\text{Tl}[\text{pf}]$ , while  $[\text{PF}_6]^-$  anions coordinate to  $\text{Tl}^I$  and lead to polymetallic species when working with  $\text{Tl}[\text{PF}_6]$ .<sup>140</sup>

#### 1.07.2.2.3.3 Formation of polycationic group 13 clusters

Since organometallic group 13 element compounds are inherently electron deficient compounds, the vast majority of group 13 metal clusters are neutral or anionic.<sup>141–152</sup> In order to obtain group 13 metal clusters, subvalent cations have to be employed since their  $ns^1$  or  $2$  electrons are required for bond formation. Cationic cluster formation is hampered by the accumulation of positive charge, which has to be overcome using electron rich  $\sigma$ -donating ligands, which delocalize the positive charge. Generally, the disproportionation energetics is much more favored for the lighter group 13 elements, suggesting that polycationic cluster

**Fig. 25** Formation and molecular structure of the one-dimensional coordination polymers that are formed upon reaction of  $\text{cycloE}_5$  ligand complexes with the  $\text{pf}$  salts of monovalent  $\text{Ga}^+$ ,  $\text{In}^+$ , and  $\text{Tl}^+$ .<sup>134,135</sup>

formation is possible with the heavier congeners, i.e., Ga, In and Tl.<sup>108</sup> The energetics underlying either a disproportionation or a cationic cluster formation suggest that cationic cluster formation can only be achieved employing WCAs instead of small anions.<sup>108</sup>

**Gallium Clusters:** Indeed, the formation of tetracationic clusters with a Ga<sub>4</sub> core was observed upon mixing [Ga(PhF)<sub>x</sub>][pfl] and bis(dimethylphosphino)ethane (DMPE)<sup>153</sup> or *tert*-butylisocyanide (CN<sup>t</sup>Bu)<sup>107</sup> as  $\sigma$ -donating ligands. With 4-dimethylaminopyridine (DMAP), even a pentacationic cluster was obtained, representing the first salt with an ionic 1:5 packing.<sup>154</sup> The molecular structures of these cationic Ga<sup>I</sup> clusters are shown in Fig. 26. The CN<sup>t</sup>Bu- and DMAP-supported clusters are essentially planar, while the DMPE-supported cluster is slightly puckered, probably due to steric repulsion of the methyl groups. Quantum chemical calculations and the Ga–Ga bond lengths (246–250.5 pm) suggest that the Ga–Ga bonds are best described as single bonds.<sup>107,153,154</sup>

In the presence of non-innocent, chelating, pyridine-based aromatic ligands, Ga<sup>+</sup> tends to disproportionate. For example, the reaction between [Ga(PhF)<sub>x</sub>][pfl] and phenanthroline (phen) results in the formation of elemental gallium and [Ga<sup>II</sup>(phen)<sub>4</sub>]<sup>4+</sup>, a dimeric tetracation with relatively short Ga<sup>II</sup>–Ga<sup>II</sup> bond (256 pm).<sup>107</sup> With bipy and a substituted derivative, Ga<sup>I</sup> disproportionates to elemental gallium and mononuclear Ga<sup>III</sup> complexes (*vide supra*).<sup>107,108</sup>

**Indium Clusters.** In contrast to the more limited propensity of Ga<sup>+</sup> to aggregate towards clusters, In<sup>+</sup> readily forms cationic clusters with the non-innocent ligands bipy and phen. With [In(PhF)<sub>x</sub>][pfl] and bipy, one rhombohedral, tetracationic and two triangular, tricationic clusters were isolated, depending on the exact crystallization conditions and molar ratios (Fig. 27).<sup>108</sup>

The rhombic In<sub>4</sub> motif was reproduced by employing phen instead of bipy; both contain the shortest known In–In bonds around 259 pm.<sup>108</sup> As a side product, [(phen)<sub>2</sub>In<sup>I</sup>Ag<sup>I</sup>(PhF)]<sup>2+</sup>, the first monomeric and dicationic In–Ag adduct was isolated.<sup>108</sup>

In addition, the synthesis of a tetracationic In<sup>I</sup> cluster was recently reported with DMPE as a ligand.<sup>153</sup> In this polycationic cluster, the In<sub>4</sub> core forms a nearly perfectly planar square, unlike the puckered Ga<sub>4</sub> moiety in the analogous, isostructural gallium cluster (cf. Fig. 26). By contrast, <sup>t</sup>BuNC does not induce the formation of cationic indium clusters, but only of the monocationic pyramidal [In<sup>I</sup>(<sup>t</sup>BuNC)<sub>3</sub>]<sup>+</sup> and, probably due to traces of water, the OH-bridged dimeric [(<sup>t</sup>BuNC)<sub>4</sub>In<sup>III</sup>( $\mu$ -OH)<sub>2</sub>In<sup>III</sup>(CN<sup>t</sup>Bu)<sub>4</sub>]<sup>4+</sup>.<sup>107</sup>

#### 1.07.2.2.4 Reactive group 14 cations: Carbocations and their heavier homologues

##### 1.07.2.2.4.1 Tricoordinate carbenium ions

In the course of our investigations into new arsenic-halogen-cations we fortuitously prepared a simple, but electronically very interesting carbenium ion<sup>155</sup>: the [CS<sub>2</sub>Br<sub>3</sub>]<sup>+</sup> cation, which may be obtained by the quantitative reaction of [AsBr<sub>4</sub>]<sup>+</sup> with CS<sub>2</sub> yielding [CS<sub>2</sub>Br<sub>3</sub>]<sup>+</sup> and a polymeric As<sup>I</sup>Br (Eq. 6).

Fig. 26 Molecular structures of polycationic, subvalent Ga<sup>I</sup> clusters that were isolated as their respective [pfl]<sup>−</sup> salts. Only one out of many possible resonance structures is shown, respectively.<sup>107,153,154</sup>

Fig. 27 Molecular structures of selected In<sup>I</sup>-bipy clusters obtained upon mixing [In(PhF)<sub>x</sub>][pfl] and 2,2'-bipyridine, isolated as their respective [pfl]<sup>−</sup> salts.<sup>108</sup>

The C–Br bond length in  $[\text{CS}_2\text{Br}_3]^+$  is very close to that expected for the simple  $\text{CBr}_3^+$  cation (181.7 vs. 181.3 pm @MP2/TZVPP) and thus it appeared likely that simple binary carbon-halogen cations such as  $[\text{CX}_3]^+$  may also be accessible by metathesis of  $\text{CX}_4$  with silver aluminates. Therefore, we decided to examine the reaction of  $\text{CX}_4$  ( $X = \text{Cl}, \text{Br}, \text{I}$ ) and  $\text{Ag}[pf]$  or  $\text{Ag}[alfal]$  with the goal to prepare  $[\text{CX}_3]^+$  salts (and  $\text{AgX}$ ). These reactions are successful and quantitative with both anions, but need different solvents for optimal performance (Eq. 7):  $\text{CH}_2\text{Cl}_2$  for  $[\text{Cl}_3]^+$ .<sup>156–158</sup>  $\text{SO}_2$  for  $[\text{CBr}_3]^+$ <sup>159</sup> and  $\text{SO}_2\text{ClF}$  for  $[\text{CCl}_3]^+$ .<sup>159</sup>

For the successful preparation of  $[\text{Cl}_3^+][pf]^-$ , the complete exclusion of light and the use of carefully purified diiodine free  $\text{Cl}_4$  is absolutely necessary. Solutions of  $[\text{Cl}_3]^+$  are stable at RT (exclusion of light), while those of  $[\text{CCl}_3]^+$  decompose at RT with half-lives of about 1–2 h. The solid salts are more robust and survive a few hours at RT without decompositions and may be stored without noticeable decompositions for months at  $-20^\circ\text{C}$ . In the framework of these experimental investigations, also the theoretical aspects of these  $[\text{CX}_3]^+$  salts was thoroughly investigated<sup>160</sup> and compared to the bonding in the isoelectronic boron halides.<sup>161,162</sup>

The  $[\text{Cl}_3]^+$  salts were used for further reactions with the weak nucleophiles  $\text{PX}_3$  ( $X = \text{Cl}, \text{Br}, \text{I}$ ) and  $\text{AsI}_3$  that lead to the formation of the  $[\text{I}_3\text{C-EX}_3]^+$ .<sup>158</sup> with ethane conformation (Eq. 8; but not with the hoped for non-classical structures<sup>162</sup>).

#### 1.07.2.2.4.2 Delocalized carbocations

Dibenzo[*a,e*]pentalene (DBP) is a non-alternant conjugated hydrocarbon with antiaromatic character and ambipolar electrochemical behavior. Upon oxidation, it becomes aromatic. The chemical oxidation of a planar DBP derivative and a bent DBP-*phane* was studied<sup>163</sup> and the molecular structures of its planar dication and cation radical in the solid state demonstrate the gained aromaticity through bond length equalization, which is supported by nucleus independent chemical shift-calculations. EPR spectra on the cation radical confirm the spin delocalization over the DBP framework. This is the first report on structures of a DBP cation radical and dication in the solid state. In addition,<sup>164</sup> the facile gold-mediated skeletal rearrangement of [7]-helicene into a cationic polyaromatic hydrocarbon was published. It reports in-depth studies on the structure and aromaticity of this novel stable cation and proposes a mechanism for its formation.

*Silylated Tetramethylcyclobutenyl Cation:* Instead of yielding the desired non-classical silylium ions, the reactions of different alkenes/alkynes with several  $[\text{Me}_3\text{Si}]^+$ -sources mostly led to oligomerization, or—in the presence of  $\text{Me}_3\text{SiH}$ —hydrosilylation of the alkenes/alkynes.<sup>66</sup> Yet, from the reaction of 2-butyne with ion-like  $\text{Me}_3\text{Si-F-Al}(\text{OR}^{\text{PF}})_3$  the salt of the silylated tetramethylcyclobutenyl cation  $[\text{Me}_4\text{C}_4\text{-SiMe}_3]^+[\text{alfal}]^-$  was obtained in good yield (NMR, scXRD, Raman, and IR).<sup>66</sup> All the experimental and calculated evidence suggest a mechanism in which  $[\text{Me}_4\text{C}_4\text{-SiMe}_3]^+$  was formed via a non-classical silylium ion as an intermediate.

*Delocalized Carbocations as Ligand-forming Oxidants:* Ligand-forming oxidizing agents are designed to oxidize the substrate and directly stabilize the oxidation product. An example of a “soft” ligand-forming oxidant is the hexamethylbenzene (HMB) radical cation, accessible as  $[pf]^-$ <sup>54</sup> or  $[alfal]^-$ <sup>48</sup> salt via oxidation of neutral hexamethylbenzene with  $\text{Ag}[\text{WCA}]/\text{I}_2$  as in Eq. (9) ( $[\text{WCA}]^- = [pf]^-$  and  $[alfal]^-$ ). Although no crystal structure of  $[\text{HMB}]^+[\text{WCA}]^-$  could be obtained, in situ generated red solutions of the radical cation react readily with elemental metals such as Gallium, Indium, Calcium, Strontium and Barium to form the respective cationic HMB-complexes in oxidation states +I (for Ga/In)<sup>54</sup> or +II (for Ca/Sr/Ba).<sup>48</sup>

## 1.07.2.2.4.3 Extensions to heavier homologues

**Silylium Ions:** Attempts to prepare simple  $[\text{Me}_3\text{Si}]^+$  silylium ions were futile: while  $\text{Ag}[pf]$  reacts with  $\text{Me}_3\text{SiCl}$  with formation of  $\text{AgCl}$  and likely the  $[\text{Me}_3\text{Si}]^+[pf]^-$  intermediate, the latter decomposes already at low temperatures with fluoride abstraction and formation of  $\text{Me}_3\text{Si-F-Al}(\text{OR}^F)_3$ .<sup>165</sup> The synthesis of the latter has been scaled up in an alternative direct route to 85 g batches and is now the starting point for the best  $[alfal]^-$  syntheses.<sup>12</sup> Interestingly, silver salts of the halogenated carborane anions were reported not to react with chlorosilanes,<sup>166</sup> probably due to the considerably stronger coordinating nature and thus reduced electrophilicity of their silver salts available for metathesis. See for a recent systematic investigation.<sup>12</sup> However, silylium ions  $[\text{Si}(\text{C}_6\text{Me}_5)_3]^+$  with larger residues like pentamethylphenyl form stable salts with  $[pf]^-$ .<sup>68</sup> Notably, a silylium cation stabilized by a three-center two-electron Si–C–B bond was isolated in the reaction of  $\text{Cl}(\text{Mes})\text{B-N}(\text{TMS})_2$  with  $\text{Ag}[pf]$ .<sup>90</sup> In addition, it was shown that the  $[pf]^-$  anion is very effective in performing silylium ion induced hydrosilylation and hydrodefluorination reactions at very low catalyst loadings down to 0.1 mol%.<sup>65</sup>

**A Stable  $[\text{Ar}_3\text{Ge}]^+[pf]^-$  Salt:** When changing to the larger and less electrophilic Ge atom in combination with larger aromatic ligands, a  $[\text{Ar}_3\text{Ge}]^+[pf]^-$  salt ( $\text{Ar} = 2,6\text{-(OtBu)}_2\text{C}_6\text{H}_3$ ) is straight forward to prepare (Eq. 10)<sup>167</sup>:

Trying to stabilize tin cations with the less stable  $[hf]^-$  aluminate with the smaller residue  $\text{C}(\text{H})(\text{CF}_3)_2$  led to decomposition by the intermediately prepared tin cation.<sup>168</sup>

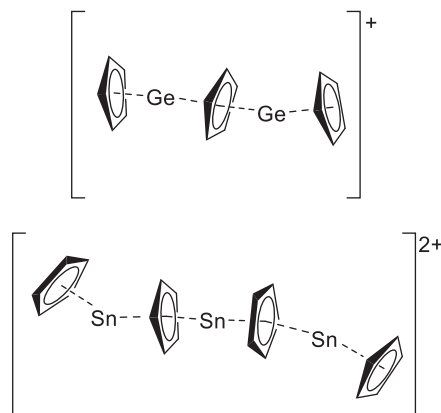

However, a masked  $[\text{R}_3\text{Sn}]^+$  cation was reported by Jäkle in 2013 in which a pyridine donor stabilizes the tin cation intramolecularly (Fig. 28).<sup>169</sup> Moreover, amine-stabilized tin cations  $[(^i\text{Pr})_3\text{Sn}(\text{L})]^+$  ( $\text{L} =$  quinuclidine, 2,4,6-collidine) were synthesized by anion exchange of the coordinating triflate anion in  $[(^i\text{Pr})_3\text{Sn}(\text{OTf})]$  with  $\text{K}[pf]$  in presence of the free amine ligands (Fig. 28).<sup>170</sup>

## 1.07.2.2.5 Low valent group 14 cations

**Jutzi's cation and derivatives:** The reactions of protonated ether  $[\text{H}(\text{OEt}_2)_2]^+$ .<sup>28</sup> with subvalent  $\text{Cp}^*\text{Si}$  and related Cp-derivatives led to the clean and simple formation of the silicocenium  $[\text{SiCp}^*]^+$  *nido*-cluster ion (Eq. 11).<sup>67</sup>

**Fig. 28** Structurally characterized tetra-valent tin cations stabilized with  $[pf]^-$ .

**Fig. 29** Multi-decker cations  $[\text{Sn}_3\text{Cp}_4]^{2+}$  and  $[\text{Ge}_2\text{Cp}_3]^+$  stabilized with  $[pf]^-$  and  $[alfal]^-$  respectively.

For the heavier tetrrels germanium and tin, even the *nido*-clusters  $[\text{MCp}]^+[\text{alfal}]^-$  with the sterically less-encumbering Cp ligands (Cp = C<sub>5</sub>H<sub>5</sub>, M = Sn,<sup>171</sup> Ge<sup>133</sup>) were made accessible by reacting  $\text{MCp}_2$  with 2 equivalents of  $\text{Me}_3\text{Si-F-Al}(\text{OR}^F)_3$  in weakly-coordinating solvents (Fig. 29). Addition of excess  $\text{MCp}_2$  to solutions of  $[\text{MCp}]^+[\text{alfal}]^-$  allowed for isolation of the multi-decker cations  $[\text{Sn}_3\text{Cp}_4]^{2+}[\text{pfl}]_2^-$ <sup>171</sup> and  $[\text{Ge}_2\text{Cp}_3]^+[\text{alfal}]^-$ .<sup>133</sup>

**Two-coordinate M(II) cations:** Two-coordinate M(II) cations (M = Si(II), Ge(II), Sn(II)) are widely investigated due to their diverse reactivity in particular towards small molecules (Fig. 30). An extensively used ligand class are the mono-anionic  $\beta$ -diketiminate ligands. The  $[(^{\text{Me}_2\text{N}}\text{BDI})\text{M}]^+[\text{pfl}]^-$  ( $^{\text{Me}_2\text{N}}\text{BDI} = \text{HC}\{(\text{Me}_2\text{N})\text{CN-2,6-}i\text{Pr}_2\text{C}_6\text{H}_3\}_2$ , M = Si, Ge, Sn) are accessible via chloride abstraction from the  $[(^{\text{Me}_2\text{N}}\text{BDI})\text{MCl}]$ .<sup>172</sup> For these heavier group 14 cations, a different reactivity towards amines was discovered. While the silicon-derivative reacted under oxidative addition into the N–H bonds, the heavier analogs did undergo Werner complex formation. Yet, cleavage of N–H bonds at a Ge cation could be achieved by combination of a cationic Ge<sup>II</sup> metal center with a C,N- and or P,N-ligands containing an amide function.<sup>173</sup> Moreover, the first isolable terphenyl-substituted germylium-ylidenes were reported as complex salts with  $[\text{pfl}]^-$  by Aldridge and co-workers.<sup>174</sup> Depending on the steric bulk of the ligands, the respective monomers or dimers were isolated (Fig. 30).

**Towards reactive one-coordinate M(II) cations:** Mono-coordinate group 14 cations are highly promising synthetic targets in main-group chemistry due to a postulated ambiphilic reactivity (Fig. 31). On the one hand these complexes are highly electrophilic due to the cationic charge and empty p-orbitals at the metal center, on the other hand the lone-pair at the low-valent metal retains an inherent nucleophilicity. On the way to an one-coordinate M(II) cation, Krossing and Jones prepared Ge(II) and Sn(II) cations stabilized by an extremely bulky amido ligand and the  $[\text{pfl}]^-$  anion.<sup>175</sup> Although being highly electropositive, the metal centers exhibit a weak intramolecular  $\eta^2$ -arene interaction (Fig. 31). Showing the high electro positivity of mono-coordinate M(II) cations, Wesemann and co-workers reported the isolation of the benzene-adduct of an terphenyl-ligated Sn(II)-cation (Fig. 31), accessible via reductive elimination of H<sub>2</sub> from the tin-hydride  $[\text{Ar}^*\text{SnH}_2]^+[\text{pfl}]^-$ .<sup>176</sup> In 2019, Hinz introduced a carbazole-ligand combining high bulkiness and electronic non-innocence. Cationic complexes of the carbazole with Ge, Sn and Pb were reported.<sup>177</sup> QTAIM analysis of the obtained complexes revealed a weak interaction between the *ipso*-C atoms of the arene substituents and the tetrrel cations. Finally, Hinz recently achieved the synthesis of the first mono-substituted silicon(II) cation via kinetic stabilization by

Fig. 30 Examples of two-coordinate M(II) cations stabilized with  $[\text{pfl}]^-$ .

Fig. 31 Examples for highly Lewis-acidic mono-coordinate tetrrel cations or their adducts stabilized with  $[\text{pfl}]^-$ .

a bulky carbazole.<sup>178</sup> The preparation was performed via reduction of the carbazole-SiI<sub>3</sub> adduct with Jones magnesium dimer and subsequent abstraction of the iodide from the halosilylene complex with Ag<sup>+</sup>[pf]<sup>-</sup> (Fig. 31). Reactivity of the isolated “supersilyene” towards <sup>t</sup>BuNH<sub>2</sub> resulted in formation of three bonds at the silicon center, hence confirming its nature as mono-coordinate Si(II) cation.

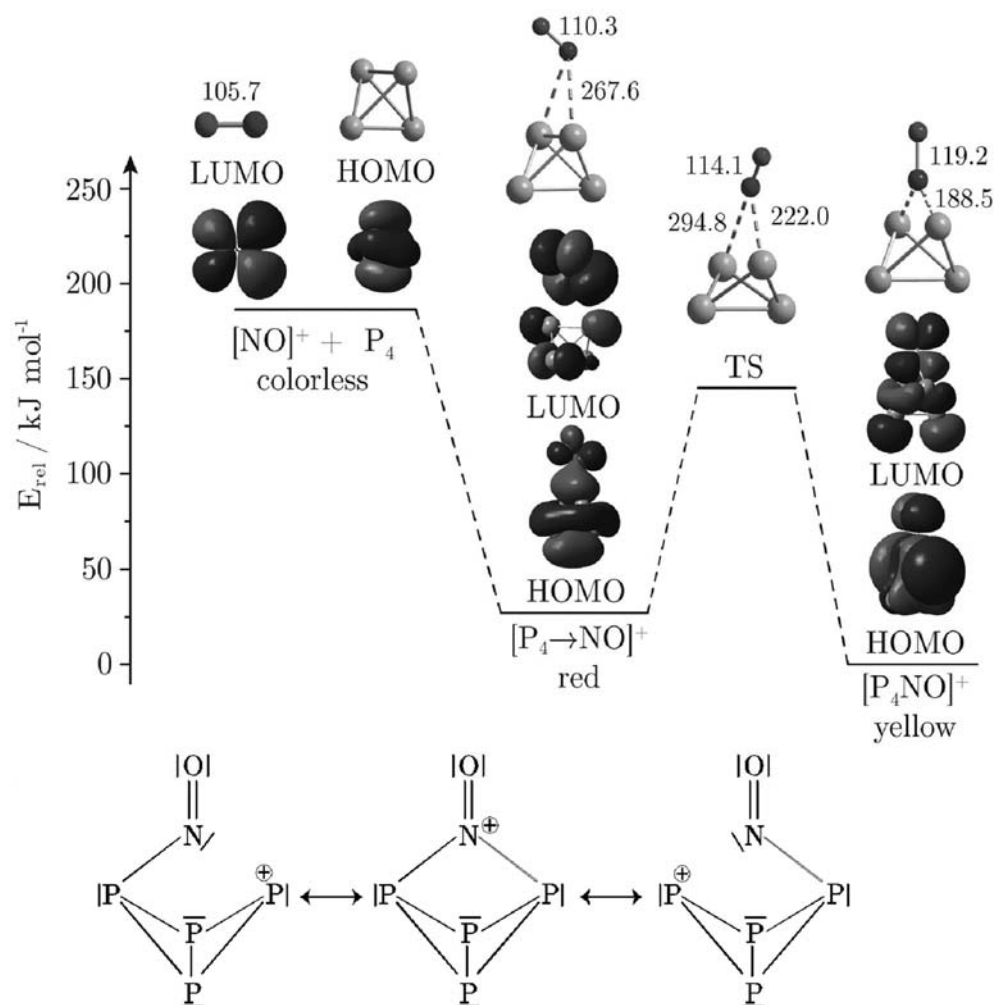

**Dicationic Sn(II) Salts:** Dicationic M(II) complexes stabilized with aluminate anions were hitherto only reported for tin. Here, oxidation of tin metal with NO<sup>+</sup>[pf]<sup>-</sup> in acetonitrile yielded the [Sn(MeCN)<sub>6</sub>]<sup>2+</sup>([pf]<sup>-</sup>)<sub>2</sub> complex.<sup>49</sup> Another route was discovered accidentally when dimethylaminopyridine was added to [SnCp]<sup>+</sup>[pf]<sup>-</sup> and [Sn(dmap)<sub>4</sub>]<sup>2+</sup>([pf]<sup>-</sup>)<sub>2</sub> was isolated.<sup>49</sup> Expanding the oxidation route, the innocent deelectronator [“phenazine”]<sup>+</sup>[pf]<sup>-</sup> (Table 2) was reacted with tin metal in the presence of acetonitrile or a tripyrazolylmethanide ligand to allow for isolation of the respective [Sn(MeCN)<sub>5</sub>]<sup>2+</sup>([pf]<sup>-</sup>)<sub>2</sub> and [Sn(CHpz<sub>3</sub>)<sub>2</sub>]<sup>2+</sup>([pf]<sup>-</sup>)<sub>2</sub>.<sup>55</sup>

### 1.07.2.2.6 Reactive group 15 cations: Phosphorus and some higher homologues

A variety of different homopolyatomic nonmetallic cations have been published and reviewed in detail.<sup>179</sup> Herein we want to highlight and complement cations that have been published using aluminate type WCAs. Phosphorus is an element that occurs in different modifications, although white phosphorus P<sub>4</sub> with its tetrahedral structure represents a frequently used starting point to obtain cations in condensed phase.

**Towards homopolyatomic Phosphorus Cations:** The reaction of [NO]<sup>+</sup> and [NO<sub>2</sub>]<sup>+</sup> salts of the [pf]<sup>-</sup> aluminates with white phosphorus P<sub>4</sub> lead to the [P<sub>4</sub>NO]<sup>+</sup> cage cation; while [NO]<sup>+</sup> inserts directly into P<sub>4</sub>, [NO<sub>2</sub>]<sup>+</sup> is first reduced by P<sub>4</sub> to [NO]<sup>+</sup> and then reacts accordingly in an orbital controlled reaction (Fig. 32).

From the spectroscopic and structural data as well as the first reaction chemistry of the [P<sub>4</sub>NO]<sup>+</sup> cluster cation it followed that only the left and the right phosphonium-structure in Fig. 32 are relevant, but *not* the central iminium structure. In agreement with

**Fig. 32** The orbital controlled pathway to the  $[\text{P}_4\text{NO}]^+$  cation and the primary VB structures accounting for the charge delocalization and further “P<sup>+</sup>” reactivity.<sup>52</sup>

this, the  $[P_4NO]^+$  cluster cation served as a  $P^+$ -source upon reaction with two equivalents of  $PPh_3$  giving exclusively the  $[Ph_3P-P-PPh_3]^+$  triphosphenium cation.<sup>52</sup>

With further equivalents of white phosphorus the first condensed-phase homopolyatomic phosphorus cation  $[P_9]^+$  was prepared using a combination of the oxidant  $[NO]^+$  and weakly coordinating anion.  $[P_9]^+$  consists of two  $P_5$  cages linked by a phosphonium atom to give a  $D_{2d}$ -symmetric Zintl cluster. NMR, Raman, and IR spectroscopy, mass spectrometry, and quantum-chemical calculations confirmed the structure.<sup>180</sup> Recently the conversion of  $P_4$  using  $Ga(Ga_2Cl_7)$  or  $[Co(arene)_2][pf]$  (arene = *o*-difluorobenzene, fluorobenzene) or  $[NO][alfal]$  disclosed new pathways towards  $[P_9]^+$  including its structural characterization. Quantum chemical ccsd(t)-calculations suggest that  $[P_9]^+$  formation from  $[Co(arene)_2]^+$  occurs via the *nido*-type cluster  $[(arene)CoP_4]^+$ , which resembles the isoelectronic elusive  $[P_5]^+$ .<sup>[181]</sup>

**Related *nido*-Cations:** Along similar lines to those intermediates as well as to  $[P_4NO]^+$ , one finds the cationic cages *nido*- $[C_2^tBu_2P_2E]^+$  ( $E = P, As, Sb$ ), which are isolobal to the cyclopentadienyl or the pentaphosphorus cation, to adopt square based pyramidal structures with the heavy pnictogen atom at the apex (Fig. 33). *Inter alia*, they were stabilized by  $[pf]^-$  type WCAs.<sup>182</sup>

NMR and computational methods have been used to probe the dynamic behavior of the complexes. Related to this reaction is the abstraction of a  $Cl^-$  ion from the 1-chlorophospholes  $R_4C_4PCl$  ( $R = Me, Et$ ): It produced the P–P bonded cations  $[R_4C_4P-P(Cl)C_4R_4]^+$ , which undergo nucleophilic substitution with  $PPh_3$  to afford the triphenylphosphine analogs,  $[R_4C_4P-PPh_3]^+$ , isolated as triflate,  $[pf]^-$  aluminate, carbadodecaborate and tetrachlorogallate salts and characterized by XRD. Examination of the  $^{31}P\{^1H\}$  NMR spectrum of  $[Et_4C_4P-PPh_3]^+$  and  $PPh_3$  revealed broadening of the resonances due to both free and coordinated  $PPh_3$ . Second-order kinetics consistent with an unusual  $SN_2$ -type pathway was established. Probably, the high electrophilicity of the phosphorus center in the *nido*- $[Et_4C_4P]^+$  cation, combined with strong pi-pi interactions between the ring and the incoming and outgoing Ph groups of  $PPh_3$ , favors the  $SN_2$ -type over the  $SN_1$ -type pathway in  $[Et_4C_4P-PPh_3]^+$ .<sup>183</sup>

**Mixed Arsenic Phosphorus Cations:** The synthesis of mixed arsenic phosphorus cations was investigated on theoretical and experimental grounds by replacing  $P_4$  with  $AsP_3$  in the known syntheses of  $[P_4NO]^+$  and  $[P_9]^+$ . Calculations of  $[AsP_3NO]^+$  and  $[AsP_8]^+$  showed that 1- $[AsP_3NO]^+$  and 3- $[AsP_8]^+$  should be the most stable isomers. However, 2- $[AsP_3NO]^+$  was prepared by reacting  $[NO]^+[pf]^-$  with  $AsP_3$  with a regioselectivity of 45:1. The kinetic control of this reaction was proven by calculation of the complete reaction mechanism. Examination of the formation energetics of the  $[As_xP_{4-x}NO]^+$  ( $x = 0, 1, 4$ ) and  $[As_xP_{9-x}]^+$  ( $x = 0, 1, 9$ ) cations at the CCSD(T)/complete basis set limit level showed that for  $[As_xP_{4-x}NO]^+$  ( $x = 0, 1, 4$ ), the replacement of phosphorus by arsenic leads to more exergonic formation energetics. For the  $[As_xP_{9-x}]^+$  clusters ( $x = 0, 1, 9$ ), the reaction to  $[AsP_8]^+$  is slightly more exergonic compared to the synthesis of  $[P_9]^+$ . The calculation of the reaction to the homopolyatomic arsenic cation  $[As_9]^+$  suggested that this reaction will at least be very difficult. Attempts to prepare  $[As_xP_{9-x}]^+$  from  $AsP_3$  as well as  $[As_x]^+$  from gray arsenic led to the formation of  $[AsP_3NO]^+$ ,  $[P_4NO]^+$ ,  $[P_9]^+$  and  $P_4$  in case of  $[As_xP_{9-x}]^+$  and decomposition products (e.g., novel  $As(OR^F)_3$ ) for  $[As_x]^+$ .<sup>184</sup>

**Arylphosphine Radical Cations and Dications:**  $[pf]$ -Salts containing triarylphosphine radical cations  $[(Mes)P(Trip)_2]^{\bullet+}$  and  $[P(Trip)_3]^{\bullet+}$  ( $Mes = 2,4,6$ -trimethylphenyl;  $Trip = 2,4,6$ -triisopropyl) have been isolated and characterized by electron paramagnetic resonance (EPR) and UV/Vis absorption spectroscopy as well as scXRD. Radical  $[(Mes)P(Trip)_2]^{\bullet+}$  exhibits a relaxed pyramidal geometry, while radical  $[P(Trip)_3]^{\bullet+}$  becomes fully planar. EPR studies and theoretical calculations showed that the introduction of bulky aryl groups leads to enhanced p character of the singly occupied molecular orbital, and the radicals become less pyramidalized or fully flattened.<sup>185</sup> Furthermore  $[pf]$ -salts of tetraaryldiphosphine radical cation  $[(Trip)_2P=P(Trip)_2]^{\bullet+}$  and dication  $[(Trip)_2P=P(Trip)_2]^{2+}$  have been isolated and were structurally characterized.  $[(Trip)_2P=P(Trip)_2]^{\bullet+}$  has a relaxed pyramidal geometry, while dication  $[(Trip)_2P=P(Trip)_2]^{2+}$  prefers a planar, olefin-like geometry with a two-electron  $\pi$  bond. The alteration of the geometries of the tetraaryldiphosphine upon oxidation is rationalized by the nature of the bonding. The EPR spectrum showed that the spin density of the radical  $[(Trip)_2P=P(Trip)_2]^{\bullet+}$  is mainly localized on phosphorus atoms, which is supported by theoretical calculation.<sup>186</sup>

**Phosphorus-Containing Four-Membered Ring Radical Cations:** Two phosphorus-containing four-membered ring radical cations (Fig. 34) have been isolated and characterized by UV-vis absorption spectroscopy, electron paramagnetic resonance (EPR), and single-crystal X-ray diffraction. Compared with neutral molecules, the radical cation of cyclotetraphosphine has elongated P–P

Fig. 33 The structure of the *nido*- $[C_2^tBu_2P_2]_3^+$  cation.

Fig. 34 Radical cations of cyclotetraphosphine and cyclodiphosphazane.

bonds and more pyramidalized phosphorus atoms, while shortened P–N ring distances and larger angles around phosphorus centers are observed for the radical cation of cyclodiphosphazane. EPR studies indicate that for the radical cation of cyclotetraphosphine the spin density mainly resides on the exocyclic nitrogen atoms with very minor contribution from endocyclic phosphorus atoms, while the situation is opposite for the radical of cyclodiphosphazane. Such an inverse spin density distribution is controlled by the exocyclic substituents, which is supported by DFT calculations.<sup>187</sup>

*N,N*-Bis(terphenyl)aminophosphenium Cations: A series of salts that contain the terphenyl-substituted bis(amino)phosphenium cation with different anions including  $[hf]^-$  have been prepared by different synthetic protocols. All of the products have been characterized spectroscopically and by scXRD studies. A detailed analysis of the interionic interactions and their influence on the molecular structure of the phosphenium cation reveals a strong dependence on the capability of the anion to enter the pocket generated by the bulky terphenyl substituents.<sup>188</sup>

*Phosphaalkene radical cations*: Two phosphaalkene radical cations  $[\text{Mes}^*\text{P}=\text{C}(\text{NMe}_2)_2]^{\bullet+}$  and the fluorene based phosphaalkene  $[\text{Mes}^*\text{P}=\text{C}(\text{C}_6\text{H}_3^t\text{Bu}_2)_2]^{\bullet+}$  have been reported with  $[pf]^-$  as counter-ion.  $[\text{Mes}^*\text{P}=\text{C}(\text{NMe}_2)_2]^{\bullet+}$  is stable in the solid state and has been structurally characterized and can be described as phosphorus-centered radical.  $[\text{Mes}^*\text{P}=\text{C}(\text{C}_6\text{H}_3^t\text{Bu}_2)_2]^{\bullet+}$  only remains persistent in solution and has a delocalized radical character with little contribution from phosphorus.<sup>189</sup>

*Phosphonium Cations*: A series of catecholato phosphonium ions, including the first stable bis(catecholato)-substituted derivatives, were isolated and fully characterized. The cations rank among the most potent Lewis acids on the Gutmann-Beckett and ion affinity scales. In contrast to halogenated or multiply charged phosphorus cations, Lewis superacidity is imparted by structural constraints, as disclosed by energy decomposition analyses. The modular access provides a tunable scaffold while maintaining extreme affinities, as demonstrated by the synthesis of a chiral Lewis superacid. The combination of electrophilic phosphorus and basic oxygen substituents leverages new reactivity modes by phosphorus-ligand cooperativity. With this, a phosphorus-mediated C–H bond activation was accomplished.<sup>190</sup>

*Pnictocenium cations*: Complementing the already known pnictocenium salts  $[(\text{Cp}^*)_2\text{Pn}]^+$  (Pn = As,<sup>191</sup> Sb,<sup>192</sup> Bi,<sup>193</sup>), structural characterization of  $[(\text{Cp}^*)_2\text{P}]^+$  has been achieved with the chloride equivalent WCA  $[\text{ClAl}(\text{OR}^{\text{PF}})_3]$  and  $[(\text{R}^{\text{PF}}\text{O})_3\text{Al}-\text{Cl}-\text{Al}(\text{OR}^{\text{PF}})_3]$  via halide abstraction from the respective halopnictines with the Lewis superacid  $\text{PhF}-\text{Al}(\text{OR}^{\text{PF}})_3$ . Furthermore the chloropnictocenium salts  $[\text{Cp}^*\text{P}^+\text{Cl}]^+$ ,  $[\text{Cp}^*\text{As}^+\text{Cl}]^+$  have been prepared with those WCAs. The X-ray crystal structures of these cations established that in the half as well as in the sandwich cations the  $\text{Cp}^*$  rings are attached in an  $\eta^2$ -fashion.<sup>194</sup> Also the antimony analogue  $[(\text{Cp}^*)_2\text{Sb}]^+$  has been synthesized using  $[pf]^-$ .<sup>195</sup>

Stable acyclic arsenium cations like  $[(\text{Cp}^*)_2\text{As}]^+$  are rare in comparison to the corresponding phosphenium cations. The first example of a diphosphaarsenium salt,  $\{[(\text{Dipp})_2\text{P}]_2\text{As}\}[pf]$  exhibits remarkable stability due to the delocalization of a lone pair from a planar phosphorus center into the vacant p-orbital at arsenic; the bonding has been probed by DFT calculations.<sup>196</sup> In 2015 Chloro-pnictocenium cations of the type  $[\text{R}^{\text{Ar}^*}\text{N}(\text{SiMe})\text{ECl}][hf]$  were published ( $\text{R}^{\text{Ar}^*} = 2,6\text{-}(\text{CHPh}_2)\text{-4-R-C}_6\text{H}_4$ , R=Me, *t*Bu; E=Sb, Bi).<sup>197</sup>

Fig. 35 Structure of the  $[\text{EP}_3]^+$  cations (E = S, Se, Te) and  $^{31}\text{P}$  NMR spectra.

**Binary Phosphorus-Chalcogen Cations and heavier homologues:** While neutral tetrahedral structures ( $P_4$ ,  $AsP_3$ ) are well known, cationic structures remained elusive until first experimental evidence  $[EP_3]^+$  ( $E = S, Se, Te$ ) in the condensed phase was achieved through the reaction of  $ECl_3[A]$  ( $[A] = [pf]^-$  or  $[alfal]^-$ ) with white phosphorus (Fig. 35). Previously,  $[EP_3]^+$  was only known from gas phase MS investigations. By contrast, the reaction of  $ECl_3[A]$  with the known  $[P_3]^{3-}$  synthon  $Na[Nb(ODipp)_3(P_3)]$  (enabling  $AsP_3$  synthesis), led to formation of  $P_4$ . The cations  $[EP_3]^+$  were characterized by multinuclear NMR spectroscopy in combination with high-level quantum chemical calculations. Their bonding situation is described with several approaches including Atoms in Molecules and Natural Bond Orbital analysis.<sup>137</sup>

Another mixed group 15–16 cage cation resembles  $[As_3S_4]^+$  and  $[As_3Se_4]^+$ , which were obtained by the reaction of  $As_4S_4$  with the Lewis acids and oxidants  $AsF_5$  and  $SbF_5$ .<sup>198</sup> Oxidation with  $Ag[pf]$  in *o*DFB resulted in the analogous  $[pf]^-$ -salt.<sup>199</sup> The one-electron deelectronation of main-group heteronuclear species  $Nap(SPh)(P(Mes)_2)$  (1),  $Nap(SePh)(P(Mes)_2)$  (2),  $Nap(-SPh)(As(Mes)_2)$  (3) and  $Nap(SePh)(As(Mes)_2)$  (4) ( $Nap = naphthalin$ ) with  $NO[pf]$  produced persistent radical cations  $1\bullet^+ - 4\bullet^+$  in solution. DFT calculations indicate large amounts of spin densities over heteroatoms and the formation of  $2c-3e^-$   $\sigma$ -bonds between chalcogen and pnictogen atoms.<sup>200</sup>

**Binary Phosphorus-Halogen Cations:** In the course of our investigations directed to the preparation of the at that time still unknown homopolyatomic phosphorus cations we—fortuitously—found a simple approach to generate new binary phosphorus halogen cations. When we began our investigations in 2001,<sup>201–203</sup> the knowledge on cationic or neutral binary P-X-species, where X may be F, Cl, Br, I, was sparse and limited to  $P^VX_5$  ( $X = F, Cl$ ),  $[P^VX_4]^+$  ( $X = F-I$ ),  $P^{III}X_3$  ( $X = F-I$ ),  $[P^{III}_2I_5]^+$ ,  $P^{II}X_4$  ( $X = F, Cl, I$ ) and  $P_3X_5$  ( $X = F, I$ ) (Fig. 36).

Solution studies showed the additional existence of small amounts of the phosphorus rich cage molecules  $P_4Br_2$  and  $P_7I_3$  in  $CS_2$  solutions of  $P_4$  and  $X_2$  mixtures ( $X = Br, I$ ). Structural data of the cations was only available for  $[PX_4]^+$  ( $X = Cl-I$ ) and  $[P_2I_5]^+$ .

Binary phosphorus-iodine cations are very electrophilic and  $[P_2I_5]^+$  immediately decomposed the  $[EF_6]^-$  counterions, when prepared from  $P_2I_4$  and  $I_3^+[EF_6]^-$  ( $E = As, Sb$ ) at  $-78^\circ C$ .<sup>204</sup> This kind of decomposition can be avoided by the use of the weakly basic  $[pf]^-$  anion. Thus, a silver-salt metathesis of  $Ag[pf]$  with  $PX_3$  resulted in the formation of the highly reactive “ $[X_2P-X-Ag]^+$ ”—perhaps the closest possible approximation to the still unknown free “ $[PX_2]^+$ ” intermediates—which were previously only investigated in the gas phase. Probably the active ingredient of such reactions is the  $[(CH_2Cl_2)Ag-X-PX_2]^+$  cation shown in Fig. 37.<sup>205</sup>

**Fig. 36** Previously known<sup>201,202</sup> neutral or cationic binary P-X-species ( $X = F, Cl, Br, I$ ) prior to our work in 2001; note that some compounds only exist with one type of X.

**Fig. 37** Frontier orbitals of  $[(CH_2Cl_2)Ag-Br-PBr_2]^+$ —the hypothetical source of the “ $[PX_2]^+$ ” intermediate.

This formal "[PX<sub>2</sub>]<sup>+</sup>" equivalent is a good [PX<sub>2</sub>]<sup>+</sup> source and reacted with X<sub>2</sub>, PX<sub>3</sub> and P<sub>4</sub> to quantitatively give stable but highly electrophilic and soluble [PX<sub>4</sub>]<sup>+</sup>, [P<sub>2</sub>X<sub>5</sub>]<sup>+</sup>, phosphorus rich [P<sub>5</sub>X<sub>2</sub>]<sup>+</sup>, as well as subvalent [P<sub>3</sub>I<sub>6</sub>]<sup>+</sup> salts of the weakly basic [pf]<sup>-</sup> anion (Fig. 38).

Thus, the preparation of [PX<sub>4</sub>]<sup>+</sup>-salts (X = Br, I) with the [pf]<sup>-</sup> counterion is possible.<sup>201</sup> This reaction was extended to the [AsBr<sub>4</sub>]<sup>+</sup>-salt.<sup>206,207</sup> These solid [EX<sub>4</sub>]<sup>+</sup>-salts are stable at room temperature for days. This stability may be contrasted by the absence of experimental evidence for PI<sub>5</sub> and AsBr<sub>5</sub>, while AsCl<sub>5</sub> decomposes already at about -50 °C.<sup>208</sup> Similarly solid PI<sub>4</sub><sup>+</sup>[MF<sub>6</sub>]<sup>-</sup> (M = As, Sb) decomposes already at 0 °C.<sup>209</sup>

Using two equivalents of PX<sub>3</sub> for the reaction, [P<sub>2</sub>X<sub>5</sub>]<sup>+</sup>-salts (X = Br, I) and the mixed [I<sub>2</sub>P-AsI<sub>3</sub>]<sup>+</sup> were prepared.<sup>201,206</sup> Dissolved [P<sub>2</sub>X<sub>5</sub>]<sup>+</sup> is fluxional on the time scale of <sup>31</sup>P NMR spectroscopy and disproportionates for X = I into reduced [P<sub>3</sub>I<sub>6</sub>]<sup>+</sup> and an oxidized species that was assigned as [PI<sub>4</sub>]<sup>+</sup>.<sup>201</sup> [P<sub>2</sub>Br<sub>5</sub>]<sup>+</sup> is even more fluxional than [P<sub>2</sub>I<sub>5</sub>]<sup>+</sup> and is probably in equilibrium with [PBr<sub>2</sub>(CH<sub>2</sub>Cl<sub>2</sub>)]<sup>+</sup> and PBr<sub>3</sub> (Fig. 39).

Due to this equilibrium, [P<sub>2</sub>Br<sub>5</sub>]<sup>+</sup> serves as a "[PBr<sub>2</sub>]<sup>+</sup>" source and reacts with insertion into the P<sub>4</sub> cage to give [P<sub>5</sub>Br<sub>2</sub>]<sup>+</sup> and PBr<sub>3</sub>.<sup>201,202</sup> However, the amount of free [EX<sub>2</sub>]<sup>+</sup> available in the equilibrium in Fig. 39 is highest for the (hypothetical) [As<sub>2</sub>Br<sub>5</sub>]<sup>+</sup>. Therefore, we did not succeed to prepare an [As<sub>2</sub>Br<sub>5</sub>]<sup>+</sup> salt but rather observed the immediate decomposition of the counterion due to the [AsBr<sub>2</sub>(CH<sub>2</sub>Cl<sub>2</sub>)]<sup>+</sup> readily available in the equilibrium.<sup>206,207</sup>

Unlike other oxidative methods, the silver salt metathesis approach also allowed to stabilize reduced subvalent cations. Thus, the interaction of the "[PI<sub>2</sub>]<sup>+</sup>" intermediate with P<sub>2</sub>I<sub>4</sub> results in formation of the subvalent [P<sub>3</sub>I<sub>6</sub>]<sup>+</sup> cation<sup>203</sup> (av. valency: 2.33), a derivative of the poorly characterized P<sub>3</sub>I<sub>5</sub>. The solid-state structure of [P<sub>3</sub>I<sub>6</sub>]<sup>+</sup>[*alal*]<sup>-</sup> (R<sup>F</sup> = C(CF<sub>3</sub>)<sub>3</sub>) is known, [P<sub>3</sub>I<sub>6</sub>]<sup>+</sup>[pf]<sup>-</sup> is only marginally stable in the solid state.

The synthesis of [P<sub>5</sub>X<sub>2</sub>]<sup>+</sup> (X = Cl,<sup>16</sup> Br,<sup>202</sup> I<sup>201,203</sup>) salts with [pf]<sup>-</sup> revealed that the "[PX<sub>2</sub>]<sup>+</sup>" intermediate likely reacts with insertion into the P-P bond of P<sub>4</sub>. The [P<sub>5</sub>X<sub>2</sub>]<sup>+</sup> cations are the first phosphorus rich binary P-X cations known and include a prior

Fig. 38 Reactions of the "[PX<sub>2</sub>]<sup>+</sup>" intermediate. For [P<sub>3</sub>X<sub>6</sub>]<sup>+</sup>, X may be I, for [P<sub>2</sub>X<sub>5</sub>]<sup>+</sup> Br and I, for the rest X = Cl-I.

Fig. 39 Proposed mechanism for the formation of the [P<sub>2</sub>X<sub>5</sub>]<sup>+</sup> cations.

Fig. 40 Possible insertion- or coordination-sites of the P<sub>4</sub>S<sub>3</sub> cage.

unknown  $C_{2v}$ -symmetric  $P_5$ -cage. The solid-state structure of  $[P_5Br_2]^+[pf]^-$  is also known. In the meantime more than 30 structures with this cage are known, mainly by the work of Jan Weigand et al.<sup>210,211</sup>  $[P_5X_2]^+$  resembles a fraction of the known homopolyatomic phosphorus cation  $[P_9]^+$  and contains the hitherto elusive " $[P_5]^+$ ".<sup>180</sup> However, isolobal analogs of this substance class are known (see above).

**Ternary Phosphorus Cations:** To further investigate the nature of the formal " $[PX_2]^+$ " equivalent, a substrate with a limited number of bonds eligible for insertion or atoms available for coordination was chosen<sup>205</sup>: The  $P_4S_3$  cage in the nortricyclane-structure. Fig. 40 shows the possible sites for simple insertion and/or coordination.

However, nature rendered these initial thoughts useless: The system apparently prefers the orbital controlled addition of a P–X bond of the formal " $[PX_2]^+$ " equivalent to the basal P–P bond of the  $P_4S_3$  cage giving initially at  $-78^\circ\text{C}$  the  $[P_5S_3X_2]^+$  cation (X = Br, I; Fig. 41).<sup>205</sup>

The  $[P_5S_3X_2]^+$  cation intermediate (NMR) disproportionates upon warming to  $-20^\circ\text{C}$  with separation of tentatively assigned  $P_6X_6$  giving the  $[P_4S_4X]^+$  (NMR, IR, Raman) and the  $[P_5S_2X_2]^+$  (XRD, NMR, IR, Raman) cations.<sup>205</sup> From this work it was clear that mixed P–S–X cations are accessible. Therefore, the reaction of  $P_4S_3I_2$  in its  $\alpha$ - and  $\beta$ -form with the silver aluminates was investigated.<sup>212</sup> The two main group cages may be coupled by a  $Ag^+$  ion:  $P_4S_3I_2$  is ionized by  $Ag^+$  to sulfonium  $[P_4S_3I]^+$  that reacts with another  $P_4S_3I_2$  molecule either to give an iodophosphonium  $[P_4S_3I_3]^+$  (NMR simulated and assigned) and  $P_4S_3$  or to give several isomers of a metastable compound that probably is  $[P_8S_6I_3]^+$ . The intermediate likely loses  $1/n(PI)_n$  and forms the spirocyclic  $P_7S_6I_2^+$  phosphonium cation (Fig. 42), which includes the largest hitherto characterized P–S cage and the first example of main

**Fig. 41** Orbital controlled<sup>205</sup> addition of the P–X bond of the formal " $[PX_2]^+$ " equivalent (=  $[(CH_2Cl_2)Ag-X-PX_2]^+$ ) to the basal P–P bond of the  $P_4S_3$  cage giving initially at  $-78^\circ\text{C}$  the  $[P_5S_3X_2]^+$  cation, which then disproportionates with separation of  $P_6X_6$  giving the  $[P_4S_4X]^+$  and the  $[P_5S_2X_2]^+$  cations (X = Br, I).

**Fig. 42** Reaction of  $Ag^+$  with the  $P_4S_3I_2$  molecules: Intermediate formation of  $[P_4S_3I_x]^+$  (x = 1, 3) and disproportionation to  $[P_7S_6I_2]^+$  (XRD), the largest P–S cage known to date incorporating the first cages that are coupled through a phosphonium center.<sup>212</sup>

group cages connected through a phosphonium center, which was successfully achieved towards homopolyatomic phosphorus cation  $[P_9]^+$  (see above).<sup>180,212</sup>

*Decomposition of the Less Stable Aluminate WCAs:* When using the less stable aluminate  $[hf]^-$  to stabilize phosphazanium cations, the anion reacted with the cation intermediate and served as a clean source of the  $OC(H)(CF_3)_2$  alkoxide.<sup>213</sup>

### 1.07.2.2.7 Reactive group 16 cations

*$[ChX_3]^+$  cations:*  $[ChX_3]^+$  cations (Ch = S, Se, Te) were already reported in 1954.<sup>214</sup> Since they were often obtained via solvothermal syntheses and show poor solubility in many solvents, other counterparts are needed, making these cations suitable starting materials for further chemistry. In 2012  $[TeX_3]^+$  cations (X = Cl, Br, I) were obtained by halide abstraction with  $Ag[pf]$  in liquid  $SO_2$ .<sup>215</sup> Except for  $[SI_3]^+$ , which remained elusive, all  $[ChX_3]^+$  cations (Ch = S, Se) stabilized with  $[pf]^-$  as well as  $[alfal]^-$ .<sup>137</sup>

Upon reacting  $SeCl_4$  with  $Me_3Si-F-Al(OR^F)_3$ , unexpected methylation was observed and the selenonium salt  $SeMeCl_2[alfal]$  was obtained and thoroughly characterized. The only previous example of a salt with the  $[SeMeCl_2]^+$  cation is  $SeMeCl_2[SbCl_6]$ , which was never structurally characterized and is unstable in solution over hours.<sup>216</sup>

*Organic sulfur radical cations and heavier homologues:* Sulfur radical cations are key intermediates in biological processes and organic reactions and claim an important role in materials science. Two different classes are observed, either where the electron is  $\pi$ -delocalized over one or more sulfur atoms containing heterocyclic rings, or where the unpaired electron resides on sulfur 3p-orbitals. To obtain these radical cations a typical starting point is the neutral compound, which is then deelectronated with  $NO[pf]$  or other innocent oxidizers. A series of radical cations respectively their neutral starting molecules I-L that have been published are shown in Fig. 43.

Using silver salts of smaller WCAs ( $[BF_4]^-$ ,  $[SbF_6]^-$ ) to deelectronate  $BP_nT$  ( $n = 1-3$ ) (I) led either to no reaction or to insoluble solids. By contrast, deelectronation with  $Ag[pf]$  resulted in the sought for radical cations, which led in case of  $[BP_2T]^+$  to meso-helical stacking.<sup>217</sup> Also radical cations and dications of tetrathiafulvalene (J) derivatives were obtained via deelectronation with  $Ag[pf]$ .<sup>218,219</sup> With *in-situ* generation of  $NO[pf]$  from  $NO[SbF_6]$  and  $Li[pf]$ , a dithiophene dication that enabled temperature controlled covalent connection and disconnection was obtained.<sup>220</sup>

Also, p-localized sulfur and selenium radical cations are known.  $[Nap(SPh)_2]^+$  formed an unusual sulfur-sulfur three electron  $\sigma$ -bond. In contrast,  $[Nap(SPh)(Se(Ph))]^+$  dimerized in the solid state and formed a S-Se bond (K).<sup>221</sup>

Extension towards tetrachalcogenides (L) showed that two-electron deelectronation formed a closed-shell singlet ground state for sulfur with a quinoidal backbone while for selenium a diradical dication was obtained.<sup>222</sup> Another diradical dication was obtained via deelectronation of a pyrene derivative.<sup>223</sup> Just recently a sulfur tri-cation that contain three radicals resulting in an excited quartet state was published and stabilized with  $[pf]^-$ .<sup>224</sup>

### 1.07.2.2.8 Lanthanide and actinoid complexes

*Synthesis, Structures and Characterizations of Homoleptic Acetonitrile  $Ln^{3+}$  Complexes:* Total halide abstraction from  $LnCl_3$  by  $Ag[pf]/CH_3CN$  yielded  $[Ln(CH_3CN)_n][pf]_3$  ( $n = 9$ ,  $Ln^{3+} = Nd, Eu, Gd, Dy$ ;  $n = 8$ ,  $Ln^{3+} = Tm$ ) complexes.<sup>50</sup> Both in the solid state (X-ray, IR and Raman spectroscopy) and in acetonitrile solution (conductivity, EPR and NMR measurements) the  $[pf]^-$  anion coordinates very weakly to the  $Ln^{3+}$  ions. Lanthanides at the beginning (Nd) and the middle (Eu, Gd, Dy) of the Ln series are typically nine-coordinated, with a mono-capped square antiprismatic arrangement of the N donor atoms around the metal centers. Homoleptic eight-coordinated acetonitrile species are characteristic for those from the end of the series (Tm). Conductivity measurements revealed 3:1 electrolyte types for these species in acetonitrile. EPR and  $^{19}F$  NMR line broadening measurements suggest that the lanthanide complexes are free of any  $[pf]^-$  anion coordinating.<sup>50</sup>

Fig. 43 Selection of different sulfur and selenium compounds and radical cations that have been characterized.

**Fig. 44** Molecular structure of  $[\{\text{Ln}(\text{Cp}^*)_2(\mu\text{-Me}_3\text{AlNEt}_3)_2\}][\text{pf}]_2$  ( $\text{Ln} = \text{Dy}, \text{Y}$ ).<sup>226</sup> The  $[\text{pf}]^-$  counteranions are not shown for clarity.

*A Dysprosium Metallocene Dimer:* Replacing half of the  $[\text{BPh}_4]^-$  anions by  $[\text{pf}]^-$  in the dysprosium metallocene  $\text{DyCp}^*_2\text{BPh}_4$  results in the first example of  $[\text{BPh}_4]^-$  acting as a bridging ligand in 4f metal complexes.<sup>225</sup> The dimer shows improved slow relaxation of the magnetization compared to its mononuclear congener, resulting in waist-restricted hysteresis up to 6.5 K.<sup>225</sup>

*A Double-Dysprosocenium Single-Molecule Magnet:* Weak interactions between  $[\text{Dy}(\text{Cp}^*)_2]^+$  fragments and neutral  $\text{NEt}_3\text{AlMe}_3$  molecules have been observed in a dinuclear dysprosocenium dication with a  $[\text{pf}]^-$  counterion (Fig. 44).<sup>226</sup> These equatorial interactions perturb the axiality of the  $\text{Dy}^{3+}$  crystal fields. A magnetic hysteresis up to 12 K and relatively large effective barrier to magnetization reversal of  $860(60) \text{ cm}^{-1}$  are reported for this compound.<sup>226</sup> The synthesis of an isostructural Yttrium complex has also been reported, along with a doped Y/Dy system.<sup>226</sup>

*A Bis-Monophosphohyl Dysprosium Cation:* Bis-cyclopentadienyl lanthanide sandwich complexes are promising candidates for single-molecule magnets (SMMs) that show magnetic memory at ca. 77 K.<sup>227</sup> However, the relaxation mechanisms mediated by aromatic  $\text{C}_5$  rings are not fully understood yet. A bis-monophosphohyl dysprosium SMM  $[\text{Dy}(\text{Dtp})_2][\text{pf}]$  ( $\text{Dtp} = [\text{P}(\text{C}^i\text{BuCMe})_2]$ ) has been synthesized by the treatment of in situ prepared “ $[\text{Dy}(\text{Dtp})_2(\text{C}_3\text{H}_5)]$ ” with  $[\text{HNEt}_3][\text{pf}]$ .<sup>227</sup> The Dysprosium-*pf* salt shows magnetic hysteresis up to 48 K and an effective barrier to magnetization reversal of 1760 K ( $1223 \text{ cm}^{-1}$ ).<sup>227</sup> The preparation and analysis of this compound allows to improve the understanding of relaxation processes in bis- $\text{C}_5/\text{C}_4\text{P}$  sandwich lanthanide SMMs, which is pivotal for rationally achieving higher magnetic blocking temperatures in these systems.

*A  $\beta$ -diketiminate Uranium Complex:* A homoleptic, octahedral  $\text{U}^{\text{III}}$  complex  $[\text{U}^{\text{III}}(\text{NacNac}^{\text{Ph}})_3]$  ( $\text{NacNac}^{\text{Ph}-} = [\text{PhNC}(\text{CH}_3)_2\text{CH}^-]$ ) was obtained after transmetalation of the alkali metal  $\beta$ -diketiminate salts  $[\text{M}][\text{NacNac}^{\text{Ph}}]$  ( $\text{M}^+ = \text{Na}^+$  or  $\text{K}^+$ ) with  $\text{U}(\text{THF})_4$ . Oxidation with mild oxidants, such as  $[\text{FeCp}_2][\text{pf}]$ , yields the discrete  $\text{U}^{\text{IV}}$  salt  $[\text{U}^{\text{IV}}(\text{NacNac}^{\text{Ph}})_3][\text{pf}]$ .<sup>228</sup>

### 1.07.2.3 Complexation of weak ligands: Coordination compounds of the transition metals stabilized by $[\text{pf}]^-$ aluminates

*Anion Effects:* To stabilize weakly-bound Lewis acid-base adducts of the type presented in this section, anion-cation as well as solvent-cation interactions have to be minimized and must be smaller in magnitude than the interaction with the weakly basic ligand. The influence of the counterion may be illustrated by the following series of silver complexes in (i) and (ii); here the univalent silver cation serves as a prototype for any weak acceptor:

- (i) *role of the counterion:* From the determined solid-state structures it is evident that  $[\text{Al}(\text{OR}^{\text{F}})_4]^-$  anions with  $\text{R}^{\text{F}} = \text{C}(\text{H})(\text{CF}_3)_2$  and  $\text{C}(\text{CH}_3)(\text{CF}_3)_2$  coordinate to the  $\text{Ag}^+$  cation and give molecular compounds like  $(\text{L})_{1,2}\text{Ag}[\text{hf}]$  (Fig. 45a). With the least basic anions,  $[\text{pf}]^-$  and  $[\text{alfal}]^-$ , also the very weak ligands  $\text{C}_2\text{H}_4$ ,  $\text{C}_2\text{H}_2$ ,  $\text{P}_4$ ,  $\text{S}_8$ , etc. are stronger Lewis bases towards the cation than the anion. Consequently, in the analogous reactions the  $\text{Ag}^+$  cation coordinates  $n$  ligands  $\text{L}$  and forms  $[\text{Ag}(\text{L})_n]^+[\text{pf}]^-$  complexes with truly ionic structures ( $n = 2, 3, 4$ ; Fig. 45b).

Similarly, in almost all investigated cases, the fluoride bridged  $[\text{alfal}]^-$  anion remained non-coordinating to any cation, with the only exception of the ion-paired crystal structure of the donor free silver salt  $\text{Ag}[\text{alfal}]$  obtained by crystallization from a solution in extremely non-polar perfluorohexanes (!).<sup>31</sup>

Limiting cases that lead to ion-pairing are the molecular structures of the solvate free compounds  $\text{Li}[\text{pf}]$ ,<sup>40</sup>  $\text{Ag}[\text{pf}]$ <sup>40</sup> and  $\text{Ag}[\text{alfal}]$ ,<sup>31</sup> two of which are included in the next Fig. 46.

**Fig. 45** Counterion dependence of the structures of weakly-bound Lewis acid-base adducts of the silver cation. In addition, we have never observed ion-pairing as in (a) with the least coordinating anion  $[\text{alfal}]^-$  but only salt formation as in (b).

**Fig. 46** Molecular structures of the solvate-free compounds Li[*pf*] and Ag[*pf*] obtained by crystallization from perfluorohexanes.

**Fig. 47** Solvent dependence of the stability of the structures of weakly-bound Lewis acid-base adducts of the silver cation.

- (ii) *role of the solvent*: When  $\text{Ag}^+[\text{pf}]^-$  and 2  $\text{P}_4$  are mixed in  $\text{CH}_2\text{Cl}_2$  the equilibrium of the reaction shown in Fig. 47 lies completely on the right hand side.<sup>229,230</sup> However, replacing the weakly basic solvent  $\text{CH}_2\text{Cl}_2$  for the more strongly coordinating solvent benzene  $\text{C}_6\text{H}_6$  led to the replacement of  $\text{P}_4$  by  $\text{C}_6\text{H}_6$  in the  $[\text{Ag}(\text{P}_4)_2]^+$  cation to give  $[\text{Ag}(\text{C}_6\text{H}_6)_2]^+$ . Thus, in benzene the equilibrium lies completely on the left side.<sup>229,230</sup>

### 1.07.2.3.1 Complexed olefins and acetylenes

*Parent  $\text{H}_2\text{C}=\text{CH}_2$ -Complexes*: Since the discovery of Zeise's salt  $\text{K}[\text{PtCl}_3(\text{C}_2\text{H}_4)]$  in 1827 the investigation of simple ethene-metal complexes is an area of continuing interest in all fields of chemistry, fueled by the interest in transformations of the coordinated  $\text{C}_2\text{H}_4$  molecule. Several ethene-metal coordination modes including  $\mu$ ,  $\eta^2$ : $\eta^2$  are known. Ethene-silver complexes with very little back bonding served to formulate the Dewar-Chatt-Duncanson model for the binding of olefins to transition metal atoms. Although  $\text{Ag}-\text{C}_2\text{H}_4$  complexes are textbook compounds, experimental information on this system was very limited and only one disordered solid-state structure of a  $[\text{Ag}(\text{C}_2\text{H}_4)_n]^+$  unit was determined prior to our work (see ref.<sup>231</sup> for a literature overview). In the gas phase,  $[\text{Ag}(\text{C}_2\text{H}_4)_n]^+$  cations were already characterized by MS for  $n = 1$  and 2.<sup>232,233</sup>

Using [*pf*]<sup>−</sup> as the WCA, a cationic  $[\text{Ag}(\text{C}_2\text{H}_4)_3]^+$  complex with an ionic lattice in the solid state and an almost planar  $D_{3h}$  symmetric cation in a spoke wheel arrangement was synthesized in 2003 (Fig. 48).<sup>231,234</sup>

The synthesis and full characterization of  $[\text{Ag}(\text{C}_2\text{H}_4)_3]^+[\text{pf}]^-$  in condensed phases is rather remarkable, especially since initially only  $[\text{Ag}(\text{C}_2\text{H}_4)_n]^+$  complexes with  $n = 1, 2$  were observed in the gas phase. This is probably due to the low (calculated) binding energy of the third  $\text{C}_2\text{H}_4$  molecule of  $\Delta G^\circ = -55 \text{ kJ mol}^{-1}$  in the gas phase (MP2/TZVPP). However, in 2005 the formation of gaseous  $[\text{Ag}(\text{C}_2\text{H}_4)_3]^+$  was reported also with MS. Subsequently also the analogous copper and gold complexes  $[\text{M}(\text{C}_2\text{H}_4)_3]^+$  were prepared ( $\text{M} = \text{Cu}$ ,<sup>236</sup>  $\text{Au}$ <sup>235</sup>). When the more coordinating aluminates  $[\text{Al}(\text{OR}^F)_4]^-$  with  $\text{R}^F = \text{C}(\text{H})(\text{CF}_3)_2$  and  $\text{C}(\text{Me})(\text{CF}_3)_2$  were used, molecular ion pairs  $(\text{C}_2\text{H}_4)_n\text{Ag}[\text{Al}(\text{OR}^F)_4]$  with  $n = 1$  and 2 resulted.<sup>231</sup> A general method for the determination of the C=C bond lengths from the Raman stretch of the coordinated ethene molecule was developed. Structure and

**Fig. 48** Formation of the homoleptic coinage metal-ethene complexes  $[\text{M}(\text{C}_2\text{H}_4)_3]^+[\text{pf}]^-$  ( $\text{M} = \text{Cu, Ag}$ ). Later also  $\text{M} = \text{Au}$  was published.<sup>235</sup>

**Fig. 49** Formation of the asymmetrically bound molecular isobutene complex in  $(\text{C}_4\text{H}_8)\text{Ag}[\text{Al}(\text{OR}^F)_4]$  ( $\text{Ag}-\text{C}$  distances given in pm).

**Fig. 50** Metathesis reaction leading to the trigonal planar  $[\text{Cu}(\text{c,c,c-cdt})]^+[\text{pf}]^-$  complex.

bonding of those ethene complexes and the related isoelectronic but neutral  $\text{M}(\text{C}_2\text{H}_4)_3$  molecules ( $\text{M} = \text{Ni}, \text{Pd}, \text{Pt}$ ) was investigated with experiments and quantum chemical calculations including (theoretical) charge density studies.<sup>231</sup>

*Substituted Olefin Complexes:* Using the aluminate with the more basic  $\text{OC}(\text{Me})(\text{CF}_3)_2$  residue, an interesting asymmetrically bound isobutene complex was obtained (Fig. 49).<sup>231</sup>

This structure, with a short  $\text{Ag}-\text{C}$  bond to the  $\text{CH}_2$ -group and a long  $\text{Ag}-\text{C}$  bond to the  $\text{CMe}_2$ -group, points to the similarity of  $\text{Ag}^+$  and  $\text{H}^+$  in that the silver ion induces the formation of an asymmetric complex, which resembles in a way the Markovnikov-product  $[\text{C}(\text{CH}_3)_3]^+$ .<sup>231</sup>

Also the  $\text{Cu}^{\text{I}}$ -complex of *cis,cis,cis*-1,5,9-cyclododecatriene (*c,c,c-cdt*) was reported.<sup>237</sup> It was prepared in the metathesis reaction of the silver aluminate with  $\text{CuI}$  in the presence of the olefin shown in Fig. 50—a reaction that also proved suitable<sup>236</sup> for the preparation of the related  $[\text{Cu}(\text{C}_2\text{H}_4)_3]^+[\text{pf}]^-$  salt.

It should be noted that with the smaller and more coordinating  $[\text{BF}_4]^-$  WCA as counterion, tetracoordinate copper ions resulted: either including a coordinated solvent molecule ( $\text{MeOH}$ ) or, in the absence of coordinating solvents, the coordinated anion, i.e.,  $(\text{c,c,c-cdt})\text{Cu}-\text{F}-\text{BF}_3$ . Only with the least coordinating  $[\text{pf}]^-$  WCA access to the truly undistorted and crystallographically almost  $\text{C}_3$ -symmetric  $[\text{Cu}(\text{c,c,c-cdt})]^+$  complex cation was possible.<sup>237</sup>

*A  $[\text{Ni}^{\text{I}}(\text{cod})_2]^+$  Salt:* The straightforward synthesis of the cationic, purely organometallic  $\text{Ni}^{\text{I}}$  salt  $[\text{Ni}(\text{cod})_2]^+[\text{Al}(\text{OR}^{\text{F}})_4]^-$  was realized through a reaction between  $[\text{Ni}(\text{cod})_2]$  and  $\text{Ag}[\text{Al}(\text{OR}^{\text{F}})_4]$  ( $\text{cod} = 1,5$ -cyclooctadiene).<sup>238</sup> Crystal-structure analysis and EPR, XANES, and cyclic voltammetry studies confirmed the presence of a homoleptic  $\text{Ni}^{\text{I}}$  olefin complex. Weak interactions between the metal center, the ligands, and the anion provide a good starting material for further cationic  $\text{Ni}^{\text{I}}$  complexes, i.e. even linear  $[\text{Ni}(\text{P}^t\text{Bu}_3)_2]^+$ .<sup>239,240</sup>

*$\text{HC}\equiv\text{CH}$ -Complexes:* Also the simplest ethyne,  $\text{HC}\equiv\text{CH}$ , may be bound to the weak acceptor  $\text{Ag}^+$  with the suitable counterion.<sup>241</sup> Again, the more coordinating  $[\text{Al}(\text{OR}^{\text{F}})_4]^-$  WCA with  $\text{R}^{\text{F}} = \text{C}(\text{CH}_3)(\text{CF}_3)_2$  forms a molecular complex, which binds only one ethyne per  $\text{Ag}^+$  ion in  $(\text{C}_2\text{H}_2)\text{Ag}[\text{Al}(\text{OR}^{\text{F}})_4]$  (Fig. 51).

Fortunately, the quality of this batch of single crystals was extremely good and so an experimental charge density study at 9 K could be performed on this compound. This revealed for the first time the long theoretically predicted T-shaped bond path for the  $\text{AgC}_2$  plane. This T-shaped bond path with an electron density on the critical point of  $\rho(\mathbf{r})_{\text{TCP}} = 0.47 \text{ e}\text{\AA}^{-3}$ , implied an admixture in-between electrostatic and covalent bonding with almost no back-bonding from the silver ion.

With the much less coordinating  $[\text{pf}]^-$  WCA ( $\text{C}(\text{CF}_3)_3$  residue), homoleptic tris- and tetra-ethyne complexes  $[\text{Ag}(\text{C}_2\text{H}_2)_{3,4}]^+[\text{pf}]^-$  were realized (Fig. 52).

**Fig. 51** Synthesis of the molecular ethyne complex  $(\text{C}_2\text{H}_2)\text{Ag}[\text{Al}(\text{OR}^{\text{F}})_4]$ . The  $\text{C}\equiv\text{C}$  distance, given in pm, stems from the charge density study at 9 K and is considered to be the best experimental  $\text{C}\equiv\text{C}$  distance determined for any ethyne complex. It implies almost no back-bonding.

**Fig. 52** Molecular structures of (a) the  $\text{C}_2$ -symmetric  $[\text{Ag}(\text{C}_2\text{H}_2)_3]^+$  and (b) the  $\text{S}_4$ -symmetric  $[\text{Ag}(\text{C}_2\text{H}_2)_4]^+$  cation in the salts  $[\text{Ag}(\text{C}_2\text{H}_2)_{3,4}]^+[\text{pf}]^-$ .

Here it is interesting to analyze the structure of the  $C_2$ -symmetric  $[\text{Ag}(\text{C}_2\text{H}_2)_3]^+$  cation: From an initial guess one would have expected the cation to exhibit  $D_3$  or even  $D_{3h}$  symmetry, and not  $C_2$  with two ligands in plane and one ligand out of plane. However, DFT and ab initio calculations revealed that in a  $D_{3h}$ -structure the H-atoms come too close and therefore distort the system either to  $D_3$  or alternatively and unexpectedly to  $C_2$ ; both forms are within 1 or 2  $\text{kJ mol}^{-1}$  isoenergetic in the gas phase. This again points to the capability of the least coordinating aluminate WCA to introduce *pseudo gas phase conditions*<sup>2,3,10,242</sup> in the condensed phase.

### 1.07.2.3.2 Homoleptic transition metal carbonyl cations (TMCCs)

Since the discovery of  $\text{Ni}(\text{CO})_4$  by Mond in 1890,<sup>243</sup> transition metal carbonyls were continuously and extensively studied. Especially homoleptic transition metal carbonyls fascinate due to their simplicity, fundamental bonding characteristics and rich substitution and redox chemistry. Transition metal carbonyl often obey the 18-electron rule and their bonding is well described by the Dewar-Chatt-Duncanson model.<sup>244–247</sup> However, compared to their anionic and neutral counterparts, TMCCs exhibit a reduced  $\pi$ -back bonding, which leads to a weaker M–CO bond and usually to blue-shifted CO-stretching frequencies compared to free CO ( $2143 \text{ cm}^{-1}$ )<sup>248</sup> that may reach values up to  $2295 \text{ cm}^{-1}$  in  $[\text{Ir}(\text{CO})_6]^{3+}$ .<sup>249</sup> In the last decades, TMCCs like  $[\text{Au}(\text{CO})_2]^+$ ,<sup>250</sup>  $[\text{Pt}(\text{CO})_4]^{2+}$ ,<sup>251</sup>  $[\text{Co}(\text{CO})_5]^{2+}$ <sup>252</sup> and  $[\text{Fe}(\text{CO})_6]^{2+}$ <sup>253</sup> were mainly generated and stabilized in superacidic media and these compounds were already reviewed elsewhere.<sup>247,249,254,255</sup> However, the superacidic media hampers the access of the TMCCs to a broader community and the investigation of follow-up chemistry. Additionally, the accessible TMCCs were limited by the quality of the  $[\text{SbF}_6]^-$ / $[\text{Sb}_2\text{F}_{11}]^-$  anions as a WCA.

*Access to known TMCCs:* Consequently, a more appropriate WCA like the fluorinated alkoxyaluminates, enables the synthesis of TMCCs in standard organic solvents. This was proven by isolation of a series of coinage metal carbonyl cations including  $[\text{Cu}(\text{CO})_n][\text{pf}]^-$  ( $n > 2$ ),  $[\text{Ag}(\text{CO})_2(\text{hf})]$  and  $[\text{Au}_2(\text{CO})_2\text{Cl}][\text{pf}]^-$  by a metathesis reaction of the corresponding metal halide and  $\text{Li}[\text{pf}]$  in dichloromethane and CO atmosphere<sup>256</sup> and the synthesis of  $[\text{Co}(\text{CO})_5][\text{pf}]^-$  by deelectronation of  $[\text{Co}_2(\text{CO})_8]$  with  $\text{Ag}[\text{pf}]$  in 1,2-difluorobenzene under CO atmosphere.<sup>257</sup> Fortunately, the CO stretching frequency responds noticeably to the interaction of the TMCC with the environment and the observed frequencies of the  $[\text{Cu}(\text{CO})_n]^+$  and  $[\text{Co}(\text{CO})_5]^+$  cations in combination with fluorinated alkoxyaluminates were the most similar to the corresponding gas phase values, which justifies the declaration of pseudo-gas phase conditions.<sup>256,257</sup>

*The first Heptacarbonyls  $[\text{M}(\text{CO})_7]^+$ :* The reaction of  $[\text{M}(\text{CO})_6]^-$  ( $\text{M} = \text{Nb}, \text{Ta}$ ) with two equivalents  $\text{Ag}^+[\text{pf}]^-$  under CO pressure led to stable salts of the first transition metal heptacarbonyls  $[\text{M}(\text{CO})_7]^+$  in the condensed phase. In addition, the reaction of  $[\text{Ta}(\text{CO})_6]^-$  with  $[\text{Ta}(\text{CO})_7]^+$  led to  $\text{Ta}_2(\text{CO})_{12}$  with a long, unsupported Ta–Ta bond.<sup>258</sup>

*Radical Cations  $[\text{M}(\text{CO})_6]^{+\cdot}$ :* Homoleptic carbonyl radical cations are a textbook family of complexes. The 17-electron  $[\text{Cr}(\text{CO})_6]^{+\cdot}$  salt was synthesized by deelectronation of  $\text{Cr}(\text{CO})_6$  with  $[\text{NO}]^+[\text{pf}]^-$  in  $\text{CH}_2\text{Cl}_2$  and removal of the NO gas.<sup>259</sup> In contrast, the higher homologues  $[\text{M}(\text{CO})_6]^{+\cdot}$  ( $\text{M} = \text{Mo}, \text{W}$ ) were not accessible by deelectronation of the respective metal hexacarbonyls with nitrosyl cations and the synergistic  $\text{Ag}^+[\text{pf}]^-/0.5 \text{ I}_2$  system at  $-20 \text{ }^\circ\text{C}$  was necessary for the successful synthesis of the 17 valence electron species.<sup>260</sup>

*Nickel Tetracarbonyl Radical Cation:* With the same  $\text{Ag}^+[\text{pf}]^-/0.5 \text{ I}_2$  system, also the synthesis of the nickel tetracarbonyl radical cation  $[\text{Ni}(\text{CO})_4]^{+\cdot}$  was achieved, as the last missing entry among the structurally characterized TMCCs of Groups 6 to 11.<sup>261</sup>

*Iron Pentacarbonyl Radical Cation:* While the deelectronation of the pentacarbonyl iron failed with common inorganic oxidants, the usage of the innocent deelectronator  $[\text{phenazine}^{\text{F}}]^+[\text{pf}]^-$  has allowed the preparation of the open-shell  $[\text{Fe}(\text{CO})_5]^{+\cdot}[\text{pf}]^-$ . The pentacarbonyl iron radical cation is a novel example of low-valent iron and has thus been fully characterized including Mößbauer and SQUID.<sup>56</sup>

*Homotrinary TMCCs  $[\text{M}_3(\text{CO})_{14}]^{2+}$ :* The use of innocent deelectronations also allows the isolation of the first homotrinary TMCCs  $[\text{M}_3(\text{CO})_{14}]^{2+}([\text{pf}]^-)_2$  ( $\text{M} = \text{Ru}, \text{Os}$ ) through the reaction of  $\text{M}_3(\text{CO})_{12}$  with two equivalents of  $[\text{anthracene}^{\text{Hal}}]^+[\text{pf}]^-$  under a CO atmosphere.<sup>63</sup> The metal atoms are arranged in a linear chain and have each a nearly octahedral coordination geometry. The structural characterization and the DFT calculations as well as vibrational and NMR spectroscopies are indicating the presence of three electronically independent sets of carbonyl ligands, which almost mimic  $\text{M}(\text{CO})_5$ , free CO and even  $[\text{M}(\text{CO})_6]^{2+}$  in one and the same cation.

*Currently Known TMCCs:* All currently known TMCCs are collected in Table 4. Entries marked in bold are only known with a perfluoroalkoxyaluminate anion.

**Table 4** Structurally characterized homoleptic TMCCs.<sup>247,249,254,255</sup>

### 1.07.2.3.3 Transition metal carbonyls as complex ligands

The reaction of the silver(I)-cation with Transition Metal Carbonyls (TMCs) leads in a few cases to a deelectronation of the TMCCs. However, an often-encountered side-reaction is the formation of a metal-only Lewis-pair (MOLP),<sup>262</sup> in which the Lewis-acidic silver(I) cation is surrounded by Lewis-basic TMCs.

**Fe(CO)<sub>5</sub>-Complexes:** In an attempt to deelectronate pentacarbonyl-iron to its radical-cation with Ag<sup>+</sup>[*pf*]<sup>-</sup> the silver-complex [Ag{Fe(CO)<sub>5</sub>}<sub>2</sub>]<sup>+</sup> formed instead.<sup>263</sup> Inspired by this work, Dias et al. synthesized further silver-complexes with Fe(CO)<sub>5</sub> as ligand and with other WCAs including [B{3,5-(CF<sub>3</sub>)<sub>2</sub>C<sub>6</sub>H<sub>3</sub>}<sub>4</sub>]<sup>-</sup> and [SbF<sub>6</sub>]<sup>-</sup>.<sup>264</sup> A few years later Dias et al. showed, that Fe(CO)<sub>5</sub> reacts also with the other coinage-metals completing the [M{Fe(CO)<sub>5</sub>}<sub>2</sub>]<sup>+</sup> (M = Cu, Ag, Au) triad.<sup>265</sup>

**M(CO)<sub>6</sub>-Complexes:** Although the metal-centers of the group 6 hexacarbonyls seem to be sterically inaccessible for the coordination, molybdenum and tungsten hexacarbonyl form silver(I)-complexes [Ag{M(CO)<sub>6</sub>}<sub>2</sub>]<sup>+</sup> (M = Mo, W) in the same 2:1 stoichiometry as pentacarbonyl iron, while the lightest group 6 silver(I)-complex, [Ag{Cr(CO)<sub>6</sub>}<sub>2</sub>]<sup>+</sup> remained inaccessible.<sup>266</sup>

**Hexacarbonylate Anions as Ligands:** When the group 5 hexacarbonylate anions [M(CO)<sub>6</sub>]<sup>-</sup> (M = Nb, Ta) were treated with silver(I) in absence of uncoordinated monoxide, different clusters, depending on the stoichiometry formed.<sup>267</sup> Those included also large heterobimetallic cluster cores, i.e. a supertetrahedral Ta<sub>4</sub>Ag<sub>6</sub>- or a Ta<sub>5</sub>Ag<sub>6</sub>-core, in which five Ta(CO)<sub>6</sub>-moieties cap the five faces of a Ag<sub>6</sub>-trigonal prisma.

**M<sub>3</sub>(CO)<sub>12</sub>-Complexes:** The trimetal dodecacarbonyls M<sub>3</sub>(CO)<sub>12</sub> (M = Ru, Os) react with silver(I) in the same 2:1 stoichiometry to the respective [Ag{TMC}<sub>2</sub>]<sup>+</sup> complexes. Yet, the trimetal dodecacarbonyls are coordinating over the metal-metal bond to the silver-cation, which leads to an elongation of this bond and strong interaction energies, which surpass the interaction energies of the other metal carbonyls with the silver(I) cation.

### 1.07.2.3.4 Further transition metal cations with gaseous ligands

**Transition Metal Nitrosyl Complexes:** Transition metal nitrosyl complexes exhibit an interesting bonding situation due to the covalency of the M–NO bond.<sup>268,269</sup> Attempts to synthesis TMCCs, like [Cr(CO)<sub>6</sub>]<sup>+</sup>, by deelectronation of a neutral starting material with NO<sup>+</sup> often leads to NO/CO ligand exchange and to a rather scarce family of *pseudo*-ternary mixed carbonyl/nitrosyl cations.<sup>270</sup> Whereas longer reaction times are necessary for the ligand exchange to the thermodynamically more stable 18-electron species [Cr(CO)<sub>5</sub>(NO)]<sup>+</sup>, the higher homologous [M(CO)<sub>5</sub>(NO)]<sup>+</sup> (M = Mo, W) are formed exclusively by reaction of NO<sup>+</sup> with the corresponding metal carbonyl.<sup>259</sup> The non-innocent character of NO<sup>+</sup> as deelectronater was also observed during the deelectronation of nickel powder under CO atmosphere and Fe(CO)<sub>5</sub> resulting in [Ni(CO)<sub>3</sub>(NO)]<sup>+</sup><sup>261</sup> and [Fe(CO)<sub>4</sub>(NO)]<sup>+</sup>.<sup>270</sup> Further addition of NO gas to [Fe(CO)<sub>4</sub>(NO)]<sup>+</sup> yielded [Fe(CO)(NO)<sub>3</sub>]<sup>+</sup>,<sup>270</sup> which completes the series of heteroleptic iron carbonyl/nitrosyl complexes, since the discovery of the anionic [Fe(CO)<sub>3</sub>(NO)<sub>2</sub>]<sup>-</sup><sup>271</sup> and the neutral [Fe(CO)<sub>2</sub>(NO)<sub>2</sub>].<sup>272</sup>

**Homoleptic [Mn(NO)<sub>4</sub>]<sup>+</sup>:** In contrast to the homoleptic TMCCs, only one truly homoleptic transition metal nitrosyl cation is hitherto known. [Mn(NO)<sub>4</sub>][*pf*]<sup>-</sup> and [Mn(NO)<sub>4</sub>][*alfal*]<sup>-</sup> were synthesized from in situ generated “Mn(CO)(NO)<sub>3</sub>” and NO[WCA], which could be used as well-characterized model system for the further investigation of the metal nitrosyl bonding.<sup>273</sup>

**A Copper-N<sub>2</sub>O-Complex:** Compared to CO and NO, nitrous oxide (N<sub>2</sub>O) is considered an even poorer ligand due to the low dipole moment and weak σ-donor and π-acceptor properties.<sup>274</sup> However, solvent free Cu[*pf*], obtained by oxidation of copper powder with the synergistic Ag<sup>+</sup>[*pf*]<sup>-</sup>/0.5 I<sub>2</sub> system in perfluorinated hexane, is able to reversibly bind N<sub>2</sub>O over the terminal nitrogen atom.<sup>275</sup> [Cu(N<sub>2</sub>O)(*pf*)] is one of only four structurally characterized N<sub>2</sub>O transition metal complexes,<sup>274–276</sup> and exhibits a blue-shifted N–N and N–O vibrational band compared to free N<sub>2</sub>O.<sup>275</sup>

### 1.07.2.3.5 Transition metal carbonyl cations as starting materials

Due to the reduced π-back bonding, the carbonyl ligands in TMCCs are typically only weakly bound to the metal centers, which is why they present excellent starting materials for a rich substitution chemistry.

For instance, [Co(CO)<sub>5</sub>]<sup>+</sup> reacts with different arenes like toluene, benzene or 1,2-difluorobenzene to the cationic two-legged piano-stool complexes [(arene)Co(CO)<sub>2</sub>]<sup>+</sup>.<sup>277</sup> To complete the conversion, the reaction has to be performed under reduced pressure or at elevated temperatures in an open system to obtain the respective [Co(arene)<sub>2</sub>]<sup>+</sup> sandwich complexes.<sup>43</sup> Fortunately, as the gaseous CO can be easily removed from the equilibrium, even sandwich complexes with the weakly Lewis basic 1,2-difluorobenzene are accessible, although the reaction from [Co(CO)<sub>5</sub>]<sup>+</sup> to [Co(*o*DFB)<sub>2</sub>]<sup>+</sup> is endergonic by +45 kJ mol<sup>-1</sup> (Fig. 53).<sup>43,277</sup> The resulting [Co(*o*DFB)<sub>2</sub>]<sup>+</sup> complex can then be utilized as a “Co<sup>+</sup>” synthon leading to complexes like [Co(P<sup>*t*</sup>Bu<sub>3</sub>)<sub>2</sub>]<sup>+</sup>.<sup>43</sup>

Although in part endergonic, the reactions proceed due to the irreversible removal CO at lower pressures.<sup>43,277</sup>

**Fig. 53** Reaction scheme for the synthesis of [(arene)Co(CO)<sub>2</sub>]<sup>+</sup> and [Co(arene)<sub>2</sub>]<sup>+</sup>, together with the calculated Gibbs free energy for different arenes.<sup>43,277</sup>

Similarly, when the  $[M(\text{CO})_7]^+$  ( $M = \text{Nb}, \text{Ta}$ ) cation are dissolved in *o*DFB, they form the  $[(\text{oDFB})M(\text{CO})_4]^+$  piano-stool complexes. In the case of  $[(\text{oDFB})\text{Nb}(\text{CO})_4]^+$ , the reaction is reversible on addition of CO pressure.<sup>258</sup> The deelectronation of the  $\text{Nb}(\text{arene})_2$  (arene = toluene, mesitylene) complexes are yielding the respective 16-valence electron  $[\text{Nb}(\text{arene})_2]^+$  complexes, which react with carbon monoxide to the 18-valence electron  $[(\text{arene})_2\text{Nb}(\text{CO})]^+$  complexes. An excess of carbon monoxide leads to the piano-stool complexes  $[(\text{arene})\text{Nb}(\text{CO})_4]^+$ .<sup>278</sup>

### 1.07.2.3.6 Complexed free elemental clusters

The activation and complexation of small elemental clusters like  $\text{P}_4$ ,  $\text{S}_8$ , etc. has sparked considerable interest over the past decades. However, only by using the least coordinating  $[pf]^-$  and  $[alfal]^-$  aluminates, truly undistorted and even homoleptic  $[\text{M}_n(\text{cluster})_x]^{n+}$  ions could be realized. Those often served as structural model for the complexes that were earlier already observed in the gas phase by one of the advanced mass spectrometry methods. Moreover, direct access to metastable or unknown allotropes of the elements like  $\text{Se}_6$  and  $\text{E}_{12}$  ( $\text{E} = \text{S}, \text{Se}$ ) was provided by the weak complexation. Recent additions are the complexes of the heavier dihalogens  $\text{X}_2$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ),<sup>40</sup> of which  $\text{I}_2$  showed a diverse coordination chemistry<sup>41</sup> towards  $\text{Ag}^+$ .

**Complexes with  $\text{P}_4$ :** In a pioneering MS study, two binary silver-phosphorus cations were observed:  $[\text{AgP}_4]^+$  and  $[\text{AgP}_8]^+$ . On the basis of this mass spectrometric experiment and initial DFT-calculations a structure with two  $\eta^1$ -bound molecules was predicted. In agreement with this,  $\text{Ag}^+-\text{P}_4$  complexes containing one or two almost undistorted tetrahedral  $\text{P}_4$  units can be formed, i.e., molecular  $(\text{P}_4)\text{AgAl}(\text{OC}(\text{R})(\text{CF}_3)_2)_4$  ( $\text{R} = \text{H}, \text{Me}$ ) and  $[\text{Ag}(\text{P}_4)_2][pf]$ , which contains the first homoleptic metal  $\text{P}_4$  cation (Fig. 54).<sup>229,230</sup> In contrast to the initial computational prediction, the crystal structure determination revealed a  $[\text{Ag}(\text{P}_4)_2]^+$ -cation with  $D_{2h}$ -symmetry and two coplanar  $\eta^2$ -bound  $\text{P}_4$ -molecules. The synthesis of the  $\text{Ag}(\eta^2-\text{P}_4)_2^+$  complex was also carried out using the fluoride bridged  $[alfal]^-$  anion,<sup>16</sup> where the least coordinating character of this anion was employed to clarify the question of the ground state geometry of the  $[\text{Ag}(\eta^2-\text{P}_4)_2]^+$  cation ( $D_{2h}$ ,  $D_2$  or  $D_{2d}$ ?). Calculations showed a very small energy difference of  $5.2 \text{ kJ mol}^{-1}$  between the planar ( $D_{2h}$ ) and tetrahedral ( $D_{2d}$ ) conformation.<sup>16,229,230</sup> According to other calculations, the most favorable structure is of  $D_2$  symmetry.<sup>279</sup> In agreement with this computational data and NMR spectra it could be shown on experimental grounds that several orientations of the  $[\text{Ag}(\eta^2-\text{P}_4)_2]^+$  cation are very close in energy, that the rotation around the  $\text{Ag}-(\text{P}-\text{P}-\text{centroid})$  axis has no barrier and that the finally realized geometry in the solid state clearly depends on packing effects. These effects lead to an almost  $D_{2h}$  symmetric  $[\text{Ag}(\eta^2-\text{P}_4)_2]^+$  cation (0 to  $10.6^\circ$  torsion) for the more symmetrical  $[pf]^-$  anion, but to a  $D_2$  symmetric  $[\text{Ag}(\eta^2-\text{P}_4)_2]^+$  cation with a  $44^\circ$  twist angle of the two  $\text{AgP}_2$  planes for the less symmetrical  $[alfal]^-$  anion (Fig. 54).<sup>16</sup>

In a metathesis reaction from the silver salt,  $\text{CuI}$  and white phosphorus, later also the isostructural  $\text{Cu}(\eta^2-\text{P}_4)_2^+[pf]^-$  salt was prepared.<sup>236</sup> Compared to the silver complex, the bonding to the  $\text{P}_4$  moiety is stronger in  $[\text{Cu}(\eta^2-\text{P}_4)_2]^+$  and accordingly the  $^{31}\text{P}$  NMR chemical shift ( $-460 \text{ ppm}$ ) is by  $36 \text{ ppm}$  more deshielded than that of the homologous silver complex ( $-496 \text{ ppm}$ ), but still very much in the range of a true  $\text{P}_4$ -complex and *not* a coordinated phosphidic tetraphosphabicyclobutane-moiety. To complement the series  $[\text{Au}(\eta^2-\text{P}_4)_2]^+$  has also been reported but only stabilized with  $[\text{GaCl}_4]^-$  ( $\delta = -452 \text{ ppm}$ ).<sup>280</sup> With  $[(\text{NHC})\text{MP}_4][pf]$  ( $\text{M} = \text{Au}, \text{Cu}$ ), functionalization of  $\text{P}_4$  using Aryl lithium compounds was investigated resulting in a doubly complexed  $\text{RP}_4$  butterfly derivative.<sup>281</sup> Since phosphorus is a rather electronegative element, transition metal complexes tend to form a phosphidic tetraphosphabicyclobutane-moiety instead of an intact  $\text{P}_4$  tetrahedron.

For  $[\text{CpFe}(\text{CO})_2(\eta^1-\text{P}_4)]^+[pf]^-$ , strong blue-shifting of the  $\text{P}_4$  vibrational modes vs. neutral  $\text{P}_4$  indicates mainly  $\pi$ -donation with minor  $\pi$ -back donation. This results in an *Umpolung* of the usually more phosphidic character of  $\text{P}_4$  to a phosphonium character, opening up a possibility of  $\text{P}_4$  functionalization via nucleophiles.<sup>282</sup>

**Complexes with  $\text{As}_4$ :** Yellow arsenic is far less stable than  $\text{P}_4$  and polymerizes to gray arsenic within minutes in solid state or in presence of light. Nevertheless, the group of Prof. Manfred Scheer reported side-on coordination of  $\text{As}_4$  tetrahedra  $[\text{Ag}(\eta^2-\text{As}_4)_2]^+[pf]^-$  in analogy to white phosphorus. This salt can be used as  $\text{As}_4$  transfer agent, e.g., generating  $[(\text{PPh}_3)\text{Au}(\eta^2-$

Fig. 54 Temperature and anion dependence of the orientations of the  $[\text{Ag}(\eta^2-\text{P}_4)_2]^+$  cations ( $[pf]^-$  and  $[alfal]^-$  salts).

**Fig. 55** (a) Section of the solid-state structure of  $(S_8)_2AgSbF_6$ : coordinated  $[MF_6]^-$  anions that lead to a distortion of the  $[Ag(S_8)_2]^+$  structure. (b)  $(S_8)Ag[hf]$  and (c)  $[Ag(S_8)_2][pf]$  including the undistorted  $[Ag(S_8)]^+$  and  $[Ag(S_8)_2]^+$  cations.

$As_4)]^+[pf]^-$ .<sup>283</sup> The reaction of  $[Ag(\eta^2-As_4)_2]^+[pf]^-$  with  $[Cp^*Ru(dppe)Cl]$  leads to  $[Cp^*Ru(dppe)(\eta^1-As_4)]^+[pf]^-$  with an unprecedented end-on-coordinated  $As_4$  tetrahedron. A second cationic ruthenium complex fragment does not lead to a second end-on coordination but to the cleavage of one basal As–As bond, which differs from its phosphorus analogs.<sup>284</sup>

**Complexes with  $S_8$ :** It has been shown by mass spectrometry that  $Ag^+$  and  $S_8$  give complexes of type  $[Ag(S_8)_x]^+$  ( $x = 1, 2$ ).<sup>285,286</sup> The only available structural model for such complexes was  $(S_8)_2Ag[MF_6]$  ( $M = As, Sb$ ),<sup>242,287</sup> however, due to anion coordination it is unlikely that the gaseous  $[Ag(S_8)_2]^+$  cation will adopt the same geometry (Fig. 55a). Therefore, the larger  $[pf]^-$  anions were used to approximate the still unknown geometries of gaseous  $Ag(S_8)_x^+$ . The compounds  $(S_8)Ag[Al(OC(H)(CF_3)_2)_4]$  and  $[Ag(S_8)_2][pf]$  were obtained<sup>242</sup> and include the first examples of undistorted homoleptic metal  $S_8$ -complexes, i.e., the almost  $C_{4v}$ -symmetric  $[Ag(\eta^4-S_8)]^+$  and the approximately centrosymmetric  $[Ag(\eta^4-S_8)_2]^+$  cations in Fig. 55b and c. As also shown by quantum chemical calculations, they provide the best structural models for the gaseous  $AgS_8^+$  and  $AgS_{16}^+$  cations.

It should be noted that quantum chemical calculations of these cations are rather difficult due to the substantial participation of dispersion in the bonding. Without the experimental structures, it would have been hard to establish the quality of the computation.<sup>242</sup> Weak dispersive Ag–S interactions are structure determining and, therefore, DFT and HF-DFT theory failed to describe the  $Ag(S_8)_x^+$  cations. Only MP2 calculations with a larger basis set (TZVPP) gave minimum geometries close to the experiment. After these initial calculations, we were able to also characterize  $Cu(S_8)$  complexes.<sup>37,288</sup> However, these were only accessible with the

**Fig. 56** Calculated energies (PBE0/TZVPP,  $\Delta H_{(g)}^\circ$ ,  $\text{kJ mol}^{-1}$ ) and experimental values *italics* for the interconversion of cyclooctasulfur into  $S_n$  species and possible  $[Cu(S_x)(S_y)]^+$  ( $x + y = 12$ ) structures. Relative energies to the most favorable complex  $C_{3v}\text{-}[Cu(S_{12})]^+$  **bold**. Cu–S distances [*italics*] given in pm.

more coordinating  $[\text{Al}(\text{OR}^{\text{F}})_4]^-$  aluminates with  $\text{R}^{\text{F}} = \text{C}(\text{H})(\text{CF}_3)_2$  and  $\text{R}^{\text{F}} = \text{C}(\text{Me})(\text{CF}_3)_2$ ; with the least coordinating  $[\text{pf}]^-$ -aluminate, the formation of  $\text{S}_{12}$ -complexes was observed (v.i.). In the  $\text{Cu}(\text{S}_8)$ -complexes, the  $\text{S}_8$ -molecule may also serve as a bridging ligand.

**Complexes including the  $\text{S}_{12}$  molecule:** Besides  $\text{S}_8$ ,  $D_{3d}$ - $\text{S}_{12}$  is the thermodynamically second most stable allotrope of sulfur. By MS it was shown,<sup>285,286</sup> that the  $\text{Cu}^+$  ion only forms  $\text{S}_8$ -complexes immediately after mixing of the vapors in the MS. Within 10 s, almost all of the  $\text{S}_8$  was transformed into gaseous  $[\text{CuS}_{12}]^+$ . Unfortunately, MS provides no structural information on the nature of the involved sulfur ligands being  $\text{S}_{12}$ , two  $\text{S}_6$ , three  $\text{S}_4$  or even a mix of  $\text{S}_4$  and  $\text{S}_8$ . First insights were gained by DFT calculations that suggested a  $[\text{Cu}(\text{S}_{12})]^+$  complex including the  $D_{3d}$ - $\text{S}_{12}$  molecule to be the global minimum (Fig. 56).

It was therefore interesting to see, as to whether the  $\text{Cu}[\text{pf}]$  starting material<sup>37</sup> including the least coordinating aluminate WCA could induce this reaction also in condensed phases. However, nature always has its surprises, and so two substances could be isolated from the reaction of  $\text{Cu}[\text{pf}]$  and excess  $\text{S}_8$ <sup>37,288</sup>. Depending on the sonication time, single crystals of  $[(\text{S}_8-\eta^1)\text{Cu}(1,5,9-\eta^3-\text{S}_{12})]^+[\text{pf}]^-$  or  $[(\text{CH}_2\text{Cl}_2)\text{Cu}(1,5,9-\eta^3-\text{S}_{12})]^+[\text{pf}]^-$  were repeatedly isolated from several independent reactions. Both copper complexes contain almost undistorted  $D_{3d}$ - $\text{S}_{12}$  and both provide the first examples of any metal- $\text{S}_{12}$  complex. Additionally the  $[(\text{S}_8-\eta^1)\text{Cu}(1,5,9-\eta^3-\text{S}_{12})]^+$  cation is the first example of a metal complex, in which two different ring sizes of an element are bound to a metal (Fig. 57).

Probably the  $[(\text{CH}_2\text{Cl}_2)\text{Cu}(1,5,9-\eta^3-\text{S}_{12})]^+$  cation, containing a very weakly bound  $\text{CH}_2\text{Cl}_2$  molecule, is the best structural approximation of gaseous  $\text{C}_{3v}$ - $[\text{CuS}_{12}]^+$ . It could be shown by DFT calculations that the formation of the  $\text{S}_{12}$ -complexes is thermodynamically driven upon  $\text{S}_8$  complexation to copper.<sup>37,288</sup>

**Complexes with metastable  $\text{Se}_6$ :** The gray, semi-metallic form is the thermodynamically most stable modification of selenium. Red selenium, a mixture of mainly  $\text{Se}_8$  and some  $\text{Se}_6$  with traces of  $\text{Se}_7$  also exists in condensed phases. With considerable effort, pure  $\text{Se}_8$  and pure  $\text{Se}_6$  were prepared. It has been shown that complexation with  $\text{Ag}^+$  and the least coordinating  $[\text{pf}]^-$  WCA leads to the

**Fig. 57** Cation structures of the  $\text{S}_{12}$ -complexes in (a)  $[(\text{CH}_2\text{Cl}_2)\text{Cu}(1,5,9-\eta^3-\text{S}_{12})]^+[\text{pf}]^-$  and (b)  $[(\text{S}_8-\eta^1)\text{Cu}(1,5,9-\eta^3-\text{S}_{12})]^+[\text{pf}]^-$ . Experimental distances are given in pm in bold and PBE0/TZVPP calculated values in brackets in italics.

**Fig. 58** Section of the  $[(\text{SO}_2)_2\text{Ag}]_2(\mu:\eta^3,\eta^3-\text{Se}_6)]^{2+}$  dication stack in  $[(\text{SO}_2)_2\text{Ag}]_2(\text{Se}_6)]^{2+}$  ( $[\text{pf}]^-$ )<sub>2</sub>.

thermodynamically preferred transformation of gray selenium into weakly complexed metastable  $\text{Se}_6$  in the dicationic  $[\text{Ag}_2(\eta^3, \eta^3\text{-Se}_6)]^{2+}$  heterocubane,<sup>289</sup> which is coordinatively saturated on each silver ion by further ligation of two sulfur dioxide molecules. Overall, these  $[(\text{SO}_2)_2\text{Ag}]_2(\eta^3, \eta^3\text{-Se}_6)^{2+}$ -moieties further form slightly aggregated 1D chains, as shown in Fig. 58.

A related isolated structure was observed, when the similarly large and weakly coordinating  $[\text{Sb}(\text{OTeF}_5)_6]^-$  WCA was employed.<sup>290</sup> However, upon changing to the smaller  $[\text{MF}_6]^-$  anions ( $\text{M} = \text{As}, \text{Sb}$ ), aggregated 1D-stacks of composition  $([\text{Ag}(\mu\text{-}\eta^3, \eta^3\text{-Se}_6)]^+)_\infty$  partly also crosslinked by  $\mu\text{-}\eta^1, \eta^1\text{-Ag}$ -ions. But in all cases the thermodynamically preferred complexes of the metastable hexaselenium allotrope formed by reaction of silver ions with gray selenium.<sup>289</sup> It appears that the size of the anions governs the formation of molecular or polymeric structures (see also  $\text{P}_4\text{S}_3$  below).

*A complex of the unknown  $\text{Se}_{12}$  allotrope:* When using red, instead of gray selenium as a starting material, again a dicationic silver-selenium complex resulted:  $[\text{Ag}_2(\text{Se}_{12})]^{2+}([\text{pf}]^-)_2$ .<sup>291</sup> The only other account of  $\text{Se}_{12}$  is a structure as a cocrystal with mixed molybdate  $(\text{NH}_4)_2[(\text{Mo}_3\text{S}_{11.72}\text{Se}_{1.28})(\text{Se}_{12})]$ . Again, complexation with silver leads to the reproducible formation of the unknown modification and also bulk characterization of a salt with the  $D_{3d}$ - $[\text{Ag}_2(\text{Se}_{12})]^{2+}$  dication. To our knowledge this presents a novel 14 cornered closed polyhedron built from six-membered rings in the boat conformation (Fig. 59).

The cross-cluster Ag–Ag separation is with 286 pm weakly bonding and presents a rare example for an argentophilic interaction in a dication. Further research regarding other coinage metals as well as different allotrops of Selenium resulted in the report of a dicationic  $[\text{Cu}_2(\text{Se}_{19})][\text{pf}]_2$  salt. This  $\text{Se}_{19}$  cycle represents the first  $\text{E}_{19}$  cycle of any element.<sup>292</sup>

*Complexes of the Dihalogens  $\text{X}_2$ :* Due to their low Lewis basicity, complexes of dihalogens  $\text{X}_2$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ) with a Lewis acid are rare. Nevertheless  $\text{Ag}^+[\text{pf}]^-$  forms  $[\text{Ag}(\text{X}_2)][\text{pf}]$  complexes with the respective dihalogens and  $\text{X} = \text{Cl}, \text{Br}, \text{I}$  in non-coordinating solvents like perfluorohexane (Fig. 60).<sup>40,41</sup>
