CONTENTS

DEDICATION

This book is dedicated to the memory of Professor Bernhard Ilschner
of the Ecole Polytechnique Fédérale de Lausanne,
who was among the six Editors-in-Chief
of the Encyclopedia of Materials: Science and Technology.

EDITOR'S PREFACE

This book is a "remake" of a successful predecessor: it follows, in nature, format and ambition, the *Concise Encyclopedia of Composite Materials* that was edited in 1989, and then re-edited in 1994, by Anthony Kelly using the 1986 *Encyclopedia of Material Science and Engineering* as a starting point.

Like the first *Concise Encyclopedia of Composite Materials*, the present volume is a collection of articles from a much larger Encyclopedia. Entries presented here come from the 2001 *Encyclopedia of Materials: Science and Technology*, an entirely rewritten successor to the 1986 *Encyclopedia of Materials Science and Engineering*. The wider scope of the new Encyclopedia of Materials, together with the simple fact that it is more up-to-date, motivated this new edition of a smaller, more easily distributed and shelved, "concise" encyclopedia focused on composite materials.

Composite materials have become so ubiquitous and important a class of materials that many books now exist on the subject. Some offer wide and advanced level coverage of the subject; *Comprehensive Composite Materials*, an extensive six-volume treatise edited by A. Kelly and C. Zweben, which covers in-depth nearly all facets of these variegated materials, stands out in this category. Other books provide more concise and introductory coverage of the subject, while some focus on specific subtopics such as the mechanics of composites.

This book is different; it stands out in two respects.

The first is that it enables quick reference. By virtue of its format, this volume is very easy to search. Many subjects, related to composites but quite disparate, are presented in an independent and brief fashion, contrary to what is provided by a monograph where subject matter is presented incrementally, or a treatise where subject matter is presented exhaustively. The reader interested in rapidly learning essentials of, say, rubber tires (one of the most impressive structural composites if one thinks of their service conditions) or the plastic deformation of cellular materials, will find this book very useful. This, of course, is the main purpose of any encyclopedia.

The second distinguishing feature of this book is more specific to its origin. The fact that it was constructed by gleaning articles from a much wider collection makes it possible to define broadly the subject and its coverage. This Concise Encyclopedia thus contains many bridges between its main subject, composite materials, and the wider discipline of Materials Science and Engineering. Choosing articles from an Encyclopedia containing around two thousand entries makes it possible to give access to topics that are clearly relevant, but often considered peripheral, to composites. One example of this is in the rapidly growing discipline of Biomaterials. Nature's materials are often composites, in both their making and their structure. There are many entries on Biomaterials in the *Encyclopedia of Materials: Science and Technology*; a selection of these, relevant to composites, is included herein. Another example is given by a property such as creep: coverage includes dispersion and particle hardening in a single article; this provides a bridge to the broader subject of metal creep. A third is in applications: some important but less conventional composites will be found here, such as metal-reinforced polymers (used as electrically conductive adhesives) or liquid-crystal containing polymers (used in visual displays). A fourth example is given by highly porous materials: these are often engineered composites of a solid and a gas; several articles in this book concern these materials.

The scope and size of the *Encyclopedia of Materials: Science and Technology* are so large that it has not been possible to fit into this single volume all entries on the subject matter of this book while keeping its size reasonable. Decisions therefore had to made in compiling and editing the selection of articles included herein. The reader should thus be forewarned that these decisions were subjective and that there are other articles relevant to composites as defined here within the *Encyclopedia of Materials: Science and Technology*.

The unique breadth in coverage of composite materials that the reader will find in this single volume was made possible by pooling the contributions of many different authors and editors. Articles concerning the more classical "core" facets of composite materials were mostly commissioned and edited by the undersigned; however, many other articles that the reader will find here were defined and edited by his colleagues among the sixty-two "Subject Editors" of the *Encyclopedia of Materials: Science and Technology*. Their important contribution is herewith acknowledged, all the while pointing out that only the undersigned bears responsibility for the (obviously debatable) choice of articles included herein.

Andreas Mortensen
Lausanne, 2006

A NOTE ON USING THE ENCYCLOPEDIA

Like its predecessor, this book begins with an introductory article on composite materials, entitled *Composite Materials: Overview* (see page xvii). All other articles are presented alphabetically by title and an alphabetic listing of the titles is given on page xi.

The title of an article provides a first guide towards researching a given topic. The multilevel Subject Index at the end of the book offers more detailed guidance. An alphabetic list of the contributors names and their affiliations, is also provided as part of the Endmatter in the book.

As in the full *Encyclopedia of Materials: Science and Technology* (EMSAT), articles contain cross references to related articles. Cross references occur both within the text, and in some cases as a listing near the end of an article (in a "See also" section).

Most cross references refer to other articles within the present volume – these are marked by an asterisk (∗). Cross references that refer to articles held only in the parent collection (in EMSAT, available for example through Science Direct) are marked by a hash sign (#). All articles end with a Bibliography that gives other sources for further information.

Since Composite Materials is a diverse subject and covers many classes of materials, another point of access to the range of topics covered within a particular subject area is provided by the Topical Listing of Articles (starting on page xiii). Here titles are included in a two-level subject "map" of the contents of this volume.

COMPOSITE MATERIALS: OVERVIEW

The term "composite" originally arose in engineering when two or more materials were combined in order to rectify some shortcoming of a particularly useful component. For example, cannons that had barrels made of wood were bound with brass because a hollow cylinder of wood bursts easily under internal pressure. The early clipper sailing ships, which were said to be of composite construction, consisted of wood planking on iron frames, with the wood covered by copper plates to counter the attack of marine organisms on the wood.

For the purposes of this Encyclopedia, a composite material can be defined as a heterogeneous mixture of two or more homogeneous phases that have been bonded together. The phases can be of essentially any material class, including metal, polymer, ceramic, carbon, or even a fluid or void space: indeed, most highly porous materials are also composites. Provided the existence of the two phases is not easily distinguished with the naked eye, or provided the structural scale of the distribution of the two phases is far smaller than that of the structure that uses them, the resulting composite can itself be regarded as a homogeneous material with physical and mechanical properties of its own. Such materials are familiar. Many natural materials are composites, such as wood. Other examples are automobile tires, glass fiber-reinforced plastics (GRPs), the cemented carbides used as cutting tools, and paper—a composite consisting of cellulose fibers (sometimes with a filler, often clay). Paper is essentially a mat of cellulose fibers, combined with open pore space, with interfiber bonding being provided by hydrogen bonds where the fibers touch one another.

It is sometimes difficult to draw a distinction between a composite material and an engineered structure that contains more than one material and is designed to perform a particular function. The combination is usually referred to as a composite provided it has its own distinctive properties, such as being much tougher than any of its constituent elements alone, having a negative thermal expansion coefficient, or having some other property not clearly shown by any of the component materials.

The breaking strength of fibers of glass, of graphite, and of many whisker crystals, is much greater than that of bulk pieces of the same materials. In fact, it may be that all materials are at their strongest when in fiber form. In order to use the strength of such strong fibers, they must be stuck together in some way: for example, a rope is made up of fibers of hemp or flax, and indeed carbon or glass fibers are often twisted into tows. However, for maximum use, a matrix in which to embed such strong fibers is required, in order to provide a strong and stiff solid for engineering purposes. The properties of the matrix are usually chosen to be complementary to those of the fibers: for example, great toughness in a matrix complements the tensile strength of the fibers. The resulting combination may then achieve high strength and stiffness (owing to the fibers), and resistance to crack propagation (owing to the interaction between fibers and matrix).

The term "advanced composite" means specifically this combination of very strong and stiff fibers within a matrix designed to hold the fibers together. This type of composite combines the extreme strength and stiffness of the fibers and, owing to the presence of the matrix, shows much greater toughness than would otherwise be obtainable.

In many cases, the dimensions of one of the phases of a composite material are small, say between 10 nm and a few micrometers, and under these conditions that particular phase has properties rather different from those of the same material in the bulk form. When the microstructural scale falls in the range of a few nanometers, such a material is referred to as a "nanocomposite."

1. Making Composites

It is the act of artificially bonding distinct phases that makes a material a composite; this also creates a distinction between composite processing and bulk material processing. Many multiphased materials, such as high-carbon steel or porcelain, can indeed be produced by conventional bulk processing; however, in these the various phases are produced by internal phase transformation.

Most composite fabrication processes comprise two main steps: (i) separate production of the two phases to be combined, and (ii) combination of these two phases. The second step can be viewed as composite production in the stricter sense. Often, among the phases making a composite, one is distinguished

as being the "reinforcement": this is generally the strongest phase of the material. In most cases, the reinforcement is also geometrically distributed as discrete elements (fibers, particles) within the composite. The other phase, which bonds the reinforcement lements together and percolates throughout the composite, is then called the matrix. Although generally the weaker phase, the matrix influences markedly the properties of the composite. Composites are therefore classified according to the nature of their matrix: polymer, metal, and ceramic matrix composites, often designated PMCs, MMCs, and CMCs, respectively. In some cases, both phases of the composite percolate in all three dimensions throughout the material; the distinction between matrix and reinforcement then disappears to some extent. These composites are termed interpenetrating phase composites (IPCs).

Reinforcements are distinguished by their shape. They can be (i) long, essentially continuous fibers, (ii) short fibers, (iii) whiskers, which are small elongated single crystals of high perfection, or (iv) equiaxed particles of a wide variety of materials and forms. Processes by which the reinforcements are produced vary widely, and depend strongly on the reinforcement shape.

Fibers generally start as a viscous mass that is spun. This can be the material itself in molten form: glass is spun directly into fibers, as are metallic "melt-spun" ribbons. The fiber can also be spun in precursor form. This can be a slurry that is later dried and sintered, a polymer that is later pyrolyzed into a ceramic or into carbon, or pitch that can also be pyrolyzed into high-modulus carbon. Sometimes, fibers are not spun but gradually built by deposition onto a finer continuous fiber core. Thicker fibers result, which are generally called monofilaments. Thin metallic wires or filaments can also be produced in the solid state by drawing through a series of dies.

Short fibers can be spun directly if the process is sufficiently turbulent, or can start as continuous fiber that is chopped. Whiskers are grown using relatively complex processes that most often involve material transport from a vapor.

Equiaxed reinforcements are produced by many different processes: most ceramic particles are made by crushing bulk material, a process called comminution. Alternatively, equiaxed particles can be precipitated from a solution using sol–gel processing. Metallic particles can be solidified directly from the melt by atomization, can be produced from a precursor by precipitation or direct reduction, or can be cut from the bulk by machining.

With such a wide spectrum of production routes, composite reinforcements include the cheapest materials available (sand qualifies as an equiaxed reinforcement, as do waste products such as flyash—in these cases, the reinforcement is often called a "filler"), as well as some of the most expensive structural materials on the market (e.g., boron monofilaments).

The process by which matrix and reinforcement are combined is dictated by the shape of the reinforcement and by the nature of the matrix. With polymer matrices, the composite can be produced at, or near, room temperature. This eases processing considerably: both directly because tooling is far simpler, and also indirectly because at high temperature one often encounters problems of chemical reactivity between reinforcement and matrix.

Polymer matrix composites with equiaxed reinforcements can be produced by simply stirring the particles into the matrix before curing the latter (with thermoset matrices) or at slightly above room temperature (with thermoplastic matrices). Short fibers can similarly be mixed into fluid polymers. Resulting viscous slurries can then be shaped in a closed mold or alternatively be coated onto a form; tooling required varies significantly with production volume and can be quite simple for small runs.

With continuous fiber reinforcements, processing becomes more complicated because of the need to control precisely how the fibers are handled and laid up. One method is to introduce the matrix into the tow, and then wind or stack the matrix-wetted tows to build up the composite. This route comprises filament winding and pultrusion processes used to produce composite cylinders or profiles (Fig. 1(a)). Alternatively, one can first lay up the dry fibers into a preform, and then infiltrate the fiber preform held in a mold with the matrix. These infiltration processes carry various names, one of the more usual being resin transfer molding (RTM) (Fig. 1(b)). For this latter class of processes, one can prepare the preforms by winding the fibers, or by weaving them into two-dimensional cloths or three-dimensional profiles. Woven fiber cloths can be stacked by hand, again allowing for relatively lightly tooled hand processing of composites.

With metal or ceramic matrices, processing becomes more complicated. This is the main reason why these two classes of composite materials lag far behind polymer matrix composites in engineering usage. One difficulty is that far higher temperatures must be employed, making handling and tooling more complex. Another difficulty stems from the fact that liquid metals and ceramics have far higher surface tensions than polymers, a result of the absence, in these matrices, of the weaker strictly physical bonds present in polymers. Although there are exceptions, molten inorganic matrices therefore tend not to wet spontaneously usual reinforcements. Here again, processes depend largely on the reinforcement geometry. Equiaxed reinforcement particles or short fibers can be stirred into the molten matrix. Alternatively, matrix and reinforcement powders can be blended and consolidated by conventional powder densification processes; this is, for example, how tungsten carbide tools are produced. With fibrous reinforcements, processes often start with the
Figure 1
Two processes used in the fabrication of fiber-reinforced polymer composites: (a) fiber tow impregnation and consolidation, often termed filament winding or pultrusion (depending on how impregnated tows are consolidated); (b) infiltration, often termed resin transfer molding (RTM).

production of a fiber preform that is subsequently infiltrated. Fiber-reinforced aluminum diesel engine pistons and SiC/SiC fiber composites are thus produced by liquid and vapor infiltration, respectively.

Since composites are generally produced by combination of two pre-existing phases, the interface between matrix and reinforcement is accessible during processing. Consequently, its nature and properties can be engineered to improve the composite or make it easier to produce. Depending on the desired composite properties, the interface can, for example, be made weak or strong, electrically insulating, or optically reflective. This is particularly important in brittle matrix fiber composites that are toughened by the fiber pull-out mechanism, in which the interface must be sufficiently weak to cause fiber/matrix debonding once the interface is reached by a crack. Continuous fibers destined to be combined with a polymer matrix are thus generally coated with a thin layer of "sizing," which protects the dry fibers against mutual rubbing and produces an optimal bond between matrix and reinforcement. In metal and ceramic matrix composites, interface engineering is often conducted with the aim of protecting the reinforcement from chemical attack by the matrix, or to promote wetting of the reinforcement by the matrix. To this end, coatings of many different types have been employed. Perhaps the most sophisticated example is that of layered carbon/SiC coatings applied to SiC monofilaments for combination with titanium-based matrices: the carbon layer makes the interface weak, while the SiC protects the carbon layer from the titanium.

Sometimes, the two main steps of composite processing, namely (i) reinforcement and/or matrix production and (ii) combination of the two phases, occur simultaneously or in inverse order. Such processes are generally called "*in situ*" processes, because one of the phases, generally the reinforcement, is created by chemical reaction within a bulk material that is a precursor to the composite. Examples include the directed oxidation of aluminum to produce its oxide toughened by channels of remanent metal, or the consolidation of powder blends of different phases that react with one another to form, for example, an intermetallic and a ceramic. Many highly porous materials are also produced using in-situ processes; an example is with polyurethane foam, which is produced by reactive gas evolution within a viscous liquid precursor of the material containing surface-active additions that stabilize thin cell walls against rupture. Although often essentially "bulk" in nature, *in situ* composite processes can generally be distinguished from alloying or other conventional bulk material processes by the fact that they involve phase formation by chemical reaction instead of phase transformation. Still, the term "*in situ* composite" has often been used by analogy to designate some conventionally processed bulk materials, either because of the fibrous microstructures produced (*in situ* eutectic composites fall in this class), or because the two phases are widely different, such that the material behavior is similar to that of certain composites with equiaxed reinforcements (metal

alloys containing brittle nonmetallic second phases have thus at times been termed composites).

Cost is of course an important consideration in composite processing, as it ultimately determines whether composites will be used in practice. Many composites can be molded and shaped into highly complex shapes: this can make these materials cost-competitive despite higher material prices if one composite part replaces a structure that would otherwise be assembled by welding or riveting several metallic components. Tooling is a particularly important issue in composite mass production. With composites, tooling can suffer because of wear (e.g., ceramic particle-reinforced aluminum or PEEK/carbon composites tend to erode dies rapidly), or can be critical because, unlike a metal that can be bent back to shape, polymer composite components are systematically rejected if tolerances are not respected. With composites, recycling is also a complex issue. The material can sometimes be reused; however, other methods of recycling may be opportune, such as separating matrix and reinforcement before recycling each separately. The competitiveness of composites thus hinges on many issues other than the intrinsic cost or performance of the material itself.

2. Predicting Properties of Composites

An important question, both for engineering design of a composite material and for scientific understanding of its properties, is that of how the overall properties of the composite depend on those of the individual constituents.

Properties of a composite material can be considered under two headings. (a) those that depend solely upon the geometrical arrangement of the phases and their respective volume fractions, and not at all upon the dimensions of the components, and (b) those that depend on structural factors such as periodicity of arrangement or the sizes of the pieces of the two or more component phases. Indeed, in many instances the properties of phases making the composite start changing when the smallest dimension of the phase (the diameter of a fiber, the thickness of the cell wall in a foam) falls below a certain dimension. The plastic deformation of metals is for example strongly altered when metal elements are less than 1 μm thin, and the band gap of semiconductors starts changing radically when their size falls below roughly 10 nm.

2.1 Properties Determined by Geometry—Additive Properties

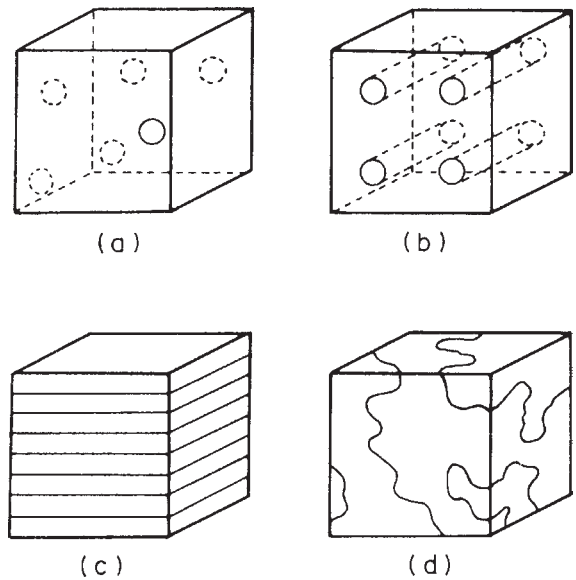
The geometrical arrangement of the phases in a composite material can be often described in simple terms (Fig. 2); these can also be quantified using principles of image analysis. Modern computed tomography gives access to a full three-dimensional description of


Figure 2
Composite geometries: (a) random dispersion of spheres in a continuous matrix; (b) regular array of aligned filaments; (c) continuous laminas; (d) irregular geometry (after Hale 1976).

the material microstructure if there is sufficient X-ray contrast between the phases. Such is obviously the case with highly porous materials such as foams and microcellular materials, for which the technique is proving very powerful indeed (Baruchel *et al.* 2000, Maire *et al.* 2003).

The simplest physical property of a composite, namely its density, ρ_c, is given by the volume-weighted average of the densities of the components:

$$\rho_c = \rho_1 V_1 + \rho_2 V_2 \tag{1}$$

where V is the volume fraction and subscripts 1 and 2 refer to the components. If there are no other phases (including voids), $V_1 + V_2 = 1$. The volume fraction of each phase in the composite can thus be computed by measuring its density knowing that of its components; since the precision of this measurement increases with increasing density contrast between the phases, it is particularly simple and trustworthy for highly porous materials such as a foam.

More complicated physical properties, e.g., those described by a second-rank tensor, relate two vectors: a solenoidal vector and an irrotational vector (as with magnetic or electric susceptibility), or else a flux vector and the gradient of a scalar function (as with diffusivity and electric and thermal conductivity). The relationships derived for these properties for a composite material in terms of the same property in each of the submaterials or components are all

formally identical. They have usually been discussed in terms of the dielectric constant, ε, and, because of this, the general attempt to predict the overall physical properties of a multiphase composite from the same properties of the individual phases is sometimes called the dielectric problem. Attempts to devise exact, generally applicable theoretical expressions for the dielectric constants of mixtures of unknown phase geometry are futile. However, the dielectric constant of a mixture of two phases, ε_c, must lie between certain limits, whatever the geometry. If some knowledge of the phase geometry is available, still closer bounds can be set on the value of ε_c; the same is true of other properties. There is, therefore, a good deal of utility in the search for bounds on the properties. For a few special properties, exact solutions can be obtained. Approximate solutions are also often obtained for two-phase composites when the volume fraction of one of the components is low. Such solutions are often extended to nondilute situations by use of a self-consistent scheme, in which each particle of the minor component is assumed to be surrounded not by the other component but by the average composite material. For example, as given by Hashin and Shtrikman (1962), the effective dielectric constant of an isotropic composite must lie in the range

$$\varepsilon_1 + \frac{V_2}{\dfrac{1}{\varepsilon_2 - \varepsilon_1} + \dfrac{V_1}{3\varepsilon_1}} \leqslant \varepsilon_c \leqslant \varepsilon_2 + \frac{V_1}{\dfrac{1}{\varepsilon_1 - \varepsilon_2} + \dfrac{V_2}{3\varepsilon_2}} \qquad (2)$$

where $\varepsilon_2 > \varepsilon_1$. These are the best possible bounds obtainable for the dielectric constant of an isotropic two-phase material if no structural information, apart from the volume fractions, is available.

Figure 3 compares the predictions of those bounds for the cases $\varepsilon_1/\varepsilon_2 = 0.1$ and $\varepsilon_1/\varepsilon_2 = 0.01$ with the most elementary bounds that can be rigorously derived for an isotropic composite. These elementary bounds correspond to simple Voigt (polarization in parallel) and Reuss (polarization in series) estimates. The Voigt estimate is of the form of Eqn. (1), while the Reuss estimate gives the composite dielectric constant as

$$1/\varepsilon_c = V_1/\varepsilon_1 + V_2/\varepsilon_2 \qquad (3)$$

If ε_1 and ε_2 do not differ greatly, the bounds given by Eqn. (2) are very close together, but for $\varepsilon_1/\varepsilon_2 = 0.01$ they are far apart (such as in Fig. 3). Therefore, in many practical cases, better bounds are required.

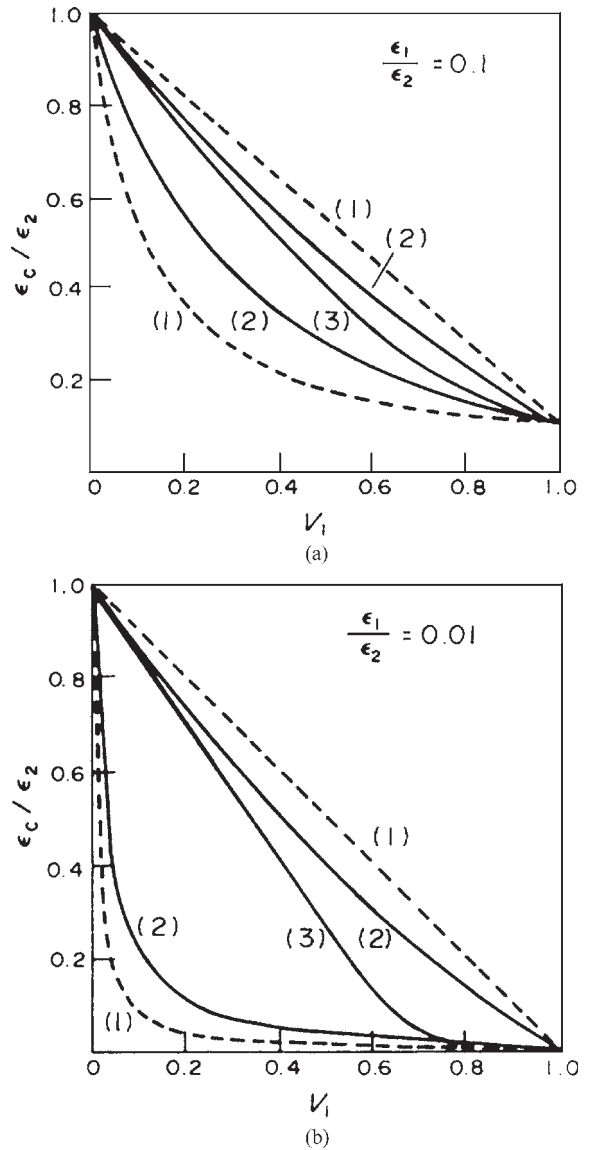
In the above discussion, the properties of the individual components or submaterials within the composite are assumed to be identical with the same properties measured in a piece of the submaterial outside the composite. In addition, the composite is taken to be statistically homogeneous in the sense that, if small elements of the material were extracted,


Figure 3
Dielectric constant of composite materials: (a) $\varepsilon_1/\varepsilon_2 = 0.1$ and (b) $\varepsilon_1/\varepsilon_2 = 0.01$. (1) Bounds from Eqns (1) and (3); (2) Hashin and Shtrickman bounds for arbitrary geometry (Eqn. (2)); (3) self-consistent approximation for spheres in a continuous matrix (after Hale 1976).

these would have the same physical properties as the whole sample. In addition, the implicit assumptions are made that there are no voids, that space-charge effects and polarization are absent (in the case of electrical conductivity), and that there is no discontinuity in temperature at the interface (in the case of heat flux).

Thermal expansion coefficients of composites involve both the elastic constants and the thermal expansion coefficients of the individual phases. An important function of reinforcing fillers and fibers in plastics is the reduction and control of thermal expansion. For example, with dental filling materials, a difference in thermal expansion between the filling material and the tooth substance can lead to a marginal gap, and hence composite filling materials are designed to have a thermal expansion coefficient very close to that of the tooth substance.

With some components, especially at low fiber volume fractions, the transverse thermal expansion coefficient of, for example, a glass-fiber epoxy-resin composite, can be greater than that of the matrix. This effect is particularly noticeable with fibers of high modulus and low expansion coefficient (e.g., boron or carbon) in a low-modulus matrix.

Fibers are often used in laminated arrangements because properties parallel to the fibers are very different from properties perpendicular to the fibers. The effective in-plane thermal expansion coefficients for angle-ply laminates (in which the fibers are arranged at plus and minus an angle θ to a particular direction) show that in such laminates a scissoring or lazy-tongs type of action can occur, and, with appropriate values of θ, can lead to a zero or even negative thermal expansion in one direction.

2.2 Special Property Combinations—Product Properties

Composite materials can, in principle, be thought of as materials that produce properties unobtainable in a single material. For example, by combining a piezoelectric material with a material showing magnetostriction, the composite should allow a magnetoelectric effect: i.e., an applied magnetic field would induce an electric dipole moment; or a material could be produced in which an applied magnetic field produced optical birefringence, by coupling a material that shows strain-induced birefringence with one showing magnetostriction.

This idea led van Suchtelen (1972) to classify such effects as product properties of composites and so now there are considered to be two different types of physical property of composite materials.

The first is the type discussed in Sect. 2.1. These are sum or additive properties where the composite property is related to that same property of each of the components and so depends on the geometry of arrangement of the two components. The geometry of arrangement includes of course the volume fraction. Examples are elastic stiffness, relating applied stress and measured strain, or electrical resistance, relating applied electric field and measured current density, or the simple example of mass density. The value of the physical property of the composite in general lies between those of the components.

There is a subclass of additive properties in which the value of the property of the composite can lie well outside the bounds set by the values of the property of the components. Examples are Poisson's ratio involving the ratio of two compliance coefficients under the action of a single applied stress, or acoustic wave velocity, which depends on the ratio of elastic modulus to density. Here, because the elastic modulus and the density can follow quite different variations with volume fraction, e.g., elastic modulus following Eqn. (3) and density following Eqn. (1), the acoustic wave velocity of the composite can lie well outside the value for either component. A further, but less obvious, example is the thermal expansion coefficient, which depends on the thermal expansion coefficients and the elastic constants of the two phases.

Product properties are those cited at the beginning of this section: the property of the composite depends specifically on the interaction between its components. Any physical property can be considered as the action of a physical quantity X resulting in physical quantity Y giving the X–Y effect. Product properties are those in which an X–Y effect in submaterial 1 produces a Y–Z effect in submaterial 2, producing in the composite an X–Z effect. A good example is that of a magnetoelectric effect in a composite material having one magnetostrictive and one piezoelectric phase. Application of a magnetic field produces a change in shape in the magnetostrictive phase that then stresses the piezoelectric phase and hence generates an electric field. In this case the coupling is mechanical but the coupling could also be electrical, optical, magnetic, thermal, or chemical (van Suchtelen 1972).

Viewed in this way, sum properties are those in which an X–Y effect in submaterial 1 and the same X–Y effect in submaterial 2 combine to give an X–Y effect in the composite.

Table 1 classifies some physical properties or phenomena according to the input–output parameters X and Y. A small selection of possible product properties is given in Table 2.

2.3 Properties Dependent on Phase Dimensions and Structural Periodicity

In Sects. 2.1 and 2.2 the physical properties of the components or submaterials are assumed to be unaltered by the incorporation of the component into the composite. This is usually not the case. The effects of phase changes or chemical reactions during fabrication are of importance in a wide range of composites. Excessive shrinkage of one component can result in high internal stresses, which may lead to premature failure or even preclude successful fabrication. Matrix shrinkage also has an important indirect effect on the mechanical behavior of fiber

Table 1
Matrix classification of some physical properties or phenomena in materials according to the type of input and output parameters (after van Suchtelen 1972)

Output parameter (Y)	Input parameter (X)

composites, since the resulting internal stresses can determine the frictional forces at the fiber/matrix interface.

The dimensions and periodicity of a composite structure also have an important effect on the properties when they become comparable with, for example, the wavelength of incident radiation, the size of a magnetic domain, or the thickness of the space-charge layer at an interface. The dimensions are also particularly important when the properties of a material depend on the presence of defects of a particular size (e.g., cracks). The strength of a brittle solid containing a crack depends on the square root of the length of the crack. Since very small particles cannot contain long cracks, and because the surface region of most solids behaves differently from the interior (a small fiber or sphere contains proportionately more surface material than a large piece), the breaking strength depends on the dimensions of the piece tested. This is particularly important when considering mechanical strength and toughness of composites.

Many of the optical effects that depend on structural dimensions also depend in a very complex way on other factors, and optical effects produced by dispersion of a second phase within a material are often used to determine the distribution of that phase (e.g., determination of the molecular weights of polymers or of the size of crystal nuclei in glasses), rather than regarding the material as a composite with special optical properties. However, a composite material containing aligned elongated particles of an optically isotropic material in an optically isotropic matrix may exhibit double refraction as a straightforward consequence of the relationship between dielectric constant and refractive index.

In a ferromagnetic material at temperatures below the Curie point, the electronic magnetic moments are aligned within small contiguous regions—the magnetic domains—within each of which the local magnetization is saturated. Magnets of very high coercivity can be obtained by using very fine particles: a particle with a diameter of between 10^{-1} μm and 10^{-3} μm would be magnetized almost to saturation since the formation of a flux-closure configuration would be energetically unfavorable. Magnetization reversal cannot take place in a sufficiently small single-domain particle by boundary displacement; it must occur by a single jump against the magnetocrystalline anisotropy and the shape factor. Fine-particle permanent magnets of the rare-earth alloys such as $SmCo_5$, enveloped in an inert matrix such as tin, have been developed that have superior properties.

3. *Advanced Fiber Composites*

The best-known and striking example of a modern composite material is, as mentioned above, the fiber composite, designed for high strength, high stiffness, and low weight.

The stiffest materials are ceramics composed of elements from the first rows of the periodic table (B, C, SiC, Al_2O_3, etc.). This is because these elements contain the highest possible packing of strong covalent bonds directed in three dimensions. Such materials also each have a high melting point, a low coefficient of thermal expansion, and a low density. All of these are very desirable engineering properties.

In all structural applications, the weight of the structure necessary to bear a given load and to do so with a minimum elastic deflection is important, and so strong fibers are compared on the basis of specific modulus and specific strength, i.e., modulus or strength divided by density, respectively. When this is done the stiffest materials on a weight-for-weight basis are the plastics (PET, PBT, Kevlar) and the glasses. The metals make a very poor showing on either specific stiffness or specific strength. However, fibers cannot be used directly and must be bound together with a matrix.

A set of aligned fibers in a pliant matrix is only useful as an engineering material under direct tensile forces parallel to the fibers. The salient properties are represented by those of a pocket handkerchief, which is stiff in the direction of the warp and weft (parallel to the fibers) but shears easily parallel to these. Hence the properties of fiber composites are very directional, being strong and stiff parallel to the fibers, but rather weak in shear parallel to the fibers (because this property depends on the shear properties of the matrix), and often very weak indeed in tension perpendicular to the fibers. In order to overcome this, the fibers can be packed along several directions; patterns exist that permit this in three dimensions, some of which actually produce fully isotropic structures (Parkhouse and Kelly 1998). In practice, as advanced fiber composites are often used to produce relatively thin shell structures (such as the hull of a sailboat, the body of an automobile or the wing of an airplane), the fibers are arranged in planar sheets called laminae, each containing parallel fibers, and these are stuck together so as to provide a more isotropic material with a high volume loading of fibers.

Alternatively, the fibers may be randomly arranged in a plane or in three dimensions; such arrangements limit the obtainable fiber packing density (Parkhouse and Kelly, 1995). Fibers are also often woven into mats before incorporation into the composite because this aids the handling of fiber arrays.

When carbon- or other fiber-reinforced plastics are made with woven fabric rather than nonwoven material, distortion of the load-carrying fibers parallel to the applied stress reduces the tensile strength and reduces stiffness and toughness. When, however, woven fabric is oriented at $45°$ to the load direction these properties compare favorably with those for nonwoven $\pm 45°$ material. Indeed, the residual strengths after impact can be greater.

The anisotropy of the properties of advanced fiber composites represents a unique feature in engineering design using advanced composites. The anisotropy can be varied; in fact it is possible now to place the fibers precisely where they are needed in a structure to bear the loads. It is also possible, for instance, to vary the amount and stacking of the fibers in various directions along the length of a beam so as to vary the stiffness and torsional rigidity of the material.

It would be impossible to make use of the inherent advantages of anisotropic materials such as carbon fiber reinforced plastics (CFRPs) without the invention of computer-aided methods. The reiterations and the number of variables involved require computer programs both to relate the properties of the individual laminae to the properties of the fibers and to take into account the interactions in term of bending–twisting coupling between the various laminae. Initially, of course, these complications were viewed as a great disadvantage of the material, since the engineer was not happy with anisotropy. Now the problem of how to use it and make a virtue, not so much out of necessity, but of a supposed vice, has been solved. The Grumman X29 aircraft makes use of bending–twisting coupling so that, as the loads on an aircraft wing increase, the structure can deform but remain tuned to the aerodynamic requirements. The material possesses almost a form of "gearing", so that it changes its shape automatically without the need for sensors and levers.

The very strong and stiff fibers comprise asbestos (a naturally occurring fiber), boron, and carbon of varying degrees of graphitization, made in principle from a number of starting materials but in practice mainly two: PAN (polyacrylonitrile) and pitch. Inorganic glasses based on silica yield many fibers. Those made in the form of continuous filaments are most important for composite materials. Many linear polymers, such as polyparabenzamide or simple polyethylene, can be processed to form very stiff and strong fibers. Ceramic fibers, of Al_2O_3, mullite, and silicon carbide and nitride, are important for high-temperature use, either as a reinforcement for metals or ceramics, or in filtration and other applications because of their chemical inertness. Additionally, fibers can be sensors. For example, if made of shape memory alloys (SMAs) the composite material can then react to its environment, by sensing or by deforming under the influence of variations in its mechanical or thermal environment. Such composites have been termed "smart" or "intelligent".

Strong fibers, whether they are stiff or not, also have the great advantage of restraining cracking in what are called brittle matrices. It is this use of fibers

Without fibers

With fibers
Figure 4
Demonstration of how cracks are prevented from
running in a brittle material because of fibers in their
path.

that is often referred to when showing how the an-
cients employed composite materials. Quotations
from the Bible are made, such as that from Exodus,
Chapter 5, verses 6 *et seq.*, which refer to the diffi-
culty of making bricks without straw. Fibers restrain
cracking because they bridge the cracks. The prin-
ciple is very simple. It has been used in asbestos-
reinforced cement and the principle of reinforced
concrete is not too far from the same idea. The prin-
ciple is illustrated in Fig. 4. A crack passing through a
brittle material may not enter the fibers but leaves a
crack straddled by fibers so that a material that
would normally have broken with a single crack now
has to be cracked in a large number of places before
the fibers themselves fail or pull out. This is used in
fiber-reinforced cement, which is based on the same
principles as reinforced concrete, but since the fibers
are very much finer than reinforcing bars and are
often not visible to the naked eye, a homogeneous
material is effectively produced that can show quasi-
plastic deformation.

4. Composites with Short Reinforcements

Many composite materials are reinforced not with
continuous fibers but with more or less equiaxed re-
inforcements, such as particles or short fibers. In
these, the transfer of applied stress from matrix to

reinforcement is less effective than it is with a con-
tinuous fiber reinforcement; the properties of such
composites are, therefore, dominated to a far higher
degree by those of the matrix. Still, equiaxed rein-
forcements can significantly improve the properties
of the matrix, and generally do so at far lower cost
than with fibers. The reinforcement cost can even be
so low that it is mainly added to the matrix because
it is cheap: mineral particulate fillers are at times
incorporated in polymers or low-cost construction
materials chiefly for this reason. Generally, however,
one adds the reinforcement in order to improve matrix
properties.

Friction and wear resistance can, for instance, be
much improved with equiaxed reinforcements: tribo-
logical behavior being largely determined by super-
ficial material only, it matters less if the reinforcement
is fibrous or not. Particles of hard ceramic added to
polymers or metals thus produce very good improve-
ments in wear and abrasion resistance, and do so
about as well as fibers would. An example is provided
by SiC particle-reinforced aluminum. This composite
is used to produce high-performance brake disks,
which are strong, light, excellent heat conductors,
and sufficiently refractory. Cemented carbide cutting
tool materials provide another example of a compo-
site with an equiaxed reinforcement that is largely
designed to resist abrasion. Composites containing
lubricating reinforcements (generally graphite) can
also be produced to reduce dry friction.

Although less spectacularly than with a fiber, the
toughness of a brittle matrix can also be improved with
the addition of whiskers, short fibers, or equiaxed par-
ticles. This can be accomplished by several mecha-
nisms. The reinforcement can be a far tougher phase
than the matrix, which (provided the crack does not
meander its way between particles) prevents crack
propagation by creating bridges that pull together ma-
trix crack faces. Elastomeric additions to polymers and
metal islands or channels within a ceramic matrix play
this role. Another effective toughening mechanism
achieved with equiaxed reinforcements is obtained in
monolithic ceramics with the addition of zirconia par-
ticles that present a tetragonal to monoclinic phase
transformation. More simply, equiaxed reinforcements
can also toughen a brittle matrix by creating a site for
localized deflection of cracks along their path.

With equiaxed reinforcements, the composite be-
havior is more like that of conventional bulk materi-
als. The science of multiphase metal alloys or ceramics
can thus be used to a large extent towards under-
standing the behavior of this class of composites.
However, composites are often combinations of highly
dissimilar materials, such as a metal and a ceramic,
and this exacerbates the complexity of their interac-
tion. Another complication in analysis is, as discussed
above, that the properties of each phase may be dif-
ferent in the composite than in the same phase when it
is in bulk form. Its microstructure may differ (e.g., if

the reinforcement nucleates matrix crystallization), as may its strength, either because the defect population differs or because the agents of deformation, such as dislocations, move and interact differently in the narrow space between two matrix/reinforcement interfaces. These effects increase in importance as the scale of the microstructure of the composite is refined.

Sometimes it is their greater similarity and compatibility with isotropic bulk material that makes composites reinforced with short or equiaxed reinforcements attractive. If isotropic properties are desired, for reasons of design or for ease of processing, equiaxed reinforcements are thus useful. Also, particulate composites may be preferred over fiber composites because they are far easier to join, particularly with bulk material components. For example, particle-reinforced metals can be welded, which enables their economical use in bicycle frames or automotive driveshafts.

5. *Porous and Cellular Materials*

A special class of composite materials are those in which a material is combined with empty pore space. Indeed, although porosity is a defect in many materials, causing premature failure in incompletely sintered ceramics or poorly fed metal castings for example, sometimes it is desirable.

There are various reasons why one might want to introduce pores in a material. One is to create a light and soft material: polyurethane foam is a commonplace example that is used in applications requiring a low modulus or high compressibility: furniture, sports shoes are examples. Another is thermal insulation. Indeed, small empty pores are about as good an insulator as can be found; hence materials designed to resist heat conduction are generally very porous: styrofoam and glasswool are examples. Filters, sieves, catalysts, fuel cell electrodes, sound absorbers are all applications that call for highly porous materials. Also, many of Nature's materials are microcellular: wood and bone for example; artificial tissue and bone replacement materials are hence also often porous.

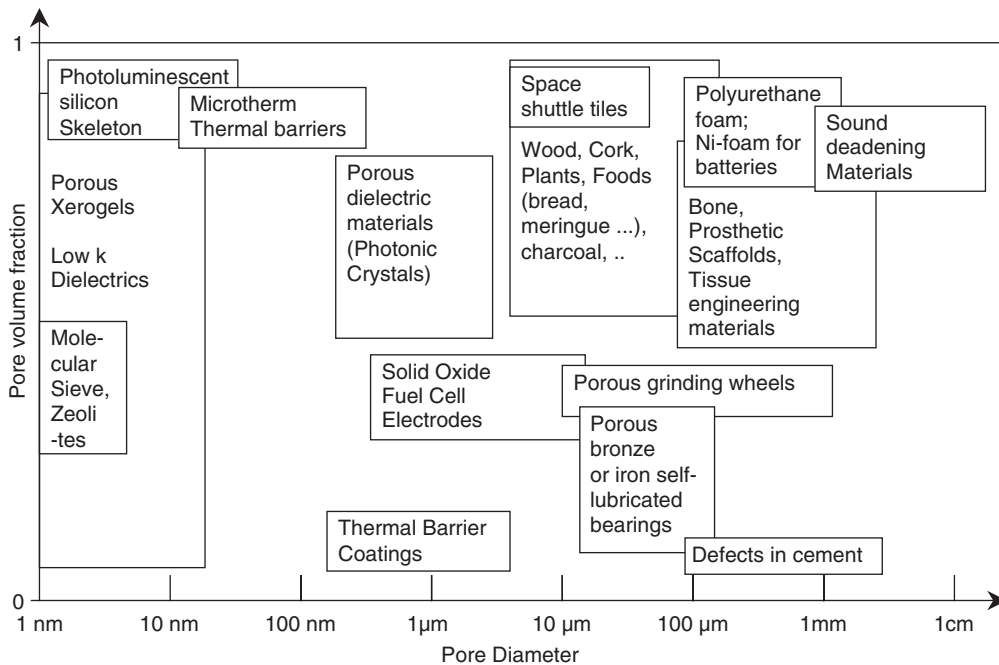
Porous materials are often composites in the sense that pores are deliberately introduced into the base material; also, these are engineered in that the pore size and shape are purposefully controlled. Many methods exist to produce highly porous materials. One is foaming: if a reactive gas former is mixed into a viscous material, or if a material is highly supersaturated with gas, bubbles can be made to nucleate and grow. If these are sufficiently stable, the bubbles can grow to many times the volume of the material in which they have nucleated. Bubble stability is promoted by a "disjoining" pressure that pushes apart two liquid/gas interfaces as they approach one another; reducing the surface tension of the liquid
Figure 5
Highly porous microcellular nickel material produced by electrodeposition onto a metallized open-pore polyurethane foam. (Sample produced by Nitech S.A., France; sample kindly provided by Dr. Croset).


Figure 6
A map giving roughly the scale and level of porosity of various porous materials. Illustrations for several of these can be found in (Kelly, Clyne, Bonfield, and Willoughby, 2006).

also helps: these are engineered to prevent bubble walls from becoming unstable and bursting. After solidification of the material if it is liquid, the result is a highly porous solid foam, in which pores are individually isolated, or "closed".

In another class of highly porous materials, the pores are "open" or interconnected, and hence accessible to an external fluid: filters or paper are examples. Open-pore materials can be made by bursting the walls between bubbles in a foam, by partially bonding or sintering a packed bed of particles or short fibers, by infiltrating a fine-scale place holder material that is later removed, or by chemical attack of alloyed materials. Figure 5 gives an example of an open-pore microcellular material: this is a nickel battery electrode material that was created by electrodepositing the metal onto an open-pore polyurethane foam.

Polymers, metals, ceramics, carbon and biomaterials have all been used to produce highly porous or microcellular materials, featuring both open and closed pores (Gibson and Ashby, 1997; Schüth *et al.* 2002; Kelly *et al.* 2006). In some cases, the porous material is itself a composite: solid oxide fuel cell electrodes, generally a highly porous nickel/ceramic composite, are one example.

An important parameter in most porous materials is the pore size; essentially, one can distinguish between microporous and nanoporous materials. In polyurethane foams, highly porous metals, or many natural microcellular materials such as wood and bone, the pores are many micrometers in diameter. In other porous materials, individual pores are only a few nanometers in diameter: natural zeolites are one example; nanoporous silicon is another. Such small pores can have interesting properties. For example, when solid struts in nanoporous silicon are only a few nanometers across they become photoluminescent. Thermal insulators also become particularly efficient if the pores are less than 100 nm in diameter. Figure 6 illustrates the wide range of pore scale and "relative density" (i.e., the solid phase volume fraction in the porous material, equal to one minus the pore volume fraction) that are found in today's highly porous materials.

6. Conclusion

The term "composite material" collects under one heading a very large and now ubiquitous class of materials. Their common and defining trait is that composites are combinations of phases that are bonded together instead of being created by phase transformation within bulk materials. Composites can therefore contain widely different and interacting

materials, combined at a scale and with a microstructural architecture that are controlled with considerable latitude. This enables the generation of materials with special and controlled properties, making composites unique among materials. Their main limitations are generally their cost, as well as the challenges they pose in design, recycling, shaping, and assembly. These limitations are offset by significant and often spectacular gains in performance, such that the use of composite materials, already very high, is still increasing rapidly.

Aircraft Materials

The selection of materials for aerospace is a complex decision-making process, always involving tradeoffs. It involves consideration of numerous factors such as environmental (temperature, corrosion) loading parameters, stiffness, durability, and damage tolerance. Cost, which includes raw materials and all subsequent processing costs, is becoming more dominant in today's global market, and the industry is directing an increasing portion of the materials development effort to this area.

1. Historical Development

Prior to World War II, aluminum was used almost exclusively in metal aircraft construction with some steel in selected areas where its higher strength and stiffness was required, such as landing gear and engine support structure components. With the development of the Kroll process as a production means of economically extracting titanium from its ore, titanium began being used for aerospace applications in the 1950s, driven primarily by the engine companies. It is now a key material for both airframe and engine structure due to its high specific strength and corrosion resistance relative to aluminum. In the early-to-mid 1960s, composite materials consisting of boron-based fibers impregnated with various polymers were introduced into aerospace structure. These composites soon evolved into the present-day carbon fiber composites, commonly referred to as CFRP (carbon fiber reinforced plastic) or GR/EP (graphite/epoxy) or PMC (polymer matrix composites). (The earlier boron fiber composites were very costly, and very difficult to machine. Development of the graphite fibers then displaced the earlier boron composites.) The polymeric matrices, graphite fibers, and processing have constantly evolved to the point where cost and structurally efficient airframe structure can be produced. They are attractive materials due to their low density, high strength and stiffness, and excellent fatigue characteristics in conjunction with the ability to tailor the composite layup to the specific requirements of the component. Thermoset epoxy-based resin systems typically have dominated the airframe industry. However, more specialized systems have been used for applications requiring higher operating temperatures, such as bismaleimides (BMI). Significant advances have also been made with regard to the development and application of aluminum (ARALL and GLARE) and titanium hybrid laminates (polymer matrix composite/Ti), and aluminum and titanium metal matrix composites, though their usage has been limited by high costs.

2. Temperature Considerations

Subsonic airframes are exposed to a wide range of temperatures; exterior structures exposed to the atmosphere can reach $-54\,°C$ to $-73\,°C$ while structures in the nacelle area may reach several hundred degrees. Typically, 7075-type high-strength aluminum alloys are used up to about $120\,°C$. Moderate-strength 2024-type alloys can be used up to $175\,°C$ for short times, and the 2219 alloy can be used up to about $205\,°C$ with the same caveat. High-strength low-alloy steels such as 4330M, 4340, and 4340M (300M) may be used up to about $205\,°C$. This limitation is governed by three factors: (i) restrictions due to the finish used for corrosion protection, (ii) retention of the residual stresses due to shot peening, and (iii) must be used at least $28\,°C$ below the tempering temperature to prevent overtempering. Stainless and corrosion-resistant steels such as 15-5PH and PH13-8Mo may be used up to temperatures of ~315–$480\,°C$. Iron and nickel-based heat-resistant alloys are used at temperatures up to $705\,°C$ and higher (most airframe structures experience temperatures below about $95\,°C$ to $150\,°C$, with structures in the engine areas reaching about $370\,°C$.

Alpha or super-α alloys such as Ti–6Al–2Sn–4Zr–2Mo + Si are used at temperatures up to $540\,°C$ for structural applications. The plug and nozzle on some of the newer transport engines use a titanium alloy (Beta-21S) at temperatures up to $705\,°C$ for short times. The temperature is normally in the $540\,°C$ to $565\,°C$, and lower, range.

Fighter aircraft operate over a similar temperature range as commercial aircraft. However, supersonic-capable aircraft have higher temperature requirements.

The existing $80\,°C$-cure epoxy PMC materials are presently characterized for use at temperatures to $\sim35\,°C$. Higher operating temperatures have been demonstrated on military applications. They have pushed epoxies to $135\,°C$ (over limited load-bearing structures) and BMI to a continuous operating temperatures of $165\,°C$, with higher excursions in isolated cases. The reader must note that military applications have lives that are typically less than half that of commercial aircraft, from a flight hour standpoint.

The processability of the epoxies and BMIs is typically well-known and characterized, and both systems are commercially available. Certain systems have a desired characteristic, such as controlled flow, for example. This allows for panels to be fabricated utilizing various low-weight core materials (honeycomb)

---

to provide panel stiffness. Nomex or fiberglass core impregnated with phenolic resin is extensively used in structural applications. Controlled flow allows the use of this lightweight honeycomb without resin flowing into the cells, and subsequently resulting in a low fiber volume fraction in the facesheet plies. Alternate core materials are also utilized based upon the design/cost/performance requirements.

Specialized materials such a polyamides have been used in excess of the above stated temperatures. Several engine exit and compressor stator vane components have been fabricated. In addition, specialized structures that are "washed" with engine exhaust gases have also been produced.

3. Design Considerations

The design of aircraft structure must take into account four major failure modes

- Static
- Stiffness
- Durability, considering both fatigue and damage tolerance (crack growth, residual strength, and damage detection)
- Environmental resistance (corrosion and temperature considerations)

With the recent refinements of analysis methods, the safety factor of 1.5, component verification, and airplane proof and ultimate tests, there is an extremely low probability of a static failure of any undamaged structure. Many airframe components are designed by elastic stiffness or specific stiffness (modulus/density) considerations to minimize weight. With the widespread introduction of dissimilar composite and metallic structural materials, the requirement to match stiffness properties can be an important design criterion. Similar to the static analysis gains, technology improvements in design and analysis to meet the fatigue life requirements have minimized these concerns, though problems still exist in certain areas. Most of the fatigue problems in service have been on aircraft that have exceeded the design service objective (DSO). Safe operation of aircraft also hinges on design for damage tolerance. Commercial aircraft inspection periods are determined by the detectable defect size, crack growth rate and critical crack length. It must be demonstrated, by test or analysis, that if a crack of the minimum detectable size initiates between inspection periods, the aircraft may be operated until it is detected. Military aircraft take this concept one step further; defects are assumed present when the aircraft rolls out of the door and analysis must demonstrate that the aircraft can operate safely for two lifetimes (and actually test for four lifetimes) with this assumed flaw in the most critical location of a given component. This concept

is designed to be safe with extensive damage—it *assures* the operator that they will have sufficient opportunity to detect and repair any damage before it becomes flight critical. A large portion of US Air Force aircraft structure is designed with this criterion. The US Navy tends more towards a safe-life approach, where aircraft life is designed by the number of cycles (flights) to initiate a detectable fatigue crack.

Critical requirements for a transport-type aircraft are summarized in Table 1.

The above criteria are specifically for transport-type aircraft, military or commercial. The differences in design considerations between military and commercial transports are relatively minor, the most significant being the need for rough runway capability for the former, and military transports are generally designed for a significantly shorter number of flight hours and the design is more driven by damage tolerance considerations. The differences are more substantial for fighter-type aircraft which also have shorter design lives (8000 hours as opposed to something of the order of 40 000 hours) and significantly higher loads, which means that design considerations are quite different, with damage-tolerance considerations driving US Air Force applications and fatigue-crack initiation driving US Navy designs.

Many steps have been taken to improve the corrosion protection of aluminum and steel alloys but this is still a maintenance issue with aircraft of today—though they are much improved in comparison to older aircraft.

Organic matrix composite materials are used to reduce weight, improving structural efficiency, and the design considerations for composite versus metallic structures are quite different. The primary difference in certifying these structures for service is accounting for barely visible impact damage for the composites. They can sustain significant damage that is not visible to the naked eye. The design allowable used to size structure is premised on several considerations, which includes barely visible damage, where applicable. It must be demonstrated that the airplane is capable of making a safe landing after the composite structure suffers an obvious in-flight discrete-source damage event. This would include events as severe as loss of a fractured engine turbine blade going through the structure. Potential environmental degradation must also be accounted for. Similar to the metallic structure, in addition to analytical verification, testing is carried out at the coupon, element, subcomponent, and component levels as well as full-scale limit-load testing to verify damage and environmental effects such as fluid sensitivity, moisture absorption, UV radiation, and oxidation.

4. Materials Used

Aluminum, steel, and titanium alloys and composites comprise ∼99% of the structural materials used on

Table 1
Critical requirements for transport aircraft component design.

Wing
Lower surface
   Skin (2XXX plate)[a]   Damage tolerance, fatigue
   Stringer (2XXX extrusion)   Fatigue, damage tolerance, tension strength
Upper surface
   Skin (7XXX plate)   Compression strength (damage tolerance for heavy-gage skins)
   Stringer (7XXX extrusion)   Compression strength
Ribs
   Shear tied (7XXX plate)   Shear strength
   Intermediate (7XXX sheet)   Stiffness, shear strength

Fuselage
Monocoque
   Skin (2XXX sheet)   Fatigue, damage tolerance, corrosion resistance
   Stringer (7XXX sheet)   Fatigue, compression strength
   Frames (7XXX sheet)   Stiffness, fatigue, compression strength, damage tolerance
Floors
   Beams (extrusion, sheet)   Static strength
   Seat tracks   Corrosion resistance, static strength
Bulkheads   Fatigue, damage tolerance

Stabilizer
Lower surface
   skin (7XXX plate)   Compression strength
   stringer (7XXX extrusion)   Compression strength
Upper surface
   skin (2XXX) plate   Tension strength, damage tolerance, fatigue
   stringer (2XXX extrusion)   Tension strength

Fin
   Skins (7XXX plate)   Compression strength, damage tolerance
   Stringer (7XXX extrusion)   Compression strength

[a] 2XXX and 7XXX refer to 2000 and 7000 series aluminum-type alloys, respectively.

commercial aircraft. Advantages and disadvantages of these materials systems are indicated in Table 2. Some nickel-based alloys and specialty materials are used for specific applications.

The primary structural construction material for commercial aircraft, transports, and bombers (with the exception of the B-2) is aluminum alloys. (The wing/fuselage skins of the B-2 are PMC, using an unmodified 175 °C-curing epoxy resin matrix.) The materials breakdown for transport/cargo type aircraft is shown in Fig. 1; it can be seen that the trend is towards increased composites and titanium usage, primarily at the expense of aluminum. It should be noted that 2.5% of the 78% aluminum on the C-17 is Al–Li (2090 sheet and extrusions used in the cargo floor area). The materials selection is much different from that of fighter aircraft (Fig. 2). As can be seen, the materials mix varies widely for fighters depending on their missions. Current day fighters tend to have composite skins, operating temperature permitting. A significant change in the F-18 materials mix occurred

as the performance requirements were increased. Titanium and PMC usage increased substantially at the expense of aluminum structure.

Aluminum alloys have been the backbone of aircraft construction since just prior to 1920, and most of the advanced alloys are simply variants of 2024, which was introduced in 1921, and 7075 which was introduced in 1943. Refinements in the chemistry, processing, and heat treatment have led to the evolution of properties illustrated in Fig. 3. There has been a continuous evolution of 2024 with emphasis on improving fracture toughness, fatigue-crack initiation and crack-growth resistance; with 7075 type alloys the emphasis has been to improve the strength (primarily compression strength) and fracture toughness, without sacrificing the other properties in either case. Along with the cited desired performance improvements, means of improving corrosion resistance are always of interest. The heat treatments selected for both alloy types have sacrificed some strength capability for the sake of corrosion resistance.

Table 2
Advantages and disadvantages of specific alloy systems.

Advantages	Disadvantages
Aluminum alloys	
Low density; good mechanical properties; low cost; low manufacturing costs; good toughness, da/dN, fatigue properties combinations; excellent machining characteristics	Corrosion; high-strength alloys not weldable[a]; high-strength alloys only used to 95 °C; not compatible with composites[b]
Titanium alloys	
High strength/density ratio; corrosion resistance; high operating temperatures; compatibility with composites; SPF; SPF/DB capability	High initial cost; high machining costs; difficult to form; high notch sensitivity
Low-alloy steels	
Highest strength; moderate toughness; low raw material cost	High density; corrosion; rigorous heat treatment and machining requirements for highest strengths
Corrosion-resistant steels	
Corrosion resistance; moderate-to-high strength; good fracture toughness; reduced manufacturing costs/flow time relative to low-alloy steel.	High density; low strength relative to the high-strength low-alloy steels
Nickel and heat-resistant alloys	
Moderate to high strength; excellent corrosion resistance; high operating temperature	High density; high cost; difficult to form and machine
Polymer matrix composites (PMC)	
Light weight; low density; high stiffness; high strength; can "tailor" properties; fatigue not an issue	Property characterization due to moisture equilibration and UV absorption; possibility of significant undetected damage; galvanic incompatibility with Al and low alloy steels

[a] Most aluminum–lithium alloys are weldable. [b] Corrosion protection must be used to fabricate Al/PMC structure.
Figure 1
Structural materials usage: transport-type aircraft.

The latest alloys utilized on the Boeing 777 include:

Upper wing—skin, 7055-T7751, high strength, good corrosion resistance; extrusions 7055-T77511.
Lower wing—skin, 2324-T39; stringers, 2224-T3511.
Fuselage—skin, 2524 (still 2024-T3 on other Boeing commercial aircraft); upper crown stringers, 7150-T77511; lower surface stringers, 7075-T6. The primary forging alloys are 7075-T73 and 7050-T74. The latter alloy is higher strength than

the former. It also provides better properties in heavy sections. The high-strength aluminum alloy used on the C-17 was primarily 7150 in the T7751 temper. The MD-11 utilized the same alloy in the higher strength T6 condition.

Alloy 6013 is used for formed parts of secondary structures in place of 2024 due to its superior formability (the fatigue performance is slightly inferior to that of 2024). The 6013 alloy can be formed in the T4 condition and aged to the T6, whereas 2024 must be
Figure 2
Structural materials usage: fighter aircraft.
Figure 3
Aluminum alloy evolution.

formed in the "O" condition for optimum formability, then solution treated and aged. The requirement for solution treatment often creates distortion problems with formed parts. The 2024 and 7075 alloys can be procured in the "Hi-form" condition, a processing route developed by Kaiser, to provide a finer grain size and better formability. These can be formed in the "W" condition, to bend radii comparable to the conventional alloy in the "O" condition and aged to the proper temper. If formed in the "O" condition, it can be formed to tighter bend radii than that of the conventional material in the "O" condition, but it must be solution treated and quenched prior to aging, creating the potential for distortion.

The aluminum alloys used on fighter aircraft are similar to those on commercial aircraft, primarily 7050, 7175, and 2124. Major bulkheads typically use thick plate, such as the 2124-T81851 used on the F-16 and F-22. Additionally, 7000 series alloys 7075-T76 and 7475-T761 and 2000-series alloys 2024-T81 and 2124-T81 are used for sheet applications, while 2124-T81 plate is used for plate applications. Additionally, 6013 sheet has potential for future applications because of its improved formability (as defined earlier), excellent exfoliation corrosion resistance, and lower cost.

The first Al–Li wingskin (8090 T851) was flown on an F-15 as a demonstrator. Al–Li has not been used since then in production for these types of applications. Thick-section 2097 Al–Li alloys offer significant benefits for aircraft with severe fatigue requirements due to reduced cracking rates and alloy density benefits.

The 5XXX series Al–Mg–Sc alloys exhibit similar mechanical properties to 2024-type aluminum alloys, while perhaps avoiding the need for protective alclad surface finishes.

Historically, the prevalent structural steel alloys used on commercial aircraft are the high-strength low-alloy steels such as 4340, 4330M, and 4340M. These alloys have been used in situations requiring very high strength (as high as 1900–2070 MPa), such as the landing gear and flap tracks. While these materials are structurally efficient, they require extra attention to design and protective finishes to address general corrosion and stress-corrosion issues. Despite protective finishes such as Ti–Cd plating, primer, and enamel, in-service inspection and maintenance are still significant.

More recent commercial models and derivatives have increased the use of high-strength corrosion-resistant steels such as 15-5PH wherever possible. Relative to the high-strength low-alloy steels, corrosion-resistant alloys like 15-5PH reduce processing flow time and cost in production (the processing of high-strength low-alloy steels, particularly machining, must be accomplished within a narrow window and is quite time consuming and costly). The need for protective finishes is also minimized which decreases cost, flow time, and environmental impact (the raw material costs are on a par with the low-alloy steels.) The primary limitation of these alloys has been strength (1240–1380 MPa is the maximum ultimate tensile strength for 15-5PH). Development of new corrosion-resistant alloys which come closer to matching the strength of high-strength-low alloy steels will increase the use of these alloys.

Due to stress-corrosion and fracture-toughness requirements, imposed primarily by the US Navy, the steel alloys used for military applications tend to be a

little more "exotic." Primary landing gear components are fabricated from Aermet 100, which is used at a tensile strength level of 1930–2070 MPa. Preference for this alloy is driven primarily by its high toughness (minimum K_{Ic} requirement of 110 MPam$^{1/2}$) and improved stress-corrosion resistance. (4340M has a typical K_{Ic} of ~ 65 MPam$^{1/2}$.) The Aermet alloy is also weldable, and can be used up to temperatures of about 425 °C. Its attributes would be attractive in the commercial sector, but the alloy is considerably more costly than 4340M. Reduced maintenance could result in lower life-cycle costs, but these can be difficult to assess. For the lower-strength (1415–1585 MPa) steel damage-tolerance applications, PH13-8Mo is utilized. This alloy has higher strength and toughness than 15-5PH, with superior thick-section properties. Some 15-5PH is also used for noncritical applications—it has lower cost than PH13-8Mo.

Titanium alloys used cover the entire range of conventional titanium alloys commercially produced. From commercially pure titanium, where formability and corrosion resistance drive its use, to α- or super-α-type alloys such as Ti–6Al–2Sn–4Zr–2Mo for high-temperature applications, to α/β alloys such as Ti–6Al–4V, which is the workhorse alloy of the aerospace industry, and β alloys such as Ti–10V–2Fe–3Al. Ti–6Al–4V was developed in the late 1950s and still represent $\sim 80\%$ of the aerospace market. It is a moderate-strength alloy (with a minimum UTS of about 895 MPa) which is quite forgiving in its processing, exhibits good properties combinations and can be utilized for every product form. The properties of the alloy can be tailored to the application. For instance, a β-annealed extra-low-interstitial (ELI) grade is used for damage-tolerance applications—this material is used extensively on the F-22. With a slight drop in tensile properties relative to the annealed standard grade material, the fracture toughness can be doubled and the fatigue crack growth rate decreased by an order of magnitude—however, this is achieved with a significant decrease in fatigue crack initiation life.

The β-alloys can generally be heat treated to higher strength, have deeper hardenability, and are generally easier to fabricate into a semiproduct form. These alloys tend to be utilized for specific product forms. Ti-10V–2Fe–3Al is a high-strength forging alloy, used typically at a minimum tensile strength of 1170 MPa and somewhat higher for gages less than 25 mm. (There has been a reluctance to use alloys such as this in Europe due to potential part distortion during machining because of residual stresses from the water quench associated with the solution treatment.) Ti–15V–3Cr–3Al–3Sn is used primarily for sheet (strip)—as a β-type alloy it is strip producible, which is a significant economic advantage, particularly for thin gages. This product is used at a minimum tensile strength of 1035 MPa and higher. Titanium is an excellent spring material—with a

density $\sim 40\%$ lower and shear modulus about half that of steel, a titanium spring can provide weight savings of up to 70% and volume reduction of up to 50% in comparison to steel, and eliminate the corrosion problems prevalent with most steel springs. Ti–3Al–8V–6Zr–4Cr–4Mo (β-C) is used for springs at a minimum tensile strength of 1240 MPa (flat springs are fabricated from Ti–15V–3Cr–3Al–3Sn). β-21S is a high-temperature alloy used in sheet and foil form for exhaust nozzles. As mentioned, these structures see temperatures as high as ~ 705 °C for short durations—the temperature is below 540–565 °C for normal operation.

The titanium alloys used are similar for commercial aircraft and military transports/bombers and fighters, but the heat treatments may be different due to the emphasis on damage tolerance. Ti–6Al–4V is the primary titanium alloy used for damage-tolerance (DT) applications. The ELI grade is used for these types of applications in the recrystallize annealed (RA) or beta annealed (BA) condition. The BA condition has the best DT performance as mentioned previously for commercial aircraft, but poor fatigue crack initiation resistance. This heat treatment is used extensively on the F-22. The fracture toughness and fatigue crack growth resistance is not quite as good in the RA condition but the fatigue behavior is better. This heat treatment is used on the B-1, B-2, and F-18.

Ti–6Al–6V–2Sn is used on some of the older fighter aircraft. It is generally used in the annealed condition, giving it a tensile about 70 MPa higher than that of Ti–6Al–4V, which provides some weight savings. It is not used on newer aircraft with the increased emphasis on DT, as this alloy has lower fracture toughness and stress-corrosion resistance than Ti–6Al–4V.

The processing for another, somewhat higher-strength alloy, was developed for use on the F-22, Ti–6Al–2Sn–2Zr–2Mo–2Cr. It is used at a minimum tensile strength of 1035 MPa and fracture toughness of 77 MPam$^{1/2}$ with significantly superior fatigue performance, which, again, provides some weight savings over Ti–6Al–4V. It is used for the lower keel cord and intermediate wing spars on the F-22. Greater usage is anticipated as experience with the alloy is gained. Ti–6Al–2Sn–2Zr–2Mo–2Cr is the primary structural titanium alloy (everything except sheet) for the X-33, NASA's half-scale demonstrator reusable launch vehicle.

The F-22 makes extensive use of welding for fabrication of primary structure (the forward and aft booms).

Titanium is an attractive material for aerospace applications, but its cost is quite high. Raw material costs may be several times higher than aluminum or steel, and machining times are of the order of 10 times as great in comparison to aluminum. This precludes using this material except where the added cost can be justified through improved structural performance. (This is one of the drivers for greater

utilization of castings, as parts closer to net shape, incorporating multiple parts with less machining and assembly time, can significantly reduce the cost of titanium hardware.)

In general, polymer matrix composites are used for reduced weight. They have strong advantages with regard to fatigue performance and corrosion resistance. Another key advantage is that the layup can be tailored to provide the desired properties in the critical locations/orientations.

Historically, the utilization of composites has been somewhat restricted because of its high cost. However, the situation is now changing. A good design, and taking advantage of the processing benefits of PMCs over metallic structure, can result in lower cost structure. With the development of automated material placement, the use of computers to define the specific ply layups, advances in the resin transfer molding process, etc., the costs of organic matrix composites is coming down, and cost savings are being reported. A good example is the C-17 empennage. It has 2000 fewer parts, 42000 fewer fasteners, and is 215 kg lighter. These advantages, and the requirement for 1000 fewer tools, resulted in a cost saving of ∼40% in comparison to a conventional built-up aluminum empennage. British Aerospace has indicated that processing advances along with the computer aided design of the layups enabled them to cost-effectively utilize PMC composites for the front and rear fuselage and wing assemblies of the Eurofighter Typhoon.

As mentioned previously, the PMC materials used on aircraft usually entail carbon fibers in a broad range of polymer matrices (epoxies, PEEK, BMI, phenolics, etc.). (The F-15 is a bit unusual in that the bulk of the 1.4% composite material used on that aircraft was the older technology boron fibers in an epoxy matrix, which was used in the vertical fin and horizontal stabilizer.) There is also a significant amount of glass-fiber reinforced epoxy composites for secondary structures on commercial aircraft.

The thermoset PMC structure on the F-22 consists of about half BMI and half epoxy resin parts, both tape and fabric forms, with IM7, Nicalon, and S-2 glass fibers. Toughened epoxy PMCs and BMI and epoxy RTMs are also utilized. Thermoplastics are being used for specialty items such as landing gear and weapons bay doors. A drawback to these materials (capable of higher-temperature service) has been that they typically exhibit increased difficulty in processing relative to the lower-temperature PMCs. Higher process temperatures, Kapton bagging films, low coefficients of thermal expansion, CTE, and tooling have required that modified consolidation procedures are utilized. These solvated resin systems polymerize by a condensation reaction mechanism. Processing requires high-temperature cure cycles that can vaporize the low-molecular weight solvents and reaction products, and maintain resin viscosity low

enough to achieve adequate resin flow for complete saturation of the part (100% density).

The Lockheed/Boeing F-22 is the first aircraft, commercial or military, to take advantage of resin transfer molding for fabrication of primary structure composite parts. This process is used for over 150 parts, ranging from the lip edges of the engine inlet to sine wave wing spars.

5. Future Trends

5.1 Aluminum

Development efforts in the near future will focus on several key areas. In terms of increased performance, efforts will be directed toward wing alloys with better fracture toughness at equivalent strength levels, and Al–Li alloys for weight savings. Airbus will use GLARE, an aluminum/fiberglass PMC with good fatigue, corrosion, impact, and fire resistance for fuselage structure on the A380. The size of this large airplane, and its associated weight, probably dictates implementation of new, higher-performance materials.

Cost-reduction efforts will include development of alloys which can be formed in the tempered condition and heavy-section alloys with more isotropic properties for monolithic structure. There is increasing interest in alloys and processes that integrate parts to a larger, more monolithic structure, such as castings. These provide the possibility of reducing cost, and sometimes weight, through reduced machining, and reduced part, tool, and fastener counts.

Increased use of welding in areas where it has not been possible before also address reducing the number of fasteners and the labor associated with their installation; hundreds of thousands of fasteners are used on each fuselage. Friction-stir and laser welding are being considered for aluminum fuselage sections. Airbus will use stringers laser welded to skins on the lower shell of the fuselage of the A318 and A380 (a new large airplane capable of carrying 555, or more, passengers). Their goals for welded structure are to reduce the cost by 25% and the weight by 15%. Friction-stir welding is also a high priority at Airbus.

5.2 Titanium

Improved-performance titanium alloy development will focus on alloys suitable for providing high strength combined with increased producibility. Titanium matrix composites (TMC) provide attractive properties, particularly for stiffness-driven applications, but cost is still an issue. The first TMC application, titanium actuator pistons, has been implemented on the Pratt and Whitney engine for the F-22, and General Electric has a titanium matrix

component for the F-16 engine. The F-22 program is working with the supplier to determine the feasibility of utilizing this technology for stiffness-critical airframe structure. Titanium hybrid laminates are also being studied, but their development is still embryonic in nature.

However, the bulk of the development efforts for titanium will be directed toward reduced cost. Permanent mold castings, both gravity metal and vacuum die-casting processes, show substantial promise for reducing costs for smaller, less complex castings. A new powder metallurgy process is being developed for producing relatively simple shapes via a laser process, which utilizes a stereolithography-type technique to produce a fully dense metal shape. This process is being studied for the production of machining and forging preforms.

The possibilities of further utilizing SPF and SPF/DB for fabricating complex structures are being analyzed as another means for saving cost.

5.3 Steel

Development efforts in the steel area are focusing on two primary areas; (i) improving the damage tolerance attributes of high-strength CRES at current and higher strength levels, and (ii) increasing the strength of the corrosion-resistant alloys to replace current high-strength low-alloy steels (e.g., 4330M, 4340M/330M). A current example is Carpenter's Custom 465 which is a high-strength CRES with potential for use up to 1585–1725 MPa. Work is ongoing to develop other CRES alloys with strengths approaching that of 4340M/300M, i.e., 18995–2070 MPa ultimate tensile strength.

5.4 Organic Composites

The primary development efforts in the organic composite arena will also focus on cost, via raw material and processing improvements. Focuses to accomplish this include reduced cost materials (achieved via increased volumes and improved compositions), improved assembly methods such as co-cure, thermoplastic welding, and enhanced processing/fabrication procedures. Technologies under investigation here include greater utilization of automation, larger tow placements, nonautoclave cure (E-beam), and adaptive tooling.

Technologies being studied/implemented providing both cost and performance benefits include noncrimp fabrics, stitching, and near-net-shape preforming. Processing routes to provide these benefits include resin transfer molding (RTM/closed mold and VaRTM/vacuum bag), stitched resin film infusion, liquid resin infusion, and resin transfer molding. Considerable effort is also being devoted to improving the environmental durability, to provide better UV resistance, durable paints, repair, etc.

Alternative Techniques for Manufacturing Composite Aerospace Designs, Cost of

Aerospace companies are in a continuing battle to increase the performance and reduce the weight of their aircraft structures, while lowering acquisition and operating costs. Thus, there is always interest in new materials with higher performance and lower manufacturing and ownership cost than aluminum, which is widely used in aerospace manufacture because of its strength and weight. A new material that offers to deliver these benefits is composite materials. Composite materials are made up of two components, a fiber or mat of fibers that offer stiffness, strength, and shape to the structure, and a binding material that helps to maintain the integrity of the fibers. Usually, the binding material is responsible for few of the mechanical properties of the composite system.

Although there are many possible fiber and resin material combinations, for current aerospace structures the fiber material used is almost exclusively carbon (graphite). Epoxy resins tends to be used as the binder. Other systems may be used once technical, cost, and certification issues have been overcome. It should be noted, however, that engine makers are also interested in composite materials, both carbon/epoxy systems for structures like nacelles and more advanced fiber/binder combinations (such as ceramic matrix composites) for high-temperature applications like turbine blades.

Since the introduction of the carbon fiber/epoxy composite system, each new generation of aircraft has seen a slow but steady increase in the use of composites. Nowadays, military aircraft use considerable amounts of composite materials (over 30% of the structural weight), as do light aircraft and business aircraft. Indeed, an all-composite business jet has been produced. Civil airliners have traditionally used less composite materials, where to date it has mainly been used in secondary structures such as slats and doors. The main hindrance to realizing the performance and weight advantages of composite materials has been cost; despite the promise and possibility of low-cost manufacture of composite components they have stubbornly remained more expensive than their aluminum counterparts. Reducing the cost of composite structures has been the focus of major research programs in the USA, the EU, and the Far East.

Single carbon fibers are never processed individually; the carbon fiber manufacturers provide them as tows, tapes, or fabrics. Tows are long bundles of carbon fibers, with currently 8000–24000 fibers in a tow. A greater number of fibers in a tow make it cheaper but there is less control over the number of fibers, so aerospace designers tend not to use the tows with the highest number of fibers until the manufacturers can ensure a consistent performance. As the name suggests, tapes consist of long, unidirectional bundles of fibers, currently up to 150 mm in width for aerospace applications. Tows and tapes are usually provided on an adhesive backing paper, which helps to maintain the shape of the tows and tapes during transit and storage. However, the backing paper adds an extra cost and the tow placement and tapelaying processes need to introduce steps to remove the backing paper prior to placement, which adds complexity and cost.

Fabrics are tows woven into a sheet, like the fabric of clothing. The fabrics can be crimped, so that the fiber layers are interwoven like a plaid or they can be laid in single layers, with the shape maintained by stitching the layers together. Fabrics can be over 1 m in width. The fiber layers are oriented at varying angles; $0°$, $\pm 45°$, and $90°$. By altering the number and order of layers of various orientations, the designer can design the composite material to optimally manage the stresses and loads in the structure.

Epoxy resins are generally used as the binding agent because they offer an attractive combination of strength, ease of processing, and cost. The resin can be applied to the fibers in a variety of ways. The manufacturer can coat the carbon fiber with resin (pre-preg) or the resin can be added to the structure as part of the manufacturing process. The resin needs to be heated (or cured), usually, in a pressurized vessel (an autoclave) for the resin to acquire its mechanical strength. The autoclave adds to the cost of the process, but equally significantly it can constrain the size of parts that can be processed and the factory logistics and manufacturing lead times are affected by the need for most of production to use the autoclaves. The curing process introduces some risks to the manufacturing process; uneven heating of the structure and the tooling in the autoclave may distort the final shape of the part. As a consequence, there is much interest and research in resin systems that can cure at lower temperatures, possibly even at room temperature.

Composite material is considerably more expensive than the equivalent weight of aluminum. The cost of carbon fiber varies depending upon how it is provided but typical values would be around $100 kg^{-1} for resin impregnated fabrics and $90 kg^{-1} for tape, although high quality or low volume products will cost more. In contrast, aerospace grade aluminum typically costs around $20 kg^{-1} (again, the costs depends heavily on the quantity and precise grade).

Consequently, for composite structures to be cost competitive they must be lighter (hence needing less material) and more cost-effective to manufacture. The superior properties of composites mean that they can usually perform the same structural or aerodynamic function with less material, especially as aerospace designers learn to fully exploit the properties of the material. With weight an important determinant of fuel consumption, less weight can make a major contribution to ownership costs and help to justify the use of composite structures. The manufacturing technologies also need to ensure that the cost savings in the process more than compensate for the higher material cost. They must also address material waste; because composite material is more expensive than aluminum, and currently cannot be recycled, all the manufacturing processes must focus on waste material and reduce it to a minimum.

As carbon fiber and epoxy resin technologies are mature processes with their major customers outside aerospace, the major cost savings will be from new materials, new manufacturing processes, or (most likely) a combination of the two. That has been the case to date, with new manufacturing processes prompting new ideas for fiber and resin preparation and vice versa.

One of the earliest manufacturing processes used in aerospace manufacture, and still one of the most common, is manual or hand layup. The process begins with a fabric that is cut to shape on a cutting table, usually using a numerically controlled (NC) ultrasonic knife or water jet. To achieve the required thickness of material and the shape of the structure, multiple layers of fabric are usually necessary. The fabrics are positioned in a mold-tool, whose inside surface mirrors the required outside surface of the structure. Once the fabrics have been built up to the required shape, an inflatable bag is positioned over the structure and the resin is cured in an autoclave. The purpose of the bag is to apply pressure to the structure, which helps to maintain the shape and to drive air and water out of the resin. After curing, the structure is unbagged and removed from the tool.

Another manufacturing process currently in common use in aerospace is tapelaying. This uses a CNC-controlled robot that accurately positions the tape on a mold-tool, creating the shape by building up the layers of tape. As the buildup is CNC controlled and uses a contoured head and thin tape, complex shapes can be produced. With many layers of tape, it is common to periodically remove the tool and compress the material (debulking), as the head (which needs to be light to accelerate quickly) may not provide sufficient pressure to compact the layers. Afterwards, the structure is cured and processed as before.

Rather than using tapes, filaments or tows of composite fiber can be used. The filament-winding process wraps a tow of carbon fiber around a rotating tool, with heat applied at the point of contact to

soften the resin. This process can be used for cylindrical structures, such as fuselage panels.

Several newer composite manufacturing processes are been developed and are beginning to be used in production, i.e., resin film infusion (RFI) and resin transfer molding (RTM). RFI is similar to manual layup in that the fabric is first cut to shape by a cutter. However, unlike manual layup the fabric has not been coated with resin (only a thin layer to help the resin film bind to the fibers). The layers of fabric are laid in the mold-tool and interleaved with thin films of resin, possibly using a robot or similar automated system. When the structure has been built up, the structure is bagged and processed in an autoclave.

RTM again uses fabric cut to shape and placed in a mold-tool. However, the mold-tool is part of a vacuum system, and when the structure has been built up the mold-tool is sealed, evacuated and heated. Resin is pumped into the structure and the combination of heat and vacuum enable the resin to flow through the structure. Unlike the other processes described, the structure does not need to be cured after processing, as the cure occurs *in situ*.

Pultrusion is widely used for the manufacture of low cost, constant cross-section products like pipes and gutters. Some aerospace structures, particularly stringers (and possibly skins) maintain nearly continuous cross-section and pultrusion processes to manufacture these components are under development. The precise details of the pultrusion processes vary, but they all pull fibers through a mold of constant (or nearly constant) cross-section and then through an in-line oven to cure the resin.

As discussed, each method varies in technical performance as well as cost, but the decision on which process to use should not be based solely on cost. Illustrative costs are shown in Table 1. Consideration of the respective cost of these processes is hampered by the fact that much of the data is held by companies and is confidential. However, enough experience

Table 1
Comparative costs of composite materials and processes.

Material/process options	$\pounds kg^{-1}$
Unidirectional tape layup	129
Woven pre-impregnated tape laid by hand	104
Woven fabric hand laid by hand followed by RTM	72
Tow placement followed by RTM	50
Tow placement followed by RFI	61
Unwoven fabric machine laid using a laminator followed by RTM	59
Unwoven semi-impregnated fabric laid using a laminator and autoclave cured (similar to RFI)	105

in research and production has been gained for some conclusions to be drawn.

The costs of the manual layup process are dominated by direct labor and material costs; little automation is used so the capital costs are proportionately low. This process tends to be most cost-effective for low-volume applications, where the production run is insufficient to absorb the cost of automated equipment. ''Low volume'' will depend upon the application, but for production runs greater than a few hundred, the long layup times and consequently high labor costs mean that manual layup tends not to be cost competitive with other manufacturing processes.

Unlike manual layup, the labor content of the tapelaying process is small, as the tapelayer needs little manning when in operation (some labor is needed to load the tape and to respond to breaks in the tape). However, the capital costs are high since the tapelaying head is a complex structure and the supporting structure needs to be quite large and rigid to provide dimensional control. Hence, tapelayers cost a few million dollars each, and if used for low volume production the cost of the process per part can be high (over twice the cost of competing processes not so reliant on expensive capital equipment). The tapelayer is advantageous if high volume production of parts is required as the volume can absorb the capital charges. Tapelaying can produce complex shaped parts and, because of the control of fiber orientation tapelaying makes possible, this process can produce the highest quality structures. Another advantage this approach offers is that it minimizes material waste.

Filament winding requires little in the way of capital or labor, making it in normal circumstances the cheapest composite manufacturing process. However, the restricted shapes that can be produced means that it has so far found few applications beyond making fuselage panels.

The RFI process was designed to achieve high deposition rates of composite material, a drawback of processes requiring tapes and tows; current RFI technology may achieve deposition rates of $100\,kg\,h^{-1}$, as opposed to 4–$10\,kg\,h^{-1}$ often seen for tapelaying. The use of fabrics, however, means that RFI has difficulty in making small complex shapes and its main application is likely to be in large, simple structures such as wing skins and spars.

Like filament winding, RTM needs little equipment and labor, the main equipment cost being the resin injection system and the tooling. As the tool needs to include a heating element and support an airtight seal, an RTM tool costs up to twice as much as conventional tooling. However, the autoclave curing is removed which makes this a very cost-competitive process. Most applications of RTM to date have focused on fairly complex parts. However, with further development and production experience, the combination of low cost and part variety that can be

manufactured make RTM likely to become one of the major composite production processes.

These processes are not exclusive, and in some applications a "mix and match" approach would be the most cost-effective. Wing skins build up using RFI with hand layup for the small features such as pylon supports could be one example where the technology is selected for the application for which it is most suited.

Table 1 gives an indication of the relative costs of several composite manufacturing processes (based on research undertaken in the UK). The material types include tapes, tows, and fabrics (unwoven fabrics have planes of fabric held together by stitches, whereas woven fabric interleave the layers in order to maintain the shape). The manufacturing processes are tape layup, RTM, RFI, and hand layup. The laminator is used to transport the cut fabrics into the tool. The structure used as an example for this costing exercise was an aircraft tail skin.

Much of the potential savings from composite technologies lie in the possibility of major reductions in assembly costs. For metallic structures, assembly techniques have used highly specialized, highly expensive fixtures and jigs with parts assembled using mechanical fasteners (such as rivets). As well as the high capital outlay for the fixtures and jigs, the assembly process is very slow and labor intensive with long lead times and high inventory levels. Composite structures may offer two advantages. The part count can be significantly reduced, and bonding the structure using resins or adhesives can significantly reduce the assembly time and cost.

The part count can be reduced in two main ways. Complex shapes can be manufactured, especially with tapelaying and RTM, which combine in one structure several pieces that would have been made separately and joined if made of metal. In addition, processes such as RFI can make very large single piece structures (such as wing skins) which can replace numerous metal plates bolted together.

The second potentially major cost advantage of composite structures is that they can eliminate the mechanical fasteners needed to assemble the structure. Assembly can account for up to half the recurring cost of an aluminum structure, and much of this cost is in fastening. The structures can be bonded using adhesive and specially designed joints. Indeed, some of these assembly steps can be combined with part curing, so that parts of the structure are cured and bonded in the same operation. Eliminating 20–40% of the fasteners by using adhesive bonding offers a considerable cost saving.

However, for large civil aircraft many of these potential benefits have yet to be seen, and assembling composite structures has still tended to be more expensive than assembling similar metallic structures. The certification and testing of bonded structures requires a major effort to demonstrate the safety and reliability of the technique, especially for civil airliners, and until this is undertaken composite structures will still be mainly bolted. Composite structures are more expensive to drill and bolt, as special drill bits and bolts are needed, and there is the potential of damaging the structure through delamination. The composite structures sometimes require shimming, a process where the gaps caused by variances in the parts are filled either with inserts for large gaps or an adhesive if the gap is small. As this is a manual process, it can add considerably to the cost.

The tooling of composite parts differs from metallic parts in a number of respects. For most composite manufacturing processes, the resin is cured while the part is in the tool (as it is needed to help maintain the shape). As the tool and the structure are heated, the designer must take account of mismatches in the thermal expansion coefficients that may introduce stresses into the composite structure resulting in its shape being distorted when it is remove from the tool (springback). Composite tooling can be used to eliminate this problem, but composite tools have significantly shorter lives than their metallic counterparts, although their initial cost is lower. Uncured composite structures are sticky and the tooling for composite structures needs to be cleaned at regular intervals.

Aircraft with composites have the potential to offer significant improvements in ownership costs. In addition to their lighter weight, experience with composite structures shows that they demonstrate little material fatigue and reduced corrosion. Water ingress and delamination are concerns with composite structures, but with proper preparation and maintenance practices the performance of these structures does not diminish with time to the same extent as their metallic counterparts. Repairing composite structures is currently more expensive; costly autoclaves, inventories of different carbon materials and epoxies, and other significant infrastructure costs need to be provided. In addition, faults in composite structures such as internal delamination are difficult to inspect and repair. It is expected, nonetheless, that the cost differential between metallic and composite repair will narrow as users gain more experience in their use.

It can be seen that comparing the cost of composite manufacturing technologies is not straightforward; most manufacturing technologies have a niche in which they are likely to be the most cost-effective technology. Technologies using fabrics, such as RFI, are most suited for large, thick structures without complex shapes, whereas RTM may be more suited to smaller, more complex structures. Thus, the manufacture of composite structures on aircraft is likely to use several process technologies, suited to the applications where they have a cost (and technical advantage). For assembly, composite structures offer a significant cost advantage when structures are bonded, and the constraints that exist with bonded

structures arise from testing and certification issues, as opposed to production concerns.

To conclude, carbon fiber composite materials have the potential to reduce the manufacturing and operating cost of aircraft, but challenges remain in developing the manufacturing technologies to realize this potential and in designing structures that fully exploit the potential of both the material and the manufacturing processes under development. So far, composite materials are primarily used on aircraft because of the performance and weight advantages it offers. It should soon be feasible for composite structures to compete on cost as well.

Asbestos

Asbestos or amiante (from Greek *Asbestos* (inextinguishable) and *amiantos lithos* (unstained stone), respectively) is a commercial ancient name for fibrous, naturally occurring inorganic materials that are valued in the industry for their resistance to heat and high tensile strength (Michaels and Chissick 1979, Hodgson 1986, Habashi 1988, Virta 1999). The fibers are formed under rare conditions when certain silicate minerals crystallize in bundles of hundreds of thousands of strong, flexible fibrils that look like vegetable fibers. Chemically, they have the same composition as the other minerals found in the rock within which they are formed. Asbestos is an extremely useful natural resource, and has been studied extensively mineralogically and for industrial application. Its extraction from ores has been greatly improved with respect to safety in the work place.

Asbestos is usually present to the extent of about 5% in its deposits. To recover 1 ton (t) of asbestos, about 20 t of waste rock must be removed. This is achieved by fracturing the rock in crushers and other impact hammer mills to liberate the fibers. These are then fed to shaking screens equipped with suction hoods. Large fans provide the suction that lifts the fiber from the screen and carries it to collecting cyclones. A plant in Australia is said to be separating asbestos fibers from the rock by wet methods (Stewart 1986). Such a process would be interesting because it minimizes the presence of fibers in the work place. World production of asbestos is about 4 million tons per year, 55% of which is contributed by Russia and 20% by Canada. Each of the following countries contributes less than 4%: South Africa, China, Zimbabwe, Italy, Brazil, and the USA.

1. Properties

Asbestos has a relatively large specific surface area of $3-9 \text{ m}^2 \text{ g}^{-1}$. When suspended in distilled water (5 g l^{-1}) the pH sets at about 10 and Mg^{2+} can be identified in solution in an amount near to the solubility product of magnesium hydroxide. In the presence of acids, more magnesium can be solubilized and complete extraction can be achieved by long contact time or by boiling under a reflux condenser for about 2 h. Magnesium-free asbestos still retains its original shape but becomes fragile.

When heated in the temperature range 600–780 °C, chrysotile asbestos loses water due to dehydroxylation (an endothermic reaction). In the temperature range 800–850 °C, the dehydroxylated product undergoes crystallization to forsterite (an exothermic reaction). The overall reaction is:

$$2 \text{ Mg}_3(\text{Si}_2\text{O}_5)(\text{OH})_4 \rightarrow 3 \text{ Mg}_2\text{SiO}_4 + \text{SiO}_2 + 4 \text{ H}_2\text{O}$$

The forsterite persists together with silica up to 1000 °C, but above this temperature some enstatite is formed:

$$\text{Mg}_2\text{SiO}_4 + \text{SiO}_2 \rightarrow \text{Mg}_2(\text{Si}_2\text{O}_6)$$
Chrysotile asbestos usually contains small amounts of brucite, $Mg(OH)_2$, which dehydroxylates at 400 °C. It loses strength when heated and it melts at 152l °C.

2. Uses

The two unique properties of asbestos, its heat resistance and its fibrous nature, render it most suitable for the manufacture of heat-resisting textiles, e.g., garments and gloves used to protect workers exposed to high temperatures, and fire fighters. Textiles in which asbestos constitutes 75–99% can protect a person from temperatures of 200–480 °C. However, the consumption of asbestos in this area is only about 1%. The major use of asbestos is in the manufacture of asbestos cement. In this product, asbestos constitutes 12–15%, greatly increasing the resistance of cement as a construction material. Asbestos in admixture with plastics and asphalt features in the manufacture of a variety of tiles and sheets used as a covering material. Because of its heat resistance, asbestos mixed with metallic fibers and resins to the extent of 40% is used in the manufacture of what are called friction materials, e.g., brakes for motor cars and airplanes. Asbestos also features in the manufacture of certain industrial papers and gaskets.

3. Structure

There is a large variety of asbestos minerals, but the most important is chrysotile which represents more

than 90% of the asbestos used; it is a hydrated magnesium silicate, $3MgO \cdot 2SiO_2 \cdot 2H_2O$. The given formula, however, represents only the ratio of the components and a more exact formula would be $Mg_3(Si_2O_5)(OH)_4$. To understand the properties of this material it is essential to know its structure. The basic building block of the silicates is the $(SiO_4)^{4-}$ tetrahedron. The variety in the structures of the silicates is due to the various possible combinations of these tetrahedra, both with each other through oxygen atoms and also with other ions. The negative charge on the tetrahedra is compensated by cations attached to the silicate structure by electrostatic forces, e.g., the single isolated tetrahedra, the double isolated tetrahedra, the rings, the chains, and the sheets. In the framework structure, the tetrahedra are connected together in three dimensions forming silica, a giant $(SiO_2)n$ structure.

Hydrated silicates are formed in nature by the weathering of anhydrous silicates. Serpentine is the rock that undergoes transformation to asbestos. The asbestos fibers that are visible to the naked eye are composed of hundreds of thousands of monofibers called fibrils in close-packed, parallel arrangement (Fig. 1). The monofibers have a tubular shape formed by the rolling up of a sheet composed of hydrated magnesium silicate. A typical fiber consists of 12–20 layers rolled up like a scroll (Fig. 2). The inner and outer diameters are in the order of 5–25 nm. The hydration represents about 10% of the mass and is in the form of hydroxyl groups linked to the magnesium and covering the external surface (Fig. 3). A sliver of chrysotile asbestos with a cross-section 0.1 mm

square contains about 2×10^7 fibrils all in parallel orientation. It is possible, therefore, to strip from an asbestos fiber bundle very fine threads each of which still contains many thousands of fibrils.

4. Problems and Suggested Solutions

There are two problems facing the asbestos industry in the early 2000s: its toxicity and the residues generated from its extraction. Both problems are under intensive investigation and potential solutions have been found.

4.1 Toxicity Issue

Asbestos is claimed by some to be a workplace problem, rather than an environmental issue, that can be adequately addressed with current dust control technology and appropriate workplace practices and by others to be a toxic and carcinogenic material that must be banned immediately (Selikoff and Lee 1978). It was demonstrated, for example, that heavy smokers in particular are more susceptible to have cancer of the lung; it seems that any fiber lodging in the lung because of its large surface area is capable of adsorbing carcinogenic substances from tobacco smoke. The accumulation of silicious dust in the lungs may result in causing silicose; in the case of asbestos this condition is known as asbestosis. But this may be cured by surgery. In the case of lung cancer due to asbestos, however, this is not possible because the disease spreads rapidly from the lungs to other organs.

As a result of this controversy, the consumption of asbestos in the USA, one of the world's largest consumers, has been decreasing gradually since the late 1990s. This has forced production decline and in some cases plant shutdown. The US industry is looking for substitutes for asbestos, but the long-term environmental effects of other minerals or synthetic substitutes that have been proposed are unknown. There are two widely accepted screening toxicity tests for asbestos:

(i) *Hemolytic*. In these tests, red blood cells are left in contact with a certain amount of fiber and after various periods of time the cells are centrifuged, and the hemoglobin content of the supernatant solution is measured using spectrophotometric methods. Usually, 72% of the cells undergo hemolysis when contacted with dry fiber, and 65% when contacted with wet fibers.

(ii) *Cytotoxicity*. In these tests, P $388D_1$ cells are incubated with a certain amount of fibers for various periods of time. The number of healthy and dead cells are then measured using Trypan Blue dye. Usually, 81% of the cells die when contacted with dry fiber and 50% when contacted with wet fibers.

While hemolysis is a short-term test in which the membrane stability is involved, cytotoxicity as outlined above gives a global picture of the cellular toxicity of the fibers. Hence, the two tests do not necessarily correlate, since the factors involved are not the same. Research effort is now directed towards understanding this toxicity problem and finding solutions. Two main routes have been so far proposed: reaction with phosphorus compounds, and reaction with chelating agents. These routes were chosen because it was observed that Belgian workers exposed to asbestos cement dust were exempt from developing cancer as compared to those exposed to asbestos alone or cement alone. The same phenomenon was confirmed by experiments carried out on rats at Battelle North West in the USA. It seems, therefore, that modifying the asbestos surface is a valid approach.

(*a*) *Reaction with phosphorus compounds*. Intensive research was conducted in Québec based on the treatment of the fiber with a dosed amount of gaseous phosphorus oxychloride, $POCl_3$, at about 200 °C to fix about 1% phosphorus on the fiber, thus rendering it nontoxic but maintaining all the desirable properties of asbestos. The asbestos so treated is known by the trade name *Chrysophosphate* (Khorami and Lemieux 1987). The reaction on the surface can be represented by:

$$3\ Mg(OH)_2\ \text{in asbestos} + 2\ POCl_{3(g)} \rightarrow Mg_3(PO_4)_2$$
$$+\ 6\ HCl_{(g)}$$
Phosphorus oxychloride, however, is a reactive chemical that reacts with humidity in the air and requires special handling, and the Chrysophosphate releases phosphate and chloride ions when it comes into contact with water, e.g., in the manufacture of asbestos cement. Work at Laval University has shown that a similar product could be obtained by reacting the asbestos with an aqueous solution of ammonium phosphate, $(NH_4)_2 \cdot HPO_4$, at ambient conditions, followed by filtration and washing (Awadalla *et al*. 1990). The reaction on the surface can be represented by:

$$3\ Mg(OH)_2\ \text{in asbestos} + 2\ HPO_4^{2-}{}_{(aq)} \rightarrow Mg_3(PO_4)_2$$
$$+\ 4\ OH^- + 2\ H_2O$$
(*b*) *Reaction with chelating agents*. Certain chelating agents that react with magnesium ions in aqueous solution to form precipitates were found at Laval University to reduce the toxicity of asbestos (Habashi *et al*. 1991, Habashi 2001). The amount of chelating agent sorbed on the fiber is 2–5%. Chelating agents are organic compounds, usually with high molecular weight, that react with magnesium ions to form a ring structure through the lone pair of electrons on the oxygen or nitrogen atoms of the reagent. For example, the reaction of alizarin with magnesium ions forms an insoluble six-membered ring chelate; the covalent bond between the magnesium atom and oxygen of the quininoide structure is due to the lone

pair of electrons belonging to the oxygen, while that between magnesium and the other oxygen of the hydroxyl group is due to equal sharing of electrons.

Asbestos fibers treated with chelating agents are vividly colored. The color has been shown to be stable on boiling with distilled water under a reflux condenser for 1 h, thus indicating that the organic reagents are chemically bound to the surface of asbestos and not physically adsorbed by the weak van der Waals forces. If they were physically adsorbed they should have been washed away by boiling. Under the microscope the colored asbestos samples were fully homogeneous and no precipitates were visible. This was also confirmed by examination with scanning electron microscopy. Appearance of new peaks in X-ray diffraction patterns and in infrared spectra, together with the absence of precipitates as revealed by scanning electron microscopy, supports the view that chelates are formed with asbestos, apparently with its $Mg(OH)_2$ component.

Chelate formation on asbestos fibers is similar to the formation of insoluble complexes of acid and basic dyes with metallic hydroxides precipitated on textile fibers by the process known as "mordant dyeing". In this process, the fabrics are soaked in a solution of aluminum or magnesium acetate, squeezed to drain excess solution, then heated in steam chambers to decompose the acetate and precipitate the metal hydroxide on the surface. The fabrics are then immersed in a dye solution whereby a colored chelate is precipitated on the surface known in the industry as a "lake" (Habashi 1992).

Among the dyes that were found to decrease the toxicity of asbestos were Thiazol Yellow G (a monoazo dye) and Trypan Blue (a diazo dye), but of course more dyes have to be tested to find the most effective and economic ones.

4.2 Stabilization or Utilization of the Tailings

As already mentioned, to recover 1 ton of asbestos, about 20 tons of waste rock must be removed. In the Province of Quebec alone, when 1.5 million tons of asbestos were produced annually during peak production, about 30 million tons of waste rock were rejected. More than 600 million tons of such waste have accumulated over the years. The problem with this waste is that it is now finely ground and, therefore, no longer stable as it is before mining, i.e., when wind blows, fibers and dust particles are scattered in the environment, which is undesirable. Regular attention is required to prevent excessive dust in the surroundings. Research has shown that the tailings can be stabilized by vegetation. Due to their high alkalinity, however, it would be necessary to add some sulfide tailings from a nonferrous metal mine or flower of sulfur to lower the pH to near normal values.

The tailings have practically the same chemical analysis as the asbestos fibers; their magnesium oxide content is about 40%. The following solutions have been proposed and tested and the results seem to be promising:

(i) Asbestos tailings represent an appreciable nickel reserve. Nickel is mainly in isomorphous substitution with magnesium; the remainder is in the form of a magnetic Ni_3–Fe alloy and the sulfide pentlandite. It is therefore possible to subject it to magnetic separation to obtain a concentrate rich in nickel and iron.

(ii) The tailings can be melted with carbon in an electric furnace to produce a molten silicate phase and an iron–nickel alloy containing 5% Ni. The silicate phase can be blown by air to form mineral wool for insulation.

(iii) Asbestos tailings can be leached to recover magnesium. The leach solution can be best purified by precipitating the impurities at pH 7 using MgO. The purified solution can then be subjected to crystallization. Hydrochloric acid is the preferred acid for leaching:

$$Mg_3Si_2O_5(OH)_4 + 6\ HCl \rightarrow 3\ MgCl_2 + 2\ SiO_2 + 5\ H_2O$$
because the crystals obtained can be dehydrated to get $MgCl_2$ for metal production, or decomposed to get MgO for refractories. When H_2SO_4 is used, $MgSO_4$ can be recovered and be utilized as a fertilizer. Another route suggested for producing metallic magnesium directly from the tailings is based on a process similar to the Magnetherm Process, i.e., the dehydroxylated tailings are mixed with ferrosilicon and heated in an electric furnace to vaporize magnesium which can be condensed and recovered.

(iv) When the tailings are calcined at 1300 °C in the presence of minor amounts of bentonite, a granular product suitable for use as foundry sand is obtained.

(v) The fact that serpentine loses its water when heated and the forsterite formed at high temperature reacts with silica present to form enstatite suggests that asbestos tailings may be used as a raw material for manufacturing refractory products.

Automotive Body Materials

The materials employed in high-volume mass produced passenger vehicles (cars and light trucks) are the result of a long evolutionary process begun at the beginning of the automotive industry and still continuing. Over time, the functionality and requirements for vehicles have increased. Today's vehicles must meet a wide variety of customer needs and societal and legislative imperatives, e.g., safety and crashworthiness, fuel economy, affordable cost, repairability, performance, styling, exhaust emissions, and recyclability. Materials influence or determine most of these characteristics and features and, therefore, selections of materials for automotive applications are part of design solutions, which can and do profoundly influence customer purchase decisions and the vehicle ownership experience. Many of the technical improvements in vehicles have been directly or indirectly enabled by developments in materials technologies. Fuel economy, emission, and safety improvements have been the key motivators for evolutionary material changes in the recent past. In the near future a combination of customer expectations, environmental stewardship, and tightened regulations will lead to significant changes in the technologies employed in automotive vehicles; materials will be at the forefront. For example, development programs around the world, such as PNGV in the USA and the 3-liter program in Europe, have goals of achieving quantum improvements in fuel economy and emissions are underway. Vehicle weight reductions, through the use of lower density materials such as aluminum, magnesium, and polymer composites to replace heavier materials are a key element in achieving these goals. The implementation of more efficient, alternate powertrain systems, such as hybrid-electrics or fuel cells, will also lead to significant changes in materials. Table 1 shows the trends in material selection for a number of major parts or subsystems of the vehicle.

Table 1
Vertical body panels—plastics and composites.

Component or subsystem	Current materials— widespread application	Aggressive material—implemented on some vehicles	Future potential— developmental
Body-in-white	Stamped steel, including high strength steel	Increased high strength steel usage; aluminum	Stamped aluminum; hybrid materials: aluminum, polymer
Body panels	Stamped steel	Stamped aluminum, SMC, thermoplastic moldings	Stamped aluminum, SMC, thermoplastic moldings
Engine block	Cast iron	Aluminum	Magnesium, elimination in favor of fuel cell
Transmission case	Aluminum		Magnesium
Suspension	Steel and cast iron	Cast aluminum	Magnesium, polymer composites
Brake system	Cast iron	Aluminum calipers	MMC aluminum rotors or drums
Wheels	Formed steel	Cast aluminum	Magnesium
Seat structure	Steel	Aluminum	Magnesium, polymer composites
Instrument panel beam	Steel assembly	Cast magnesium	Polymer composite

In order to be used in mass-produced consumer products such as automobiles and light trucks, materials must exhibit a number of general characteristics:

Plentiful and readily available supply of raw materials
Affordable cost
Fabricated at low cost at mass production volumes
Affordable tooling
Highly reliable parts and assemblies
Recyclability

These requirements tend to limit the choices and represent a significant (but appropriate) barrier to implementation of new materials. Changes in the materials used in production vehicles therefore tend to be evolutionary and based on the validated achievement of worthwhile benefits. Selection of materials for the various parts of the vehicle are based on the specific requirements, which in turn vary with vehicle size, type, regulations, and requirements for the geographic location of sale and use. The final selection of materials is, however, also influenced by the manufacturer's policy concerning such factors as pricing, purchasing, investment, employment, service, length of production series, and image. Because of this complexity of material selection, several different materials may be used in analogous parts for different vehicles or by different manufacturers.

Figure 1 shows the materials content of a medium-size passenger automobile, exhibiting what might be regarded as aggressive or state-of-the-art materials content for a current mass-produced vehicle. More typically, ferrous metals, sheet steel, forgings, and cast iron generally constitute up to about 70% of the vehicle by weight. Nonferrous metals together account for about 10% and plastics, both filled and unfilled, also account for about 10%. A passenger vehicle, automobile or light truck, has about 15000 parts. In the following sections the materials and manufacturing processes are described for the major subsystems of the vehicle. The selection has been made to illustrate the wide range of these materials.
Figure 1
Typical materials content for a medium-sized automobile.

1. Steels

Automotive body components are currently manufactured predominately from ferrous materials, and this will likely continue for some time due to the advantages offered by ferrous materials such as low cost, formability, and recyclability. Most components are cold formed by stamping and then joined together by welding, usually spot-welding. The exterior body parts of the outer structure of a vehicle, such as panels, doors, and hoods, are coated for corrosion protection where necessary. The selection of a particular grade of steel is generally driven by either manufacturing requirements of the component such as formability, or by service requirements such as durability; the predominate requirement may limit the choice of grade. Formability is generally sacrificed for increased strength. Steel companies have remained competitive over the years by offering the ground vehicle industry a wide variety of products and improvements in the final quality through advances in processing. One of these advancements is continuous annealing. With the advent of continuous annealing, it became possible to develop steels with more uniform properties and lower alloy content that exhibit the same or better properties as box-annealed steels. Some of the main families of steels used in the ground vehicle industry are discussed below in general terms. Typical mechanical property values of the major automotive steels are summarized in Table 2.

Interstitial free steels contain carbon levels of about 0.004 and have the best formability characteristics of any grade of steel. The ability to routinely produce such steels is the result of advances in steel manufacturing. These ferritic structures have yield strengths of about 160 MPa and tensile strengths of about 300 MPa. Tensile testing may be used to assess formability through examination of the total elongation (%EL), the anisotropy parameter R, and the work hardening exponent n. For interstitial free steels these are 44%, 2.1, and 0.25, respectively.

Somewhat less formable are the mild steels that have been the standard for a number of years and are still a major body material. Mild steels encompass a wide variety of compositions and grades and are manufactured under less stringent composition and process conditions thus offering a cost advantage. Mild steels are all fully aluminum-killed, with the varying degrees of formability resulting from proprietary processing. Typically mild steels are ferritic in structure and have yield strengths of about 170 MPa and tensile strengths of about 310 MPa. Parameters for a deep drawing quality mild steel that reflect formability are 40% EL, R of 1.7, and n of 0.22.

Currently, mild steels are often being replaced by a relatively new grade of steel known as bake hardenable for exterior panels when dent resistance is a criterion. Bake-hardenable steels are made only on continuous annealing lines and as a family exhibit

Table 2
Mechanical properties of several steel grades.

Grade of steel	Yield strength (MPa)	Tensile strength (MPa)	Elongation (%)

DP370-600	370	600	22

higher yield strength and similar formability compared to mild steel. Strengthening of bake-hardenable steels occurs through two mechanisms. The first is the obvious strengthening that occurs due to cold work, which occurs during forming. The second mechanism is by heat treatment of the steel, which occurs during the paint bake cycle which is applied to the entire automotive body. This strengthening occurs by carbon in solid solution preferentially locating to the generated dislocations and impeding further dislocation movement with subsequent deformation. Therefore, the higher yield strength is the result of both the heat treatment and cold work. Components that receive no deformation in the forming process, such as flat panels, would require some type of uniform strain in order for this grade of steel to be effective. A strain of about 2% and heating for 30 minutes at 175 °C will increase the yield between 55–82 MPa.

To obtain even higher strength, several different strengthening mechanisms are used. High-strength, low-alloy steels (HSLA) obtain their properties through careful thermomechanical treatment. This processing controls the grain size and precipitate distribution. The final properties result from the combination of grain size, solid solution strengthening, and a small contribution from precipitation hardening. The use of continuous-annealing lines has eliminated the variability of HSLA steels that was often found with box-annealed products.

Re-phosphorized steels are a grade of mild steel which offer increased strength while still maintaining reasonable formability. These steels are strengthened by phosphorous through solid–solution strengthening. Careful control over the sulfur and carbon content must be maintained in order to avoid spot welding problems.

Dual phase steels obtain their properties from a microstructure that contains a martensitic phase uniformly distributed throughout a ferrite structure. The strength of these steels can be varied significantly by varying the amount of martensite. The formable grades are characterized by a low yield-to-tensile strength ratio, high elongation, and work hardening. The amount of martensite is generally controlled by the amount of carbon, and the creation of the dual phase structure results from the presence of manganese in combination with appropriate choices of rolling practice and cooling.

1.1 Precoated Steel

The use of thinner, lighter weight sheet coupled with legislation that dictates corrosion standards make

coated corrosion–resistant steel essential in many areas of a vehicle. For steels produced by continuous annealing, the reheating that occurs in hot-dip galvanizing may cause marked deterioration in properties. Therefore electro-galvanizing and zinc-rich paint systems are the only feasible means of corrosion protection. However, high temperature paint cure cycles can cause unacceptable stretcher strain problems or can change properties in some products, particularly those that depend on some type of mechanical abrasion such as shot-peening for their final properties. Table 3 lists some typical mechanical properties of coated steels.

In-line, hot-dip galvanizing produces the best potential corrosion protection, provided an adequate thickness of coating is achieved. Zinc acts as the sacrificial anode and is extremely effective as long as the protective layer remains intact. However, hot-dipped galvanizing can affect the final properties of sheet steel, particularly HSLA steels, by reducing both their strength and formability. The zinc layer can also interfere with spot welding by reacting with the electrode tip, causing the need for increased tip dressing.

Over the years, significant weight savings have been realized in automotive structures and components by vehicle downsizing and/or incorporating lighter weight materials such as aluminum, magnesium, and plastics. Weight savings are also being achieved with ferrous materials with judicious design and new technologies in the steel industry. Weight savings may be obtained through the use of higher strength steels (DP, HSLA), but the most effective method is to use

them in conjunction with new technologies such as tailor-welded blanks and hydro forming.

1.2 Aluminum

Aluminum is increasingly used in body applications as a method of reducing vehicle weight. Table 4 lists some typical aluminum alloys used in automotive body components. Most current applications are 6000 (Al–Mg–Si) series alloys used for exterior panels, such as hoods, deck lids, and fenders. These are formed in the T4 temper and undergo precipitation hardening during the subsequent paint baking process thus increasing the yield strength to provide dent resistance in the finished panel. (Aluminum sheet producers have developed proprietary variations of the T4 temper, which enhance the aging behavior.) The use of aluminum for body structures is more developmental. Most manufacturers have developed prototypes, but only a few lower volume vehicles have reached commercial production. There are two main approaches to the design of aluminum vehicle bodies: (i) Monocoque construction (analogous to steel vehicle construction) consisting mostly of stamped sheet components joined by spot welding, riveting, and, in some examples, in combination with adhesive bonding. Bodies of this type are mainly composed of 5000 series (Al–Mg) alloys, which provide adequate strength and offer better formability and lower cost compared to other alloy types. Specific monocoque designs may also include the use of

Table 4
Examples of aluminum alloys for automobile body applications.

Alloy	Type	Yield strength (MPa)	UTS	Elongation (%)	Typical applications
Sheet (nonheat-treatable)					
5754	Al–3Mg	100	220	26	Body structure, inners for exterior panels
5182	Al–4.5Mg	130	275	24	Body structure, inners for exterior panels

castings, extrusions, or other product forms in selected components. Examples of monocoque aluminum vehicles include the Ford AIV and P2000, the GM EV1, and the Honda Insight. (ii) 'Space Frame' bodies in which the load carrying elements consist primarily of extrusions and castings with use of conventional stamped sheet more limited. Joining methods may include some combination of rivets, spot, MIG, and laser welding. The Audi A2 and A8 and the Ferrari 360, although different from one another, are vehicles based upon the space frame concept.

With respect to weight reduction, aluminum is an attractive body material, since reductions on the order of 50% compared with steel can be achieved. Although much progress has been made in the development of technologies for body applications it is still a higher cost alternative. Future growth in the number of applications will depend on achieving reductions in both material and manufacturing costs.

1.3 Plastics and Composites

Since the mid-1970s, the use of plastics and composites in automobile components has expanded from approximately 4% (by weight) of a typical car or truck in 1975 to more than 10% (by weight) in 2000. These materials can now be found across the entire gamut of vehicles produced by automotive industry including cars, light- and medium-duty trucks, sport utility vehicles, and mini-vans (see Table 5). Furthermore, they are used in a variety of applications including interior and exterior of vehicles, structural parts, and under-the-hood components. Of these applications, exterior components represent the most challenging use of plastics and composites because of the Class 'A' surface finish requirements and the fact that most automobile manufacturers attach these parts to the vehicle in the body shop and they must withstand the high temperatures associated with the paint shop's bake ovens. Nonetheless, plastics and composites are now commonly used for horizontal body panels (i.e., hood and deck lids), vertical body panels (i.e., front fenders, rear fenders, and door outer panels), and several emerging applications that require a combination of structural properties and surface finish.

(*a*) *Horizontal body panels*. Horizontal body panels represent the most demanding application of plastics

Table 5
Vertical body panels—plastics and composites.

Material	Process	Application	Vehicle
SMC	Compression molding	Front and/or rear fenders	Lincoln Continental Plymouth Prowler Ford F-150 Flareside Ford Ranger Splash Chevrolet C/K Pickup Truck
SMC	Compression molding	Door outer panels	Pontiac Firebird Chevrolet Camaro Chevrolet Corvette Saturn EV1
Polyurethane with mica or wollastonite filler	RRIM	Front and/or rear fenders	Pontiac Firebird Chevrolet Camaro Chevrolet Corvette Saturn EV1 Dodge Ram T-300 Chevrolet Silverado
PPE/PA blends	Injection molding	Front and/or rear fenders	VW Beetle Land Rover Freelander Mercedes A-Class Renault Clio II Renault Megane Scenic

and composites because of their location on the vehicle. This refers to both the performance requirements (i.e., part stiffness, fit and finish, thermal loads, and environmental degradation) and the appearance requirements since the customer constantly views these components whether they are driving their vehicle or simply walking past. To date, plastics have not been able to meet these requirements, however, through the inclusion of fibers and fillers in a neat plastic, thermoset composites provide all the properties necessary.

The composite material most commonly used for a horizontal body panel is sheet molding compound (SMC), which is processed by compression molded into its final form. To meet the structural requirements for hoods and deck lids, a two-piece design (i.e., inner and outer panels bonded together with an epoxy adhesive) is typically used. With this design, metal inserts, which are bonded and riveted to the inner panel, are used to attach the body panel to the rest of the vehicle. This approach leads to weight savings of 15–25% relative to steel. A short list of some of the vehicles that currently use SMC for horizontal body panels includes the Ford Mustang, the Lincoln Continental, and the Chevrolet Corvette.

Composite hoods and deck lids have also been fabricated by resin transfer molding (RTM); however, this process has only been used for low volume vehicles (i.e., < 10 000 units per year) such as the Aston Martin DB7 and the Dodge Viper because of the long cycle times associated with this process and the amount of re-work required to achieve a Class 'A' surface finish.

(*b*) *Vertical body panels*. Vertical body panels offer a wide variety of material/processing combinations because their performance requirements (i.e., part stiffness, dimensional tolerance, etc.) are less demanding than those of horizontal body panels. Compression molded SMC, reinforced reaction injection molded (RRIM) polyurethanes and injection molded polyphenylene ether/polyamide (PPE/PA) blends have all been used to fabricate fenders for cars and/or light trucks. Regardless of the technology selected, fenders are manufactured as a complex shaped, single shell structure, which leverages the design/styling flexibility that plastics and composites offer. Table 5 contains a list of plastic and composite materials, processes, applications, and some of the vehicles on which they are used. Most of these parts are assembled onto the vehicle in the OEMs body shop, which means that the plastic or composite body panel must withstand the temperatures associated with the electro-coat, primer/surfacer, basecoat, and clearcoat bake ovens. In some cases, however, automobile manufacturers have made allowances for the plastic and/or composite material and either they attach the part after the electro-coat process or they slow down their assembly line and use lower bake oven temperatures. These strategies provide a mechanism for managing the thermal growth associated with RRIM polyurethanes and injection molded PPE/PA blends.

(*c*) *Emerging applications of plastics and composites.* Recent developments in the automotive industry such as the growth of derivative vehicles and the increased interest by OEMs in the automotive aftermarket provide new opportunities for plastics and composites. Foremost of these new opportunities is the use of composite materials for pickup truck box inner structures. Not only does the use of composites in this application eliminate the current steel box inner, but it also eliminates the plastic bedliner used to protect the steel from damage. Currently, two approaches exist for the fabrication of a composite pickup truck box inner: Ford is using compression molded SMC for the Explorer Sport Trac while GM is using structural reaction injection molding (SRIM) for the Chevrolet Silverado. Although a composite box inner structure does not require a Class 'A' surface finish, it must meet some appearance standards and all performance requirements including weathering and off-road durability.

Other emerging automotive applications for plastics and composites include removable hardtops for convertibles, rigid tonneau covers, and truck caps. These applications may actually be more complicated than composite pickup box inner structures because not only do they require similar levels of performance but they also all require a Class 'A' surface finish and their fit to the rest of the vehicle is extremely demanding. Because of these requirements, automotive OEMs have only used compression molding of SMC to fabricate these components for vehicles such as the Ford Explorer Sport Trac and the Ford Ranger.

(*d*) *Benefits and limitations of plastics and composites.* Perhaps the primary reason that plastics and/or composites are used to fabricate exterior components for low- to medium-volume vehicles (i.e., < 100 000 units per year) is the lower investment costs associated with this class of materials relative to steel stamping. For example, to fabricate a plastic or composite fender by RRIM, injection molding or compression molding requires only one mold cavity where as progressive stamping dyes are needed to stamp an equivalent part out of steel. However, at higher volumes, the reduced investment costs does not offset the higher variable costs associated with plastics and composites when compared to steel. Other benefits for plastics and composites relative to steel include reduced weight, improved corrosion resistance, improved dent/ding resistance, and greater design/styling flexibility.

In addition to the higher raw material costs of plastics and composites discussed above, there are some drawbacks to the use of plastics and composites for the fabrication of Class 'A' body panels. Surface defects such as pits and porosity can render a body panel unacceptable for the exterior of a vehicle. Other defects associated with Class 'A' plastic and composite panels include delamination, bond line read thru, sealer redeposition, surface waviness, and handling related problems such as cracking.

Automotive Chassis/Suspension Materials

This section will examine the large number of elements connected to the vehicle frame that steer and stop the vehicle and support/suspend/isolate the body (and the passengers) from road vibrations. These elements are collectively termed chassis components and include the three vehicle subsystems: suspension, steering, and brakes. These three systems all interact to affect the ride and handling of the vehicle.

The suspension system is composed of five main subsystems: front suspension, rear suspension, shock absorbers, load leveling, wheels and tires. The steering system is composed mainly of vehicle interior elements (steering column, steering wheel, power steering subsystem); but there are a few chassis-mounted components (steering linkages) in this group. The brake system includes both a front and rear drum or disk subsystem, and other power/electronic elements that are not discussed here since they are not part of the overall vehicle handling (braking, steering, vibration) experience.

The front and rear suspension elements are only subtly different in their responsibility for supporting the front and rear of the vehicle. The main difference is that the front has a cross member, also called the subframe or cradle, while the rear has a unique rear cross member. Components that are more-or-less similar in the front and rear include the right/left upper and lower control arms, right/left knuckles/spindles, springs, shock absorbers, wheels and tires, and sway/stabilizer bars; in some classifications, the rear differential and nondriven axles and hubs are also included as chassis members. Within each element are complicated assemblies of elastomeric bushings that help isolate the vehicle body from undesired vibration and shocks without affecting the unique steering, ride, and handling characteristics that define how the manufacturer differentiates each vehicle. Wheels and tires perform both a suspension as well as steering and handling function. Front and rear brake components influence vibration and handling through two- and four- wheel disk brake rotors/drums, calipers, and friction materials. Master cylinder, brake booster assembly, pedals and brackets control the braking action but are not discussed here as part of the suspension–chassis package.

1. Design Considerations

Suspension characteristics are defined by the assembly of suspension components, and are designed by marketing and sales people, who try to translate customer wants into unique and saleable vehicle dynamics. Engineers try to translate the customer wants into definable suspension kinematics and compliance characteristics. In a recent article by GM engineers on the 1997 Corvette, Fuja *et al.* (1997) indicated that there were 60 suspension attributes or design factors that had to be monitored analytically in the development of the 1997 Corvette's overall vehicle dynamics, handling, and performance. As with any complex system, modifications that improve one particular suspension attribute may cause degradation in another; this will often require additional redesigns of all the elements in the system to ensure that the desired vehicle response has been achieved. In addition to vehicle dynamic constraints, there are often packaging and cost issues which impact on the final suspension design selected.

All chassis and suspension systems are now designed using extensive computer modeling. For example, cornering forces, and transient roll behavior can be predicted to be affected by shock absorber structure, spring effects, and other suspension elements. If there are 60 elements in a suspension system, there are probably a similar number of attributes in the braking system and wheel and tire system that can affect vehicle dynamics.

2. Introduction to Materials Selection Criteria

The materials selected for chassis and suspension components differ from company to company, since each is trying to develop a unique product for its perceived market. Any change in design will interact with the materials employed, and the manufacturing process used to fabricate each component will be affected by the material choices. This is true of the individual metallic components as well as the rubbers and elastomeric materials used; all changes will cause a noticeable change in the vehicle's dynamics.

It is almost impossible to describe and classify the large number of materials employed in the various automotive chassis and suspension components in the ~ 50 million vehicles that are produced annually around the world. We have seen that each unique design will employ a unique suite of materials and fabrication process to achieve unique performance, as required for the vehicle's market niche. An important selection criterion is based on the fact that each component must satisfy its expected service conditions (straight driving on flat surfaces and over cobblestones, cornering, braking, accelerating over rough roads, sliding against curbs/potholes, etc.) and must satisfy some expected durability condition (primarily

a fatigue lifetime of $10^7 - 10^8$ cycles versus a defined stress loading and stiffness criteria) with the required reliability and safety. Another issue that constrains material choices is whether the component will be installed on an automobile (usually of 1700 kg mass or less), or a truck (where the mass can exceed 3000 kg). In the latter case, the duty cycle is more aggressive, the loads are higher, and there is more concern about very long-term durability ($> 400\,000$ km); automobiles are usually expected to survive about 200 000 km.

Each material can be fabricated into a component in many ways, depending on the alloy selected, the shapes required, the section thickness(es), and the packaging (space available). As an example, consider a cast lightweight (aluminum) control arm. There are only a couple of alloy choices, viz. Al 356 or Al 357, out of which control arms are cast. And while there are seven ways to produce a cast control arm (gravity, low pressure, tilt, VRC/PRC (Alcoa), squeeze, semi-solid, and high pressure), there is a wide range of heat treatments: annealing-soaking temperatures and times, quench medium/quench temperature, and aging (and preaging) times/temperatures. These combinations are selected by individual foundry preferences to achieve the required tensile strength, fatigue strength, and ductility necessary for the component's durability.

Material selection is not a standardized process. Each company has a set of preferred suppliers who are authorized to fabricate desired components based on the complex set of criteria that define best-in-class function. The choice of material is not as important as is the demonstration of functional excellence, component durability, and of critical importance, the component price. In Table 1 the reader will see a set of preferred materials' choices for the major suspension and chassis components.

The criteria for future materials selection are based on five current pressures that are promoting technological change in the automotive industry: worldwide legislation to reduce automotive emissions; continuing increases in the price of petroleum-based fuels; improvements in vehicle safety; competitive requirements to reduce noise, vibration, and harshness (NVH) and improve vehicle handling; ability to reduce vehicle cost while adding value. These criteria essentially predicate ultra lightweight materials: new steels (high-strength low-alloy (HSLA) steels), lower-cost cast irons (compacted graphite (CG) irons), and aluminum and magnesium components. New computer-control-led processing techniques (e.g., hydroforming, laser welding, computer-controlled casting, etc.) are being developed to fabricate these new materials into low cost, durable, high-strength components and assemblies.

Many components, such as wheels, sway bars, front and rear subframes, shocks, and springs have historically been produced from steel fabrications.

Table 1

Materials used in suspension and chassis for trucks (T) and automobiles (A).

Component	Pre 1990		1990–2000		2005 +	
	T	A	T	A	T	A
Subframes	fabricated steel		steel fabs	aluminum fabs, cast Al	steel, HSLA steel, cast Al	
Springs	steel		Steel		steel, HSLA steel, reinf plas	
Control arms	fab steel	SGI	fab steel	cast Al (50%)	steel, HSLA steel, cast Al	
Knuckles	SGI		SGI	CGI, SGI, cast Al	Cast Al	
Shocks	fabricated steel		fabricated steel		fab steel	Ti, steel
Wheels	steel	cast Al	cast Al, steel	cast Al, steel	cast Al, steel	cast Al, Mg
Brake rotors	GCI		GCI		GCI	GCI MMC Al
Brake drums	GCI		GCI	GCI, MMC Al	GCI	GCI, MMC Al
Calipers	SGI		SGI	GCI, Al, MMC Al	SGI	Al, MMC Al

SGI, spheroidal graphite or ductile cast iron; CGI , compacted graphite cast iron; GCI, gray cast iron; reinforced plastic, composite of polymer with fiber glass; MMC Al, composite of aluminum with SiC particles; SSM Al, semisolid molded or cast aluminum; fab steel, fabricated, usually by welding steel tubing; HSLA steel, high-strength low-alloy steel.

But there has been a gradual increase in the use of aluminum for lightweight replacements. Aluminum subframes are being fabricated from extrusions, stampings, and castings, with a beginning use of hydroforming technology. Cast aluminum wheels now make up over 50% of road wheels in cars and light trucks; forged wheels are used at the higher end (such as the 2002 GM Corvette). Cast magnesium wheels have been used on racing vehicles, and as magnesium ingot prices drop and R&D continues to grow, we can expect a continuing presence of this ultra lightweight metal in automotive components. Suspension control arms currently are being produced from steel, ductile iron castings, and, recently, aluminum castings. Many steering knuckles have been produced since 1970 only as ductile iron castings (prior to being a malleable iron casting); recently there has been an increase in the number of vehicle lines using cast aluminum knuckles, produced by the semisolid molding process as well as by pouring into conventional permanent molds. One or two vehicle lines have used compacted graphite cast iron due to its lighter weight and lower cost. Springs and shocks play an important role in vehicle stability. The new steels and associated processing required to develop lightweight springs requires higher hardness steels (>52 Rc) and the associated higher strength to >1200 MPa which can satisfy the high corrosion fatigue criterion that dominates this application (Yoneguchi *et al.* 2000).

Disk and drum brakes are made by casting a gray iron shape and then machining to a very high tolerance of flatness and parallelism ($12\,\mu$M). But there has been considerable R&D to improve the iron's strength, as well as to increase its thermal conductivity, to increase overall heat transfer and thereby reduce brake temperatures; this will reduce distortion, and improve the vehicles' NVH characteristics. One vehicle line in both Germany and North America has seen the introduction of cast aluminum MMC for additional weight-reduction opportunities.

The growing demand for lighter-weight solutions is anticipated to consume a larger and larger fraction of a vehicle's total materials content. In addition to aluminum forgings, extrusions, and castings, high-strength steel fabrications, magnesium castings, and polymer composite assemblies are beginning to appear in production components. The critical issue is the ability to demonstrate lightweight designs that have good function, while satisfying long-term ($200\,000$ km) durability and have a lower cost. New materials, component designs, and assembly processes are being developed continuously by the automotive industry. To understand the changing strategies of chassis and suspension components, the interested reader can read the references below, to see the work that has been recently performed and published in the US Society of Automotive Engineers (SAE) transactions.

Bearing Materials: Plain Bearings

This article is concerned with the materials which form the working surface of plain bearings. They are most commonly non-ferrous alloys, but may be polymers or polymer-based composites or, rarely, ceramics. Rolling-element bearings and the properties of the steels used in their construction are outside the scope of the present article.

Most plain bearings are oil- or grease-lubricated, and among the major factors determining the choice of bearing material for a particular application are the type, amount, and quality of the lubricant. Some polymer-based bearing materials and composites incorporating solid lubricants have been formulated so as to operate without lubricant.

1. Crankshaft Bearing Materials

The major impetus to development of bearing materials over the second half of the twentieth century has been the internal combustion engine. Depending on the number of cylinders, the crankshaft is carried by between three and thirteen pairs of half bearings (the main bearings) and there are three to twelve pairs of rod bearings housed in the connecting rods and operating against the crankpins. World production of crankshaft half bearings for the various forms of internal combustion engine is something like one billion each year.

The increasingly severe operating conditions which new designs of engine have imposed on the crankshaft bearings have led to the virtual disappearance of the once familiar tin- and lead-based Babbitt alloys, and to their replacement by a range of stronger alloys based on aluminum or copper.

1.1 Aspects of Crankshaft Bearing Performance

(*a*) *Fatigue strength.* The crankshaft bearings of the internal combustion engine are hydrodynamically lubricated; that is, oil is supplied to them under pressure, and an oil film separating the bearing and the crankshaft is generated by the rotation of the crankshaft. Very heavy loads are applied to the bearing surface through the oil film, the two components of the load being the firing load, applied through the piston and connecting rod as each cylinder of the engine fires, and the inertia load, resulting from rotation of the piston and connecting rod relative to the crankshaft.

It is the prime requirement of the bearing that it should be able to carry these loads without suffering damage. The common crankshaft bearing has a steel backing with a thin lining of bearing alloy, and to some extent it is this construction of the bearing which provides its load-carrying capability. However, the strength of the lining alloy is also important, and in choosing an alloy for a particular application the first step is to compute the maximum value of the dynamic pressure generated in the oil film, and to ensure that the alloy has the strength to survive. The choice is made by experience, since there is no simple relationship between any mechanical property of the lining measured in the laboratory and the ability of the lining to provide the necessary fatigue life in engine service. If an alloy of insufficient strength is chosen, fatigue cracks will eventually appear in the lining, pieces of the lining will be lost and the hydrodynamic oil film will be disrupted.

(*b*) *Surface properties.* If there were no other considerations, the strongest alloy available would be chosen and would perform satisfactorily. However, other factors make it undesirable to choose an alloy with a higher fatigue strength than necessary.

Firstly, the bearing and crankshaft are not always separated by a continuous oil film. Imperfect crankshaft geometry, deflections under load, and stopping and restarting all lead to some degree of contact between the crankshaft and bearing. Rubbing takes place under high load and at high speed, and high surface temperatures are generated, which in extreme instances can lead to seizure—friction becomes so great that the crankshaft can no longer rotate in the bearing. Crankshaft bearing alloys are formulated for good compatibility, that is, a minimum tendency to weld to the crankshaft in areas of rubbing. Most crankshaft bearing alloys contain a soft, low-melting-point phase which smears over the bearing surface wherever high temperatures are generated, and thus seizure is prevented.

Dirt entering the bearing clearance with the oil flow is another source of bearing damage. If the dirt cannot be fully embedded into the bearing surface, it may score the crankshaft (depending on the relative hardnesses of the dirt and the crankshaft surface), and the roughened crankshaft may in turn cause wear of the bearings. Embeddability, which is inversely related to the hardness and strength of the bearing lining, is thus an important property.

When dirt is embedded, particularly a relatively large particle of in-built dirt such as may be left in crankshaft drillings, bearing material is displaced around the particle and appears as a ring of alloy protruding from the bearing surface. This ring is rubbed by the crankshaft, but again the presence of a soft, low-melting-point phase prevents the local

welding or "pickup" of bearing alloy onto the crankshaft and avoids seizure.

Since the introduction of nodular cast iron crankshafts in passenger car engines, the crankshaft bearings have been called upon to perform another function, that of "conditioning" the crankshaft. Even after grinding and lapping, the crankshaft surface may contain around the graphite nodules ferrite "caps," which stand proud of the surface and can dig into the bearing during the thin oil film part of the operating cycle. Bearing wear and even seizure can result. In unplated aluminum bearings the incorporation of silicon, present as fine, hard particles uniformly distributed throughout the bearing lining, provides a polishing action, removing the ferrite caps and creating a non-aggressive crankshaft surface.

(*c*) *Corrosion and erosion*. Corrosion resistance and cavitation erosion resistance are another two important properties of crankshaft bearing alloys. Corrosion resistance is important because the trend to higher engine temperatures and longer oil-change intervals results in eventual degradation of the engine oil, and the appearance of an acidic component which can attack the crankshaft bearing. The lead phase of copper–lead bearings is prone to this form of corrosion.

Cavitation of the oil film results from the rapid movement of the crankshaft within the bearing during firing, or from other causes, leading to a disruption or a disturbance in the oil flow at a particular location in the bearing and a particular point in the engine cycle. Subsequent collapse of the vapor bubbles on the bearing surface leads to classic cavitation erosion. Erosion patterns generally show a recognizable symmetry, and in cross section the damage shows a distinctive undercut appearance. Cavitation erosion resistance of bearing alloys is broadly related to alloy hardness, but microstructure is also important. Tin-based whitemetal has a much higher cavitation erosion resistance than lead-based whitemetal of approximately the same hardness, probably due to the copper–tin needles in the microstructure.

(*d*) *Choice of alloy*. The foregoing considerations show that the choice of an engine bearing alloy is a compromise. Conformability—the ability to conform to a misaligned counterface—is inversely related to hardness, as is dirt embeddability, and to some extent also compatibility, because of the desirability of a soft, low-melting-point phase. On the other hand, fatigue strength and cavitation erosion resistance tend to be higher the harder the alloy. For many engines, a satisfactory compromise is found in a two-layer bearing construction, that is, a lining 0.2–0.5 mm thick of one of the alloys described in the following sections, bonded to a low-carbon steel backing. The alloy is chosen which offers the balance of bearing properties

most suited to the requirements of the particular engine under consideration.

Recently it has been found that the conformability of a relatively hard bearing alloy may be improved by the creation in the surface during final boring of circumferential microgrooves, which provide a degree of "give" in areas of crankshaft contact.

For the more severe engine applications, a three-layer construction is adopted. On top of the bearing lining a thin layer of a soft, lead-based alloy is electrodeposited as the last operation in bearing manufacture. The overlay is necessarily thin because of the high engine loads applied to it; it is commonly 0.015–0.025 mm.

1.2 Lead- and Tin-based Whitemetals

The lead- and tin-based whitemetals, or Babbitts, are alloys of lead, antimony, and tin, or tin, antimony, and copper. The most popular lead-based alloys are PbSbl0Sn6 and PbSbl5SnlAsl; the most popular tin-based alloy is SnSb8Cu3. (Formulae of this type are used in this article to indicate compositions as recommended by the International Standards Organization: $SnSb8Cu3 = Sn–8\%Sb–3\%Cu$.) The former consists of cuboids of antimony–tin compound SbSn in a pseudoeutectic of lead–antimony–tin. The latter consists of needles of copper–tin compound Cu_6Sn_5 in a tin–antimony solid solution. Tellurium has a compound refining effect on the tin-based alloys; arsenic refines the antimony precipitate in PbSb15Sn1As1.

As a class, the whitemetals have excellent surface properties: compatibility, conformability, and dirt embeddability. However, their fatigue strength is inadequate for the majority of internal combustion engines, and these alloys survive only as crankshaft bearing linings in slow-speed marine diesel engines. The tin-based alloy mentioned above, often with a 1% cadmium addition for increased strength, is the most popular alloy for marine diesel applications.

1.3 The Copper–Lead Series

When the whitemetals began to show inadequate fatigue strength, attention was turned to copper-based alloys and a range of copper–lead and lead–bronze alloys was developed. At the upper end of the lead range, that is 40–50% lead, the surface properties were found to be sufficiently good for the bearings to be operated without an overlay, and for many years the so-called "intermediate" alloys were used in the majority of passenger car engines manufactured in the USA. The term "intermediate" indicated that the alloys lay between whitemetal and those overlay-plated copper–lead alloys with a lower lead content adopted for heavy-duty engines.

The demise of the intermediate copper–lead bearing was the result of corrosion of the lead phase as

engine temperatures increased, and as adoption of lead-free fuel resulted in greater corrosivity of the engine oil.

The copper–lead alloys now in use do not exceed 30% lead and contain up to 4% tin. All are overlay-plated with lead–tin, lead–tin–copper, lead–indium, or lead–tin–indium, and it is one of the functions of the overlay to protect the underlying alloy against corrosion of the lead phase.

The microstructure of the copper–lead bearing alloys shows distinct copper and lead phases, there being virtually no lead in the copper phase or copper in the lead phase. The tin, if incorporated in the alloy, is associated with the copper phase, where it has a strengthening effect. Thus alloys such as CuPb14Sn3 or CuPb23Sn3 are capable of carrying higher bearing loads than CuPb23Sn1 or CuPb30. The higher-tin alloys are found in the most arduous applications, such as the connecting rod bearings of the high-speed diesel. Their higher hardness is compatible with the hardened crankshafts found in these engines. The CuPb14Sn3 alloy produced by a sinter process, modified to refine the lead phase, is the strongest of the overlay plated copper–lead alloys.

Still higher strength has been achieved in Germany by the application of physical vapor deposition to bearing production. An aluminum–tin overlay is applied to the surface of a copper–lead bearing by cleaning the surface in vacuum by ion bombardment, followed by the deposition by sputtering of 16 microns AlSn20. "Spütterlager" have been adopted by European engine builders for the most heavily loaded connecting rod bearings in truck and passenger car diesel engines, where the high cost of the bearings can be justified.

1.4 The Aluminum Series

Crankshaft bearing production worldwide is roughly equally divided between copper–lead and aluminum alloys, although the aluminum series covers a wider range both of alloys and engine type.

The aluminum crankshaft bearing alloys are corrosion resistant and do not therefore rely on the overlay to protect them from corrosion. Thus in passenger car engines, unplated aluminum-lined bearings are found in Europe, the USA, and Japan.

In Europe, reticular tin–aluminum, AlSn20Cu1, developed in the UK in the late 1950s, proved very successful and became well established. The term "reticular" refers to the network of tin islands, interconnected along trigonal grain boundaries, distributed throughout the aluminum–1% copper matrix. In Japan, derivatives of reticular tin–aluminum containing additions of antimony or of silicon, lead, and chromium have been developed.

In the USA, a wear problem was found with this alloy, associated with the surface finish obtained on

nodular cast iron crankshafts in the early stages of their development, and aluminum–lead took the place of aluminum–tin. The lead content of aluminum–lead is 4–8%, and there is a small tin addition of 0.5–1.5% associated with the lead phase.

The alloy also incorporates a 4% silicon addition, providing the crankshaft polishing action referred to above, and avoiding bearing wear. Minor additions of copper and magnesium or manganese are made to the alloy for increased fatigue strength.

Early versions of the aluminum–lead–silicon alloy were made either by a low quench rate, continuous-casting process or by a powder metallurgy route. Both showed a poor microstructure associated with the metallurgy of the aluminum–lead system, and in consequence a less-than-ideal fatigue strength. More recently, a high quench rate continuous-casting process for the alloy has been developed, which results in a much finer lead phase. Heat treatments have been developed to grow the silicon phase to the optimum size for its crankshaft polishing action.

In Japan, aluminum–tin–silicon alloys were developed with the tin content reduced from 20 to 12%, and a 2.5% silicon content introduced together with 1.5–2.0% lead. Copper 0.7–1.0% was incorporated, together with other minor alloying additions for improved fatigue strength. Similar alloys have been introduced in Europe and the USA. In the USA, the high quench rate casting process has been used to produce an AlSn8Si2.5Pb2 alloy with copper and chromium strengthening additions. In the UK, AlSn10–12Si4Cu1 alloys have been developed, the alloys being given a solution heat treatment so that additional strengthening is achieved during age-hardening in the engine.

Aluminum–tin–silicon is now the most popular alloy worldwide for NCI crankshaft passenger car engines. It combines good fatigue strength, crankshaft polishing action, and seizure resistance, with the added advantage of being almost or totally lead-free.

Unplated aluminum–silicon has also been used successfully in medium-speed marine engines. However, for the more highly loaded crankshaft bearings in high-speed diesel engines, stronger overlay-plated aluminum alloys are required. The early low-tin alloys AlSn6Ni1Cu1 and AlSn6Si1.5Ni0.5Cu1 are still in use, but cadmium-containing alloys AlSi4Cd1 and AlCd3Mn1.5Cu1Ni1 have been dropped on environmental grounds. A cadmium-free version of the latter alloy is operating successfully in the USA, together with a slightly stronger alloy AlSi5Sn2Cu1Mn1Ni1.

Comparable strength aluminum–zinc–silicon alloys have been developed in Japan. All are overlay plated with lead–tin or lead–tin–copper on a thin copper interlayer. The copper interlayer is preferred to nickel by one major engine builder on anti-seizure grounds.

At the other end of the spectrum a soft aluminum–tin, AlSn40, has been developed in the UK specifically for the marine diesel engine. Conformability

and seizure resistance are of paramount importance in these large engines, where the crankshaft and cross-head bearings are between 400 and 900 mm in diameter. Bearing seizure can result in a crankcase explosion and is to be avoided at all costs. This alloy has a hardness comparable with that of tin-based white metal, without the loss of fatigue strength at engine temperature associated with the latter.

1.5 Lead-based Overlays

The lead-based overlays on the crankshaft bearings of heavy-duty engines have to survive under very arduous conditions. The overlay has to be soft to provide good conformability and dirt embeddability. At the same time, it has to withstand oil film pressures which may be as high as 350 MPa.

The relationship between overlay thickness and fatigue strength is well established. For some engines, adequate overlay strength is obtained from an overlay 0.025 mm thick, although for engines with particularly high rod bearing loads an overlay thickness of 0.015 mm is preferred.

Unfortunately, none of the overlays in current use is completely stable at engine temperatures. Changes in the chemical composition of the overlay take place as a result of diffusion phenomena, and there is accompanying deterioration in both strength and corrosion resistance.

The loss of tin by diffusion from a lead–tin (PbSn10) overlay into the underlying copper–lead may be delayed by the addition of 1–5% copper to the overlay composition, and by the incorporation of a nickel barrier between the overlay and the lining. Although tin and copper are still lost from the overlay to form a ternary nickel–tin–copper compound on top of the barrier, sufficient tin is retained in the overlay to provide adequate bearing performance.

The higher-copper overlays are harder and have somewhat enhanced wear resistance: recently a change from a fluoroborate electrolyte to methane sulfonic acid has enabled both tin content and copper content to be increased. The resultant PbSn14Cu8 overlay has good wear resistance without loss of fatigue strength, and is more stable at engine temperature than other lead-based overlays, presumably as the result of copper–tin compound formation within the overlay.

Lead–indium overlays can be produced by sequentially plating the lead and indium in separate baths, and diffusing the indium into the lead by heat treatment. Under certain circumstances they offer higher fatigue strength than lead–tin, but suffer from similar diffusion problems. At engine temperature the indium diffuses into the lead phase of the copper–lead, resulting in a loss of overlay strength and of wear and corrosion resistance.

In Japan, improved wear and fatigue resistance has been obtained by the incorporation of both tin and indium in the overlay, in combination with a nickel interlayer to limit diffusion. Lead–tin–indium and lead–tin–indium–copper overlays have been adopted by Japanese engine builders.

The foregoing refers to overlay-plated copper–lead. For electrochemical reasons, lead-based overlays cannot be applied directly to aluminum. It is therefore standard practice to deposit an interlayer between the overlay and the alloy, similar to the nickel barrier used on copper–lead. The interlayer may be nickel or copper. At engine temperatures, diffusion of the tin into the interlayer takes place and there is the same danger of loss of overlay strength and corrosion resistance as exists with copper–lead bearings.

In view of the environmental problems associated with lead, there are ongoing developments among engine bearing suppliers aimed at a lead-free overlay. Tin-based compositions are being explored, as are high-temperature polymers incorporating a solid lubricant. As yet, none has reached the stage of large volume production.

2. Bearing Materials for General Engineering

In the varied category of general engineering applications, the degree of lubrication can be anywhere between hydrodynamic and boundary, the former implying complete separation of the surfaces in relative motion by an oil film, the latter implying continuous rubbing contact. Wick lubrication, splash, or oil mist lubrication and grease lubrication are intermediate forms.

The bearing conditions in this category are generally less severe than those imposed on crankshaft bearings; in the hydrodynamically lubricated applications, oil film pressures are lower, as are oil temperatures. Fatigue strength and corrosion resistance of the bearing materials thus become of less importance. On the other hand, in the nonhydrodynamic applications, wear resistance assumes a much greater importance than it does in crankshaft applications.

The majority of alloys found in this category are still copper-based, both steel-backed and solid; but steel-backed aluminum alloys are found in an increasing number of automotive applications. Lead- and tin-based whitemetals are common. Many polymers behave well in lubricated applications, and when the lubrication is sparse, polymer-based bearing materials often outperform metallic bearing alloys.

Oil-impregnated bushings in which the bushing wall is a lubricant reservoir, and which require no external application of lubricant, are included in this section. However, composites incorporating solid lubricants are considered in Sect. 3, even though they are sometimes used in conjunction with conventional oil or grease lubrication.

2.1 Copper Alloys

The lining alloy specifications for many steel-backed bushings and thrust washers are similar to those of the half bearings dealt with in Sect. 1.3. CuPb23Sn3 is a general-purpose alloy found as the bushing lining in a wide variety of applications, such as automotive automatic transmissions, refrigeration compressors, and hydraulic gear pumps.

Applications requiring a higher-strength lining use a lower-lead, higher-tin alloy, CuPb10Sn10. This alloy performs well in the heavily loaded piston pin bushing of the internal combustion engine. The high loads and oscillating motion of this application make the creation of a satisfactory oil film difficult, and a surface finish of 0.1 μm R_a is required on the hardened piston pin if an acceptable lifetime is to be obtained. Recent development trends in engine design are further increasing pin bushing loads and temperatures, resulting in corrosion by oil additives. A high-strength aluminum–bronze lining alloy CuAl8 meeting these conditions is now well established. Other lead-free, high-strength alloys such as copper–tin–nickel are under evaluation. Solid (non-steel-backed) brass bushings of composition CuZnSi1 or CuZn23 Al6Mn4Fe3 have been successfully introduced in some engines.

Solid bronze bushings are used in many applications where quantities do not justify the tooling costs associated with the forming of steel-backed bushings and a suitable stock size is not available. The bronzes are usually continuously cast as rod or tube; the larger sizes are spin-cast. Common alloy compositions are CuSn5Pb5Zn5, CuSn10Pb5 and phosphor bronze CuSn10P. The phosphor bronze is the strongest and has good abrasion resistance in difficult environments, but it is the most expensive of the three alloys and requires a hardened counterface.

2.2 Aluminum Alloys

The use of steel-backed aluminum alloy bushings is confined to oil-lubricated applications, most of which are automotive, e.g., camshaft bushings, balancer shaft bearings, and bushings for the automatic transmission. The majority are lined with aluminum–tin–silicon, occasionally with the low-tin variety of aluminum–tin. Compositions are as described in Sect. 1.4.

Solid aluminum bushings, half bearings, and washers are not uncommon in the USA, the majority being made from continuously cast or spin-cast 6% tin alloy. A heat-treatable version of the alloy containing magnesium is available. Because of the high thermal expansion of aluminum, retention of fit by the bearing in a ferrous housing requires that the yield strength be increased, either by cold work or by precipitation heat treatment. Until fairly recently, solid aluminum crankshaft bearings were used in some

large diesel engines; nowadays their use is confined to gas compressors.

In Germany, solid aluminum–zinc bearings of composition AlZn5Ni1Pb1Mg1Si1 were used successfully for many years as the main bearings of a light alloy, air-cooled automotive engine. The thermal expansion of the bearings matched that of the cylinder block and there was no problem with loss of fit.

Recently, two zinc–aluminum alloys containing 12 and 27% aluminum have been promoted as less expensive alternatives to bearing bronzes in general engineering applications. Their bearing properties appear to be good, but they have not yet significantly penetrated the bearing bronze market. Their expansion coefficients are higher than that of aluminum, which can give a problem with retention of fit at elevated temperatures.

2.3 Whitemetals

The steel-backed whitemetals used in the journal and thrust bearings of rotating plant are generally tin-based, SnSb8Cu3 being the most commonly used alloy. Higher strength can be obtained from alloys of more complex composition, but at the expense of loss of ductility. A zinc-containing alloy, SnZn30Cu1, is used in some marine applications. This alloy is anodic to steel, and hence affords cathodic protection to shafts in contact with seawater.

In some applications such as steam turbines, bearing temperatures approach the safe limit for whitemetal, usually accepted as 130 °C. Alternative materials are being sought with the attractive "wiping" properties of whitemetal—the ability of the bearing surface to flow plastically when the surface temperature exceeds the solidus temperature in areas of hard rubbing—but so far none has found wide acceptance.

Tin-based whitemetal bushings are firmly established in mid-range fractional-horsepower (fhp) motors, that is, with shaft diameters from 10 to 16 mm, where they are used in combination with oil-impregnated wick lubrication. Belt tension can apply high load to the bushings, and the reversing motion found in some domestic appliances compounds the problem of establishing a satisfactory oil film. The life of tin-based whitemetal in this application cannot be matched by lead-based or any other bearing alloys.

A 50-year-old US survivor in automotive applications is a lead–Babbitt-based bearing, in which a PbSn4Sb4 alloy is impregnated into a porous sintered bronze layer on a steel backing. After boring, the thickness of Babbitt above the sinter is less than 0.5 mm, and for many years this gave adequate strength for the automotive crankshaft bearing application. The material is now found only in US passenger car camshaft bushings.

2.4 Polymer-based Bearings

Metal-backed polymer-lined bearings offer a good combination of properties in sparsely lubricated applications. The high thermal expansion and low creep strength of unmodified polymers militate against their use in arduous bearing applications, as does their low thermal conductivity. These problems are largely overcome if the polymer takes the form of a thin layer firmly bonded to a metal backing. Load-carrying capacity, dimensional stability, and retention of fit become good, and conventional bearing clearances may be used. The advantages which such bearings offer over bearing alloys are superior compatibility, lower friction, and an ability to make better use of limited lubrication.

In this section, an artificial distinction is made between materials developed for unlubricated applications and those which require some degree of oil or grease lubrication. The former class, in which the primary polymer is polytetrafluoroethylene (PTFE), is dealt with in a later section, even though they have found some important lubrication applications.

Of the materials intended for use with oil or grease lubrication, a thermoplastic polymer, generally acetal copolymer, is keyed to a steel backing via a porous sintered bronze interlayer. The bronze layer is 0.25–0.35 mm thick, and there is about the same thickness of polymer above the bronze. Bushings, half bearings, and thrust washers may be formed by conventional means.

With grease lubrication, longer relubrication intervals are possible than are needed for bronze alloy bushings and this is of benefit in those applications— agricultural equipment, for example—where relubrication does not get the attention it should. The lubricated friction of polyacetal is less than that of bronze, and the use of the polymer-lined composite for kingpin bushings in a truck axle significantly reduces the steering effort.

Limitations of the acetal copolymer lining are its relatively low softening point and its susceptibility to attack by acidic oil. Composites based on more stable, high-temperature engineering polymers have therefore been developed and are now well established. One such product is based on polyetheretherketone (PEEK) and incorporates PTFE and other fillers; another is based on polyphenylene sulfide (PPS) and incorporates PTFE and Aramid powder.

Another type of polymer-based composite used in bearings is thermosetting phenolic or polyester resin, reinforced with randomly oriented asbestos fiber, or with cotton or asbestos cloth. The strength of these composites, particularly those incorporating cotton cloth, is high, and they perform well in heavily loaded applications such as rolling-mill bearings. Water makes a surprisingly good lubricant for these composites, which accounts for their use as marine stern tube bearings (carrying the propeller shaft) and rudder pintle bushes.

2.5 Oil-Impregnated Porous Bronze

Where a small-bore bushing is required, of bore diameter less than about 10 mm, an oil-impregnated porous bronze is often the most economic choice. Injection-molded nylon or acetal bushings may be cheaper, but they have a more limited load and speed capability.

Powder metallurgy techniques enable plain bushings, flanged bushings, and spherically backed bushings (when a self-aligning feature is required) to be readily produced. The third form is commonly found in the smaller fractional-horsepower motors. While there is no limitation technically to the size of bushing, the metal cost makes the product uncompetitive with steel-backed bushings in the larger sizes. Iron may be used instead of bronze, but the performance characteristics are not as good.

Compaction is controlled so as to leave a porosity of 10–25%, depending on the application. The pores are interconnected, and in service the oil circulates within the wall of the bushing. Because lubrication is hydrodynamic, oil-impregnated porous bronze bushings give their best performance when the operating conditions favor the formation of a hydrodynamic film, that is, continuous shaft rotation in one direction. The load-carrying capacity is less when the shaft oscillates, when there is frequent stopping and starting, or when the rotational speed is low.

3. Bearing Materials not Requiring Lubrication

3.1 Advantages of Dry Bearings

Many different types of bearing composite have been developed for operation without an externally applied lubricant. None is capable of operating at as high a combination of load and rubbing speed as a well-lubricated bearing—friction is higher, heat generation is greater, and there is no flow of oil to take away the frictional heat. There are, however, many advantages to dry bearings which account for their increasing popularity. The cost advantage resulting from the elimination of a lubricating system or of the labor of relubrication is a major consideration. Lubrication points are often inaccessible, and with a dry bearing the human factor in relubrication is eliminated.

There are also important technical considerations in many applications which favor the choice of a dry bearing:

(i) product contamination by the lubricant;

(ii) accumulation of airborne contaminant collected by the lubricant;

(iii) extremes of temperature—above the 150 °C maximum or below the −30 °C minimum at which conventional lubricants can be used;

(iv) absence of atmospheric pressure, resulting in evaporation of the lubricant (e.g., in space);

(v) motion that does not favor hydrodynamic lubrication—high loads and low speeds, frequent stop starts or oscillating motion;

(vi) flat rubbing surfaces and axial sliding in bushings (i.e., no hydrodynamic wedge of oil); and

(vii) operation in low-viscosity liquids (i.e., little load-carrying capacity of the hydrodynamic wedge).

Dry bearings based on polytetrafluoroethylene have additional advantages related to the frictional properties of PTFE: the low value of the friction coefficient at high loads and low rubbing speeds, and freedom from stick-slip (intermittent motion, resulting from a higher static than dynamic coefficient of friction). These advantages lead to the use of PTFE-based bearings in both lubricated and unlubricated applications.

3.2 Steel-backed PTFE–Lead–Bronze

The most popular dry bearing material based on PTFE is a steel-backed composite with a 0.25 mm lining of porous bronze into which a mixture of PTFE and lead is impregnated. A high degree of dry wear resistance derives from the presence in the rubbing surface of the three components.

The concept of *PV*—the product of load per unit area of the bearing and linear rubbing speed—is a useful way of describing the severity of a dry bearing application. Wear rate varies inversely with *PV*, and for several, though not all, dry bearing materials the wear rate is roughly the same for a given value of *PV* whether the product of high load and low speed or low load and high speed. Other factors such as temperature, the material and roughness of the counterface, and the type of motion must be taken into account, but with a knowledge of all these factors it is possible to predict the wear rate of many dry bearing materials with reasonable accuracy.

The steel-backed PTFE–lead–bronze composite has a very high degree of dry wear resistance confined to a thin surface layer, 0.025–0.050 mm thick. At PV of $0.5\,MNm^{-2}ms^{-1}$, wear through this layer takes place at about $0.025\,\mu m\,h^{-1}$. The usable temperature range is wide, from 200 °C below to 200 °C above zero, although at the higher temperature there is an increase in wear rate by a factor of ten or more. The friction coefficient is 0.10–0.25 under most sliding conditions, but falls to <0.05 under high-load, low-speed conditions (loads $>10\,MNm^{-2}$, speed $<0.1\,ms^{-1}$).

A lead-free version of the product is available, in which the lead is replaced by molybdenum disulfide (MoS_2). Dry wear performance is good, but not equivalent to the lead-containing product.

Applications for both products have been found in a very wide range of industries: in agricultural machinery, domestic appliances, textile machinery, machine tools, aircraft and aerospace, and civil engineering.

In two important applications for this type of composite the bushings are in fact oil-lubricated, and it was their frictional characteristics which led to their adoption. One is in the Macpherson strut, common in the suspension of front-wheel-drive cars. The other is in high-pressure versions of the hydraulic gear pump, where loads are high and thin oil films result in unacceptably high friction in a bronze bushing.

The strut application has led to the development of modified versions of the product, aimed at better satisfying the conflicting demands for low friction, high wear resistance, and resistance to cavitation erosion. One successful product incorporates fibrillated Aramid fibers in the PTFE: in another, the lead is replaced by a combination of boron nitride, molybdenum disulfide, and other fillers.

The BN/MoS_2 combination has proved successful also in unlubricated applications, and offers a performance equivalent to PTFE–lead impregnated bronze but without the environmental concerns associated with lead.

3.3 PTFE-impregnated Bronze Gauze

A product competing with the foregoing is based on a tin–bronze woven gauze impregnated with PTFE and fillers. It may be used as a floating insert or bonded to a steel backing and formed into bushings. High-volume automotive applications have been found in door hinges, pedal bushings, and gearshift linkages.

3.4 Solid Plastics

One of the advantages of the bearing construction described in Sect. 3.2 is that frictional heat is readily removed through the bearing wall, both the porous bronze lining and the steel backing being reasonably thermally conductive. Solid plastic bearings are at a disadvantage in unlubricated applications, in that frictional heat must be removed through the mating surface, which may or may not be a good heat sink. For this reason, and for the reasons of dimensional instability mentioned in Sect. 2.4, solid plastic dry bearings are restricted to applications in which PV does not exceed $0.2\,MNm^{-2}ms^{-1}$.

PTFE is the polymer on which most dry bearings in the solid plastic category are based. The PTFE may be the matrix in which such fillers as graphite or glass fiber are incorporated, or it may itself be a filler in a thermoplastic matrix such as polyacetal. In one well-established product of the latter type, the PTFE is present as randomly oriented fibers in an acetal copolymer matrix.

Unmodified PTFE is rarely used as a dry bearing material, on account of its high wear rate and low creep strength. Interesting exceptions are, however, found in civil engineering: the bearing pads supporting bridge spans and flyovers often consist of a slab

of PTFE confined in a shallow cast iron well, to prevent extrusion under the very heavy bearing loads. PTFE offers a friction coefficient as low as 0.02 under these conditions, and permits thermal expansion and contraction of the span without imposing undue stresses on the structure.

The low creep strength of PTFE may be improved by the orientation of the molecules which occurs during the drawing of fibers. The cloth woven from PTFE fibers has a high load-carrying capacity, and is found as the lining of bushings in earthmoving equipment and in aircraft control linkages. The backing is usually a thermosetting plastic such as phenolic or epoxy resin reinforced with glass fiber.

Non-PTFE composites incorporate alternative solid lubricants such as graphite or molybdenum disulfide or, in some cases, micropockets of lubricating oil. At the lower end of the cost spectrum are found the injection-molded nylons and acetals, which are both intrinsically cheap and can be processed by low-cost methods. The incorporation of solid lubricant or oil improves the friction coefficient and wear resistance, and provides satisfactory performance in many lightly loaded applications. The maximum PV at which acceptable wear rates are obtained is $0.1 \, \text{MNm}^{-2} \text{ms}^{-1}$. In the oil-containing version, the oil pockets are not interconnected and the performance does not compare with that of oil-impregnated bronze.

At the upper end of the cost spectrum are expensive, high-temperature engineering polymers such as polyimide. Graphite-filled polyimide provides good temperature resistance and a low wear rate in many difficult applications. The wear rate is relatively unaffected by increasing temperature, and acceptable performance is obtained at PV values up to and sometimes over $0.20 \, \text{MNm}^{-2} \text{ms}^{-1}$.

Intermediate in cost are thermoplastics such as polysulfone and polyphenylene sulfide reinforced with randomly oriented carbon fiber. Quantitative data on the bearing performance of these composites are not yet available.

3.5   Graphited Bronze and Carbon

Bronze and steel-backed bronze bearings incorporating pockets of a graphite-based solid lubricant in the bearing surface are used where some enhancement of wear resistance is required under sparse lubrication conditions. For operation without lubricant, a much finer distribution of graphite throughout the bronze matrix is required. Composites of this type are produced by powder metallurgy techniques; copper, tin, and graphite powders are blended, compacted, and sintered. The most common composition contains 8 wt.% (26 vol.%) of graphite. Up to 40 vol.% of graphite can be incorporated, though at some considerable sacrifice of strength and ductility. The degree

of dry wear resistance is not as high as that obtainable from the PTFE-based composites, but the graphited bronzes may be used at temperatures well above those that PTFE can withstand. They are found in hostile environments where a certain amount of wear can be tolerated, and also in some underwater applications.

Carbon bearings also have good temperature resistance, and may be used in lightly loaded applications at temperatures as high as 500 °C. They have excellent corrosion resistance and are used in pumps handling corrosive liquids. Their thermal expansion is low, and special measures have to be taken to retain fit in the housing. The counterface is usually hard and corrosion resistant.

3.6   Ceramics

Ceramics such as alumina and silicon nitride, and cemented carbides such as cobalt-bonded titanium and tungsten carbides, are used successfully against hard counterfaces in certain specialized applications. An excellent surface finish may be obtained on these hard materials; for this reason they are used in gas-lubricated bearings, in high-precision machine tools, and as the pivot bearings in horological and instrument applications. They are also found as very high-temperature bearings, and in nuclear reactors on account of their resistance to radiation.

Alumina is used as the water-lubricated thrust bearing in domestic hot water circulating pumps. Cemented carbides are used as the bearings of industrial pumps handling corrosive liquids. Their high abrasion resistance enables them to provide satisfactory performance when the medium in which they are operating is heavily contaminated by abrasive particles, such as in mining machinery.

Biological Materials: Synthesis, Structure, and Properties

The microstructure and properties of biological tissues are of interest because they influence the morphology and behavior of each species. Biological tissues are also of interest in that they can suggest new designs for synthetic materials and new ways of using synthetic materials to achieve an engineering goal. In surgery, we have the more difficult problem of developing synthetic materials that will work in tandem with animal tissues. The following article contrasts synthetic and biological approaches to processing, to material structure and to the use of materials in design. It also provides links to more detailed descriptions of individual types of plant and animal materials in this encyclopedia.

A key observation concerning biological materials is that they are all composites. At any scale above 10 μm there are no uniform structures in biology. This makes the concept of a "biological material" rather uncertain because structures and properties change with position in the body, with the individual plant or animal and with time. Thus we can consider "cartilage" to be a material, but then distinguish the structures of hyaline, fibrous, and elastic cartilage. We then subdivide each of these according to their site, such as articular cartilage and costal cartilage. Also, in contrast to assembled machines, sharp boundaries between structural materials are rare so it is quite difficult to define where one material stops and the next one starts. For these reasons it is also relatively difficult to characterize tissues and compare their properties with those of plastics, ceramics or metals.

1. Biological and Synthetic Processing

In practical engineering, where cost is very important, there is little sense in designing a part without a very good idea of how it will actually be made. Materials selections are then made once the manufacturing route and basic design have been decided. The same must be true in biology; many interesting structural features may be firstly a consequence of the growth process and only secondarily a source of improved properties.

Small numbers of synthetic parts can be made by subtractive processes such as machining but the process is slow and wasteful. Molding is generally cheaper and faster. Hot liquid material is injected into a hollow tool and allowed to solidify. Extrusion, forging, rolling, and other hot processes can be viewed as variants on molding. The sintering of ceramics is a separate case; compacted powder is heated until surface energy drives the slow shrinkage and densification to a solid. Chemical processing is not common in the synthetic world. Thermosetting resins such as epoxies are solidified by chemical reaction (see *Thermosets: Epoxies and Polyesters*[#]) and there is some exotic reactive processing of ceramics. Generally, chemistry has the problem that small changes in starting conditions or purity can cause big changes in the reaction kinetics and so reliability is poor.

In biology, all processing is essentially chemical. Soluble reagents are fed to a site where they combine to make a solid plus dissolved by-products. In the case of epoxies, mentioned above, there is little volume change between the liquid and solid states. In forming solids from solution, there is also a massive shrinkage to be accommodated. The biological equivalent of molding can be seen in the formation of isolated particles within an envelope of lipid membrane. Examples include the formation of silica in sponge spicules (Simpson and Volcani 1981) and diatoms (Li and Volcani 1984) and calcite in coccolith (Young *et al.* 1992) skeletons. The wall of the "mold" is now permeable to allow reagents in and soluble products out. This approach is suitable for isolated particles, such as the magnetic particles in magnetotactic bacteria (Frankel *et al.* 1998) and for the wall of a single celled diatom. The particles may also be later assembled into a simple framework, as in the sponges. However, this method does not lend itself to strong, dense, load-bearing structures suitable for large plants and animals.

A problem with building a large solid object by a chemical precipitation is to avoid surrounding and entombing the cellular machinery that provides the reagents and removes the products. The obvious solution is to build the solid layer-by-layer, such that a layer of cells provides material to add to the surface of the growing solid and retreats ahead of it. The layer approach is apparent in the growth rings of trees. Bone, tooth and shell form in the same way. In wood and skin, it is the cells themselves that become the structural unit by depositing solid cellulose or keratin in or on the cell. Each new layer starts as a new layer of cells.

In bone and tooth the deposition is external to the cells (see *Bone Mineralization*[#]). In the case of bone growth, the cell layer continuously forms new collagenous matrix material. This then mineralizes and

converts to hard bone as new matrix is deposited over it. The control system thus promotes crystal growth in layers several microns from the cell surface while not mineralizing the freshly formed matrix. Many proteins are known to be associated with control of this process but it is not yet clear how they work together.

One natural consequence of this layerwise growth process is that layers of different material can readily be formed within a single solid. As will be seen below, biology makes extensive use of layered structures to add toughness to strong materials. Recent developments in ceramics have also focused on the use of layered structures to add toughness. New methods of freeform fabrication (see *Freeform Fabrication*[#]) should ultimately allow the production of complex layered structures resembling those of biological materials.

A result of the chemical precipitation is that it is relatively difficult to make dense structures. The large volume change as a soluble polymer assembles into fibers or as a mineral precipitates will lead to highly porous structures unless the deposition rate is extremely slow. Any structure forming in a diffusion field will tend to grow towards the source rather than filling in gaps in a layer. Very slow growth will allow equilibration, which will favor dense structures. One solution to this is to lay down a mesh of strong fibers, fill in the pores with a softer matrix and then arrange for this to slowly expel water and harden chemically. This kind of process is seen in wood and in cuticle (see *Cuticle*[#]) and very similar issues occur in the formation of carbon–carbon composites (see *Carbon–Carbon Composites*[*]). For such reasons, biological materials must be composites.

2. Structural Biological Materials

In their survey of biological materials, Wainwright *et al.* (1986) make a division into tensile materials, rigid materials and pliant materials. Following a more conventional materials division, we will discuss polymers, ceramics and mineralized polymers, and gels. However, such boundaries are even less clear in biology than in the synthetic world.

Two processing-induced limitations should be recognized for structural polymers in biology. Firstly, they are all formed from aqueous solution and so are all very sensitive to plasticization by moisture. In most cases, the properties of the dry material have little relevance because they will only occur in a dead organism. The plasticizing effect of water on biological polymers can be regarded as parallel to the softening effect of increased temperature on synthetic amorphous polymers. As temperature will take a hard polymer through the glass transition into a rubbery state, so increased water content will convert amorphous proteins from glass to rubbery. There is little sense in measuring the mechanical properties of biological materials without defining the water content.

Secondly, the growth process allows a variety of routes to the formation of fibers but there are no simple ways to form a dense isotropic plastic. Thus, even essentially isotropic materials will have a fibrous composite microstructure. Weiner (Weiner *et al.* 2000) has recently argued that many biological structures can be viewed as a search for isotropic properties, or at least orthotropic properties (strong in two dimensions), from fibrous materials. This would reflect the unpredictability of stresses encountered by a structure in a dynamic environment.

Tables 1 and 2 compare the mechanical properties of synthetic and biological materials.

3. Structural Proteins

Many insects and arachnids make extensive use of silk protein fibers for a range of purposes (see *Natural Protein Fibers*[*]). Spiders typically produce five different silks for the radial and spiral parts of the web, for a sticky web coating, for wrapping prey and for the dragline. The property variations come from differences in the amino acid sequence of the polymer. Silks are stored in a gland as an aqueous solution, at least some of the time, in a lyotropic liquid crystalline state. For the strong silks, shear at the spinneret leads to a change in conformation to a very highly oriented and stiff fiber. The combination of strength, stiffness, and toughness shown by spider dragline silks have led to efforts to characterize, clone, and produce a synthetic version of this material (see *Silk Produced by Engineered Bacteria*[#]).

Bulk crystalline polymers, such as nylon or polyethylene, have an amorphous fraction of 30–50% that arises from the inability of entangled polymer chains to become completely ordered. This crystallinity can be controlled to some extent by processing and can be reduced by copolymerization to introduce random irregularity into the chain. Fiber structures are less easy to resolve but behave similarly. In many

Table 1
Properties of natural and synthetic ceramics

	Modulus (GPa)	Strength (MPa)	K_{1c} (MPam$^{1/2}$)	G_c (Jm^{-2})

silks the structure seems to be blocky, with irregular sections spaced along the chain to define non-crystallizable sections. We are not yet able to resolve the role of these irregular sections in stabilizing the liquid crystalline state and in defining the final structure and properties of the fiber. In all biological polymers there is a degree of control over the molecular structure that may be very important for properties and cannot be duplicated synthetically.

Collagen is the structural material of skeletal animals and has properties that are quite inferior to those of cellulose, chitin or silk. The key to its use seems to lie in the versatile processability. Soluble procollagen is formed in the cell and exported into the growing tissue. An enzyme cleaves a bulky end section from the molecule to form tropocollagen that organizes into a triple helical structure. These triple helices self-assemble into collagen fibrils that make up the bulk of tensile structures such as tendon and ligament. As it ages, the collagen becomes cross-linked, which increases the stiffness and strength but reduces the toughness. Baer *et al.* (1991) have discussed the structure and properties of collagen in tendon and ligament.

Keratin can be seen as a biological answer to the need for a tough plastic equivalent to nylon. As hair and fur, it is a fiber. As epidermis it is a film and as hoof or horn, it is tough solid. The structure contains fibrils, which are built from three-stranded ropes of alpha-helical chains in a coiled-coil arrangement. The fibrils are embedded in a cross-linked matrix of amorphous protein that is heavily cross-linked by cystines (sulfur–sulfur links). The high sulfur content is a defining characteristic of members of the keratin family and gives burning hair its characteristic smell. The fibrils confer great toughness by converting to a more extended beta-sheet structure under stress. Feather keratin is a beta-sheet structure presumably for higher stiffness. Amphibian skin is also a beta-sheet, again presumably to limit water swelling. The best-studied example of keratin is wool but there is also recent work on hoof (see *Keratin*[#]).

4. Structural Polysaccharides

Cuticle is a composite of chitin fibers embedded in a cross-linked protein matrix (see *Cuticle*[#]). Chitin is a polysaccharide, similar to cellulose but with acetyl-amino substitution. Metabolically, polysaccharides should be cheaper than protein since nitrogen has a much lower abundance in the biosphere than carbon,

hydrogen and oxygen. It is not clear what improvement in properties or processing led the insects to select chitin in the place of cellulose as their main structural material. The layered structures of cuticle, with various sequences of fiber orientation, do strongly resemble the layered structures of carbon-fiber composite laminates. Given that both insects and military aircraft are lightweight, roughly cylindrical systems, the resemblance cannot be accidental. Gunderson and Schiavone (1995) have discussed how insects adopt unbalanced or asymmetric lay-ups that would not be used in synthetic composites. Some of the patterns also involve thick layers oriented along the major structural axes, with many fine layers forming the rotation from one direction to the next, apparently to delocalize shear stresses that would cause delamination.

Many layered biological systems resemble cholesteric liquid crystals in the rotation of orientation from layer to layer. This has raised interest in whether they actually are liquid crystals, in that the rotation forms spontaneously as a result of interactions between fibers in successive layers (Giraud-Guille 1996). This would occur in a fluid state, which is subsequently embedded in a hard matrix. The core question is really whether the rotation pattern is directly controlled by some form of oriented extrusion during the deposition process or is controlled through the surface chemistry of fibrils deposited in successive layers.

The mechanical properties of chitin are hard to define because large oriented samples are unavailable. In cellulose, many plants contain bast fibers with very highly aligned polymer that allows us to calculate the stiffness of the polymer and so analyze the properties of wood and other plant materials. The stiffness of cellulose in plant fibers, 40 GPa wet and 100 GPa dry, is comparable to the stiffest synthetic fibers, such as Kevlar. The polymer chains are wholly aligned with the fiber axis.

Plant cells are hollow tubes with spirally wound fibrils. Successive layers go in opposite senses, making a criss-cross pattern. The outer and inner layers may be wound at different angles to the rest. This is very like the winding of fibers on a composite pressure vessel, such as a pressurized gas tank. The wood composite structure is designed to retain internal pressure or longitudinal compression with very high energy absorption on fracture as the windings collapse inwards.

Plants again have the problem of how to manufacture the polymer without it enveloping and choking the production site. It is laid down by "track-laying" system, which seems to carry out the polymerization at the cell surface on a moving organelle and which draws glucose for polymerization through the membrane from inside.

In wood, hemicelluloses and lignin act as a matrix bonding the cellulose fibers into a composite structure. It is a puzzle that the stiffest, strongest and cheapest of the biological polymers is not used at all in animals.

5. Mineralized Tissues

In the synthetic world, some applications involve predominantly tensile loading; the wall of a pressure vessel is one example. Much more commonly, parts will be loaded in compression or bending. While strong fibers in the form of a rope can provide excellent resistance to tension, they are of little use in compression. Large animals with an external or internal skeleton will need stiff materials that are more isotropic in their properties and so can withstand the varying stresses that come from moving around and colliding with other objects. Mineralized composites provide improved compressive properties over purely polymer structures. Compared to stiff polymers, minerals can also be formed at a lower metabolic cost for a given level of stiffness, but do increase the overall weight.

A wide range of minerals is found in microbes, plants and animals but silica, calcium carbonate and hydroxyapatite are the most important.

6. Silica

Silica occurs as spicules, short reinforcing rods, in sponges. The spicules are typically 10 μm in diameter and 100 μm long and may be simple rods or complex branched structures. They apparently form by aggregation of silica nanoparticles onto a thread of polysaccharide or protein within a vesicle, a membrane-enclosed space inside the organism. The material is amorphous, highly hydrated and not fully dense. There is one example of a deep-sea sponge, *Monoraphis*, that is attached to the seabed by a large, one meter long, silica rod. The structure of this material is a series of concentric layers where the weaker interlayer regions may enhance the toughness of the structure, like a laminated glass windshield (Levi *et al.* 1989).

Siliceous diatoms are single-celled prokaryotes, about 100 microns in diameter, enclosed by a porous silica shell, in the form of two overlapping dishes, like a petri dish. The organism multiplies by dividing into two disc-shaped cells and then forming two new dishes back-to-back. The cells then separate, each with one new half shell and one old one.

Recent work on the proteins involved in silica mineralization has started to clarify the details of silica deposition in diatoms (Kroger *et al.* 1999) and sponges (Morse 1999).

Plants often contain silica as a reinforcing material. The structure of bamboo has been much studied in this context.

Sea water and soil water contain low levels of dissolved silica as silicic acid. The cell probably binds

and transports this as a complex with catechols (di-hydroxybenzene) and then converts this to silica nanoparticles.

7. *Carbonate*

Calcium carbonate is widespread as a protective shell in marine animals including single-celled coccoliths, coral, gastropods and bivalves (Lowenstam and Weiner 1989). It also occurs as a reinforcement in the cuticle of crustaceans such as crabs. The use of calcium carbonate for shells, rather than silica, may reflect the greater control of structure available through calcium-binding proteins and through control of crystal morphology with nucleators and growth inhibitors. Silica does occur as a component of many mollusk teeth, as do various iron oxides.

There has been much work on the formation, structure, and properties of mollusk shell (see *Shell: Properties*[#]). This has been partly driven by a desire to understand why these structures are much tougher than the natural mineral. This insight could allow us to make synthetic ceramics much more useful. Most shells are constructed of calcite and aragonite in various arrangements with small amounts of protein, up to about 5% by weight. Higher protein levels would be expected to increase the toughness of the shell but at the expense of reduced stiffness. It can be assumed that the particular shell structures are adapted to the particular lifestyle of the animal and the stresses encountered. For instance, it might be expected that a swimming bivalve, such as a scallop, would have a stiffer, lighter shell structure. One of the most studied shell structures is nacre, or mother-of-pearl, which is a layered structure of aragonite plates, 0.5 μm thick by several microns wide. Between each layer of plates is a thin protein sheet that is responsible for the nucleation of the aragonite layers and acts as a crack stopper. This gives wet nacre a high fracture energy, though this toughness is lost on drying or freezing, Fig. 1.

The characteristic fracture of these tough natural ceramics is "graceful failure," shown by an extended sequence of crack formation and arrest that gives the saw-tooth stress-strain curve of Fig. 1. Conch shell shows a similar fracture curve but this arises from crack deflection within the complex lamella architecture rather than from protein layers (Kamat *et al.* 2000). In sea urchin spines there is much protein embedded as microspheres within the mineral crystals but it is not known whether this really contributes to toughness.

While the details of shell formation are not understood, it is clear the organic content contains proteins capable of selectively nucleating calcite or aragonite in a specific orientation and proteins which inhibit growth of specific crystal faces. These work in concert with the supply of calcium and carbonate from the mantle tissue. The mantle adds new shell at the existing edge by extruding over the lip to extend the outer and inner faces.

The vaterite form of calcium carbonate often occurs in laboratory crystallization and is occasionally found in shells. There is increasing evidence for precipitation of amorphous, hydrated calcium carbonate as a metastable precursor for the crystal (Raz *et al.* 2000). In some cases, including lobster cuticle and a sponge, stable amorphous calcium carbonate is found (Beniash *et al.* 1999).

8. *Hydroxyapatite*

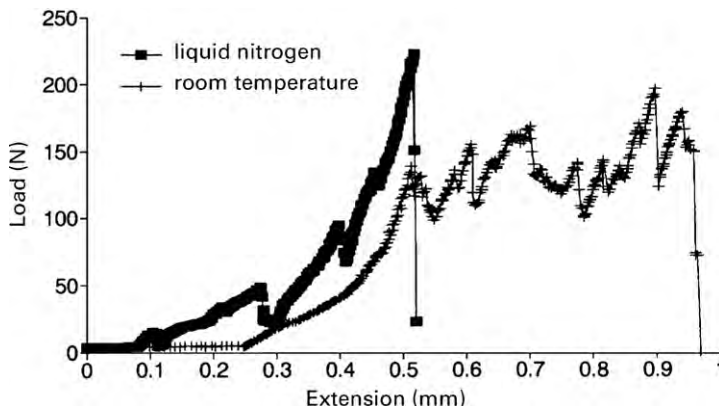
The human body is supersaturated for both calcium carbonate and for hydroxyapatite, $Ca_{10}(OH)_2(PO_4)_6$, the mineral of bone and tooth. Since the environmental availability of phosphorus is limited, its use as


Figure 1

Fracture of a nacreous shell in bending at room temperature and at liquid nitrogen temperature. Freezing the protein converts the tough material into a brittle material like a conventional ceramic.

a reinforcement seems peculiar. Possibly bone acts as phosphorus reservoir. Bone is essentially a polymer-matrix composite reinforced with ribbons of hydroxyapatite. The structure and properties of bone are discussed elsewhere (see *Bone and Natural Composites: Properties**; *Bone Mineralization*[#]). A key current question is the way the lamella structure gives rise to a combination of high stiffness, high strength and high toughness. Similar synthetic composites tend to break at relatively low strain and so have low toughness.

Dentine has a similar structure to bone but with significant differences in the mechanism of mineralization. Tooth enamel is almost wholly mineral with a fibrous structure that forms under the control of a completely different set of mineralization proteins, including amelogenin.

9. Soft Materials

Many of the materials in the human body are water-swollen polymer composites that are soft but strong. Dry proteins are stiff and brittle but a hydrophilic composition leads to increased water content, which acts in the same way as increased temperature in a synthetic polymer and moves the material through the glass transition into the rubbery region.

Elastin is such a rubbery biological polymer, though this only occurs pure, more or less, in the *ligamentum nuchae* that supports the head of grazing animals. Other biological rubbers are abductin in the hinge of bivalve mollusks and resilin, which drives the elastic rebound of insect wings.

Many soft biological materials are more like textiles with a three-dimensional arrangement of stiff fibers embedded in a hydrogel matrix. Various weaving patterns allow the material to extend greatly in directions perpendicular to the local fiber axis, while remaining stiff parallel to the fibers. Early extension occurs as a result of fiber rotation and the material then becomes stiffer when the fibers become oriented. The dermis (skin), arterial and intestinal wall are such combinations of stiff collagen fibers, rubber elastin fibers, water and proteoglycan (protein with polysaccharide side chains) gel. Mesoglea, in the body wall of the sea anemone, is a composite of collagen and polysaccharide gel. These materials also contain muscle fibers and some have reversible cross-linking mechanisms to allow the fibers to slide. This permits a combination of short-term stiffness with very large slow extensions.

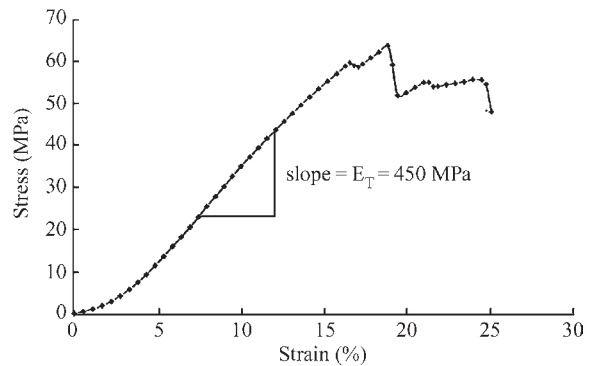
One characteristic that most of these soft materials share with textiles is a J-shaped stress–strain curve (Fig. 2). The initial response is with a low elastic modulus but the material becomes much stiffer at high strains. This form of response allows a combination of softness and flexibility with high strength. In the arterial wall, for instance, this stress–strain


Figure 2

relation allows the artery to expand and contract under normal pressure pulses while resisting balloon expansion if the pressure becomes locally high.

Cartilage contains about 50 vol.% collagen fibers in a proteoglycan and water matrix. The highly-sulfated polysaccharide component provides a high local ionic strength which causes the mesh to swell under the fibers provide an opposing stress, like a balloon inflated inside a sock. This structure shows strongly time-dependent elastic behavior as water moves in or out of the structure. There are still no good medical replacements for worn articulator cartilage in arthritic joints. The structure and properties of cartilage change with site. Costal cartilage occurs in the meniscus of the knee, the nose, ear and connection of the ribs in the sternum.

10. Active Biological Materials

A robotic system requires a skeleton, sensors, actuators, microprocessor and power supply. An animal can be viewed as the same set of subsystems, but unlike a robot, they are integrated into a monolithic body. As we seek ways of integrating active functions into materials, there is more interest in the materials properties of biological sensors and actuators.

For a discussion of the structure and properties of the eye see *Biological Optical Materials*[#]. Current studies of sensing and the nervous system are in the realm of membrane biology, which does not yet really allow a materials approach. The question of biomimetic sensing systems is treated in *Artificial Noses and Tongues*[#] and *Tactile Sensors*[#].

The materials properties of muscle are discussed in *Natural Muscle*[#]. In robotic terms this is a chemically powered actuator with a linear contraction of around 50% and excellent force control. On the other hand, the speed and peak stress are relatively low. There is a

great need for an equivalent synthetic system, preferably electrically powered (Liu and Calvert 2000).

11. Biological and Synthetic Design

A number of differences between biological and synthetic materials have been discussed above. In the synthetic world, the choice of material is often made in the middle of the design process and the design is then adjusted to the properties and processing methods for the material. In biological systems, the material structure and properties are part of the design.

Small animals, such as insects, have hard shells containing the active components. Most appliances and vehicles follow the same design. Large animals have skeletons, to carry largely compressive and bending loads, which support the active components. Large animals are much less susceptible to collision damage than most vehicles.

It may be sensible to adopt biological designs for materials and systems more in the synthetic world. However, the only real principle of evolutionary design may be that there isn't one. This is discussed further in the articles on biomimetic materials (see *Biomimetic Materials: Properties and Processing**) and design optimization (see *Mechanical Optimization in Nature, Principles of*[#]). In considering biological design, it should be kept in mind that the need to reproduce and grow impose constraints that do not apply to most synthetic systems. Recycling is clearly one area where we could learn from biology, but this is a property of the ecosystem rather than of the individual plant or animal.

Biomimetic materials are discussed in a separate article. Here the goal is to develop synthetic materials, which take advantage of biological composite structures, which allow machines to be built with more of the soft, flexible characteristics of animals or to build machines that function like animals. Biomedical materials are reviewed in *Biomedical and Dental Materials: Introduction*[#]. The need to interface synthetic materials with the body is more demanding than simply designing a synthetic material with the properties of the natural one.

Biomimetic Materials: Properties and Processing

The concept of biomimesis has long been used in chemistry in the context of compounds with enzyme-like catalytic action. Since the mid-1980s it has been applied to materials, particularly with a view to producing ceramic and composite materials with improved toughness, analogous to shell, tooth, and bone. There was some discomfort in the materials community with the idea of mimicking biological materials in the sense of producing an indistinguishable copy.

However, mimesis more generally refers to copying some essential aspects of a thing rather than duplicating or faking it. The phrase "bioinspired materials" is also used to express the idea in more familiar terms, but is grammatically less desirable as it is a
Figure 1
Assembly of a coccolith from calcite crystals (reproduced by permission of Macmillan from *Nature*, 1992, **356**, 516–8).

Greek/Latin hybrid. The field has now spread to include a group of loosely linked goals in new materials and processes. These are surveyed below.

It should be kept in mind that materials development is considerably upstream from the development of new products. It is quite typical for new materials to find their way into commercial products about 20 years after their discovery (Calvert 1994). Examples include Kevlar, high-T_c ceramic superconductors, piezoelectric polymers, and gallium arsenide. It is also typical for the first applications to be quite different from those originally proposed, and for their impact to be modest compared to that suggested during the initial excitement. A personal view of the status and prospects for biomimetic materials is given at the end of this article.

1. Inorganic Particle Formation

Coccolithophores—single-celled marine algae—assemble an external skeleton from single crystals of calcite with very complex shapes, such as that shown in Fig. 1. The growing crystal is surrounded by a lipid membrane that controls the growth orientation in the crystal, but it is not known exactly how this is achieved. As shown in Fig. 1, a series of overgrowths on the initial ring lead to the whole calcite assembly. Sponges and diatoms show similar close control of the shape of silica particles on the micron scale. Magnetotactic bacteria form single-domain iron oxide (magnetite) crystals with a very closely controlled size of a few nanometers, which then aggregate into magnetic chains (Fig. 2). These biological examples all involve growth within a compartment surrounded by a membrane. For sponge spicules there is an organic template on which the mineral grows. In other cases there may be specific nucleation sites on the membrane surface. This suggests synthetic approaches where inorganic particles are grown within a micromold—a predefined space.

There have been many efforts to grow particles in liposomes, i.e., spherical shells with a lipid bilayer wall (Mann *et al.* 1997). One solution is trapped when the liposome is formed, and precipitation occurs when a second reagent, often a base, diffuses in through the wall. Generally the trapped solution must be quite dilute in order to avoid destabilizing the liposome. As a result, the precipitate therefore only occupies a small part of the internal volume. A method is needed to introduce a continuous feed of both reagents through the membrane.

There have also been many efforts to grow particles in multiphase polymer systems, such as block
Figure 2
Magnetic particles from a magnetotactic bacterium, showing chain formation (courtesy of Professor S. Seraphin, University of Arizona).
Figure 3
Elongated titania particles formed by impregnation of a stretched two-phase polymer with titanium alkoxide, followed by hydrolysis.

copolymers (Kane *et al.* 1996). For instance, a two-phase polymer can be soaked in one reagent, which selectively absorbs into one phase. A cadmium salt could be taken up by a polyether phase. Subsequent treatment with hydrogen sulfide results in precipitation of cadmium sulfide within the polyether. While the volume fraction of sulfide formed is quite small, repeated cycles can give rise to higher fractions of the mineral.

Work on precipitation in lyotropic liquid crystalline amphiphile solutions has led to composite structures (see Sect. 4).

One characteristic of biological minerals is their elaborate shapes. For mechanical reinforcement of soft matrices, a filler should consist of high-aspect-ratio rod or plate particles. These may grow as a natural outcome of differing crystal growth rates along different crystal axes. However, most simple minerals are not sufficiently anisotropic to form such elongated particles. The shape of biological crystals is probably controlled by selective inhibition of growth on specific crystal faces. Very elongated silica particles are also formed in lipid vesicles, but it is not known how important these are for controlling shape in crystals. While synthetic methods offer many ways of controlling particle size, good methods for controlling shape are lacking. One route is to form long micromolds by phase separation in a two-phase polymer, which is cold-drawn to elongate the included phase. The included phase is then swollen with a metal alkoxide, which is hydrolyzed to oxide, Fig. 3 (Calvert 1996).

2. Toughness and Layered Structures

Large organisms operate in an environment that subjects them to fluctuating forces—from the action of wind and water on plants, and from the locomotion of animals. These fluctuating forces and collisions will often result in local damage that should not lead to catastrophic failure. As a result, many biological tissues contain structural features that add toughness without severely compromising stiffness or strength.

In mollusk shells and teeth, toughness may arise from added polymeric layers or from very fibrous structures (see *Shell: Properties*[#] and *Marine Teeth (and Mammal Teeth)*[#]). The addition of polymer could be especially effective if the polymer structure is capable of a large extension to break after yield, such as occurs in folded β-sheet proteins, where the unfolding of the chains leads to a large energy absorption, as has been discussed by Smith *et al.* (1999).

However, polymer layers will also lead to a significant loss of elastic modulus when compared to a wholly inorganic material.

Much effort has gone into increasing the serviceability of ceramic materials by improving their toughness. Much work was initially devoted to fibrous materials (see *Fibrous Ceramics*[#]), particularly silicon nitride, but the need for reliable, cheap processing methods was not met. Attention then switched to ceramic composites with fibrous reinforcements that would add toughness. These mostly proved to be unstable or reactive at the temperatures needed for turbine engines, while still being hard to process. Since then there have been many studies of ceramic/metal-layered structures, where the metal layers take the role of the polymers in mollusk shell. Such materials are of interest for use in engines and for armor. There is also interest in incorporating structured porosity into materials to improve fracture properties, or to modify elastic properties such as Poisson's ratio or piezoelectric response (Sigmund *et al.* 1998).

In the case of metal/ceramic-layered materials, the key problem is to absorb as much energy as possible within the metal layers. Hwu and Derby (1999) showed that the major energy absorption is due to metal drawing across the gap after the crack has passed. However, the extent of deformation occurring during the drawing was limited by the thinness of the metal layers. As a result, substantial increases in toughness were only seen when the volume fraction of metal was quite large. In contrast, mollusk shells show significant toughness with only a small percentage of polymer. It is likely that some combination of embedded metal, porosity, and interfacial debonding can give much enhanced toughness or impact resistance to ceramics. However, current methods for modeling fracture do not provide enough guidance for these designs and the biological models are only just being interpreted.

Recent studies on the influence of polymers on the crystallization of calcium carbonates *in vitro* has shown that metastable liquid complexes with anionic polymers can be formed which subsequently transform to calcite. Studies of carbonate biomineralization have shown that amorphous calcium carbonate does form either transiently or as a stable phase. It has also been shown that absorbed proteins do modify the fracture properties of carbonates. In particular, fracture surfaces show smooth conchoidal fracture, like glass, rather than the faceted fracture characteristic of normal crystals. This suggests that we have much to learn about the modification of the properties of crystals and amorphous solids by entrained polymer. In the example shown in Fig. 4, the polymer coating may serve to protect the surface from weakening cracks, and the entrained polymer may increase toughness. There are parallels with the Lanxide process for toughening alumina ceramic by entrained aluminum metal particles.

3. Polymers

The core difference between proteins and synthetic polymers is that protein synthesis provides total control of the sequence of units along a chain while the best-controlled polymerizations can only provide several blocks of functional units on a chain (see *Biosynthesized Materials: Properties and Processing*[#]). One obvious goal is the formation of synthetic polymers with enzyme-like catalytic activity. Many enzyme active sites have an array of active groups held in close proximity so as to interact with the substrate (target molecule), and to reduce the activation energy for reaction by a precise spatial array of ionic or hydrogen-bonding interactions. To achieve such a precise spacing of active groups on a synthetic polymer would require a rigid structure, which would in turn normally render the material insoluble and so inactive. Studies of dendrimer molecules (see *Dendrimers: Polymerization and Properties*[#]) with highly branched structures may lead to the required combination of flexible and soluble outer structures combined with a highly structured core. Many proteins also go through large changes in shape in response to the binding of substrates or other energy inputs. This seems to require a structure where two well-defined conformations are closely balanced in energy, so that the molecule can flip from one to another. Such a change is not likely in a wholly flexible system, and again some subtle combination of flexible segments and rigid units is required. There is still much to learn about these aspects of macromolecular design, but both the synthetic tools and the understanding are being acquired.

As discussed in the articles on silk (see *Silk Produced by Engineered Bacteria*[#] and *Natural Protein Fibers**), structural proteins include regular and random regions in the chain structure that would be expected to give rise to crystalline and amorphous material (Calvert 1998). In contrast, the amorphous component of synthetic polymers arises from entanglements of the coiled chains that cannot be resolved during the crystallization process. New polymer properties may be achievable once polymer chains can be designed with such controlled sequences.

There has been a report of enzyme-like activity in a block co-polypeptide which enhances the rate of hydrolysis of tetraethoxysilane (TEOS; a standard reagent in sol-gel chemistry) as a suspension in water (Cha *et al.* 2000). If this block structure is made up of a sequence of units of a hydrophilic amino acid followed by units of a hydrophobic amino acid, it would be expected to be active at a water-solvent interface. The morphology of the silica that forms is dependent on the structure of the copolymer. This system is biomimetic both in the sense of employing a polypeptide catalyst and in the sense of it functioning in a multiphase system, since biological processes rarely occur in homogeneous solutions.
Figure 4
Porous interior of a sea urchin spine (calcite single crystal).

Many tissues, such as cartilage, arterial wall, and the walls of soft marine organisms, are swollen polymer structures. Swollen polymers, such as plasticized polyvinylchloride (PVC), do occur in artificial structures but they are usually avoided because loss of plasticizer leads to shrinkage and cracking. Even the swelling of wood with changes in humidity is a major impediment to its use in structures—though years of experience have taught us how to design around this problem. Skin does change in volume and properties as it takes up or loses water. The structure of amphibian skin keratin is apparently different from mammalian keratin for this reason.

There have been many suggestions that designers should make more use of soft structures. These could take the form of composites of hard fibers with rubbers. In which case, tires (National Materials Advisory Board 1994) and reinforced plastic tubing could be considered as examples. Liquid-swollen soft structures could also be used more in the synthetic world. For purely mechanical systems this may not make much sense, but in active systems such as batteries or muscle-like actuators, a liquid component is necessary and should probably be viewed as a soft material rather than simply as a liquid to be contained.

4. Surfactants and Self-assembly

Self-assembly is a hallmark of biological systems, including assembly of protein subunits into holoenzymes, of proteins and nucleic acids into virus particles, and of tropocollagen into collagen fibers. There has been increasing interest in synthetic self-assembly. In addition to the assembly of molecules with complementary hydrogen bonding to form supramolecular clusters (Lehn 1990), there are many papers on the assembly of charged polymers and particles to form multilayers (Bertrand *et al.* 2000), and on the assembly of particles or particles and films coated with complementary biological recognition molecules, such as the biotin-streptavidin system. Synthetic peptide self-assembly is discussed further in *Molecular Self-assembly*[#] and *Self-assembly by Phase Separation in Polymer Thin Films*[#].

Work at the Mobil Corporation showed that mesoporous silica could be formed by hydrolysis of TEOS entrained in a highly concentrated water/silane/surfactant system. In this regime, the three-component mixture forms ordered structures with a range of symmetries. In one hexagonal phase, rods of water are surrounded by surfactant and embedded in a hydrophobic silane matrix. Hydrolysis of the silane

under suitable conditions followed by drying and sintering, results in a porous silica with aligned pores of a few nanometers in diameter.

Growth of the lyotropic liquid crystal precursor is very sensitive to the environment. Ozin and co-workers have shown that complex particle morphologies can result from growth of these mesoporous structures in quiescent solutions as diffusion fields and surface forces interact (Yang *et al.* 1999). Several workers have shown how the direction of the rods or plates of silica can be controlled. Polymers can be introduced to form composite structures very reminiscent of some biological composites (Sellinger *et al.* 1998). This does seem to parallel the proposed importance of liquid crystals in the growth of many biological structures.

While one would expect that this approach could be extended to many other material combinations, the rules are not understood. Efforts to form similar structures, other oxides such as titania or various crystalline materials, have been only partly successful. Any rapid or localized conversion process possibly also disrupts the liquid crystalline organization.

Stupp and co-workers have produced a range of amphiphiles, which assemble into various ribbon and wedge structures, and have explored their catalytic activity (Stupp *et al.* 2000).

5. Muscles

There is a clear need for actuators for robot arms with properties comparable to human muscle. Unlike human muscle, an artificial muscle ought to respond to an electrical impulse by a change in length, since any chemical energy source must involve a system of pipes. There are many candidate materials, but all have considerable drawbacks at the moment. Piezo-electric actuators have a rapid response but the total strain is small, less than 0.1% and, as a result, complicated linkages are needed to obtain significant motion. Electrically conducting polymers show volume changes of a few percent, but this is still much below that needed for a muscle. Shape memory alloys are promising but the response is slow and the cycle life is limited. Motorized or hydraulic arms tend to be heavy and clumsy. A soft polymer actuator is the obvious analog for a muscle for fast but gentle manipulations.

Ionizable gels that respond to electrical fields and demonstration devices are discussed in *Synthetic Muscle*[#]. There is also much interest in composites of metal and ionic polymer as synthetic muscles (Shahinpoor *et al.* 1998).

6. Processing Methods

Freeform fabrication methods allow objects to be built as a series of layers directly from a three-dimensional computer representation. Current methods are described in *Freeform Fabrication*[#]. These allow only one material, or a material plus a soluble support structure, to be used at a time. It is clearly feasible to combine several different materials into a single object, which would allow the building of something much closer to an organism. A recent report on simple robots, which were allowed to evolve in a virtual environment and then were built by freeform fabrication, shows how evolutionary methods might be applied to manufacturing (Lipson and Pollack 2000).

To build a crude organism would require resolution at the scale of about 10 microns. Most current freeforming methods allow resolution down to about 100 microns and a limited materials set. Microcontact printing and related methods allow much higher resolution—down to about 1 micron but effectively are restricted to one layer (Xia and Whitesides 1998). There is much current interest in ink-jet printing methods which could provide the required 10 micron resolution while allowing many layers to be deposited (Fan *et al.* 2000).

In both synthetic and biological structures, it is useful to keep in mind the distinction between design and patterning. Phase separation, crystallization, and aggregation processes can give rise to patterns in two and three dimensions on a scale, from millimeters to nanometers, which reflects the kinetics of the separation and diffusion processes. To form working devices or organisms, we need to build to a non-recurring design, which may include patterned elements. If we seek to adopt biomimetic processes, we will need to exploit self-assembling structures and patterns but within an overall design.

In current silicon technology, photolithographic methods can form two-dimensional designs down to less than 1 micron. Much finer resolutions are achievable in laboratory methods. Three-dimensional designs can be formed to below 1 micron using two-photon methods (Cumpston *et al.* 1999), but commercial freeforming methods are limited to about 100 microns resolution. In biology there are many examples of patterns forming at the nanometer level, but most designs are on the scale of individual cells, i.e., a few tens of microns. There are structures, such as sensing hairs, which are much finer but the spacing between them is still on the 10 micron scale.

7. Cell Adhesion and Tissue Engineering

Biomedical engineering is becoming more concerned with the problems of the long-term biocompatibility of synthetic implants. Material wear and degradation, and tissue loss or chronic inflammation due to changing mechanical loads will limit the lifetime of most implants to about 10 years. In addition, biocompatibility is not a material property but is very

dependent on the specific environment of the implant—in terms of implant site in the body, animal species, and animal age. Strategies to eliminate these problems include the use of biodegradable materials that will eventually be replaced by natural tissue, and tissue-engineered implants where as much of the device as possible is formed from tissue grown *in vitro* on a synthetic support before implantation.

Tissue engineering imposes a need to understand the interaction between neighboring cells, and between cells and synthetic surfaces. Cell binding to a biological surface proceeds through a series of stages including physical adsorption, interaction between surface macromolecules and specific binding sites on the surface, reorganization of the macromolecules in the cell membrane to bring more binding sites into contact with the surface, and then specific changes in the cell induced by the surface.

At the physical adsorption level, studies of cell attachment to self-assembled monolayers on silicon or glass have shown that attached polyethylene oxide chains form a structureless hydrophilic barrier layer and will thus prevent adsorption. Different polar end groups allow cells to absorb, and printed surface patterns with binding and non-binding areas can be used to control cell shape (Zhang *et al.* 1999). Cells recognize and bind to simple short sequences of amino acids in a protein exposed on a surface. Arginine-glycine-aspartic acid (RGD) and arginine-alanine-aspartic acid-serine (RADS) are sequences that can be used to induce strong cell attachment (see *Molecular Self-assembly*[#]). Thus suitable polymers can be produced which will promote attachment of particular cell types on the surfaces for tissue engineering.

In the case of bone implants, there has been much interest in the use of bone morphogenic proteins (now produced from cloned bacteria). These constitute one group of a family of cell-signaling proteins known to induce the development of bone or other tissues when released locally in the body. A similar set of signals induces the growth of small blood vessels and is an important factor in the development of many cancers. By allowing implants to release such signaling proteins, it should be possible to speed up the integration of the implant. However, much remains to be learnt about the appropriate concentrations, gradients, and the timing of these signals. All these efforts take us in the direction of making synthetic organs that look more like a natural organ transplanted from an identical twin.

Belcher and co-workers (Whaley *et al.* 2000) have demonstrated that a phage library, displaying 10^9 different peptide sequences at the surface, can be used to identify short peptide sequences that selectively bind to inorganic semiconductor surfaces. Sarikaya and co-workers (Brown et al. 2000) have developed a similar method for the control of gold precipitation using *Escherichia coli* genetics.

8. Applications

Vogel has discussed the importance of biomimesis in engineering, asking whether it is possible to unequivocally attribute any engineering advance to a biological inspiration (Vogel 1998). There are no unambiguous examples and there are cases, such as attempts to imitate flapping flight, where a biological analogy may have inhibited progress. At the same time, many engineering advances clearly drew some inspiration from biology. In chemistry and materials, studies of the structure and properties of biological materials do suggest alternative approaches to particular problems and illustrate new properties that should be achievable in synthetic materials.

Biomimesis clearly will have an important role in new biomedical devices, and in new devices that try to combine biological structures or organisms with electronics in sensors and actuators. In structural materials, the obvious place for advance is the introduction of greater toughness into synthetic composites and ceramics. In electronics, there are not yet many signs of a conjunction between the hard, high-resolution, two-dimensional world of silicon and the soft, larger-scale, three-dimensional design of the brain and nervous system.

Bitumens: Modified

Bitumens are the residue products from the distillation of crude oil. They are used primarily for their waterproofing properties in the construction industry and their binding properties in the road industry. Bitumens are thermoplastic materials and have important limitations due to their temperature sensitivity. With the increasing demands of modern society, it is necessary to improve these properties where possible. In order to improve the properties relevant to applications, various forms of modification have been studied and introduced. These fall into the following categories: chemical modification, blending with other binder materials, and the incorporation of polymeric materials. Because of climatic differences throughout the world, the properties required for these modified bitumens can vary from country to country and region to region. Specifications are being drawn up by the major specifying bodies throughout the world for the polymer modified bitumens (PMBs), which parallel the corresponding specifications for the unmodified bitumens.

The nomenclature used in this article is as follows:

Bitumen is the residue from the distillation of crude oil (US nomenclature: *asphalt* or *asphaltic cement*).
Asphalt is a mixture of bitumen with graded aggregates (US nomenclature: *asphaltic concrete*).
Macadam is a mixture of bitumen with single-size aggregates.
Lake Trinidad asphalt is a naturally occurring product consisting of bituminous material with sand/fine aggregate.
Pitch is the residue from the pyrolysis of coal tar.
Mastic asphalt is a mixture of bitumen and limestone flour.
Cut back bitumens are bitumens to which solvent oils have been added to reduce the viscosity (US nomenclature: *liquid bitumens*).
Coal tars are the viscous liquid distillates from the distillation of coal. Their properties and composition depend on the distillation procedure and it is usual to signify the origin (e.g., coke oven tar, low-temperature carbonization tar).

This article also covers processes used to improve the handling properties of bitumens (e.g., emulsification in water) and the use of mix modifiers in bituminous materials (e.g., fibers).

1. Chemical Modification

The oxidation of bitumen by contact with air at an elevated temperature results in an increase in the softening temperature and a decrease in the penetration in an indentation test. The resultant properties depend on the grade of bitumen used as starting material and the actual conditions used. The products are termed *blown* or *oxidized* bitumens. The term *blown bitumen* is probably the best one, since the amount of oxygen added to the bitumen is very small. The main processes involved are dehydrogenation and polymerization (Corbett and Swarbrick 1960). Various catalysts have been proposed and ferric chloride, zinc chloride, and phosphorus pentoxide have been widely used.

The performance of a bitumen for some applications is related to its actual constitution. Bitumens are colloidal systems with highly aromatic material,

asphaltenes, dispersed in a lower molecular weight medium, maltenes. The ease with which a bitumen can be emulsified in water is dependent on the degree of dispersion of the asphaltenes in the maltenes. Chemical additives (asphalt peptizing agents) are available that help to break down agglomerates of asphaltenes and disperse them in the maltenes. These include naphthenic acids and tall oil based acids. This type of treatment is particularly useful for improving the quality of emulsions that can be prepared from certain bitumens.

Another type of chemical addition treatment that gives improved strength of bituminous paving mixtures has been patented by Chemcrete Corporation (Latta and Leonard 1980). This process involves the addition of oil-soluble heavy metal salts (copper. manganese, cobalt) to the bitumen. These react with the bitumen and change its chemistry and molecular structure under the influence of temperature and oxygen.

The catalytic reaction results in the formation of ketones at the most reactive sites in the molecule, thereby reducing its susceptibility to oxidative aging and improving its antistripping properties. In a second consecutive stage, the organometallic components of the additive react with the ketones producing strong irreversible bonds between the bitumen molecules. This results in a bitumen with reduced temperature sensitivity The process is only suitable for use with "penetration grade" bitumens in coated stone preparation. The reaction does not start until the bitumen is spread in a thin film over a large surface accessible to oxygen. The process is relatively slow and the reaction is reported to be 80–90% completed in the course of the first 90 days after laying and compaction. However, there is some concern as to the extent of curing that can take place, since this could lead eventually to embrittlement of the binder.

2. Blending with Other Binders

2.1 Coal Tar

By careful selection of the origin of a tar component of low aromaticity, it is possible to prepare bitumen–tar blends that exhibit the best properties of the two components. Relative to bitumen, coal tar has better weathering properties and it shows better wetting of, and adhesion to, the surface of an aggregate. Coal tar also gives improved resistance to oil and petrol spillages. Although the coal tar industry is in decline, special areas for the application of bitumen–tar blends remain; for example, airport aprons and refuelling areas. Similarly, there are specific application areas for bitumen–pitch and bitumen–Lake Trinidad asphalt mixtures (BSI 1983, Dussek 1993).

2.2 Sulfur

The use of sulfur in bitumen–sulfur blends has been studied extensively, particularly as a means of improving resistance to permanent deformation of rolled asphalt wearing courses. The sulfur improves workability and increases dynamic stiffness as well as increasing resistance to permanent deformation. However, special equipment is needed to manufacture sulfur asphalt commercially and the mixing temperature requires very careful control (Slater and Zoumakadis 1982). Trials have been carried out using a combination of sulphur and rubber extended bitumen (Taman *et al.* 1989).

3. Incorporation of Polymer Materials

Extensive work has been carried out on the incorporation of polymeric materials into bitumen to modify the properties (Nicholls 1993, Read 1998, Bitume 1991). The following criteria have been put forward for road application (Denning and Carswell 1981). The polymer must

  (i) be readily available;
  (ii) resist degradation at asphalt mixing temperatures;
  (iii) mix easily with bitumen;
  (iv) improve resistance to flow at high road temperatures without making the binder too viscous at mixing and laying temperature or too stiff or brittle at low road temperatures; and
  (v) be cost effective.

Most types of polymer have been examined and many are being used commercially. A considerable amount of information about the polymers being used, and the properties and performance of the resultant polymer-modified bitumens is available from the in-house literature issued by the leading polymer and bitumen producers and blenders. Specific information is available from the papers presented to the international conferences of organizations such as the European Bitumen Association (Eurobitume, Brussels, Belgium) and the Asphalt Institute (Lexington, KY, USA), and in the specialist road industry journals. (e.g., *Bitumen-Arbeitsgemeinschaft der Bitumen Industrie ev*, Hamburg, Germany: *Bitume Actualite*, Groupment Professionnel des Bitumes, Paris, France; and *Bulletin des Laboratoires des Ponts et Chaussees*, Paris, France).

3.1 Thermosetting

Two-component epoxy resins blended with bitumen display the properties of modified thermosetting resins rather than those of bitumen. The amount of bitumen that can be added to an epoxy resin system is limited since phase inversion can occur. This results in bitumen becoming the continuous phase

with particles of cured resin dispersed in it, with the loss of the enhancing properties of the binder.

Since these thermosetting binders cure and harden by chemical action, they are not softened at high ambient temperatures. They are capable of resisting very high stresses imposed by traffic at difficult sites. The extended life of the binder justifies the use of a calcined bauxite as a surface dressing aggregate. This is a durable aggregate with an extremely high polished stone value (PSV). (PSV is a measure of the resistance of an aggregate to become smooth under the influence of traffic and of its retention of antiskid properties.)

Various proprietary epoxy bitumen–calcined bauxite systems have been developed and all display characteristic properties of exceptional strength, flexibility, and resistance to oil droppings and give essentially unchanged performance over a wide range of ambient temperatures.

3.2 Rubbers

Natural rubber has been used to modify bitumen for many years (Natural Rubber Producers Research Association 1964). Attention has now turned to synthetic rubbers (e.g., polybutadiene, polyisoprene, butyl rubber, neoprene, and ethylene propylene diene monomer (EPDM)). Recovered tyre crumb is also used.

(*a*) *Natural rubber.* This is used in both rubber crumb and latex form, the latex being used particularly in the preparation of rubberized bitumen emulsion and in asphalt/macadam by direct addition to the mixing box. The use of rubber crumb is limited since it tends to degrade at the temperatures needed to incorporate it into bitumen. Although the available natural latex is normally in anionic form, rubber latex in a form that is compatible with cationic systems is now available commercially or can be made *in situ* by the use of charge reversal agents.

(*b*) *Recovered tyre crumb.* This has been used in a number of proprietary processes, particularly in France and Belgium. In one process, the finely pulverized tyre crumb (18–20%) is blended with bitumen (77–79%) and an aromatic flux oil (3%) at 205 °C. Optimum performance is obtained when a mixture of equal parts of natural and synthetic rubber is used. Careful selection of the rubber crumb is needed in order to prevent the formation of a heterogeneous binder in which the rubber acts as a flexible filler (see Elastomers, Recycling of[#])

(*c*) *Synthetic rubbers.* These are used mainly in the form of latex for addition to bitumen emulsions.

They are also used to modify bitumen for asphalt production (Heather *et al.* 1988). The latex is introduced as a separate feed into the mixing box of the asphalt plant.

(*d*) *Thermoplastics.* The incorporation of thermoplastics (e.g., polyethylene, polypropylene, and EVA copolymers from the copolymerization of ethylene with vinyl acetate) into bitumen tends to increase the stiffness and viscosity of the bitumen at normal service temperatures. They do not, however, confer improved resilience (Denning 1984).

(*e*) *Thermoplastic rubbers.* Thermoplastic rubbers of the type typified by the SBS (styrene–butadiene–styrene) block copolymers of styrene and butadiene behave as a thermoplastic during hot processing and as a vulcanized rubber at ambient temperatures (Vonk 1989). Both linear and radial copolymers are used. The polybutadiene and polystyrene portions are incompatible and form a two-phase system consisting of domains of glassy polystyrene interlinked by flexible polybutadiene chains. The resulting network structure behaves as if the molecules were chemically cross-linked or vulcanized and exhibits high tensile strength (Read 1998).

The network structure can be disrupted by addition of solvent or by heating the polymer to temperatures above the melting point of the polystyrene. The network, with all of its original properties, can be restored by eliminating the solvent or by cooling the polymer to below the glass transition point of polystyrene. The tensile strength of the butadiene–styrene block copolymer depends on the styrene content, molecular weight, and temperature.

The suitability of a bitumen for modification in this way is related to its composition, in particular the percentage of asphaltenes, and to the percentage of aromatics in the maltenes fraction of the bitumen. During the dissolution of the rubber, the following phenomena occur: polymer crumbs, molten at high temperature, are sheared into small droplets and the molecules start to uncoil and disentangle, assisted by the oils and resins in the bitumen.

Depending on the concentration of rubber, a continuous bitumen or a continuous rubber phase will develop. Inversion occurs at a rubber content of 6–8%. Mixtures for road application are of the former type (continuous bitumen phase). Mixtures for roofing purposes belong to the second type (rubber network).

Good mixes exhibit the following properties:
(i) high increase in softening point;
(ii) lowering of the Fraas point (this is the temperature at which a bitumen first becomes brittle as indicated by the appearance of cracks when a thin film of the bitumen on a metal plaque is cooled and flexed in accordance with specific conditions);

(iii) high values of tensile strength and elongation: and

(iv) high cohesivity when used with aromatic oils for the improvement of low-temperature behavior.

In addition to the SBS copolymers, other systems used include SB (styrene–butadiene), SIS (styrene–isoprene–styrene), and SIBS (styrene–isoprene–butadiene–styrene), either alone or in admixture with SBS.

An alternative to the use of block copolymers described above is the incorporation into the bitumen of a low molecular weight rubber, followed by vulcanization *in situ* (e.g., ELF Union 1979, McKenna 1982). Bonding takes place between the polymers and the bitumens to produce homogeneous products with the desired increased stiffness at high temperatures and flexibility at low temperatures, combined with good cohesive strength and adhesive power. During the process, active sites in the bitumen are taken up. This results in improved resistance to oxidative aging and an increase in the working life.

3.3 Incorporation of Polymers into Bitumen

The conditions required for the incorporation of polymers into bitumen depend on the particular polymer, but normally high temperature and high shear are needed. In certain cases, diluent oils can be used to facilitate the blending, but this is not possible in every case owing to compatibility limitations. It is possible to use a polymer in latex form, although direct addition of a latex to hot bitumen must be carefully controlled to avoid frothing. Latexes, however, are used extensively in the preparation of polymer-modified bitumen emulsions. The latex may be incorporated into a bitumen emulsion by mixing the two together provided that the emulsion and the latex are ionically compatible. Alternatively, the polymer latex may form part of the aqueous-phase soap solution used in the emulsification of the bitumen.

3.4 Other Additives

Although strictly they do not modify the properties of bitumens, there are a number of additives which are used to enhance performance of the binders or bituminous products made from them.

(*a*) *Adhesion agents* (*antistripping agents*). These are cationic chemicals with long chain or cyclic amine or amidoamine structures that assist the bitumens to adhere strongly to the surfaces of stones. Also they alter the surface tension of the bitumen, which increases the contact angle between the bitumen and the stone. This helps to resist the stripping of the bitumen from the stone surface by the action of

water. The use of silanes as adhesion agents/anti-stripping agents has also been examined.

(*b*) *Fibers*. These tend to form a network structure within the bitumen with an increase in viscosity. Thus they allow for increased loading of bitumen on to the aggregate in hot-mix processes such as porous asphalt (whispering asphalt) and stone mastic asphalt (SMA). Fibers are also used in the slurry seal process to give thicker slurries. Cellulose fibers, recovered newspaper fibers, acrylic fibers, glass fibers, etc., are used in the road industry. Fibers are also used as replacement for asbestos in certain bituminous products for the construction industry.

(*c*) *Carbon black, silica*. These have been used as fillers in hot-mix processes to give improved wearing properties. This is analogous to their use in motor vehicle tires. It is believed that carbon black helps to reduce oxidative embrittlement of the surfaces.

(*d*) *Gilsonite*. This is a naturally occurring asphaltene found in Utah, USA. It is used to harden and strengthen bitumens for certain uses.

(*e*) *Waxes*. Waxes have been incorporated into bitumen for specific applications: for example, molten wax/bitumen mixtures to give a zero penetration binder that can be emulsified. The resultant emulsion is mixed with peat and pressure molded to form plant pots for the horticultural industry.

(*f*) *Amides*. The use of ethylene-bis-stearamide (EBS) to increase the softening point has been made. It is possible that the EBS may be beneficial as a slip agent in the bituminous backing of carpet tiles.

4. Applications of Modified Bitumens

The main applications of modified bitumens are in the road and roofing industries and the amounts are increasing annually.

4.1 Roofing

Oxidized or blown bitumens are used extensively in roofing applications, although the use of polymer-modified bitumens in roofing felt manufacture is increasing rapidly. The polymers used are mainly atatic polypropylene, EPDM, and SBS copolymers. The level of addition of the polymer is normally high (greater than 13%).

Emulsions of polymer-modified bitumens are also finding increasing application in the construction industry owing to the improved properties of the

resultant film over those of unmodified bitumens. One such application is the spraying of an emulsion and a breaking agent through a twin-jet spray to produce a seamless membrane on a roof, for example.

4.2 Roads

The main growth area of bitumens in road applications is the use of polymer-modified bitumens in both road construction and road maintenance. The market for modified bitumens grew by 20% between 1987 and 1988 and continues to grow. Of the different polymer types used, styrene thermoplastic rubbers showed the greatest increase. A breakdown of the West European polymer modified road binders market for 1987 and 1988 is given in Table 1.

The application areas fall into three main categories: asphalt/macadam, surface dressing, and slurry seal. The availability of polymer-modified bitumens has made possible the new generation of thin and ultrathin surfacings which are being increasingly used to repair worn surfaces. These processes also require polymer-modified bitumens to be used in the tack or bond coat.

Polymer-modified bitumens are finding increasing application in SMA, in part by virtue of the fact that the increased binder viscosity allows for higher loadings of the binder needed on the aggregate than would be possible with the unmodified bitumens.

For this application polymer-modified bitumens compete with the use of fibers in the mix (Davies 1999, Milster 1993).

(*a*) *Asphalt/macadam*. In order to offset the deformation and cracking due to increasing traffic density and axle weights, modified bitumens are becoming more widely used in new road construction and road maintenance.

EVA–bitumen systems are used extensively to give improved resistance to flow at elevated temperatures.

Table 1
West European polymer-modified bitumen road market.

Polymer	Share of market (%)	
	1987	1988
Styrene–thermoplastic rubber	27	44
Styrene–butadiene diblock copolymer	17	13
Ethylene vinyl acetate (EVA)	25	11
Reclaim rubber	10	9
EPDM		12
Polyolefins	21	10
Others		1

Source: Shell International.

This is particularly useful when rutting is a problem. SBS–bitumen systems give greater flexibility and are particularly useful in preventing cracking. The use of polymer-modified bitumens enables thinner wearing courses to laid if desired.

The amount of polymer used in asphalt mixes is in the region of 3–7% by weight of binder. Normally, the EVA or SBS is incorporated into the bitumen at elevated temperature to give the modified binder. It is possible, however, to use the polymer in latex form (synthetic rubber or natural rubber) and to add this at the actual stone coating stage (Heather *et al.* 1988). The water present in the latex flashes off during the mixing stage.

One area in which polymer-modified bitumens play an important part is in pervious macadams. These are open-textured wearing courses that allow water to penetrate and to run off sideways through the wearing course (Hoban *et al.* 1986, Coldwell and Daines 1989). This gives a considerable reduction in spray in wet weather.

Additionally, because of the open texture, there is a marked reduction in noise level. This has led to these surfaces being referred to as "whispering asphalt." The modified bitumens are needed in order to give greater strength and allow the higher binder contents needed. Various polymers have been used including SBS, EVA, and natural and synthetic rubbers. Fibers can also be used in pervious asphalt.

Polymer-modified bitumens are used in the tack (or bond) coats for pervious macadams in order to prevent the water entering the base course.

(*b*) *Surface dressing*. In the USA, surface dressing is called chip sealing. This is a process for renewing the wearing surface of a road by applying a thin coating of hot bitumen (cut back or emulsified) to the surface, followed by the application of aggregate chippings. The availability of modified bitumens has enabled the process of surface dressing to be extended to more difficult sites than can be coped with by unmodified bitumens (Hoban 1990). The modified bitumens can be applied in both cut back and emulsified form (Brule 1995). The preferred polymers are thermoplastic rubbers of the SB and SBS type and proprietary products produced by *in situ* vulcanization/chemical linking of low molecular weight rubbers dissolved in the bitumen.

In addition to the reduced temperature sensitivity and increased strength of the binder, the elastic properties of these binders confer good cohesive strength and adhesive power (i.e., they hold the aggregate chips more effectively). This gives good initial chip holding and resistance to applied strain. For very difficult sites, such as roundabouts, major road junctions, and approaches to traffic lights and other danger points, surface dressing based on the bitumen extended epoxy resin–calcined bauxite systems is the preferred treatment.

51

(*c*) *Slurry seal/microsurfacing*. The use of polymer-modified bitumens in the slurry seal process has greatly increased the scope of this type of road maintenance system (this is a process for sealing a road surface and/or renewing the wearing surface involving application of a slurry of fine aggregate and bitumen emulsion as a thin surface layer). Systems based on emulsions prepared from polymer-modified bitumens are used, as are those in which the polymer (natural or synthetic) is introduced in the form of latex. The latex can be incorporated into the aqueous phase at the preparation of the emulsion or may be blended into the bitumen emulsion prior to mixing with the aggregate.

With polymer-modified emulsions, larger-size aggregates may be used and the slurry placed in greater thickness (sometimes referred to as microsurfacing). This, combined with the better high-temperature stability and low-temperature flexibility, has enabled the scope of slurry seal to be extended to more heavily trafficked roads than is possible with slurries based on unmodified bitumen emulsion.

Slurry seal systems based on natural rubber, SBS, neoprene, EVA, etc., are operated under proprietary names, as are also systems which additionally contain fibers.

The suitability of a specific polymer depends on the polymer–bitumen–aggregate interactions. As a consequence, systems tend to be tailormade to suit the available materials. Attempts have been made to bring some order, and the International Slurry Seal Association published "Recommended Performance Guidelines for Polymer Modified Microsurfacing" AI43 in May 1987. In addition to giving recommended test methods and procedures, this publication gives a requirement of 2.5% polymer solids based on bitumen weight.

(*d*) *Miscellaneous*. Polymer-modified bitumens find application in a range of miscellaneous applications including mastic asphalt, joint sealants, waterproofing membranes, bridge deck membranes, stress absorbing membrane interlayers, etc.

5. *Test Methods for Modified Binders*

In order to determine the type and concentration of polymer present in a modified binder, use in generally made of IR spectroscopy. The morphologies of some bitumen–polymer blends can be determined by optical microscopy techniques with fluorescence. Under the test conditions, bitumen is not fluorescent, whereas plastic rubbers, for example, emit a yellow-green fluorescence. So far no standard performance tests have been adopted but the following are included in those under consideration:

(i) Mini fretting test: this determines the stone lost from a surface dressing produced and tested under standard conditions;

(ii) toughness and tenacity test: this determines the force needed to pull a steel ball from a sample under standard conditions;

(iii) ring-and-ball test: this measures the softening point;

(iv) penetration: this determines the hardness by measuring the penetration of a standard needle under standard conditions;

(v) Fraas brittleness point test;

(vi) elastic recovery;

(vii) hardening in the rolling film oven test;

(viii) storage stability; and

(ix) measurement of plasticity range.

Block Copolymers as Precursors to Porous Materials

Incorporating voids into a polymer in a controlled manner offers unique opportunities for applications in foams, membranes, filters, and microelectronic materials. Each application places demands and restrictions on both the polymer matrix and the nature of the voids. The polymer must have a high enough modulus to support the void structure while maintaining other characteristics such as thermal stability or resistance to specific solvents. Issues arise as to whether the pores are open- or closed-celled, and the size and number density of pores. As the pore size decreases, the force to collapse the pore increases, which places severe demands on the matrix polymer, particularly in terms of the mobility of the polymer over small distances.

There are several strategies for the preparation of porous materials (Khemani 1997). One uses a gas directly as a blowing agent (Shutov 1991). In a later method, a polymer is swollen with supercritical fluid (SCF), the pressure is reduced, and the SCF converts to a gas, foaming the polymer (Beckman 1995). Alternatively, a gas can be produced via a chemical reaction, whereby a gaseous by-product is generated. A different route is based on emulsion, micellization, or dispersion techniques (Ruckenstein 1997). Here, the dispersed component consists of a volatile liquid or polymer with the supporting phase comprised of a monomer, which forms a rigid matrix on polymerization. A porous medium is obtained by removal of the dispersed phase via evaporation, extraction or degradation by thermal, chemical, or photolytic means. An advantage of this approach is that the system can self-assemble into particular structures such as body-centered cubic arrays, hexagonally close-packed cylinders, or bicontinuous structures. Another approach is to use a thermally, solvent-, or chemical-induced phase separation of a polymer with a second component that is either a volatile liquid or a material that can easily be degraded (Kiefer *et al.* 1999). The size and spatial arrangements of the voids

will be dictated by the morphology generated in the phase separation process.

However, for many advanced applications, the typical size scales of the pores are too large. In microelectronics, where feature sizes are at one-quarter micron level, it is imperative that the size of the pores produced be much smaller than this. In addition, a closed-cell pore structure is essential and the porous material must have high thermal stability, high modulus, and the lowest possible density.

One route that satisfies these criteria is through the use of block copolymers. Block copolymers self-assemble into well-ordered arrays of nanoscopic domains with domain sizes defined by the length of the chain (see *Block Copolymer Phase Behavior*[#]). If one of the blocks can be degraded thermally or photolytically and the flow of second block can be arrested, a porous material can be produced where the size, shape, and spatial distribution of the pores is dictated by the original morphology of the copolymer. Whether the application be in the bulk or in thin films, key issues arise concerning the spatial organization and orientation of the pores. Here, several different approaches in the use of block copolymers for the generation of nanoporous media will be discussed.

1. Thermal Approach

One approach to nanoporous materials is to couple a thermally stable polymer, such as aromatic polyimides or poly(phenylquinoxaline)s, to a thermally labile polymer such as poly(methyl methacrylate) (Hedrick *et al.* 1993, 1999). The thermally labile polymers can be prepared via living anionic, ring opening, group transfer or controlled free radical polymerization methods (see *Block Copolymer Synthesis*[#]). In general, the thermally stable block is prepared by a condensation polymerization as, for example, in the case of polyimides, which are obtained from the cycloimidization of either a poly(amic acid) or poly(amic acid ester). By functionalization of each of the chains, the polymers are coupled to form a multiblock copolymer, which undergoes microphase separation.

Thin films are spincoated, the casting solvent is removed, and the film is annealed to promote the microphase separation of the blocks. The matrix polymer is then cycloimidized well below the decomposition temperature of the labile component. Complete conversion to the polyimide creates a matrix that has thermal stability and is partially ordered. Subsequently, the copolymer is heated to a temperature below the glass transition temperature of the matrix but above the decomposition temperature of the labile component. Degradation of the labile block occurs, volatilizing the components, leaving behind a porous polyimide.

There are several features to this approach that can lead to a collapse of the porous structure or to cell

sizes that are too large. If degradation occurs by a depolymerization or unzipping, the rate of degradation, reflected in the zip length and ceiling temperature, must not be too high. For example, the depolymerization of poly(alpha-methylstyrene) to monomer occurs more rapidly than the diffusion of the monomer out of the film. The monomer volatilizes in the matrix, forming exceptionally large pores. Poly(methyl methacrylate), on the other hand, depolymerizes less rapidly and a nanoporous structure can be generated. If degradation occurs by chain scission, the size of the fragments must be sufficiently small to allow diffusion out of the film.

Diffusion of the degradation products through the matrix poses another challenge. For diffusion to occur, the degradation products must be soluble in the matrix and, then, must permeate through the matrix. This will lead to a plasticization of the matrix and a reduction of its T_g. If the T_g is depressed sufficiently, the matrix will flow leading to a collapse of the pores (Hedrick *et al*. 1993, 1999).

Finally, the volume fraction of the labile component must be sufficiently low so that the pores are closed-cell, i.e., not interconnected. Typically, this requires that the volume fraction of the labile component be less than 0.3. Void formation can be studied *in situ* using real-time, small angle x-ray scattering SAXS and infrared absorption. Both techniques have been used effectively to monitor the kinetics of pore growth in polyimide films (Sanchez *et al*. 1995, Cha *et al*. 1996, Fodor *et al*. 1997). The ultimate test of the success of void formation is the reduction in the dielectric constant. Polyimides have a typical dielectric constant of 2.9. Using the thermal approach described above, dielectric constants have been reduced to 2.2, representing an incorporation of 23% voids by volume into the polymer while retaining a closed-cell, nanoscopic void structure.

2. Vapor and Irradiative Degradation

An alternative approach to the generation of nanoporous media using block copolymers is to expose the copolymer to a corrosive vapor that will simultaneously degrade one of the blocks while cross-linking the other. Chaikin and co-workers (Park *et al*. 1997) demonstrated the effectiveness of this approach in a study on block copolymers of polystyrene and polyisoprene denoted P(S-b-I). Using an asymmetric P(S-b-I) copolymer containing spherical polyisoprene domains, exposure to ozone cross-linked the polystyrene matrix while degrading the polyisoprene block. This left a film of cross-linked polystyrene having spherical air cavities with a morphology that was identical to that of the parent film. Subsequent, reactive ion etching of this film transferred a relief of microdomain structure into the substrate (see Block Copolymer Templates for Nanolithography[#]).

Thomas and co-workers (Avgeropoulos *et al*. 1998) treated thin films of poly(pentamethyldisilylstyrene) P(PMDSS)/PI copolymers with ozone coupled with UV irradiation. The initial copolymer had the bicontinuous gyroid morphology. Upon ozone/UV exposure, the PI block was degraded and the P(PMDSS) phase was cross-linked and converted to a silicon oxide. Consequently, a porous glass is produced having a structure similar to that of the original copolymer with void volume fractions of up to 0.51. Hashimoto and co-workers (Hashimoto *et al*. 1997) had previously performed similar studies using P(S-b-I) having a gyroid structure. These co-workers subsequently coated the structure with nickel using electroless deposition methods generating a nanohybrid structure.

Asymmetric, diblock copolymers of polystyrene and poly(methyl methacrylate), PMMA were investigated by Russell and co-workers (Thurn-Albrecht *et al*. 2000) where the cylindrical PMMA microdomains were oriented normal to the surface thin films using an electric field. Upon exposure to deep ultraviolet radiation, the PMMA was degraded and the PS matrix was cross-linked yielding a hexagonally-packed array of nanopores perforating the film. These films are being used as templates in which to grow nanowires and as etching masks for pattern transfer to the underlying substrate.

3. Partial Degradation

Rather than decomposing an entire block of a copolymer, only a fraction can be removed. Ding and Liu (1998) used diblock copolymers of poly(*t*-butyl acrylate), PTBA, with poly(2-cinnamoylethyl methacrylate), PCEMA, having PtBA cylinders. Reaction of the copolymers with trimethylsilyl iodide replaced the *t*-butyl group with a trimethylsilyl group. Exposure of the bulk copolymer to UV cross-linked the PCEMA block, freezing in the copolymer structure. Subsequently, the trimethylsilyl acrylate block is hydrolyzed, generating polyacrylic acid (PAA). The loss of the trimethylsilyl group causes a reduction in the occupied volume of this block. Upon drying, the PAA block shrinks, coating the interior walls of the cylinders in the cross-linked PCEMA matrix. PAA is water soluble, and consequently water can flow through such a membrane. However, the flow can be adjusted by a change in the pH or by the addition of Ca^{2+} ions, thereby generating a nano valve to regulate flow.

4. Mesoporous Silica

The use of amphiphilic block copolymers to direct the organization of polymerizing silica has been shown to produce well-ordered hexagonal mesoporous silica with pore sizes of 75–300 Å (Zhao *et al*. 1998, Beck

et al. 1992, Krämer *et al.* 1998). Unlike conventional surfactants, block copolymers offer the possibility of fine-tuning the polymer/solvent phase behavior by adjusting molecular weight, composition, and macromolecular architecture. Both ionic and non-ionic amphiphilic block copolymers have been used to produce mesostructured silica with the ultimate objective of producing porous systems upon calcination. For example, nonionic alkyl poly(ethylene oxide) oligomeric surfactants and poly(alkylene oxide) block copolymers in acidic media have been used to produce highly ordered mesoporous silica structures (Zhao *et al.* 1998). The periodic assembly of the organic-inorganic hybrids occurs by a hydrogen-bonding pathway involving cationic silica species that are present in strong acidic conditions. Alternatively, block copolymers with one polyelectrolyte block can be used as templates in a sol-gel process. Cationic poly butadiene-poly(vinyl pyridinium) and anionic poly(ethyl ethylene)-polystyrene sulfonate block copolymers have been used (Krämer *et al.* 1998). The pore size and connectivity in the silica gel is an exact copy of the original self-assembled structures (pore sizes 10–50 nm). Furthermore, the curvature and related aggregation structure of the ionic block copolymer could be modified by adding low molecular weight salts.

5. Summary

The generation of nanoporous media from block copolymer requires an easy means of eliminating or partially eliminating one component. The surface energy of the matrix coupled with the large increase in the surface area produces a strong driving force to collapse the structure. This mandates that the matrix component be able to overcome this force, which can be accomplished by cross-linking or ordering the matrix component. By a judicious selection of the blocks or by manipulating the processing conditions, nanoporous structures can be prepared. The applications of such structures are numerous, though the impact of nanoporous media has only recently begun to be felt.

Block Copolymers as Templates for Functional Materials

There are applications and devices which require controlled distribution of material functionality (electrical, optical, catalytic, magnetic) in two or three dimensions. At the nanometer length scale, attempts to meet this challenge have included template-mediated materials chemistry (Martin 1994) in which track-etched membranes, porous alumina, and zeolites

serve as the nanoscale reaction vessels for the synthesis of the functional materials. The ability to control both the length scale and the spatial organization of block copolymer morphologies (see *Block Copolymer Phase Behavior*[#]) makes these materials particularly attractive candidates for use as templates in the synthesis of functional nanocomposites. Appropriate choices of the repeat units of the block sequences render them capable of selectively sequestering preformed inorganic nanoclusters or selectively solubilizing inorganic reagents for *in situ* cluster synthesis. Methods exist to produce nanoscale voids (see *Block Copolymers as Precursors to Porous Materials**) which percolate through the structure, leading to processes which coat or backfill the channels with functional materials.

1. Block Copolymer Nanoreactors

The *in situ* production of inorganic nanoclusters within nanoscale-dimensioned block copolymer domains can eliminate preliminary steps to synthesize, stabilize, and store the clusters, and cumbersome mixing steps required to make nanocomposite films with uniform dispersion. The capacity for producing long-range alignment (see *Block Copolymers, Flow Alignment of*[#]) means that patterned arrays of the clusters are readily achievable. In Fig. 1 a spherical domain of a block copolymer is represented to contain receptor groups, in this case carboxylic acids capable of binding positive ions or positively charged fragments from labile organometallic species. Once loaded, the metal ions can be converted to oxides, chalcogenides, or the zerovalent metal through exposure to the appropriate second reagent. Figure 1 illustrates the particular example of loading the nanoreactors with cadmium followed by H_2S treatment to form CdS clusters, confined within the block copolymer domain. The receptor sites are regenerated leaving the nanoreactors ready for further loading/reaction cycles with the same or different reagents. In principle, doped semiconductor clusters, metallic alloys, side-by-side cluster populations, and core–shell structures can be made via this universal nanoreactor approach, as reviewed by Ciebien *et al.* (1998).

Because the spherical domains of a block copolymer are generally monodisperse in size, the number of sequestering groups in every domain should be nearly identical, and this should lead to a predictable, monodisperse cluster size distribution. Cluster size should be proportional to domain size, both being dictated by the chain length of the block sequence containing the reagent-sequestering groups. Although Chan *et al.* (1992c) have managed to generate single, monodisperse silver clusters in certain circumstances, the more general case is shown in Fig. 2 where multiple clusters appear. Both thermodynamic and kinetic limitations on cluster growth in
Figure 1

polymer films have been addressed by Kane *et al.* (1999). The block copolymer nanoreactor scheme appears to be more useful for spatial control of functional materials than for size control of inorganic clusters synthesized in this way.

2. Preloaded Nanoreactor Based on Organometallic Monomers

In a second approach, organometallic monomers are used to form one of the block sequences of the copolymer (Cummins *et al.* 1991). Spontaneous ordering of the morphology then amounts to the formation of preloaded nanoreactors ready for cluster-forming chemistry. This method eliminates the loading step of Fig. 1, which may be slow and possibly lead to nonuniform and nonselective sequestering of the reagents, but does require a new organometallic monomer for each target application. Figure 3 shows the appearance of palladium clusters in a reduced copolymer film in which one of the blocks comprises organopalladium repeat units.

Figure 3
Palladium nanoclusters synthesized in the lamellar morphology of a diblock copolymer with one block consisting of norbornene-derived palladium complexes. Scale bar = 250 Å (reproduced by permission of the American Chemical Society from *Chem. Mater.*, 1992, **4**, 885–94).

3. Self-assembling Block Copolymer Morphologies in the Presence of Preformed Inorganic Clusters

Monodisperse stabilized inorganic clusters (Stucky 1991, Murray *et al.* 1993) can be stored indefinitely for later incorporation into polymer films. If there are groups in one of the blocks which are capable of displacing stabilizing species on the surfaces of the nanoclusters, then the clusters can be selectively conveyed into this block domain during solvent processing. Nanocomposites formed in this way are shown in Fig. 4.

4. Nanoporous Block Copolymer Templates

Selective degradation of one domain and subsequent removal of the degradation products creates a set of nanochannels in which functional inorganic materials may be grown. In one example, Hashimoto *et al.* (1997) selectively ozone-degraded the 1,4-polyisoprene
Figure 4

domains of the bicontinuous gyroid morphology of a
polystyrene–polyisoprene diblock copolymer. The re-
sulting nanoporous structure (Fig. 5) was suitable for
metal plating with palladium, nickel, and gold. Trans-
mission electron microscopy indicated that the plating
process did not block the porosity of the final mate-
rial, thereby rendering it suitable for subsequent gas–
solid catalytic reactions.

For further details see *Block Copolymers as Pre-
cursors to Porous Materials** and *Block Copolymer
Templates for Nanolithography*[#].

5. Applications

The utility of the block copolymer template approach
lies in the spatial control and uniformity of dispersion
of the functional material in a thin film or bulk spec-
imen. Most applications of these nanocomposites de-
pend on the selection of the clusters or other
functional materials to be spatially sequestered or
synthesized within the morphology. For example, if
permanent information storage is desired, magnetic
clusters must be large enough and possess the nec-
essary magnetic anisotropy to retain the imposed
magnetization indefinitely. Films containing very
small superparamagnetic clusters have potential for
use as optically transparent, nonerasable magnetic
watermarks. Similarly, electro-optical properties of

the nanocomposite films are largely dictated by the
properties of clusters embedded in the films. It is
possible to envision applications that capitalize on
both the ordered morphologies of the block copol-
ymer template and its particular chemical composi-
tion, in addition to the functional characteristics of
the sequestered clusters.

Catalytic membranes could be fashioned to exploit
the selective gas transport characteristics of the do-
mains of a diblock copolymer containing catalytically
active clusters, facilitating both chemical reaction and
product separation. Photovoltaic devices that rely on
separate channels for transport of holes and electrons
away from an optically excited site could be fash-
ioned from ABC block copolymers which organize
into an ordered morphology with semiconductor
clusters at the interfaces between alternating domains
comprising a hole-transport polymer and an electron-
transport polymer.

These examples suggest that block copolymer tem-
plates may offer certain advantages for producing
functional materials. Independent control over the
physical and chemical nature of the constituent
blocks, and the properties of the sequestered (or
in situ synthesized) functional material, provides
a wide parameter space for the materials specialist
seeking optimized performance in a variety of appli-
cations.

Bone and Natural Composites: Properties

Nearly all biological skeletal materials are composites. Two composites will be dealt with that are particularly well-characterized anatomically: bone and insect cuticle. Unfortunately, little is known about the mechanical properties of insect cuticle.

The concept of "helicoids" will occur frequently. A helicoid is a multidirectional plywood. It consists of linear elements arranged in sheets. The linear elements are all oriented in the same direction in each sheet. The orientation changes between sheets (typically by between 10° and 20°), and the sense of rotation is constant between sheets. This description comes from Neville (1993), which should be referred to for a comprehensive discussion of helicoids and similar structures in nature.

1. Bone: Structure

Bone is a composite with three main constituents: the fibrous protein collagen; the mineral, carbonated apatite, close to dahllite in structure; and water. The relative weight percent values of the three components in "ordinary" bone, such as the long bone of mammals, is about 65%, 25%, and 10% for the collagen, mineral, and water, respectively. Most bone of birds and mammals is "lamellar" bone. This bone type has a hierarchical structure. At the lowest level are collagen fibrils infiltrated by and surrounded by mineral crystals. These fibrils tend to be organized in planar sheets, with a preferred orientation, and this preferred orientation may be more or less constant over many tens of micrometers. At the next level these sheets are packed together into repeating lamellae, about 4 μm thick. These lamellae may have most fibrils oriented in one direction, or they may change progressively through the thickness of the lamella in a helicoidal arrangement. At the next level the lamellae are arranged either in rather continuous blocks, many hundreds of micrometers in size, or may, as the result of the remodeling that occurs continually in bone, be arranged in tubular structures (secondary osteons, often called Haversian systems), of the order of 150 μm in diameter with the concentric lamellae surrounding axial blood vessel(s). This lamellar bone contains entombed bone cells, which connect with each other and with the nearest blood channels via tiny channels, about 200nm in diameter. Finally, these relatively large lumps of bone may form "compact" bone, containing no cavities obvious to the naked eye, or "cancellous" bone, formed of many interconnected struts or sheets, whose characteristic thickness is about 200mm. This is obviously porous to the naked eye. The struts are surrounded by marrow. The volume fraction of this cancellous bone is rarely more than 30%.

This description is of lamellar bone, of which Weiner *et al.* (1999) give a good review. Bone exists in another, much less well-structured version: woven bone. This is more highly mineralized and isotropic or, rather, random in its structure, and is almost certainly weaker. It has the advantage from the animal's point of view that it can be laid down much faster than lamellar bone. Often woven and lamellar bone are incorporated in a multiple sandwich into the final structure. This is called "fibrolamellar" bone.

2. Bone: Mechanical Properties

2.1 Elastic Properties

Table 1 gives characteristic values for "ordinary" bone as determined both ultrasonically and mechanically.

2.2 Strength Properties

There is considerable difference in the strength and ultimate strain when bone is loaded in its different directions relative to the long axis of the whole bone (Table 2). Weiner *et al.* (1999) give more information about off-axis behavior.

2.3 Fracture Mechanics Properties

Some of the criteria for the successful application of fracture mechanics analyses to bone are not fulfilled. In particular, bone frequently undergoes considerable damage well away from the point where the fracture will eventually occur, even if this fracture is induced by a sharp notch. A few values, which seem to be representative of values in the literature, are given in Table 3.

Note that in life the direction in which a dangerous crack is likely to travel is transversely, and so the longitudinally traveling cracks are not really a useful measure of the service toughness of the bone.

2.4 Fatigue

Bone often fails after cyclic loading. The results of several studies are shown in Fig. 1. This is a conventional "*S–N*" diagram showing the relationship

Table 1
Elastic moduli for bone (gigapascals).

	Ashman *et al.* (1984)		Reilly and Burstein (1975)				
	Canine	Human	Human		Bovine		
	(ultrasound)	Haversian (ultrasound)	Haversian (mechanical)		Haversian (mechanical)		Fibrolamellar (mechanical)
			Tension	Comp	Tension	Comp	Tension
E_1	12.8	12.0	12.8	11.7	10.4	10.1	11.0
E_2	15.6	13.4	12.8	11.7	10.4	10.1	11.0
E_3	20.1	20.0	17.7	18.2	23.1	22.3	26.5
G_{12}	4.7	4.5					
G_{13}	5.7	5.6	3.3		3.6		5.1
G_{23}	6.7	6.2	3.3		3.6		5.1
v_{12}	0.28	0.38	0.53	0.63	0.51	0.51	0.63
v_{13}	0.29	0.22					
v_{23}	0.26	0.24					
v_{21}	0.37	0.42	0.53	0.63	0.51	0.51	0.63
v_{31}	0.45	0.37	0.41	0.38	0.29	0.40	0.41
v_{32}	0.34	0.35	0.41	0.38	0.29	0.40	0.41

These values were determined by Reilly and Burstein (1975) and Ashman *et al.* (1984). These are old papers, but more recent results are very similar. The subscripts "1", "2," and "3" refer to the radial, tangential and longitudinal directions relative to the long axis of the bone. Reilly and Burstein did not test in all directions, and assumed that the bones were transversely isotropic. Shear values (G) are included under the heading of "tension" merely for convenience. They assumed values and G_{13} and G_{23} to be equal, and also pairs of Poisson's ratio (v): v_{12}, v_{21} and v_{31}, v_{32}.

Table 2
Strength properties of bone (megapascals).

| | Human | | Bovine | | | | | |
| | Haversian | | Haversian | | | Fibrolamellar | | |
	Longitudinal	Transverse	Longitudinal	Transverse	Radial	Longitudinal	Transverse	Radial
Tension								
Strength	133	53	150	54	39	167	55	30
Yield stress	114		141			156		
Ultimate strain	0.038	0.007	0.020	0.007	0.007	0.033	0.007	0.002
Compression								
Strength	205	131	272	171	190			
Ultimate strain	0.019	0.050		0.042	0.072			
Shear								
Strength	67		70			64		

The values were taken directly, or from information in Reilly and Burstein (1975), and Reilly *et al.* (1974). "Longitudinal," "transverse," and "radial": specimens tested longitudinally, transversely, or radially with respect to the long axis of the bone. Shear strengths are placed arbitrarily in the columns, since shear refers to two axes at the same time.

between the imposed stress and the number of cycles required to produce failure. Fatigue loading can be considered (except in the case of the rotating cantilever) to be a continually interrupted creep rupture stress. By loading at different frequencies it is theoretically possible to distinguish the effects of time and cycles. The evidence suggests that in the tension cycle, numbers are unimportant but that in compression the situation is more complex (Caler and Carter 1989).

2.5 The Range of Properties

The properties referred to previously are for "ordinary" bone, mainly long bones of bovines and humans.

Table 3
Some fracture mechanics properties of bone.

Species	Direction	K_c (MN m$^{-3/2}$)	G_c (kJ m^{-2})	Test	Rate
Bovine	Longitudinal	3.2		SENT	Slow
Bovine	Longitudinal	5.0		SENT	Fast
Bovine	Transverse	4.5		SENT	Slow
Bovine	Transverse	7.7		SENT	Fast
Bovine	Longitudinal	5.3	1.2	CT	Slow
Bovine	Longitudinal	6.3	2.9	CT	Fast
Bovine	Transverse	6.5		CT	Slow
Human	Longitudinal	4.0	0.5	CT	Slow
Antler	Transverse	5.4		SENT	Slow

"Direction," direction of crack travel relative to the long axis of the bone; "SENT," single edge notch, tension; "CT," compact tension.

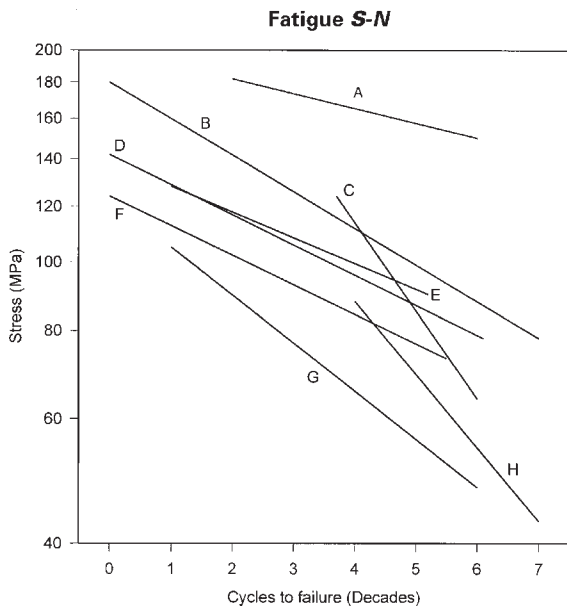
Fatigue *S-N*


Figure 1
A set of *S–N* curves for bone. The separate lines are the lines representing the equations produced by regression analysis. The lines are not extrapolated beyond the ends of the original data. In all the cases the distributions were reasonably linear. The abscissa is measured in powers of 10. Taken from various experiments, with different loading conditions. A: human, four-point bending, room temperature, 2 Hz. B: human, compression, room temperature, 30 Hz. C: bovine, rotating cantilever, room temperature, 30 Hz. D: bovine, tension, room temperature, 2 Hz. E: human (27 years old) tension, room temperature, 2 Hz. F: red deer antler, tension, room temperature, 2 Hz. G: human (69 years old) tension, 37 °C, 2 Hz. H: human, rotating cantilever, room temperature, 70Hz.

However, the properties of bone can range considerably outside the values so far described, mainly as a result of differences in the mineral content, and in the degree of anisotropy of the tissue. Table 4 gives values (from Currey 1998) for Young's modulus, tensile strength, ultimate tensile strain, and work under the stress–strain curve for various bony tissues, which all had essentially the same shape, so the results are truly comparable. They are listed in order of increasing mineral content (milligrams of calcium per gram of dried, defatted bone). Note particularly how the ultimate strain decreases with increase in mineral content. In general these differences in mechanical properties seem to accord with the requirements of the tissue, for instance deers' antlers need to be good at resisting impact while, for acoustic reasons, the ear bone of the whale needs to be very stiff and, being protected inside the skull, its poor strength properties do not matter. Figure 2, derived mainly from this data set, shows the apparent impossibility of marrying a high Young's modulus and a high ultimate strain (which is a good indicator of toughness).

2.6 Cancellous Bone

(*a*) *Structure properties.* Cancellous bone, found mainly at the ends of long bones, is made of interconnecting plates and rods that rarely achieve a volume fraction of greater than 30%. Its mechanical properties are very varied, depending on the amount of bone present, and its anatomical anisotropy. The best general treatment is by Rice *et al.* (1988). Both modulus and strength increase approximately as the square of the volume fraction of bone, and the Young's modulus of elasticity is about 100 times the compressive strength.

Table 4
Some mechanical properties of various bone tissues.

Species and tissue	Calcium content (mg g^{-1})	E (GPa)	s_{ult} (MPa)	e_{ult}	W (MJ m^{-3})

(*b*) *Material properties.* There seems to be no particular reason why the mechanical properties of cancellous bone *material* should differ much from those of compact bone. However, there have been studies suggesting that cancellous bone material is less stiff and, therefore, probably weaker than compact bone material.

Cancellous bone trabeculae are small, ragged, and thin, and difficult to test, and in testing very small specimens all sorts of size artifacts appear. Various methods have been used, including back-calculation from finite element models.

Some representative results are shown in Table 5. The consensus is that the Young's modulus for the *material* of cancellous bone is lower than that of neighboring compact bone, but it is not clear by how much. In general, the more recent studies have suggested the higher values for Young's modulus. Values that are less than about 6 GPa should be treated with skepticism because values as great as this have been obtained for *whole blocks* of cancellous bone,

completely discounting the considerable effects of the porosity itself.

If cancellous bone material has considerably lower mechanical properties than that of compact bone there is the question as to why this should be so. There are at least two possible reasons. One is that the mineral content of cancellous bone is less than that of neighboring compact bone. There is some evidence for this although the difference is not large. Another possible reason is that although the alignment of the lamellae and the general grain of cancellous bone are roughly along the line of the trabeculae, in detail it is not as well organized as it is in compact bone. Even this argument is somewhat dubious because compact bone loaded at about 90° to its predominant orientation, the worst possible orientation, has a Young's modulus about half that of bone loaded along its grain. Cancellous bone is much better oriented along the trabeculae than compact bone loaded at right angles to its grain.

3. Insect Cuticle

The skeleton of insects is an "exoskeleton" forming an almost complete covering to the body. To allow movement, stiff plates or tubes (sclerites) alternate with flexible "arthrodial membranes." However, the chemical compositions of the stiff and compliant

E vs Calcium vs Ultimate Strain

Three-dimensional diagram showing the relationship between mineral content, Young's modulus, and ultimate strain of various bony tissues. The data set is nearly the same as given in Table 4.

regions are rather similar. The main fibrous component of cuticle is chitin, a linear polysaccharide of poly-*N*-acetylglucosamine. Groups of about 20 molecules pack together, forming rods of very high aspect ratio, about 4nm in diameter. The matrix of insect cuticle is almost entirely protein, and there are many different component proteins. The protein is probably firmly attached to the chitin, by covalent bonds, but this is not certain (Andersen *et al.* 1996). The detailed arrangement varies somewhat, but the water bug *Hydrocirus* is representative. Its chitin fibrils are about 4.5nm in diameter, arranged in layers, the thickness of the layers typically being about 6nm. They are arranged either helicoidally, in which case the preferred direction changes through 180° in about 25 layers over a distance of 160nm, or unidirectionally. A remarkable (and unexplained) feature of many cuticles is that the cuticle laid down at night is arranged helicoidally but the cuticle laid down during the day is unidirectional. Sometimes the plies seem orthogonally arranged, but close examination always shows that there are some helicoidal layers leading from one orientation to the next. Naturally, with this range of possible arrangements, it is possible for almost any multilayer composite arrangement to be produced.

The mechanical properties of the cuticle can be profoundly affected by the extent to which the protein matrix is cross-linked or "sclerotized." The process is complex, but essentially involves the oxidation of *N*-acetyldopamine and *N*-β-alanyldopamine to the corresponding *o*-quinones. These products may then be further modified, and become linked to histidine and lysine residues in the cuticular proteins, and may
Table 5
Estimates of Young's modulus of cancellous bone material.

Bone	Method	Young's modulus (GPa)
Human proximal femur	Buckling	11.4

Table 6
Some mechanical properties of insect cuticle.

Animal	Cuticle type	Young's modulus (Pa)
Locusta (locust)	Female intersegmental membrane in laying mode	10^3
Schistocerca (locust)	Tendon (along length)	1.1×10^{10}
	Tendon (normal to length)	1.5×10^8
	Tibia cuticle	1.7×10^{10}
Calliphora (blowfly)	Unsclerotized pupal skin	7.3×10^7
	Sclerotized pupal skin	2.4×10^8
Phormia (hoverfly)	Wing	6.1×10^9
Rhodnius (blood-sucking bug)	Abdominal cuticle (unplasticized)	2.4×10^8
	Abdominal cuticle (plasticized)	2.5×10^6

Animal	Cuticle type	Strength(Pa)
Schistocerca (locust)	Tibia cuticle	9.5×10^7
	Tendon	6×10^8

also become attached to the chitin fibrils (Andersen *et al.* 1996). It is possible that the concomitant reduction in water content may also simultaneously affect the mechanical properties. Usually the cuticle of insects has an outer layer (the exocuticle) which is heavily sclerotized, and whose chitin is arranged helicoidally, and an inner layer (the endocuticle) which is not sclerotized, and whose chitin may be arranged helicoidally, or in various other modes.

Unlike bone, which comes in relatively large lumps, insect cuticle is often thin, highly curved, and, as in exo- as opposed to endocuticle, extremely inhomogeneous. These features make mechanical testing difficult, and in fact although many attempts to characterize mechanical properties were made in the 1970s and early 1980s, interest declined, and only revived at the end of the 1990s with the construction of micro-testing machines.

Table 6 gives values for modulus and for strength. Most of these values were originally collated by Vincent (1980). The female locust has an extremely extensible, very low-modulus intersegmental membrane that allows her to deposit eggs deep in the soil. The mechanical anisotropy of the tendon is extremely high; this is because it is essentially a unidirectional composite. Applying composite theory to this tendon allowed Ker (1977)) to estimate the moduli of the chitin and the protein components. He obtained values of 80 GPa and 0.12 GPa, respectively, a remarkably large difference between fibers and matrix. The blood-sucking bug *Rhodnius* is able to plasticize its abdominal cuticle reversibly, so that it is very compliant when a meal is being taken but becomes stiffer at other times. The very high value for tendon strength (loaded along its long axis) is probably due, again, to its being a very highly oriented composite.

We do not know its strength in the orthogonal direction.

4. Conclusion

Although bone and cuticle have been recognized as composite materials for a long time, their structural complexity (bone) or small size and convoluted shape (cuticle) have prevented satisfactory analysis. It is to be hoped that, as micro-testing methods develop, this will change, and we will gain a better understanding of these fascinating natural composites.

Bone Augmentation and Repair

Bone is a complex tissue that performs a variety of integral functions in the maintenance of many systems of the body. Bone is the primary reservoir of calcium, phosphate, and other important ions, and it acts to regulate the concentration of these minerals throughout the body. In addition, the marrow found within the bone generates red and white blood cells for immunoprotection and oxygenation of other tissues. Finally, bone provides structural support and protection and sites of muscle attachment for locomotion (Yaszemski *et al* 1996). Under normal conditions, bone has the ability to repair and regenerate itself without the formation of a scar. Under certain circumstances, however, this function of the body fails and intervention is required.

This article begins with an overview of the structural properties and natural repair mechanism of bone. It then focuses on the clinical methods and materials used for bone augmentation and repair. Finally, it addresses the development of synthetic, bioresorbable polymers for use as scaffolds for cell transplantation or conduits for guided tissue ingrowth.

1. Bone Physiology

Mature bone is a highly vacularized tissue composed of cells and an extracellular matrix (ECM). The cells include bone-forming cells (osteoblasts), bone-resorbing cells (osteoclasts), and bone-maintaining cells (osteocytes). The ECM is a composite material consisting of organic and inorganic components. The organic component, also called the osteoid, is secreted by the osteoblasts. The osteoid constitutes approximately 50% of bone by volume (25% by weight) and is composed of 90% Type I collagen and 10% amorphous ground substance (primarily glycoprotiens and glycosaminoglycans) (Bouvier 1989). The organic component gives bone its form and contributes to its ability to resist tension (Buckwalter *et al*. 1995).

The inorganic component is a mineral phase composed of calcium crystals primarily in the form of hydroxyapatite ($[Ca_{10}(PO_4)]_6(OH)_2$). This component makes up 50% of bone by volume (75% by weight) (Bouvier 1989) and gives bone most of its stiffness and strength (Buckwalter *et al*. 1995).

When bone is initially laid down, it is structurally weak and unorganized (Yaszemski *et al*. 1996). Within days, this primary bone is remodeled to become lamellar bone. Lamellar bone has alignment of the collagen fibers and mineral phase. Mature lamellar bone exists as cortical (also called compact) or trabecular (cancellous, spongy) bone. Cortical bone is found on the outer surface of most bones. It is dense with respect to trabecular bone (apparent density equal to $1.8\,\mathrm{g\,cm^{-3}}$ for cortical vs. $0.1–1.0\,\mathrm{g\,cm^{-3}}$ for trabecular), and contains closely spaced groups of concentric lamellar bone rings called osteons (Yaszemski *et al*. 1996). Cortical bone functions mechanically in tension, compression, and torsion (Buckwalter *et al*. 1995). Trabecular bone occurs near the ends of long bones and in the center of small and flat bones. It is composed of an array of plates and rods that form an open cell foam (Yaszemski *et al*. 1996). Trabecular bone functions mainly in compression (Buckwalter *et al*. 1995).

Bone has the unique ability to remodel itself along lines of stress in response to injury or other changes in its mechanical environment (Bostrom and Mikos 1997). When a bone is fractured, the body creates new bone to connect the broken fragments, and then remodels the new bone to optimize its mechanical function in the particular region of the skeleton where the fracture has occurred.

This repair process begins immediately (Yaszemski *et al*. 1996). The broken blood vessels in the vicinity of the fracture fill the space in and around the fractured bone ends with a fracture hematoma. New blood vessels grow into the defect, and bone-forming cells migrate into the area. The cells (osteoblasts) secrete the osteoid, which will be mineralized and eventually become woven bone. Woven bone is isotropic, and will be remodeled by the sequential action of removal and redeposition along stress lines. Remodeling occurs continuously in the body, and results in the anisotropic structure of lamellar bone that is mechanically and structurally optimized for each area of the skeleton (Thomson *et al*. 1995).

As many as 5–10% of the 6.2 million fractures sustained by patients in the USA each year result in fracture nonunion and decreased mechanical support (Einhorn 1999). When this occurs, an attempt must be made to induce bone regeneration for skeletal repair or reconstruction. The surgeon strives to make local skeletal conditions mimic those that the body would expect to encounter during normal fracture repair. In essence, it is attempted to "trick" the body into initiating the fracture repair cascade (Thomson *et al*. 1995).

2. Techniques

The "gold standard" for bone augmentation and repair is the trabecular bone autograft. Transplantation of autologous tissue involves the harvesting of bone from a distant location and implanting it into the defect site. A similar approach uses bone harvested from cadavers (allogenous tissue). Both techniques are aimed at the ultimate restoration of bone tissue. Transplantation provides a scaffold similar to the surrounding bone upon which bone can invade, lay down extracellular matrix, and remodel. Although these treatments are often successful, they have their associated problems and limitations. Autologous tissue is limited in supply, is often not available in the shape needed, and its relocation leaves a secondary defect site. Allogenous tissue runs the risk of pathogen transfer and immune system rejection of the foreign material. Both transplantation techniques injure local vessels and leave bleeding host bone at the defect site that will activate the coagulation cascade and may lead to necrosis of the grafted tissue (Yaszemski *et al.* 1996).

Poly(methyl methacrylate) (PMMA) is a nondegradable bone cement that is widely used to fill bone defects or provide fixation of prostheses to bone. PMMA is a biologically inert material which acts as a permanent barrier preventing fracture healing or integration with host bone. A study of 22 commercially available plain PMMA-based bone cements reports compressive strengths in the range 75–115 MPa and moduli of elasticity of 1700–3100 MPa (Kuhn 2000). Because these values are much greater than those of trabecular bone (5–10 MPa and 50–100 MPa, respectively) (Temenoff *et al.* 2000) the use of PMMA bone cements can lead to transfer of load to the material (stress shielding) and insufficient mechanical stimulation to adjacent tissue. Lack of proper mechanical loading induces bone resorption around the implant and fatigue failure of the implant (Bostrom and Mikos 1997). In addition, a number of PMMA cements have been shown to shrink more than 5% during polymerization (Kuhn 2000), which may lead to micromotion of the implant and an inflammatory response within the surrounding tissue.

3. Tissue Engineering

The limitations associated with regeneration techniques have inspired researchers to search for other methods to repair skeletal defects. New strategies to engineer bone have focused on the use of natural or synthetic materials as scaffolds for cell transplantation or conduits for bone ingrowth. Various types of scaffolds have been tested, but synthetic bioresorbable polymers that degrade by hydrolysis into natural metabolites of the body remain the most attractive. These materials are easily mass-produced, and changing the composition of the material can precisely modulate their physical, chemical, mechanical, and degradative properties. Scaffolds composed of copolymers or polymer blends can be manufactured to create materials with properties that are advantageous over homopolymers for specific applications. Biodegradable polymers offer the possibility to completely replace osseous tissue and thus overcome problems such as infection and device dislocation associated with permanent implants (Temenoff *et al.* 2000).

3.1 Scaffold Properties

Synthetic polymeric scaffolds must possess unique properties in order to optimally enhance bone formation (see Table 1). The primary role of a scaffold is to provide a temporary substrate to which cells can adhere (Thomson *et al.* 1995). How cells attach to the scaffold can affect their behavior: strong cell adhesion and spreading are associated with proliferation, while a rounded cell shape is indicative of cell-specific function (Temenoff *et al.* 2000). A scaffold must therefore act as a substrate to promote cell adhesion and maintenance of function without hindering proliferation. The effectiveness of a material in achieving this goal is dependent mainly on surface chemistry, which determines the interactions between cell and substrate (Thomson *et al.* 1995). In addition, the spatial relationship of cells within their ECM can be important for continuance of function. Therefore, three-dimensional scaffolds can assist in the organization of cell growth and the formation of ECM (Thomson *et al.* 1995).

Porosity, pore size, and pore structure are important parameters in ensuring adequate room for tissue regeneration as well as nutrient delivery to cells within a three-dimensional construct. Highly porous scaffolds with large void volume and high surface area to volume ratio are desirable to maximize space for cell seeding, attachment, growth, ECM production, and vascularization. To attain the high surface area per unit volume needed for anchorage-dependent cells, smaller pore diameters are preferred as long as the pore size is greater than the diameter of a cell in suspension (typically 10 μm). However, larger pores are required for cell migration, growth, and ECM production. Experiments suggest that a pore diameter of 200–400 μm is optimal for bone ingrowth (Temenoff *et al.* 2000). An interconnected pore network enhances diffusion within the scaffold, improving nutrient supply and waste removal, thus increasing viability of cells beyond the edges of the construct.

Initial mechanical properties of the polymer scaffold should be almost identical to the surrounding bone. If the scaffold is much stronger than bone, stress shielding occurs (Bostrom and Mikos 1997). On a microscopic scale, the local stiffness of the

Table 1
Scaffold design parameters.

Porosity	Maximum without compromising mechanical properties
Pore size	200–400 μm
Pore structure	Interconnected
Mechanical properties	
Trabecular bone	Tension and compression: strength, 5–10 MPa; modulus, 50–100 MPa
Cortical bone[a]	Tension: strength, 80–150 MPa; modulus, 17–20 GPa
	Compression: strength, 130–225 MPa; modulus, 17–20 MPa
	Shear: longitudinal, 54–70 MPa; radial, 3.3 GPa
Degradative properties	
Degradation time[b]	Less than 6 months
Degradation mechanism	Bulk or surface erosion
Time to reach gel point[c]	∼10 min
Biocompatibility	No harmful chronic inflammation
Sterilizability	Sterilizable without altering material properties

Source: Temenoff *et al.* (2000).
[a] Reported values for the strength and modulus of cortical bone were measured parallel to the long axis of the osteon. [b] Degradative time in this instance refers to the time to loss of scaffold mechanical properties (time at which the scaffold no longer shares in weight bearing). [c] Time to reach gel point is for injectable, *in situ* cross-linkable systems.

polymer may affect the mechanical tension generated by the cytoskeleton of a cell, which can control cell shape and therefore function (Temenoff *et al.* 2000). As well as providing proper support in the early stages of healing, graded load transfer is needed later in the process for creation of replacement tissue that is identical to the original. The rate of scaffold degradation, therefore, must balance the need to maintain structural support for cellular proliferation and ECM secretion with the need for polymer disintegration to leave room for new tissue ingrowth.

The mechanism by which the scaffold degrades and the degradation by-products should both be considered when developing a polymeric scaffold. Materials that undergo surface erosion degradation release products gradually. The continued renewal of the exterior of this material renders cell attachment and culture on these materials problematic. Materials that degrade through bulk erosion release their products only when the molecular weight of the polymer reaches a critical value. Past the critical point, mechanical properties are difficult to maintain. Additionally, when the degradation products are acidic, a burst effect may cause a substantial drop in the local pH, which in turn may cause tissue necrosis or inflammation. Micromotion at the implant site or microparticles formed during the degradation process may elicit an inflammatory response. For example, it has been demonstrated that polymer microparticles suppress initial rat marrow stromal osteoblast proliferation and differentiation *in vitro* (Wake *et al.* 1998).

Any material proposed for implantation must meet certain general criteria. The material must be biocompatible. In other words, it must not evoke an extreme adverse inflammatory or immunological response. Synthesis, processing, or sterilization techniques can affect certain factors that determine biocompatibility, including polymer chemical and physical structure and surface morphology. Residual chemicals involved in these processes may leach out of the construct and harm the surrounding native tissue and the newly formed tissue within the construct. Finally, to create a truly viable alternative for bone repair, a polymer must be able to be easily sterilized, be able to be manufactured reproducibly on a large scale, have a long shelf life, and be easy for surgeons to handle in an operating room environment.

3.2 Material Selection

Scaffold design parameters may be optimized through the selection of the proper biomaterial. As with the design parameters, the choice of the material depends greatly on its intended application. The poly(α-hydroxy acid) family, which includes poly(lactic acid) (PLA), poly(glycolic acid), and poly(lactic-*co*-glycolic acid) (PLGA) copolymers, has been extensively investigated for use as prefabricated scaffolds. These polymers are particularly attractive as they are already approved by the US Food and Drug Administration for certain clinical applications. The degradation products, lactic and/or glycolic acid, are found naturally in the body and are therefore processed through normal metabolic pathways (Yaszemski and Yasko 1998). However, their buildup at the implant site can lower the local pH and alter the rate of degradation.

Other polymers have been explored for their use as preformed scaffolds for bone regeneration including

polyanhydrides and polyphosphazenes. Unlike polyesters that degrade by bulk erosion, polyanhydrides degrade in a controlled fashion by surface erosion. Although this type of degradation may result in a more controlled release of by-products, these materials often display poor mechanical properties. Polyanhydride-*co*-imides have been developed to augment the strength of the polyanhydride scaffold, but imides are not biodegradable (Behravesh *et al*. 1999). Moreover, surface-eroding polymers do not facilitate cell adhesion. Polyphosphazenes have a phosphorus–nitrogen backbone, and are rendered hydrolytically degradable by the addition of imidazoyle or amino acid alkyl ester side chains. The nature of the side chain and the percent substitution can affect the degradation rate and cell attachment (Yaszemski and Yasko 1998).

Poly(propylene fumarate) (PPF) is another material extensively studied for use as a tissue guidance scaffold. PPF is an unsaturated linear polyester that can be cross-linked through its fumarate double bond. PPF degrades by hydrolysis into products that occur naturally in the body (He *et al*. 2001). In an attempt to encourage host cell attachment and migration into the scaffold, PPF has been modified with GRGD (glycine–arginine–glycine–apartic acid) peptide sequences (Jo *et al*. 2000). Both prefabricated and injectable formulations of PPF have been investigated.

Injectable polymers are valuable because they can fill irregularly shaped defects with minimal surgical intervention. In addition to the design parameters discussed above, injectable systems need to meet the additional criteria of cross-linking *in situ* in a timely fashion without detrimental effects to the surrounding tissue. All reagents, including the initial polymer/monomer formulations, initiators, cross-linking agents, porogens, and reaction products, must be nontoxic. Furthermore, reaction parameters such as heat release and pH change must be minimized.

When cross-linked *in situ*, PPF is injected into the defect with any one of a number of cross-linking agents (e.g., *N*-vinyl pyrrolidinone (Peter *et al*. 1999), poly(ethylene glycol)-dimethacrylate (He *et al*. 2000), or PPF-diacrylate (He *et al*. 2001)), the initiator benzoyl peroxide, and the leachable porogen sodium chloride (NaCl). Many of the scaffold parameters can be controlled through manipulation of the method of PPF synthesis, cross-linking agent used, and ratios of initiator and cross-linking agent to PPF. Injectable formulations of PPF have been produced that reach gel point between 5 min and 10 min and reach a maximum cross-linking temperature only $10\,°C$ higher than the normal physiological temperature of 37 $°C$. In addition, they have the desired compressive strength and modulus, both initially and during the course of degradation, for consideration for trabecular bone augmentation (Peter *et al*. 1997, 1998, 1999).

3.3 Scaffold Applications

One of the most promising techniques using bioresorbable polymer scaffolds for skeletal regeneration involves the transplantation of autologous cells. Pre-osteoblasts obtained from the patient can be harvested from a remote location, expanded and differentiated in culture, and seeded onto the appropriate scaffold (Crane *et al*. 1995). After further culture of the cells within the scaffold, the construct is transplanted to the wound site. This method is the most widely used in tissue engineering and allows the cells of the patient to fabricate an ECM with the appropriate structural properties and signaling molecules under controlled conditions in culture. All of the prefabricated scaffold materials discussed above have been investigated for this strategy, while most of the research has focused on the use of poly(α-hydroxy acid)s. Osteoblast/PGA constructs implanted subcutaneously in nude mice and in full thickness rabbit calvarial defects were shown to form new bone after 20 weeks (Vacanti *et al*. 1993) and 12 weeks (Breitbart *et al*. 1998), respectively.

Sometimes fracture fixation is required immediately, leaving no time for expansion of cells in culture. In this case, a method that relies on the ingrowth of bone into the scaffold may be employed. Osteoconduction is the provision of a scaffold to enable bone growth at a time and in a location when and where it would occur because of the presence of bone-forming cells and bioactive molecules from the surrounding tissue. Osteoinduction, on the other hand, is the process of effecting bone growth in a location and at a time where and when it would not occur by providing the scaffold, cells, and/or bioactive molecules (Yaszemski and Yasko 1998). Defects that require osteoinductive materials are called critical sized defects. Rat stromal osteoblasts have been shown to attach to and migrate upon three-dimensional PLGA foams *in vitro* (Ishaug *et al*. 1997) and *in vivo* (Ishaug-Riley *et al*. 1997) in noncritical sized defects, demonstrating the osteoconductivity of this material. PPF has also been shown to be osteoconductive both *in vitro* (Peter *et al*. 2000a) and *in vivo* (Yaszemski *et al*. 1995, Lewandrowski *et al*. 2000). Five weeks after implantation of PPF constructs into noncritical sized rat tibial defects, the degrading scaffolds exhibited ingrowth of new bone trabecuae as well as good integration with the surrounding bone (Yaszemski *et al*. 1995). The addition of peptide sequences such as GRGD (Jo *et al*. 2000) that modulate cellular behavior should augment the ability of PPF to assist in bone regeneration, possibly making it osteoinductive and available for use in critical sized defects.

Another technique employed to enhance bone regeneration in polymeric scaffolds is through the incorporation of bioactive molecules that modulate cellular activity. The most commonly investigated osteogenic factors are the members of the

transforming growth factor-β (TGF-β) "superfamily" which includes TGF-β1 and bone morphogenetic protein-2 (BMP-2). One method of enhancing the *in vivo* efficiency of these factors is to facilitate their sustained release over an extended period time. With tissue-engineered devices, there are two different potential delivery systems (Babensee *et al*. 2000). Growth factors can be incorporated directly into the scaffold and released by a diffusion-controlled mechanism regulated by pore morphology as the scaffold degrades. Alternatively, the growth factor delivery system, in the form of microparticles, nanoparticles, or rods can be incorporated into a scaffold. For these devices, the rate of release would depend on the degradation of the delivery device with some contribution from that of the scaffold, and rate of growth factor diffusion through the pores of the delivery system and of the scaffold. For both delivery systems, dosage, release pattern, kinetics of release, and duration of delivery are important parameters that need optimization (Babensee *et al*. 2000).

The use of the poly(α-hydroxy acid) family of polymers has been the main area of focus for growth factor delivery devices. Unilateral critical sized defects in rabbit radii treated with a scaffold of PLA delivering rhBMP-2 demonstrate greater radiopacity as well as greater torque at failure as compared to untreated controls (Wheeler *et al*. 1998). PLGA microparticles loaded with rhBMP-2 incorporated in an allogenic blood clot promote bone formation in rat mandibular defects (Zellin and Linde 1997). Finally, towards development of a fully synthetic carrier/scaffold system, TGF-β1 encapsulated in blended PLGA/poly(ethylene glycol) microparticles was released and promoted proliferation and differentiation of osteoblast precursor cells cultured for 28 days *in vitro* on PPF substrates (Peter *et al*. 2000b).

4. Conclusions

Bone performs many important functions in the body. When bone is deficient in one location, many of these functions can be carried out by bone at distant sites, but its mechanical role in supporting the body and assisting in body movement and locomotion cannot. The mechanical functions, once lost by trauma or disease, can only be regained by restoring skeletal continuity at the location of interest.

Tissue engineering approaches that use polymeric, biodegradable materials hold great promise for regeneration of fully functional bone. Polymeric materials are versatile; their material properties can be tailored to meet specific needs through alterations in polymer composition and structure. Before these techniques can become a reality for patients, however, additional work must be done. Novel biomaterials should be developed that will interact with living tissue and modulate bone formation and repair.

Further investigation of the bone growth factors should be done to determine the proper release kinetics most effective for particular applications. Improvements in the carriers for these molecules may be needed to achieve the proper spatial and temporal release to enhance cellular attachment and proliferation. As more information is obtained about the biology of bone fracture and repair, strategies will improve and new approaches will be developed, taking the use of bioresorbable polymers for the regeneration of bone closer to clinical application.

Buildings: Plastics and Composites

The development and application of plastics and reinforced plastic composites as building materials has grown dramatically since their modern introduction in the early part of the twentieth century. This growth has been driven by several key factors inherent in plastics technology including their suitability for mass production, high strength-to-weight ratios, ability to be molded into intricate shapes and patterns, and exceptional resistance to environmental attack. Expanded performance has been achieved by combining plastic resins with various reinforcing materials to form plastic composites. Figure 1 provides a comparison of representative properties of plastics to other types of building materials.

The earliest practical application of plastics in construction was the use of phenolic-based resins in electric insulators in the 1920s. Commercial development of important thermoplastics such as poly(vinyl chloride), polyethylene, and polystyrene took place in the 1930s and 1940s, although their use in building construction was not significant until after World War II. With rapid advances in the scientific understanding of the chemistry of plastics, and an increased recognition of their value in building applications, the plastics industry expanded rapidly over the latter half of the twentieth century. Today, plastics comprise a sizable portion of the building materials market and cover a broad spectrum of applications including architectural uses such as vinyl window parts, weather barriers such as polyvinyl roof membranes, thermal insulation such as polystyrene boards, structural components such as pultruded fiberglass beams and columns, and utility conduit such as polyethylene piping. The sales of plastics resins to the North American building and construction market is estimated at 9 billion tons (8 billion tonnes) for the year 2000 with the growth rate in sales expected to be nearly double the increase in the rate of total construction spending (Chanda and Roy 1987).

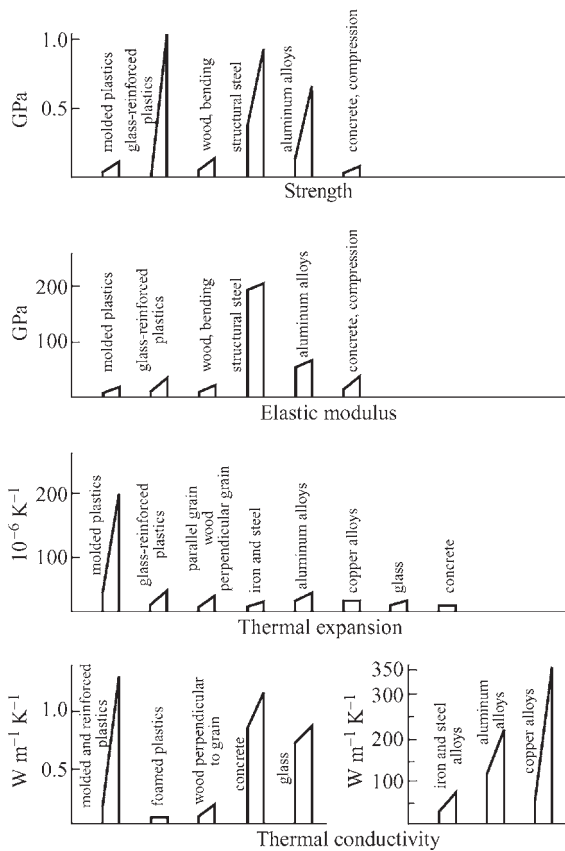
The term plastic, referring to a moldable, synthetic material composed of organic molecules forming long molecular chains (i.e., polymers), embraces a multiplicity of compositions, each developed to meet specific engineering requirements and market


Figure 1
Properties of plastics and other building materials.

demands. Within the two general classes of plastics—thermoplastics and thermosetting plastics—there are dozens of plastic compounds formulated and produced with unique properties for building uses. The versatility is increased with the use of reinforcement materials to form plastic composites. Although sharing a fundamental chemical nature and process, plastic material behavior in response to load and environmental conditions can be as varied as the differences between all other building materials.

The primary advantages of plastics and plastic composites over other building materials are:
- Formability and elimination of joints.
- Light weight and high strength-to-weight ratios.
- Corrosion resistant.
- Nonconductive, nonmagnetic, and insulating.
- Integration of color and texture within the material.
- Tough and wear resistant.

The primary disadvantages of plastics and plastic composites are:
- Loss of properties with high and low temperatures.
- Low stiffness (i.e., high deflection and high creep).
- Combustible and smoke generating.
- Susceptible to static and cyclic fatigue.
- High material and fabrication costs.

1. Properties of Basic Types

1.1 General

Structural plastics are formed from various types of thermoplastic or thermosetting resins. Fibrous reinforcements are sometimes added to the resin substrate to enhance structural properties. This is much more typical with certain thermosetting resins used to form composites with high strength and stiffness. Various additives and fillers may be added to enhance durability, stiffness, fire resistance, or other performance qualities, or to reduce material costs. In view of the large number of available combinations of resin materials, additives, fillers, and reinforcements, typical structural properties given in this section are only intended to illustrate the ranges of potential behavior of some plastic materials that are often found in building applications. Properties are highly influenced by the manufacturing process. Service environments and duration of applied forces also significantly affect properties.

In addition to basic structural properties, selections of specific plastics are related to material cost, formability, availability and cost of processing, directional variations in strength and stiffness, color and surface finish, thermal performance and expansion and contraction, toughness and impact resistance, creep and strength loss with duration of load, unit weight, effects of exposure to service environments (e.g., moisture, chemicals, UV light, etc.), fire resistance, and suitability for property enhancement with additives such as fibrous reinforcements, fillers, UV, or other stabilizers and plasticizers. See Harper (1996), Berins (1991), Seymour (1991), Hancox and Mayer (1994), and the *Modern Plastics Encyclopedia* (1998) for discussions of many of these effects on thermoplastics and thermosetting plastics.

All plastics are plastic at some stage, i.e., they are fluid or soft, and can be cast or shaped in many forms. They are organic materials based upon carbon. They are synthetic as products of chemical processes. Plastics are polymers that are comprised of groups of atoms called monomers, joined together into molecular aggregations. Large groups of such monomers, typical of most plastics, are called high polymers.

1.2 Thermoplastics

A fundamental characteristic of thermoplastics is that they soften repeatedly when heated and harden when cooled. Because of their molecular structure, at high

enough temperatures they may melt and at low enough temperatures they may become brittle. These high polymers are monomeric units attached to each other as long-chain molecules. They may be simple unbranched chains or have many branches and intricate entanglements. Chains are attracted to each other by molecular binding forces that are decreased by increasing temperature. Although generally of lower strength and stiffness than thermosetting plastics, thermoplastics are suited to a higher variety of processing techniques and formability, and therefore may provide advantages for economical production of large quantities of complex shapes.

Examples of thermoplastics that are used in the building industry are acrylonitrile–butadiene–styrene (ABS), polyethylene (PE), poly(vinyl chloride) (PVC), acrylics (PMMA), polypropylene (PP), polycarbonate (PC), polyamides (PA) (nylon), fluroplastics (TFE) (Teflon), and polystyrene (PS). Numerous variations of resin formulation, combinations with alloy materials, and additives have been developed and these materials may be manufactured in various forms (i.e., cast, extrusion, fiber, film). Process, additives, alloys, and reinforcements influence structural properties. Some typical structural properties are given in Table 1 to illustrate the general level of structural performance of these example thermoplastics. Hollaway (1994) presents more extensive data for screening and investigating a large number of thermoplastics. However, selection of materials and component design should be based on specific data from the materials supplier.

1.3 Thermosetting Plastics

Thermosetting plastics are distinguished from thermoplastics because they go through a soft plastic stage only once, then harden irreversibly, and cannot again be softened. This is because during curing of the initially soft resins by application of heat, the chain molecules of this class of plastics become crossed-linked to each other by strong chemical bonds or during application of heat and pressure become interlinked in three-dimensional clumps of monomeric units. In some cases water in the form of steam is given off as a by-product of interlinking, a reaction called condensation polymerization.

Examples of thermosetting plastics families that are used in the building industry include unsaturated polyesters, epoxies, and phenolics. Representative strength and stiffness properties for unreinforced casting or molding resins are given in Table 1. However, these plastics are usually used with fibrous reinforcement or fillers. These composites are discussed in Sect. 1.4.

1.4 Reinforced Plastic Composites

The majority of reinforced plastic composites used in building industry applications consist of a polyester resin matrix reinforced with fiberglass. A great range of properties is possible both from resin formulations and types of glass fibers. Three categories of polyesters are common: orthophthalics, isophthalics, and vinyl esters, in ascending order of cost and resistance to weathering, moisture, and chemicals. Curing can be accomplished at ambient temperature or accelerated by the application of heat. Many variations in basic resin formulation, catalysts, accelerators, and additives or fillers are used to enhance special properties, sometimes with undesirable trade-offs in other properties. However, resin manufacturers can engineer polyester systems to produce specific process

Table 1

and end-performance needs. See the *Modern Plastics Encyclopedia Handbook* (1994) for a more extensive presentation of the use of polyester resins as a matrix resin in fibrous composites. Epoxies, which are generally more costly and difficult to handle than polyesters, are also used as a resin matrix for some reinforced plastic composites, especially those with advanced fiber reinforcements. Compared to polyesters, epoxies may offer higher temperature limits, lower shrinkage, and improved bond and resistance to chemical attack.

Phenolics provide the resin matrix for non- or semistructural laminates that use various fillers to reduce cost and improve performance, or sometimes for fiber-reinforced composites.

The mechanical strength of reinforced plastic composites is primarily dependent on the amount, type, and direction of the fiber reinforcement. The amount is a function of the laminate design and manufacturing process, usually specified as a percentage by volume or by weight. The most common fiber type is E-glass fiber. Special fiber types, found in advanced composites having higher strength or stiffness that are used in a few building applications, are S-2 glass, carbon, and aramid. Fiber reinforcements may be provided in three general arrangements: unidirectional with greatest strength in the direction of the fibers, bidirectional with principal strength in each of two directions of fiber orientation, and multidirectional or isotropic with chopped fibers in random orientations or multiple orientations of continuous fibers in a fabric.

Glass reinforcement can be in the form of continuous rovings and bidirectional unwoven tapes with various proportions of fibers in each direction. Also in frequent use are bidirectional fabrics of woven rovings or cloth, and mats or chopped fibers that are essentially isotropic or with some directional variations in strength produced by bias in orientation. Combinations of the above reinforcements such as alternate layers of mat and woven roving are also used. A thin veil of light fiberglass mat is often used with a gel coat resin as a surfacing layer adjacent to a mold surface.

Reinforced plastics are often used for structural applications that also benefit from their nonstructural qualities. Some typical uses in building are described in Sect. 3. Illustrative strength and stiffness for typical fiber-reinforced plastics (FRPs) and carbon-fiber laminates are given in Table 2.

1.5 Plastic Particulate Composites

Acrylic resins and natural mineral particulates constitute CORIAN and similar commercial, artificial marble-like materials widely used for countertops, sinks, and sculptured castings. Portland cement concrete may be modified with polymers to produce polymer-impregnated concrete, polymer–cement concrete, and polymer concrete.

Polymer-impregnated concrete is produced by drying cured standard concrete, evacuating the pores and impregnating with a monomer subsequently polymerized in place by heat, chemical action, or high-energy radiation. Compressive strengths may be increased fourfold, creep drastically diminished, and resistance to sulfate attack and freezing and thawing greatly enhanced.

Polymer–cement concrete is standard concrete with a monomer or polymer latex added during mixing. It is subsequently handled like standard concrete.

Polymer concrete consists of regular mineral aggregate in a polymer matrix, customarily polyester, instead of Portland cement paste. The ingredients are mixed and cast into forms or molds where the polymer hardens, in hours at room temperature or minutes with heat. Unlike standard concrete, no curing time is needed.

1.6 Laminar Composites

For buildings, high-pressure laminated and structural sandwiches are of most interest. High-pressure laminates are most commonly decorative. They consist of layers of paper impregnated with phenolic resin faced with printed paper (sometimes fabric or wood veneer) impregnated with melamine–formaldehyde and overlaid with a melamine–formaldehyde-impregnated veil, all simultaneously pressed into a decorative laminate, usually subsequently bonded to plywood, particleboard, or other substrates. These laminates are used for counter- and tabletops, door facings, furniture, and cabinetwork. Such laminates are resistant to most household solvents and are harder than common varnishes and lacquers, but not as hard as glass.

Structural sandwiches consist of relatively thin facings of dense, strong, stiff materials bonded to relatively thick, less dense, less strong, and less stiff cores to provide lightweight combinations that are strong and stiff because of their geometry (see Fig. 2). In building panels the combination is also expected to provide thermal insulation, acoustical properties, weather resistance, and resistance to normal wear and tear. Facings most commonly employed include plywood, fiberboard, particleboard, gypsum board, steel, aluminum, high-pressure laminates, and glass-fiber-reinforced plastics. Cores include foamed plastics and honeycombs of paper impregnated with phenolic resin. Adhesives to bond facings and cores are generally based on synthetic resins. Some foamed-in-place plastics, e.g., polyurethanes, are self-adhering. The adhesive must withstand shear and tensile stresses between facing and core.

2. Design Considerations

Plastics and reinforced plastics are unique because they offer the design engineer the opportunity of selecting from a wide variety of resin materials, reinforcements, additives, and manufacturing processes to achieve a desired engineered material that provides specific performance requirements. Furthermore, they offer the following attributes that promote their creative use for structural and semistructural applications in buildings:

Formability. Plastics have no inherent form, so they can often be shaped efficiently for a given
Figure 2
Examples of structural shapes using the formability of plastics.

application. Form can also help to overcome limitations such as low stiffness (see Fig. 2).

Consolidation of parts. One-piece forming can often eliminate separate pieces, joints, seams, fasteners, and sealant.

Manufacture or fabrication in thin sections. The manufacturing methods and the toughness of many plastics and composites often allow them to be used in thin sections having efficient structural configurations; by taking advantage of formability, lightweight structural shapes such as shells, folded plates, and tension structures can be achieved. The extremely low specific gravity of plastics foams (0.015 and greater) contributes to low weight in such structures as foam-cored building sandwich panels (see Fig. 2). In sandwiches, facings form a moment-resistant couple; the core provides shear resistance and stabilizes facings.

Light weight and good strength-to-weight ratio. The low specific gravity of most plastics and reinforcing materials results in high ratios of strength to weight.

Corrosion resistance. Because they are largely immune to electrochemical corrosion, plastics and composites can often be used for applications in highly corrosive environments.

Transparency. Certain plastics are highly transparent or translucent to light for use in windows, light fixtures, skylights, and similar applications.

Integral color. Plastics integrally colored with dyes and pigments can be cut and otherwise worked without loss of color. Permanence is largely a matter of the permanence of the pigments and dyes. Surface colors may be applied as paints or gel coats.

Wear resistance and smoothness. Although they may be scratched and indented more easily than glass and other harder materials, plastics often provide good to excellent resistance to wear or abrasion. Nylon hardware parts frequently exhibit outstanding wear resistance and quiet operation. Vinyl flooring is resistant to wear and abrasion. The smooth inner surfaces of extruded pipes result in low resistance to flow of liquids.

Insulation. Many plastics exhibit low thermal conductivity and are used as insulating materials, especially when formed as rigid foams.

Nonconductive. Most plastics are very poor electrical conductors which makes them suitable for applications where electrical insulation and where nonconductive building components are required.

Energy and impact absorption. Fiber reinforcement toughens plastic composites and both rigid and flexible foam plastics absorb impact and blast effects.

Flexibility. Some plastics are inherently soft or flexible; others become so by additives and copolymerization and have both structural and nonstructural uses.

Fire resistance. Plastics are organic materials and can be destroyed by fire. Some burn readily, while others are self-extinguishing when an outside flame is removed. When fire resistance is a consideration, ease of ignition, rate of flame spread, rate of heat release, smoke release, toxicity of products of combustion, amount of combustible material, and structural property loss with temperature rise are among the factors that require consideration. Thermoplastics soften or melt at sufficiently high temperature, whereas thermosets maintain their shapes until, with enough heat, they ignite.

Structural. Unreinforced thermoplastics are used for many structural and semistructural applications in building applications. Generally, their properties are not as great as reinforced composites and feasible manufacturing procedures are suited to production of many similar components of limited size compared to reinforced composites with thermosetting resins. However, a large variety of complex shapes can be produced within the various process limitations. As was emphasized above, the structural properties of fiber-reinforced composites vary with the type, amount, and direction of the reinforcing fibers. Their properties and cost are also closely related to the available methods for fabricating a particular product or component. For example, the amount of fiber and strength of a component fabricated by hand lay-up contact molding may be less than a similar structure fabricated by high-pressure molding, or by pultrusion.

The successful use of plastics and reinforced plastic materials for structural applications in building construction requires a knowledge of performance characteristics in addition to strength and stiffness obtained from standard short-time tests. Unreinforced plastics and the resin matrices of reinforced plastics are basically viscoelastic materials whose strength and stiffness are reduced by creep under various durations of stress. For components subject to loads with significant duration, it is important to know the magnitude of expected creep strain and reduced strength as a function of time under the design maximum stress level (service load stress times a safety factor). The addition of reinforcement generally reduces losses from these viscoelastic effects, but creep and creep rupture still should be determined for reinforced plastics. Since it is expensive and time consuming to obtain adequate engineering data on the effects of long-duration forces on the many varieties of reinforced and unreinforced plastics, such data often must be obtained for design of specific structures subject to long-term loads.

The relatively low stiffness (elastic modulus) and the use of thin shapes with both reinforced and unreinforced plastics require an accurate determination of buckling resistance for elements subject to compression. This determination is more complex for reinforced elements whose elastic modulus often varies with direction. Evaluation and control of deflection also is more significant with these materials.

Thermal coefficients of expansion generally are greater with plastic materials than they are for conventional structural materials. This requires more consideration of the movements produced by thermal change with plastic structures. The thermal coefficient is reduced in the direction of increasing amounts of fiber in reinforced composites. Carbon-fiber composites have very low or negative coefficients of expansion.

Service environments also may greatly affect the structural performance of plastics and reinforced plastics. Strength and stiffness properties generally decrease when subject to increasing temperatures above normal ambient room and outdoor levels and may increase for decreasing temperatures. The effect of temperature on strength and stiffness is a significant criterion when selecting a suitable plastic for a particular application. The effect of outdoor exposure to UV light is another important design consideration. For some materials, UV stabilizers may be added to greatly improve resistance to UV degradation. Also, protective coatings such as gel coats are used. Gel coats and veil fabrics are used to obtain good surface qualities with reinforced plastics.

Applications of plastics and plastic-based composites often take advantage of their superior corrosion

resistance in many environments that are corrosive to metals. However, structural properties may be reduced by exposure to moisture or various concentrations of acids or alkalis. Manufacturers and fabricators have a great deal of data on the effects of exposure to various environments and chemicals.

3. Uses in Buildings

3.1 Architectural and Mechanical

These constitute by far the major applications in buildings. In these applications, plastics are not called upon to carry significant loads, and failure does not entail appreciable danger to occupants of buildings. Among the most important of such uses are the following.

(i) *Pipe, fittings, and conduit*. This, a very large class of uses, includes pipe and fittings mainly for drains, vents, and water and underground lines. PVC is most widely used, followed by high- and low-density PE, ABS, reinforced polyester, PP, and PS.

(ii) *Thermal insulation*. Efficient thermal insulation materials are provided by prefoamed or foamed-in-place plastics. Prefoamed plastics, such as PS and polyurethane, are typically blown as large masses and cut into slabs and blocks for use under concrete slabs, in cavity walls, and as sandwich cores. Blocks of foamed-in-place type are also available and provide good insulation if properly formulated and applied.

(iii) *Flooring*. PVC is compounded with fillers, fiber, and additives to provide resilient sheet and tile flooring. Urethane foams are employed as underlayments for rugs. Epoxies provide paving materials.

(iv) *Plumbing*. Bathtubs, shower stalls, and other plumbing fixtures use large quantities of reinforced polyesters in addition to acrylics, polyacetals, thermoplastic polyesters, and PS.

(v) *Glazing and skylights*. Flat, corrugated, and thermoformed acrylic and polycarbonate sheets are widely used, as are flat and corrugated reinforced polyester sheets. Flat reinforced plastic sheets are bonded to metal grids to form translucent structural wall and roof panels.

(vi) *Lighting fixtures*. Acrylics, cellulosics, polycarbonates, PS, and PVC provide a multiplicity of indoor and outdoor lighting fixtures.

(vii) *Moisture barriers*. Low-density PE and PVC find extensive use as barriers to prevent moisture migration through concrete slabs on grade and vapor passage through walls and roofs, and as liners for swimming pools.

(viii) *Profiles*. Window parts, rainwater conduits, moldings, and many others are chiefly extruded PVC and PE, solid or foamed.

(ix) *Wall coverings*. PVC and PS account for most wall coverings, including flexible sheets for walls subject to considerable wear.

(x) *Panels and siding*. These are mainly PVC and reinforced polyesters, with acrylics and cellulose acetate–butyrate also employed.

3.2 Structural

Use of plastics for structural building applications is increasing as more efficient processes for medium- and high-volume production become available. These usually employ plastic-based fibrous composites. Some typical applications are:

(i) Thin-walled structural shapes, such as rectangular and cylindrical tubes, I-shapes, channel and angle shapes, and roof decking manufactured by pultrusion of glass-reinforced polyester are available from stock and special order for primary structure, and wall and roof panels. These are mainly used in buildings and other structures with special requirements for corrosion resistance.

(ii) Sandwich panels with reinforced plastic facings (skins) and foam plastics or plastic-coated paper honeycomb cores. Metal or reinforced concrete are often used for facings of sandwich wall panels with foam plastic insulating cores.

(iii) Shell roof structures of various shapes such as spherical domes, hyperbolic paraboloid, and free-form doubly-curved shapes. Also, sandwich panel shells for larger spans (see Fig. 2).

(iv) Thermoplastics for low-maintenance fencing and small yard buildings.

(v) Thermoformed acrylic (Plexiglas) skylights and polycarbonate (Lexan) window panels.

(vi) Recycled thermoplastic lumber for replacing wood in low-stiffness, rot-resistant applications.

(vii) Plastic-coated fabrics for tensioned roof structures. Vinyl coated nylon is a common example for roofs of air-inflated buildings and pretensioned tents.

3.3 Restoration

Plastic-based composites of various types are widely used in building restoration work. Some typical applications are described below:

(i) Glass-fiber-reinforced polyesters are used for replacing deteriorated stone, terracotta, or concrete ornamental friezes, statues, and other decorative components on building facades.

(ii) Polymer-impregnated concrete is used to replace deteriorated concrete wearing surfaces in parking structures and bridge decks.

(iii) Carbon-fiber/epoxy reinforcement strips are applied to the exterior of deteriorated concrete beams and slabs to restore structural strength.

(iv) Various types of reinforced polyester and epoxy resin reinforcement is wrapped around reinforced concrete to improve ductility and seismic resistance.

3.4 Utility/Corrosion-resistant Structures

Various thermoplastics and glass-fiber-reinforced polyesters are widely used for buried and above-ground structures that require long-term resistance to corrosion. Examples include:

(i) Buried FRP petroleum storage tanks.

(ii) Buried FRP pressure piping and FRP piping that transmit corrosive fluids or operate in corrosive environments such as sewage treatment plants.

(iii) Above-ground FRP tanks and ducts in corrosive environments.

(iv) ABS and PVC drain, vent, and waste piping for domestic and industrial building service.

(v) PVC electrical conduit.

(vi) Gratings, railings, and stairways in place of metal components in sewage treatment plants, industrial plants, and similar facilities with corrosive environments.

3.5 Auxiliaries to Other Materials

Among the principal uses of plastics as auxiliaries to other building materials are: (i) protective and decorative coatings (paints, varnishes, and lacquers); (ii) structural adhesives and resin-bonding agents, especially for wood products; and (iii) building sealants in the form of caulking compounds and gaskets. Contemporary sealants augment the older oil- and resin-based varieties, and may be two-component (mixed on the job) or single-component (ready to use, often as cartridges for sealant guns). Polymers employed include polysulfide rubber, acrylics, silicones, chlorosulfonated PE, and urethanes. Similarly, gaskets draw upon various polymers including natural and synthetic rubbers and PVC.

4. Resources

The designer, specifier, and user of plastics and composite materials will find numerous resources to aid in the selection and application of these materials in building construction. Resin suppliers and plastic product manufacturers are primary sources for test data, design properties, and installation specifications for their products. Governing building codes, reference standards, and third-party design guides provide specific requirements for material selection. Additional resources are available from industry trade associations.

4.1 Codes and Standards

Building codes and design standards for plastics and composites have not advanced to a state comparable to that of more traditional building materials such as wood, steel, and concrete. This is due largely to the multiplicity of plastic formulations and complexity of properties, and to some extent to the proprietary nature of the plastics industry. However, concurrent with the increased use of plastics in building construction, building codes are increasingly incorporating specifications for plastic products and adopting existing national test standards for qualifying plastics materials in building components. This is exemplified in the 1997 Uniform Building Code (UBC) (Uniform Building Code 1997, Vols. 1 and 3). Following are UBC citations for plastic building materials:

Volume 1, Uniform Building Code

• Section 601.5.5. Trim: allowance of foam plastic trim for ceilings and walls.

• Section 1404. Vinyl siding: allowance for vinyl siding on exterior walls complying with UBC Standard 14-2.

• Chapter 26. Plastics: requirements for foam plastics, light-transmitting plastics, and plastic veneers.

Volume 3, Material, Testing and Installation Standards

• UBC Standard 14-2. Vinyl siding.

• UBC Standard 15-6. Modified bitumen, thermoplastic and thermoset membranes use for roof coverings.

• UBC Standard 25-1. Plastic cement.

• UBC Standard 26-3. Room fire test standard for interior of foam plastic systems.

• UBC Standard 26-4. Method of test for the evaluation of flammability characteristics of exterior, nonload-bearing wall panel assemblies using foam plastic insulation.

• UBC Standard 26-5. Chamber method of test for measuring the density of smoke from the burning or decomposition of plastic materials.

• UBC Standard 26-6. Ignition properties of plastics.

• UBC Standard 26-7. Method of test for determining classification of approved light-transmitting plastics.

• UBC Standard 26-8. Room fire test standard for garage doors using foam plastic insulation.

Similar code requirements and standards references can be found in other national building codes, such as BOCA (1996).

Traceski (1990) provides a thorough summary of national and international standards for plastics and composites for all application industries. Some of the major standards-writing organizations and resources for building materials, including plastics, are listed below:

(i) *American Society of Testing and Materials* (*ASTM*). Develops consensus standards for test methods, specifications, recommended practices, nomenclature, and definitions for materials.

Committees:

Committee D20 on plastics

Committee D30 on high modulus fibers and their composites

Committee F17 on plastic piping systems.
Publications:

Annual Book of Standards. Vols. 08.01, 08.02, and 08.03 on plastics and Vol. 08.04 on plastic pipe and building products.

Special Technical Publications (STPs) presenting articles on current research and applications: over 30 volumes on composites and plastics.

(ii) *International Organization for Standards* (*ISO*). An international standards-developing body comprised of national standards bodies from over 90 countries; promotes worldwide standardization.

Committee: ISO Technical Committee 61 on plastics.

Publications:

ISO Standards Handbook 21. Vol. 1, Plastics: terminology, sampling and properties; Vol. 2, Plastics: materials and products.

ISO/TC 61. Plastics: Instruction and Guide Manual, Document No. 570E.

(iii) *German Institute for Standardization* (*DIN*). Most German standards for plastics, textile glass reinforcements, and glass-reinforced plastics have related ISO standards.

(iv) *British Standards Institute*. Promulgates the official standards for the UK. British Standards (BS) for plastics and polymer products are available from the US Department of Commerce, National Institute of Standards and Technology.

4.2 Design Guides

No comprehensive code-sanctioned design standards for plastics and composites exist. However, authoritative design guides have been promulgated by professional organizations and consortiums. Notable examples are:

(i) *Structural Plastics Design Manual* (ASCE 1984).
(ii) The *EUROCOMP Design Code and Handbook* (Clarke 1996).

4.3 Trade Organizations

Trade organizations provide information on manufacturing sources, applications, and design and specification guidelines. Key organizations are listed below:

(i) The Society of the Plastics Industry (SPI), Washington, DC.

(ii) SPI-Composites Institute, Harrison, NY.

(iii) Society of Plastics Engineers (SPE), Brookfield, CT.

(iv) Composites Fabricators Association, Arlington, VA.

Carbon Aerogels

Sol–gel polymerization of metal alkoxides leads to the formation of highly cross-linked and transparent gels. If the gels are dried by hot air, they shrink owing to a large capillary force and the gel structures are often collapsed. To preserve the gel structure and to minimize the shrinkage during drying, it is useful to remove the solvent from the gel under supercritical conditions. The gel dried under these conditions is called an *aerogel*.

Although the most common aerogels are synthesized by sol–gel polymerization of silicon alkoxide, Pekala *et al.* have synthesized organic hydrogels by sol–gel polycondensation of resorcinol (1,3-dihydroxybenzene) with formaldehyde and prepared resorcinol–formaldehyde (RF) aerogels by supercritical drying with carbon dioxide (Pekala 1989, Pekala *et al.* 1992). They have pyrolyzed the aerogels in an inert atmosphere at 1323K obtaining carbon aerogels (Pekala and Alviso 1992). RF and carbon aerogels have a high porosity ($>80\%$), and a high surface area ($400-900\,m^2\,g^{-1}$). The aerogels are expected to be used as adsorbents, electric double layer capacitors, and materials for chromatographic separation.

The method proposed by Pekala *et al.* is extremely interesting from the viewpoint of developing mesoporous carbons. They have characterized organic and carbon aerogels and reported their electrochemical applications (e.g., Ruben *et al.* 1992, Pekala and Schaefer 1993, Wang *et al.* 1993, Pekala *et al.* 1994, Alviso *et al.* 1997, Pekala *et al.* 1998, Reichenauer *et al.* 1998). Tamon *et al.* have experimentally elucidated the influence of the amounts of resorcinol, water, and basic catalyst used in the sol–gel polycondensation on the porous structures of RF and carbon aerogels (Tamon *et al.* 1997, Tamon and Ishizaka 1998a). They have also proposed a control procedure of porous structures of organic and carbon aerogels (Tamon *et al.* 1998). They have also confirmed that carbon cryogels prepared via sol–gel polycondensation, freeze drying, and pyrolysis have a similar porous structure to carbon aerogels (Tamon *et al.* 1999).

1. Synthesis of Carbon Aerogels

The synthesis procedure of RF hydrogels is shown in Figure 1. When resorcinol (R) reacts with formaldehyde (F), RF hydrogels are synthesized via polycondensation, cluster formation, and gelation (Pekala 1989). Here, sodium carbonate (C) and ionized and distilled water (W) are used as a basic catalyst and a diluent, respectively. RF aerogels are prepared by
Figure 1
Synthesis of resorcinol–formaldehyde hydrogel.

supercritical drying with carbon dioxide and carbon aerogels are obtained by pyrolyzing the aerogels.

The small-angle x-ray scattering (SAXS) technique has been applied to the gelation process of RF hydrogels (Tamon *et al.* 1998b). The structure formation of the hydrogels during the sol–gel transition is revealed by applying Guinier and power-law equations to the SAXS data. At the initial stage of the synthesis of RF hydrogels, small clusters of approximately 2 nm consisting of branched polymeric species form that show a mass fractal dimension. The clusters aggregate and form particles of about 3–6 nm that show a surface fractal dimension. The hydrogel structure is fixed by gelation and the particles grow to approximately 4–7 nm. Finally the surface becomes smooth by aging. The pores in RF aerogels are the voids formed by the interconnected particles because the surface area of the particles roughly coincides with the BET (Brunauer–Emmett–Teller) surface area of aerogel determined by applying the BET equation to the adsorption isotherm of nitrogen at 77K.

2. Porosity of Carbon Aerogels

Table 1 shows the BET surface area S_{BET}, the mesopore volume V_{mes}, the peak radius of pore size distribution r_{peak}, the surface area of micropores S_{mic}, the micropore volume V_{mic}, and the macropore volume V_{mac} of carbon aerogels. The mole ratio of resorcinol to basic catalyst R/C, the ratio of resorcinol to water R/W, and the mole ratio of resorcinol to formaldehyde R/F used in the synthesis of RF hydrogels are shown in this table. One can see that S_{BET} and V_{mes} are much larger than S_{mic} and V_{mic} of the

---

aerogels except for B2. It is also interesting that the V_{mes} of all the aerogels except B1 are larger than V_{mac}. Consequently, it is considered that the carbon aerogels prepared under the conditions of R/W $\geqslant$ 0.25 have few macropores. This is because the mesopores and macropores are the gel voids formed by the interconnected particles and the voids depend on the amount of distilled water used as diluent in the synthesis of the RF hydrogels.

Figure 2 shows pore size distributions of the carbon aerogels determined using nitrogen adsorption (radius $r_p \cdot$ ca. 25 nm) and mercury porosimetry (radius $r_p \cdot$ ca. 10 nm) methods (Tamon and Ishizaka 1998a). One can see that the aerogels except B1 have sharp mesopore size distributions. On the other hand, B1 has a broad distribution of $r_p =$ 5–400 nm. For the same R/W, the peak radius of the distribution r_{peak} increases with increasing R/C. For the same R/C, r_{peak} increases with decreasing R/W.

3. Control of Porous Structure

Mesoporous structures of carbon aerogels can be controlled by choosing synthesis conditions of RF hydrogels (Tamon *et al.* 1998). First, low R/C should be chosen to prepare RF aerogels with sharp mesopore size distributions. For example, RF aerogels of $r_{peak} =$ 2.5–4.0 nm are obtained by adjusting R/W at R/C = 12.5. To prepare RF aerogels of larger pore radius, R/W is changed at larger R/C. One can prepare the aerogels with r_{peak} ranging from 2.9 nm to 6.0 nm at R/C = 25, from 3.9 nm to 6.9 nm at R/C = 75, and from 4.5 nm to 9.2 nm at R/C = 100. Hence, RF aerogels of $r_{peak} =$ 2.5–9.2 nm can be prepared by this procedure. To prepare the aerogels of $r_{peak} <$ 2.5 nm, the amount of distilled water used in the sol–gel polycondensation should be decreased but resorcinol cannot be dissolved in the solution. When trying to prepare RF aerogels of $r_{peak} >$ 9.2 nm, R/C must be > 100. In this case, other peaks appear in pore size distributions (Tamon *et al.* 1997).

Although RF aerogels shrink by 1–4 nm during pyrolysis, the shape of the pore size distribution is retained and r_{peak} can be controlled in the range of 2.0–6.1 nm by changing R/C and R/W. The following equations are useful to control r_{peak} and V_{mes} of carbon aerogels:

$$\ln r_{peak} = 0.226\ln(R/C) - 0.452\ln(R/W) - 0.254$$

$$(R/F = 0.5, 12.5 \cdot R/C \cdot 100, 0.125 \cdot R/W0.5, \cdot$$

$$= 0.953) \quad (1)$$

$$\ln V_{\text{mes}} = 0.406 \ln(\text{R/C}) - 0.812 \ln(\text{R/W}) - 2.476$$

$$(\text{R/F} = 0.5, 12.5 \cdot \text{R/C} \cdot 75, 0.125 \cdot \text{R/W} \cdot 0.5, = 0.974)$$

$$(2)$$

where $\cdot$ is a correlation coefficient.

4. Carbon Cryogels

Although carbon aerogels are unique materials with high surface areas and large mesopore volumes, the cost of supercritical drying is extremely high. Hence, RF cryogels are prepared by freeze drying with *t*-butanol and carbon cryogels are obtained by pyrolyzing the cryogels (Tamon *et al*. 1999). Table 1 also shows porous properties of carbon cryogels. The values of V_{mes} of the cryogels are around 60–120% of those of carbon aerogels. Carbon cryogels are mesoporous materials with high surface areas $> 800 \, \text{m}^2 \, \text{g}^{-1}$ and large mesopore volumes $> 0.55 \, \text{cm}^3 \, \text{g}^{-1}$.

5. Conclusion

Carbon aerogels are mesoporous materials with high surface areas and large mesopore volumes. The mesoporous structure of the aerogels can be controlled by choosing the synthesis conditions of RF hydrogels. Carbon cryogels also have similar porous properties to those of carbon aerogels. Various practical applications of carbon gels should be studied in the future.

Carbon Blacks

Carbon black is produced by the incomplete combustion of hydrocarbons such as those found in petroleum oil or natural gas. In its basic form, the smallest primary units of carbon black are aggregates, which in turn comprise partially "coalesced" colloidal sized spheroidal particles with a paracrystalline graphitic microstructure (Fig. 1).

1. Historical Perspective

For many thousands years carbon black was used exclusively as a pigment. However, in the early part
Figure 1
Transmission electron micrograph of carbon black ($\times 100\,000$). Note that carbon black is a distributional material.

of the twentieth century its utility broadened, and it is now used in a wide variety of applications. Some examples of the applications of carbon black today include use as a reinforcing agent in tires and rubber goods, as a pigment in inks, paints, and toners, an electrical conductor, and for ultraviolet light protection in plastics.

1.1 The Worldwide Market

In 1997 the worldwide demand for carbon black was 6.36 million tonnes (Columbian Chemicals Company estimate). This demand is expected to grow by over 15% by 2002. Of this volume, most carbon black, 93%, is used in rubber-related applications (tires—71%, mechanical rubber goods—22%). The remaining 7% is used in nonrubber applications such as in plastics, inks, and paints. Globally, the usage of carbon black is split as follows: Americas—35%, Asia—35%, Europe/Africa—30%, with demand in the Asian region expected to grow rapidly during the initial years of the twenty-first century.

2. Production Methods

A number of other processes have been used or are still used today, including (Kuhner and Voll 1993):

(i) The thermal black process—utilizing natural gas and oil as the feedstock. This produces very large primary particles of the order of ~ 300 nm mean diameter (other processes: ~ 10–100 nm).

(ii) The acetylene black process—utilizing acetylene gas as the feedstock. Excess heat produced during the formation process results in a less active surface. Carbon black produced by this method is primarily used in conductive applications.

(iii) Channel black process—utilizing natural gas as the feedstock. This process produces a highly oxidized surface, and sees limited use today.

(iv) The lamp black process—utilizing a petroleum oil feedstock. This process is essentially obsolete.

(v) The furnace black process (Fig. 2). Since its introduction in the 1940s, the furnace process has become the predominant method of carbon black production. The furnace itself is a heated, cylindrical, refractory-lined vessel into which a feedstock oil (such as petroleum, coal tar, or ethylene tar) is injected. Process conditions such as temperature, air-to-oil ratio and oil spray position are controlled to allow for partial combustion of the oil, and to manipulate the fundamental properties of the carbon black. After the furnace, this process is not significantly different from other carbon black processes, with heat exchangers (to remove heat from the process stream and aid in heating the furnace), bag collectors (to separate the carbon black from the process/tail gases and begin densification of the carbon black smoke stream), pelletizing/beading
Figure 2
The oil furnace carbon black process.

equipment, dryers, and various packaging, loading, and storage equipment.

3. Carbon Black Formation

Though not completely understood, carbon black formation is believed to occur through the following phases:

(i) atomization and vaporization of the feedstock oil (Fig. 3(a));

(ii) nucleation of the primary particles and initial surface growth (Fig. 3(b));

(iii) collision of primary particles to form aggregates, with continued surface growth (Fig. 3(c));

(iv) dehydrogenation, carbonization, and possible secondary oxidation (leading to porosity) until the reaction is quenched (Fig. 3(d)).

4. Fundamental Properties of Carbon Black

4.1 Particle Size and Distribution (Fineness)

Particle size can be measured accurately only by electron microscopy (e.g. according to ASTM D3849) (Fig. 4). However, other tests such as tint, iodine number, and nitrogen surface area can also give indications of relative particle size. Typical mean particle size ranges for furnace process grades are 10–100 nm.

Particle size distribution can also play a role in carbon black performance. For example, for a certain mean particle size, a broader particle size distribution will give a lower surface area and tint, resulting in lower viscosity and jetness in plastics and coatings, and lower hysteresis properties in rubbers.

4.2 Aggregate Size and Distribution (Structure)

Aggregate size and distribution properties are also best measured by electron microcopy (ASTM

Figure 3
The four primary phases of carbon black formation.
Figure 4

Figure 5
Four classes of carbon black aggregate morphology.

D3849). However, dibutylphthalate absorption (DBPA) (ASTM D2414) is also commonly used to determine the structure of carbon blacks relative to one another.

Aggregates can be categorized into four basic types: spheroidal, ellipsoidal, linear, and branched (Hess and Herd 1993) (Fig. 5). Every carbon black contains a distribution of each of these types, with the higher structure grades containing more branched and linear aggregates, and the lower structure grades containing more ellipsoidal and spheroidal aggregates.

It is also interesting to note that the linear and branched aggregates tend to break down to some degree during intense mixing. However, no aggregate can be broken down to individual primary particles.

Research has shown that aggregates exhibit an anisotropic morphology, tending to be somewhat more two-dimensional or planar in nature than originally believed. Better understanding of these characteristics may give better insight on carbon black formation and performance.

4.3 Porosity and Pore Size Distribution

Most porosity in carbon blacks is characterized as microporosity, or pores less than 2 nm in diameter. Techniques for measuring porosity in carbon black are based on gas absorption or density. Information derived from nitrogen surface area measurement data is one common way to estimate the relative porosity of a carbon black (ASTM D5816).

4.4 Surface Activity and Activity Distribution

Surface activity is a measure of the interaction between carbon black and the system into which it is mixed. It is an exceedingly complex phenomenon in strongly interactive systems such as common elastomers. For weaker interactions, such as in inks and plastics, it may be related to surface oxides. Manufacturers may intentionally oxidize the surface of carbon black particles for these special applications.

5. Common Characteristics of Carbon Black—Definition, Testing, and Relation to Fundamental Properties

5.1 Tint (ASTM D3265)

Tint strength is mainly a function of particle size, with smaller particles generally giving a higher tint. At constant particle size, DBPA can influence tint (i.e. lower DBPA gives higher tint). Higher tint carbon blacks generally give higher jetness and viscosity.

5.2 Iodine Number (ASTM D1510)

Iodine number generally increases with increasing surface area, although residual oil on the surface can suppress the iodine number. Higher iodine number carbon blacks generally give higher tinting strength.

5.3 Nitrogen Surface Area (ASTM D4820)

Nitrogen surface area generally increases with decreasing particle size and increasing porosity. Higher surface area carbon blacks generally give higher tinting strength.

5.4 DBPA (ASTM D2414)

DBPA provides an indication of the average aggregate size and aggregate void volume of the carbon black. Higher DBPA indicates larger aggregate size, and generally gives increased viscosity and dispersion, and lower tinting strength.

5.5 Volatile Level (ASTM D1509)

Volatile level gives an indication of functional groups on the carbon blacks surface.

5.6 Impurities

Impurities in carbon black are commonly measured by ASTM D1514 (water wash residue) or by ASTM D1506 (ash content). Common impurities in carbon black include:
   (i) refractory—from the brick furnace lining;
   (ii) metal—from other process equipment;
   (iii) coke—hard carbonaceous particles typically resulting from poorly atomized feedstock oil;
   (iv) ash—residual inorganic material from the feedstock oil or water used in the process (for quench, beading, etc.).

6. Typical Applications of Carbon Black

6.1 Rubber

As mentioned above, $\sim 93\%$ of carbon black usage is in rubber applications, and can be classified into two main categories: tires and mechanical rubber goods (e.g. automotive belts and hoses). The reinforcing properties of carbon black provide enhanced performance and durability to the rubber compounds in which they are used. Carbon blacks used in rubber applications are typically categorized as N100–N900 series blacks, where increasing N number correlates with decreasing nitrogen surface area (ASTM D1765).

The influence of carbon black fundamental properties on in-rubber performance is as follows:

Smaller particle size:
    increases tensile strength;
    increases abrasion resistance;
    reduces rebound;
    reduces dispersibility.

Higher DBPA or structure:
    increases modulus;
    increases hardness;
    increases viscosity;
    reduces die swell;
    increases dispersibility.

Higher porosity:
    increases tear strength;
    increases conductivity;
    reduces rebound.

Higher surface activity:
    increases abrasion resistance;
    increases rebound;
    increases modulus.

6.2 Nonrubber (Plastics, Inks, Coatings, etc.)

The remaining $\sim 7\%$ of carbon usage falls into a broad group of applications, of which the most predominant are plastics, inks, and coatings. Additional applications are varied, and include sealants, toners, and batteries. In these applications, carbon black is used for such properties as appearance (blackness, tint, gloss), conductivity, and ultraviolet light protection.

The influence of carbon black fundamental properties on nonrubber applications is generally as follows:

Smaller particle size:
    increases blackness and tinting strength;
    increases viscosity;
    increases ultraviolet protection;
    increases conductivity;
    decreases dispersibility.

Higher DBPA or structure:
    increases viscosity and vehicle demand;
    increases dispersibility;
    increases conductivity.

Higher porosity:
    increases viscosity and vehicle demand;
    allows reduced loadings in conductive
    applications.

Higher surface activity:
    improves wetting, microdispersion, and stability;
    reduces viscosity of liquid systems.

Carbon Fibers

Carbon fibers have proved to be the main reinforcement for advanced composites for a wide range of applications since the 1960s, but the majority of products still belong to high technology space and aeronautics (Fitzer 1985, Donnet and Bansal 1984). Carbon fibers are a few microns thick, light-weight, very strong, and stiff black synthetic fibers with long aromatic molecular chains, comprising mainly carbon. These fibers are capable of maintaining this structure under extreme conditions of temperature and pressure and, therefore, can be used with all types of matrices, i.e., polymers, ceramics, and metals employing different composite processing techniques.

Though the historical development of carbon fibers goes back to 1879 when produced by Edison for the electric light bulb, the interest in carbon fibers as a reinforcement for composites for structural applications started in the 1960s with the demand from the aeronautical sector for light-weight, strong, and stiff materials. The elastic constant of the graphite lattice is 1060 GN m^{-2} along the layer planes. In order to realize this property in bulk graphite, the graphite material should be in an ultra-thin form, i.e., fibers with layer planes oriented along their length. This generated interest in the development of high-performance carbon fibers with a perfect graphitic structure with the layer planes oriented along the fiber axis.

1. Carbon Fiber Processing

Carbon fibers are produced by the controlled pyrolysis of a carbonaceous material in fibrous form. Therefore, though basically any fibrous material made from a carbonaceous precursor can be used to produce carbon fibers, only rayon, polyacrylonitrile (PAN), and pitch-based fibrous precursors have been used for producing commercial carbon fibers (Fitzer and Heine 1988). A schematic comparison of the processing routes for carbon fibers from these three precursors is shown in Fig. 1. Precursor weight loss and retention of orientation of the graphitic planes had been the central issue in the processing and economics of carbon fiber technology. Recently the carbonization behavior of many other polymeric materials has been studied as potential precursors for

carbon fibers. These include phenolics, polyimides, polyamides, polyphenylene, polybenzimidazole, polyethylene, polypropylene, and polyvinylchloride (Bahl *et al.* 1998). Though some of these polymers exhibit high char yield, the properties and structure of the ultimate carbon fibers is not suitable for their application as a high-performance material. However, phenolic-based carbon fibers are used to produce activated carbon fibers.

1.1 Rayon-based Carbon Fibers

Rayon-based carbon fibers were the first to be commercialized and remained dominant up to the early 1970s. Though at present the majority of carbon fibers produced worldwide are derived from PAN and
Figure 1
Schematic comparison of processing routes for carbon fibers.

pitch precursors, the pyrolysis of cellulosic fibers and the development of high-modulus carbon fibers from them is quite significant from the point of view of basic carbonization chemistry. A special grade of rayon fiber with a high degree of crystallinity containing no defects or inclusions is used for carbon fiber manufacture. The processing of carbon fibers from rayon consists of a low temperature (200–400 °C) heat treatment, preferably in air to stabilize the fibers, followed by pyrolysis to 1000 °C in an inert atmosphere (Bacon 1973). During the early stages of decomposition of levoglucosan there is an evolution of H_2O, CO, CO_2, CH_4, etc., and in the later stage a rearrangement of the planes occurs. These are the most important steps in the production of carbon fibers from a rayon precursor. The highly oriented crystalline structure of the precursor fiber is lost due to cleavage of glycosidic linkages during pyrolysis, resulting in a linear shrinkage of 20–25% and a cross-sectional shrinkage of 40–60%. Therefore, carbon fibers (1000 °C) from viscose rayon are low density (1.6–1.7 g cm^{-3}) with a very low strength of 400–700 MPa and a modulus of 30–50 GPa. These fibers are good enough for nonstructural applications only, such as ablative applications or as activated carbon fibers. Treatment of the precursors with Lewis acids or ammonia inhibits excessive degradation of levoglucosan, lowers the tar formation, and increases the char yield.

Properties of ex-rayon carbon fibers are improved on further heat treatment to 2500–3000°C especially if the heat treatment is carried out under tension (Bacon and Schalamon 1969). The fibers exhibit plasticity in this temperature range and, hence, orientation of the graphitic layers can be achieved through application of stress, i.e., stress graphitization. Although these carbon fibers posses good mechanical properties ($\sigma = 3.0$–3.5 GPa and $E = 600$–650 GPa) they are very expensive.

1.2 Carbon Fibers from Acrylic Precursors

(*a*) *Polyacrylonitrile precursor*. Among all possible carbon fiber precursors, PAN turned out to be the most suitable precursor from the point of view of overall carbon content (67%), high carbon yield ($\sim$54%, more than 80% on the basis of carbon content), processing, structure, properties, and cost. As a result, PAN-based carbon fibers account for more than 70% of the world's total carbon fiber production and are used in the majority of current advanced composites.

The first extensive study on carbonization of PAN fibers was reported by Shindo in Japan in 1961. However, the breakthrough in the development of high quality carbon fibers came from a British team. Johnson *et al.* (1966), through their experiments on the stabilization of PAN under stress, demonstrated

that molecular arrangement and, hence, carbon fibers with high strength and modulus, are obtained through stretching the fibers during stabilization.

PAN is an atactic, linear polymer containing highly polar nitrile pendant groups. The PAN fibers suitable for conversion into high-strength or high-modulus carbon fibers are high molecular weight copolymers having an average molecular weight of $\sim 2.6 \times 10^5$ containing more than 90% acrylonitrile. The comonomers are usually methyl acrylate, methacrylic acid, acrylamide, quaternary ammonium salts of amines, or ethyl methyl propenoate with some itaconic acid or sodium styrene sulfonate (Fitzer 1989a, Edie and Diefendorf 1993). However, the last of these is found to limit the properties of the carbon fiber products at high-temperature treatment. Therefore, PAN precursors with about 2–3% itaconic acid are preferred. The compositions of the PAN precursor, as well as the spinning solution and other spinning conditions, have a great influence on the final carbon fiber properties.

The fundamental fiber structure needed to develop high strength and stiff carbon fibers is created during the initial fiber forming step. Wet, dry, and melt spinning processes have been used to spin PAN precursor fibers. PAN fibers spun from inorganic solvents are found to be, in many respects, superior precursors for the production of carbon fibers. Wet spinning and dry spinning result in circular and dog bone shaped fibers whereas multilobal cross-section fibers can be formed by melt spinning. In wet spun fibers, PAN molecules are organized into fibrils which are generally oriented parallel to the fiber axis and are joined together in a 3D network. This fibrillar network appears to be the precursor for the graphene network that develops during final heat treatment. Leading carbon fiber manufacturers now use dry-jet-spun PAN fibers which result in carbon fibers with much higher mechanical properties than those from wet-spun fibers. Moreover, to produce high quality carbon fibers, the starting PAN precursor fiber should have small diameter, maximum possible orientation of the molecular chains along the fiber axis, maximum crystalline content, and low activation energy for cyclization. Improvement in the precursor fiber can be achieved by post-spin stretching of PAN fibers before stabilization. PAN fibers may be stretched up to 200% during spinning and this improves the structure of the fibers, especially the orientation of molecular chains with respect to the fiber axis, ultimately leading to carbon fibers with better mechanical properties. Therefore, for making carbon fibers, PAN precursors are made under specific controlled conditions and are termed special acrylic fibers (SAF). The precursor cost adds to the end cost of the carbon fibers. Though each producer has its own propriety technology, the basic process involves three steps; preoxidation stabilization, carbonization, and a high-temperature heat treatment. Figure 2 shows
Figure 2
Chemical structure during processing of carbon fibers on mechanical properties of PAN.

the chemical structure of the fibers after the various process steps. From a process engineering viewpoint, mass and heat transport are the major considerations in optimizing the processing parameters.

(*b*) *Stabilization of PAN precursor fibers*. The stabilization step converts the precursor from a linear polymer to a highly condensed, thermally stable ladder polymer structure. The primary function of this step is to cross-link the as-spun structure ensuring that both molecular and the fibrillar orientations will not be lost during final heat treatment (Bahl and Manocha 1974, 1975a). The stabilization is considered to be the most decisive step in the production of carbon fibers because the stabilized fibers are considered to be the template for graphitic structures and, hence, mechanical properties of the ultimate carbon fibers.

During stabilization, the incorporation of oxygen-containing groups into the polymer chain occurs concurrently with the cyclization (Fig. 1) and dehydrogenation reactions. It is very difficult to know the exact succession of the reactions because they are dependent on the precursor constituents and processing conditions but they are probably very close to each other. The cyclization reaction is highly temperature dependent with rate determined by initiation. In copolymer fibers the comonomer acid groups dominate initiation. In the absence of an initiator, the cyclization is believed to occur by a free radical mechanism whereas in the presence of an acid initiator, an ionic mechanism predominates and occurs at a lower temperature (Fitzer 1989b). This allows better control of heat evolved in copolymers than in PAN homopolymers. The controlled cyclization reaction requires uniform heating of the fiber or heat transport to, and within, the fibers. The oxidation (intake of oxygen) is a diffusion-controlled process (mass transport) and demands uniform uptake of oxygen throughout the cross-section of the fibers. During oxidative stabilization of the fibers some oxygen-containing groups (e.g., –OH, $C = O$,

–COOH) are formed in the backbone of the ladder polymer. These oxygen-containing groups promote cross-linking reactions in the early stages of carbonization. The rate of intake of oxygen is also influenced by the stabilization temperature. In general, during stabilization the oxygen content of the precursor fiber increases from 8% to 11% with a change in color of the fibers from white to silky black (Peebles 1995). The evolution of CO_2 due to decarboxylation reactions and HCN due to uncyclized nitrile groups causes the carbon content of the PAN fiber to decrease while the evolution of HCN and the dehydrogenation reaction evolving H_2O cause the hydrogen content to decrease. Overall, during stabilization, the fiber suffers a net weight loss of ∼5–8%. The fiber shrinks in the longitudinal direction by ∼10–18% and in the radial direction by ∼40–45%. This results in close packing of the structure and an increase in density of ∼20–25%. Ladder polymer formation and cross-linking through oxygen are both exothermic processes. Taking these into consideration, oxidation stabilization has to be carried out at a carefully controlled heating rate and end temperature. In most commercial processes, the stabilization of PAN precursor fiber is done at a heating rate of 2–4 °C min^{-1} at temperatures ranging from 220 °C to 350 °C in the presence of air.

Alternative approaches to air stabilization have also been studied. These include the use of sulfur dioxide or bromine atmospheres, treatment of PAN fibers with cuprous chloride or potassium permanganate solution followed by air oxidation, etc. (Bahl *et al.* 1998). Though these treatments reduce the processing time, their commercial viability has yet to be established especially with respect to effluent and by-product evolution and their treatment.

Another important parameter in processing PAN-based carbon fibers is restraining the molecular chains so that they do not become disoriented during heat treatment at all stages. The chemical reactions taking place during thermal stabilization of the fibers to a ladder polymer can disrupt the orientation of molecular chains and result in linear shrinkage varying from 10–18% (Bahl and Manocha 1975b, Fitzer 1989b). In order to obtain high modulus carbon fibers it is essential to restrain the fibers from shrinking or even to elongate them by applying tension. Thus, the preferred orientation needed for the final high-performance carbon fibers is achieved by stretching the polymeric precursor fiber when it is still thermoplastic. The stretching during stabilization also results in an increase in the tensile modulus of the polymer fibers. It has been established that PAN fibers with higher elastic modulus as precursor fibers, produce carbon fibers with a higher Young's modulus. In commercial production the length change permitted may vary from −5% to +30% depending on the type of precursor fiber and its prior process history during spinning and post spinning.

(*c*) *Carbonization of stabilized PAN fibers.* The second step during the conversion of PAN fiber to carbon fiber is carbonization at temperatures of 1000–1500 °C in an inert atmosphere, usually ultrapure nitrogen. In the early stage (500–700 °C) a pyridinic structure is formed which on further heat treatment (1000–1500 °C) collapses into a turbostratic, stacked ring structure. The chemical reactions during the early carbonization stage lead to the evolution of water, ammonia, hydrogen cyanide, carbon dioxide, carbon monoxide, methane, etc. As in stabilization the sequence, nature, amount, and rate of evolution of these depend on the compositions of the precursor PAN fibers, the extent of stabilization, and the carbonization conditions. The low temperature carbonization (500–700 °C) is extremely important since it is during this stage that the maximum mass transfer takes place and the carbon building block is laid. Therefore, a low heating rate (<5 °C min^{-1}) should be adopted in this temperature range to avoid fast evolution of gaseous products and, hence, defects in the carbon fibers. In the temperature range of 700–1500 °C, H_2, HCN, and nitrogen are evolved due to intermolecular cross-linking of the polymeric chains. The amount of evolution of these gases is very low (<10%) and, hence, higher heating rates can be used in this temperature range. During carbonization the fibers suffer a weight loss of ∼45–55% and shrink in diameter by ∼40–50%. With heat treatment, the carbon content increases (92%), the nitrogen content decreases (7%), and the hydrogen content decreases (0.3%). The strength, as well as modulus, increase as shown in Fig. 3. Research work since 1985 on the stabilization and carbonization of PAN fibers has resulted in a many fold decrease in the processing time and an increase in mechanical properties.

Fibers heat treated to 1500 °C are termed high strength carbon fibers and consist of oriented small crystallites. Higher heat treatment (to 2500–3000 °C) continues to improve the graphitic structure with an increase in crystallite size, preferred orientation, and, hence, elastic modulus. The strength of the fiber, however, decreases, reaching a minimum at about 1800 °C and a slight improvement after heat treatment of 2000 °C (Fig. 3). This is due to the development of flaws as a result of the evolution of nitrogen and lattice rearrangement and defect removal at high temperatures. The carbon fibers heat treated in this temperature range consist of more than 99% carbon and are termed *high modulus carbon fibers*.

(*d*) *Structure of PAN-based carbon fibers.* The structure and structure-property relationships of various ex-PAN carbon fibers have been studied by many scientists (Diefendorf and Tokarsky 1975, Johnson 1987, Guigon *et al.* 1984). The structure of PAN-based carbon fibers is fibrillar in nature, similar to
Figure 3
Influence of heat treatment on mechanical properties of PAN and pitch-based carbon fibers (after Edie 1998).
Figure 4
Johnson's (1987) model for the structure of HM PAN based carbon fibers.

that of the original precursor fiber but consisting of layers of carbon. A 3D schematic representation of the microstructure of PAN-based carbon fibers given by Johnson (1987), is given in Fig. 4. The structure of high-modulus carbon fibers consists of extensively folded and turbostratic layers of carbon with an interlayer spacing of 0.34–0.37 nm, considerably larger than that of pure graphite and crystallite size $L_a \sim 16$–23 nm and $L_c \sim 6.2$–7.0 nm, and much smaller than those of pure graphite. The structure of the fibers varies from surface to the center and is thus termed a skin-core structure, possessing no regular 3D order. In the outer region of the fibers, the turbostratic layers within the fibrils tend to be oriented parallel to fiber axis but contain needle shaped voids within the crystallites. In the core region the layer planes are folded extensively. Guigon *et al.* (1984) proposed the structure of PAN-based carbon fibers consisting of wrinkled aromatic carbon layer sheets called basic structural units (bsu) which are then crumpled along the fiber axis and are folded and entangled across the section. This disordered fibrillar structure of ex-PAN carbon fibers makes it less prone to flaw-induced failure.

1.3 Pitch-based Carbon Fibers

(*a*) *Pitch precursor and fiber spinning.* Pitch, because of its high carbon content and yield, is the prime precursor for more than 80% of industrial carbon products. Being a cheap raw material, it can bring down the cost of carbon fibers and widen the application of these materials. Therefore, concurrently with the development of PAN-based carbon fibers, efforts have also been made to develop pitch-based carbon fibers. Otani (1965) developed the first pitch-based carbon fiber from isotropic pitch. The mechanical properties

were not very attractive and the fibers were termed general purpose carbon fibers. Subsequently they made carbon fibers from mesophase pitch possessing a high modulus (Otani *et al.* 1972). Like rayon-based carbon fibers, pitch-based carbon fibers could also be hot stretched in the temperature range 2000–2800 °C resulting in a two to three fold increase in Young's modulus. But commercial exploitation of the process is difficult. Barr *et al.* (1976) at Union Carbide found that an oriented fibrous microstructure could be obtained during spinning while the pitch is in the liquid crystalline state. Carbon fibers produced by this process possessed very high modulus. Therefore, Union Carbide was the first to commercialize pitch-based, high-performance carbon fibers. Since then there has been continuing interest throughout the world, especially in the US and Japan, in producing pitch-based carbon fibers with Young's modulus and thermal conductivity values approaching those of single crystal graphite (Singer 1989). While most of the PAN-based carbon fiber researchers have focused on oxidation and high temperature treatment of PAN fibers, most pitch-based fiber scientists have concentrated on pitch precursor chemistry, development of suitable mesophase pitch, and mesophase pitch spinning.

Pitches consist of a wide range of polyaromatic and cyclic aliphatic hydrocarbons containing linear aliphatic side chains. Molecular weights of the polyaromatic compounds vary from 200 to 1000. Because of this variation in molecular composition, the melting of pitches from natural sources such as coal tar and petroleum occur over a wide temperature range. When a highly aromatic pitch is heated to 400–500 °C for extended periods, called thermal polymerization, a liquid crystalline material consisting of large polynuclear aromatic hydrocarbons, a mesophase, is formed. Following its discovery by Brooks and Taylor (1965), the formation of mesophase, mode of growth, and its properties have been the subject of much research. The formation reaction and also the extent of mesophase formation depend on the carbon to hydrogen ratio of the aromatic pitches as well as the heat treatment temperature. In addition to the production of mesophase from natural sources such as coal tar and petroleum pitches, significant success has been achieved in producing synthetic mesophases with improved uniformity and purity from pure aromatic hydrocarbons (Mochida *et al.* 1995). The first commercial mesophase precursors were produced by Union Carbide using a thermal polymerization process. In addition to thermal polymerization techniques, solvent extraction, supercritical fluid extraction (Bolanos and Thies 1996), and catalytic polymerization techniques have been explored to produce mesophase pitches. The mesophase products produced by these techniques differ considerably in terms of molecular weight distribution and concentration of aliphatic side chains on the mesophase molecules. The aromatic molecules in the

liquid crystalline mesophase can be depicted as a collection of slippery sheets. These can be easily extended and drawn into highly oriented filaments or fibers by shear or elongational forces applied above the melting temperature of the mesophase (Edie 1998). In order to reduce the viscosity of the pitch and the spinning temperature, which would allow for easier processing, a small amount of isotropic pitch could be added to the mesophase pitch. However, due to the solubility of the two phases in one another and interactions on heating, the melt spinning of pitches containing less than 100% mesophase is extremely difficult. There is also a stability problem encountered with two-phase extrusion.

The mesophase pitches used to produce carbon fibers are normally a mixture of high molecular weight molecules containing a small number of side groups. Both of these characteristics are vital for the melt spinning of pitch. Mesophase pitches of high molecular weight compounds with no side groups, or containing compounds with a high specific softening point, often decompose before flowing and, hence, are not preferred for high performance carbon fibers.

In contrast to PAN or rayon-based carbon fiber processing, in the pitch route, the pitch has to be first spun into fibers. The type and composition of pitch yielding ultimate carbon fibers with desired properties can be selected for making pitch fibers and even the melt spinning conditions can be controlled and regulated. Moreover, the transverse microstructure and necessary axial orientation in pitch-based carbon fibers is achieved during melt spinning of the liquid crystalline mesophase. These are maintained during stabilization and are further improved during carbonization and high-temperature heat treatment. Therefore, the pitch route offers significant advantages over the other processes. The viscosity of mesophase pitches, and hence, their flow characteristics are extremely temperature dependent. Figure 5 (Edie 1998) shows a schematic diagram of a typical melt spinning process used to produce mesophase pitch precursor fibers. The molten pitch precursor, after being transferred to a metering pump by extruders, is forced into a spin pack consisting of a filter and a spinneret. As fibers are drawn through the spinneret, they are simultaneously quenched by the surrounding atmosphere. This also induces stresses in the fibers, which in turn affect the ultimate microstructure. In order to obtain the desired structure and mechanical properties of the end carbon fibers, it is important to have precise control of the spinning conditions.

(*b*) *Stabilization of pitch fibers.* The second step in pitch carbon fiber processing is the thermostabilization of pitch fibers. Stabilization before carbonization is necessary to prevent the fibers from melting or relaxing during the final heat treatment. This can be accomplished either by heating the pitch fiber to a
Figure 5
Schematic melt spinning process to produce mesophase pitch fibers.

temperature below its softening point in the presence of oxygen for an extended period or by immersing the precursor fiber in a strong oxidizing liquid. During this step, the large plate-like molecules become cross-linked through carbonyl and phenoxy groups formed by oxygen. According to Mochida *et al.* (1995) the stabilization reaction first occurs at the aliphatic side chains of the mesogen molecules with the introduction of oxygen functional groups. This is followed by aromatization and cross-linking. The reactivity of a mesophase pitch fiber depends on the amount of naphthenic and alkyl groups present in the material. The weight of the fibers is also increased by 5–10%. Like PAN fibers, the oxidative stabilization of pitch fibers involves simultaneous diffusion of oxygen and chemical reaction.

Both phenomena are temperature and time dependent and have to be optimized from both a processing point of view as well as the fiber properties. Typically, the pitch fibers are stabilized in the temperature range 250–300 °C for a period of 2–5 hours. Often the stabilization temperature begins near the softening point of the mesophase and is increased in a series of steps to the end temperature. Isotropic pitch fibers are stabilized at higher temperatures and take longer to stabilize than anisotropic pitch fibers. Also the oxygen uptake is greater in the former than in the latter. There is a difference of opinion about the need to stretch the pitch fibers during stabilization. However, since the as-spun fibers are already oriented,

tension is not applied during stabilization in the commercial process. Because the pitch fibers have very low strength and are brittle, which poses handling problems, the stabilization is carried out on conveyer belts or on bobbins in batches.

(*c*) *Carbonization and high temperature heat treatment of pitch fibers.* The stabilized pitch fibers are further heat treated to 1500–3000 °C in an inert atmosphere during which most of the noncarbon elements escape in the form of hydrogen, carbon monoxide, methane, etc. leaving behind carbon in a well-oriented form. Carbonization or heat treatment of pitch fibers is carried out in steps. First the fibers are heat treated at ∼700 °C wherein not only the carbon content in the fibers increases but they also attain flexibility (5–8%) making them easier to handle. They are further heat treated to the desired temperature of 1600–2800 °C. Since pitch-based fibers are rich in carbon content, the yield of the fibers during carbonization is very high (70–80%), and the cross-sectional shrinkage is low (25–30%). The graphitic content, as well as the degree of preferred orientation of the crystallites within the fiber, increases with heat treatment temperature.

(*d*) *Structure of pitch-based carbon fibers.* Pitch-based carbon fibers primarily consist of axially oriented graphene layer planes having different transverse microstructures. The transverse texture of most commercial pitch carbon fibers are either random, onion skin, flat layer, radial, or radial folded as shown in Fig. 6 (Fitzer and Manocha 1998). These textures are developed during mesophase spinning and are retained during subsequent stabilization and heat treatment steps. Different textures can be obtained either by disrupting the flow during extrusion, varying extruder geometry, or through variation of temperature and flow during spinning (Hamada *et al.* 1987). According to Rey (1995), a high temperature of extrusion would favor the formation of onion skin textures, low temperature would favor radial textures while intermediate temperatures result in random textures in the ultimate carbon fibers. By using stirrers of different shapes, pitch fibers with random, onion, and quasi-onion shaped microstructures can be obtained. Edie *et al.* (1994) used rectangular extrusion capillaries to develop ribbon shaped fibers with a linear transverse texture (Fig. 7). The microstructure of pitch-based carbon fibers may be considered as consisting of plates made of graphene layers oriented at angles of 2–15° to the fiber axis. The plates may be flat or constitute folds with crystallite dimensions, L_a and L_c, of 54–87 nm and 13–30 nm, respectively and interlayer spacing (d_{002}) of 0.338–0.340 nm. This plate-like structure of the mesophase pitch carbon fibers makes it more flaw

sensitive. Mesophase pitch carbon fibers with random or radial folded textures exhibit higher tensile and compressive strengths whereas those with a linear transverse texture develop better lattice dependent properties (modulus and conductivities).

1.4 Vapor Grown Carbon Fibers

Another variety of reinforcement with high mechanical and thermal properties and significant commercial potential is carbon fibers produced by direct growth from the vapor phase, i.e., vapor grown carbon fibers (VGCF). These are also called catalytic chemical vapor deposition (CCVD) carbon fibers. These fibers are produced by catalytic decomposition of a hydrocarbon such as benzene, methane, or propane at 1000–1500 °C in the presence of a transition metal (Fe, Ni, or Co) or metallo-organics such as ferrocene, $(C_5H_5)_2Fe$ (Tibbetts *et al*. 1987). The catalyst plays a vital role in the growth of VGCFs. The carbon fiber yield is enhanced if a catalyst with a

small but broader distribution of particle sizes is used. VGCFs are produced in short lengths (50–70 mm) and small diameter (0.5–2 µm). Benzene, or other hydrocarbons which generate benzene during decomposition, are preferred as a precursor for a higher rate of production. These fibers have also been produced from low cost sources such as linz-donawitz converter gas and coal-derived hydrocarbons. These fibers possess very high mechanical properties but have a large scatter in the values.

The structure, and thus the mechanical properties of VGCF, are independent of the precursor gas source employed, but are extremely dependent on processing parameters such as temperature of growth, type and distribution of catalyst, etc. The aspect ratio of VGCF is found to be dependent on catalyst to hydrocarbon flow ratio. Low temperature deposition (<900 °C) results in vermicular filaments, while high temperatures (1500–2500 °C) favor the growth of long, straight filaments. Since VGCF are produced in a one-step process, these possess significant commercial potential as low cost carbon fibers.

Based on electron microscopic studies on the structure of the fibers, the growth process has been proposed consisting of two parts (Endo *et al*. 1977). In the primary process a thin tube of carbon is formed by catalytic growth on a catalyst particle. This is followed by secondary growth onto the first tube. VGCF consists of turbostratic carbon layers parallel to the fiber axis arranged in annular concentric sheets like rings in a tree trunk. The core is more perfectly ordered while the secondary sheets may contain some defects. VGCF are graphitizable carbons, and when heat treated to more than 2500 °C, develop a well-oriented graphitic structure and increase in density and Young's modulus.

2. Properties of Carbon Fibers

The mechanical properties of ex-PAN and ex-mesophase pitch (MP) carbon fibers are dependent on the heat treatment temperature of the fibers. The variation of mechanical properties of MP carbon fibers with heat treatment temperature is also included in Fig. 3. The tensile strength of PAN-based carbon fibers goes through maxima at about 1500 °C and 2000 °C, whereas the tensile strength of mesophase pitch-based carbon fibers continuously increases with heat treatment temperature. However, it is always lower than that of ex-PAN carbon fibers. The Young's modulus of both types of fiber increases continuously with heat treatment temperature. PAN-based carbon fibers heat treated to 1500 °C are termed high strength (HT) fibers, those heat treated to ~2000 °C are termed high strength high modulus (IM) fibers, and those heat treated to 2500 °C and above are termed high modulus (HM) fibers. Mesophase pitch (MP) carbon fibers consisting of
Figure 8
Present status of mechanical properties of commercial PAN-based and MP-based carbon fibers (after Edie 1998).
Figure 9
Young's modulus, thermal conductivity, and electrical resistance of some commercial carbon fibers.

well packed highly oriented graphitic layers posses very high densities ($>2.0\,\mathrm{g\,cm^{-3}}$) and a Young's modulus close to that of perfect graphite. MP carbon fibers possess a higher Young's modulus (600–700 GPa) than PAN-based carbon fibers. Mechanical properties of some of the commercial carbon fibers are shown in Fig. 8. Although VGCF posses a highly oriented graphitized structure, their mechanical properties are in the same range as for PAN-based carbon fibers. The thermal properties of carbon fibers are also controlled by the size, orientation, and

perfection of crystalline regions. Since Young's modulus is known to be directly related to the microstructural parameters, correlation is often derived between Young's modulus and the thermal properties of various carbon fibers. Figure 9 shows the correlation between Young's modulus and thermal conductivity of various carbon fibers. In general, PAN-based carbon fibers exhibit lower thermal conductivity than pitch-based carbon fibers. High performance MP pitch-based carbon fibers with ordered microstructure exhibit very high thermal conductivity nearing $1000\,\mathrm{W\,m^{-1}\,K^{-1}}$. These are known as high thermal conductivity carbon fibers. VGCFs with much higher thermal conductivity, in the order of $2000\,\mathrm{W\,m^{-1}\,K^{-1}}$, have been developed on a pilot scale. Mesophase pitch-based HM carbon fibers also possess excellent electrical and electronic properties.

3. Concluding Remarks

Carbon fibers are commercially available in different forms, e.g., short fibers, continuous tows, woven and nonwoven fabrics, braids, hybrid cloths, UD tapes, and MD woven preforms. They can be combined with virtually all types of matrices, i.e., polymer, ceramic, carbon, cement, and metal to manufacture composite products for different end applications. Most applications are found with polymeric

composites. Carbon fibers are given specific surface treatments and finishes compatible with a particular thermoset or thermoplastic resin system. Though initially developed for aerospace and aeronautics applications, in the 1990s these composites have been increasingly used in general industries such as sporting goods, automobiles, machinery, adsorbents and catalysts, electrical and electronic applications, and building materials. PAN-based carbon fibers, due to their balanced strength and modulus, dominate such applications whereas MP carbon fibers, with their high thermal conductivity, dominate the thermal management areas.

Isotropic pitch and rayon-based carbon fibers are excellent materials for the production of activated carbon fibers with very high surface areas (>1500 $m^2 g^{-1}$) and are likely to dominate as materials for liquid as well as gaseous adsorption and environmental protection.

In the energy sector, VGCF and carbon fibers with a platelet structure exhibit excellent hydrogen storage capacity. Carbon fibers can act both as a conductor, like metals, as well as a semiconductor. Therefore, these materials open up the possibility of their use in smart structures. Carbon fibers are known to have excellent biocompatibility and as such, as well as in composite form, have been successfully used as bioimplants (see *Carbon in Biomedical Engineering*[#]). Carbon fibers have low noise characteristics and have been successfully used in neurobiology for electrochemical detection of released compounds from single brain cells. Newer applications are being explored in various fields.

Future efforts are likely to concentrate on producing PAN-based carbon fibers with much higher strength and moduli, approaching those of pure graphite. General purpose, low cost, noncircular fibers with balanced mechanical properties, in addition to high thermal conductivity, will continue to be an attraction in the pitch sector.

Carbon Nanofibers

Considerable interest has been shown in understanding the process mechanism for the formation of carbon nanofibers, also commonly referred to as filamentous carbon. Carbon nanofibers are produced from the catalytic decomposition of hydrocarbon gases or carbon monoxide over selected metal particles that include iron, cobalt, nickel, and some of their alloys at temperatures over the range 400–1000 °C. Initial investigations in this area were motivated by the need to inhibit the growth of carbon nanofibers because of the persistent problems caused by accumulation of the material in a variety of commercial processes. Fundamental studies have demonstrated that carbon nanofibers possess an unusual combination of properties that include high surface area and high electrical conductivity. It is these features that have stimulated research efforts that are designed to optimize and control the formation of this type of carbon. One of the most outstanding characteristics of highly graphitic nanofibers is the presence of a large number of edges, which provide a tailored surface consisting of sites that are readily available for interaction with gases, liquids, or other solids. In this article the key steps in the growth mechanism of carbon nanofibers will be discussed, with emphasis being placed on the factors that control the degree of crystalline perfection and molecular architecture that can be achieved with these materials. Attention is also focused on the unique set of physical and chemical properties exhibited by carbon nanofibers, and areas where the material is finding application.

1. Growth Mechanism of Carbon Nanofibers

The growth mechanism leading to the formation of carbon nanofibers has been studied by many different groups and has been a source of debate, particularly with regard to the chemical state of the catalyst species and the driving force for the reaction. *In situ* electron microscopy techniques were used to observe directly the manner by which small metal particles generated carbon nanofibers during the decomposition of acetylene (Baker *et al*. 1972). From analysis of the recorded videotape sequences it was possible to measure rates of growth of the material and determine some of the kinetic parameters involved in the process. On the basis of these experiments, a growth mechanism was proposed that was later refined to include the following steps: (i) adsorption and decomposition of the reactant hydrocarbon molecule at a certain set of metal crystallographic faces, (ii) dissolution and diffusion of carbon species through the metal particle, and (iii) precipitation of carbon at a different set of crystallographic faces to form the nanofiber structure. It was argued that diffusion of carbon through the metal catalyst particle was the rate-determining step. This claim was substantiated by the close agreement between the measured activation energies for nanofiber growth and that for carbon diffusion through the respective metals that were used as catalysts in the process.

The chemical nature of the metal catalyst, the reaction temperature, and the composition of the reactant gas dictates the morphology and degree of crystalline perfection exhibited by the carbon nanofibers. Figure 1 is a schematic diagram designed to illustrate the key features of the growth mechanism
Figure 1
Schematic rendition of a graphite nanofiber and associated catalyst particle highlighting the key steps in the growth process.

for a particular type of carbon nanofiber structure. The hydrocarbon gas or carbon monoxide is initially absorbed and decomposed on the metal face (A) of the catalyst particle. This reaction with the surface results in the formation of chemisorbed carbon species that proceed to dissolve and diffuse through the bulk of the metal particle (B), ultimately leading to precipitation of carbon in the form of graphite platelets at the rear of the metal particle (C). The nanostructure formed in this example adopts a "herringbone" stacking arrangement (D) of the graphite platelets. As the heat balance is maintained in the reaction system, the carbon structure will continue to grow until perturbations occur in the chemistry of the leading face of the metal catalyst, thus causing a buildup of solid carbon at this interface, which results in deactivation and culmination in nanofiber growth. The driving force responsible for the carbon diffusion step is still not well understood. In the initial studies it was hypothesized that a temperature gradient was established within the catalyst particle, which resulted from an exothermic hydrocarbon decomposition reaction at the metal/gas interface and an endothermic precipitation reaction at the metal/solid carbon interface. An alternative and somewhat more plausible rationale has been suggested that relies on the participation of a carbon concentration gradient across the particle (Alstrup 1998).

One of the ramifications of the nanofiber growth process is that these structures can provide a means of transport for small metal particles. Initially the catalytic entity may be located on a support medium, at the grain boundary of a bulk piece of metal or part of a large powdered granule. As the growth of the nanofiber proceeds, the catalyst particle is detached from its original location and carried away from such a surface since it is now attached to part of the solid carbon structure. This aspect can have serious repercussions with regard to the behavior of a heterogeneous catalyst system, since the nature of the interaction with the support is being radically changed from the original state to one where the metal is exclusively in contact with carbon. This type of perturbation can cause major modifications in the performance of the catalyst system and in certain circumstances can lead to premature deactivation.

2. Synthesis of Carbon Nanofibers

Carbon nanofibers can be prepared in relatively large quantities using a variety of metals either in a powdered or supported form as the catalytic entities. The following protocol is followed for the synthesis of this form of carbon by the research group at Northeastern University. The metal catalyst is dispersed in a uniform manner across the bottom in a ceramic boat that is positioned in the center of a horizontal tube furnace. Initially, a 10% hydrogen/helium gas

mixture is introduced into the system to reduce the sample at 600 °C and after an appropriate interval of time the temperature is quickly brought to the desired reaction condition. A predetermined hydrocarbon/hydrogen or carbon monoxide/hydrogen reactant mixture is introduced into the system and the reaction generally allowed to proceed for periods of up to two hours. It is essential to regulate the supply of the various reactant gases by using well-calibrated mass flow controllers. Immediately following the growth sequence the reactant gas is replaced with helium and the sample cooled to room temperature. This is the general method for growing the carbon nanofibers in the laboratory and can produce various quantities of fibers; the most active systems can produce as much as 15 g quantities from a 100 mg catalyst charge weight.

In addition to powdered metals, other catalyst configurations are equally effective for the growth of carbon nanofibers: these include gauzes, foils, wires, or supported metal particles. These approaches can offer a simpler method for handling the nanofibers for various applications. When the nanofibers are generated from a supported metal catalyst system, it is of paramount importance to take into consideration the effect of the metal–support interaction on the subsequent mode of growth of the solid carbon. The nature of the support material will also have a direct impact on the location and size of the metal catalyst particles. These factors will in turn dictate the morphology and the properties exhibited by the nanofibers produced when the catalyst system is reacted in a hydrocarbon environment. When preparing a supported catalyst, the goal is to achieve a uniform distribution of the metal particles on the support medium. The metal particles for a given metal can be introduced onto the support surface using various methods and these are based on either aqueous or nonaqueous impregnation with solutions of metal salts or by evaporation of organic compounds that contain the metal particles. Indeed, if the aim is to optimize and engineer the growth characteristics of the nanofibers, this can be most easily accomplished by the careful choice of the support medium.

3. The Events Occurring at the Metal–Gas Interface

One of the major factors associated with the initiation of nanofiber growth is the nature of the interaction between the metal catalyst particle and the carbon-containing reactant gas. In order for the reaction to proceed, the hydrocarbon must undergo dissociative chemisorption on the metal surface, a process that leads to rupture of C=C and C—H bonds in the molecule. In many cases, this step requires a rearrangement of the metal atoms in the set

of crystallographic faces at which adsorption of gas-phase species occurs. Since hydrogen is known to facilitate the reconstruction of metal surfaces, the presence of this gas in the reactant mixture plays a key role in the carbon nanofiber growth and also has a direct impact on the catalyst lifetime. It is important to note that even though a given series of metals have similar surface orientations, the characteristics exhibited by the faces do not exhibit the same pattern of behavior with respect to adsorption and decomposition of hydrocarbons. Various options are available to increase the catalytic activity of a given metal towards the growth of carbon nanofibers that are based on the introduction of other elements either directly into the catalyst particles or as additives to the gaseous reactant mixtures. These two aspects will be discussed under separate headings.

3.1 Incorporation of Solid Additives

The introduction of other metallic components into a host metal has been found to exert a dramatic impact on the behavior of the catalytic system towards the growth of carbon nanofibers. It is frequently found that when copper is added to one of the iron-type transition metals there is an enhancement in the formation of the solid carbon product and furthermore, the morphology and degree of crystalline perfection of the nanofibers is altered to a significant extent. Perhaps one of the most intriguing reactions was observed with the copper–iron system. When copper or iron powders were heated in the presence of an ethylene/hydrogen mixture at 600 °C the metals exhibited little or no ability to catalyze the formation of carbon nanofibers. In sharp contrast, when a very small amount of one of these metals was added to the other component then, on subsequent exposure to the same reactant gas, prolific growth of this form of solid carbon was achieved (Krishnankutty *et al.* 1996). In other investigations it was found that if as little as 1.0 wt.% of either silver or tin (Chambers *et al.* 1996, Nemes *et al.* 1998) was added to powdered cobalt, these additives also caused a dramatic increase in the activity of the host metal towards the production of carbon nanofibers from the decomposition of ethylene. It was suggested that some of the observed enhancement in catalytic activity could be due to the existence of electronic perturbations of cobalt, induced by the presence of either tin or silver, that are manifested in modifications in the adsorption characteristics and subsequent decomposition characteristics of ethylene on the bimetallic surface.

3.2 Incorporation of Gas-phase Additives

In investigating the various features of carbon nanofiber growth one thrust of the research has focused on the effects of incorporating controlled

amounts of certain nonmetallic species into the catalyst system via the addition of such species to the gaseous reactant mixture. Studies indicate that the activity of the metal catalyst towards carbon nanofiber formation can be promoted to a significant degree by introducing controlled amounts of certain gas-phase additives such as hydrogen, sulfur, carbon monoxide, and chlorine (Kim *et al.* 1993, Rodriguez *et al.* 1993, Chambers and Baker 1997).

Treatment of iron in an ethylene/hydrogen mixture at 600 °C was found to result in only minor decomposition of the hydrocarbon and, as a consequence, under these conditions the formation of carbon nanofibers was insignificant. The addition of carbon monoxide to the reactant, however, caused a dramatic change in the catalytic activity of the metal particles, and under these circumstances relatively large amounts of solid carbon were produced. Maximum reactivity of iron was realized from the interaction with a C_2H_4–CO–H_2 (3:1:1) mixture. Removal of carbon monoxide from the system resulted in a rapid decline in activity; however, upon re-introduction of the additive activity was restored to its previous high level, showing that the activation–deactivation processes associated with the iron catalyst were completely reversible in nature. The pattern of behavior exhibited by the catalyst was rationalized in terms of reconstruction of the iron surface in the presence of coadsorbed carbon monoxide, a process that is responsible for the creation of faces that favor dissociative chemisorption of ethylene (Rodriguez *et al.* 1993).

In an analogous set of experiments the influence of small concentrations of chlorine (75–100 ppm) on the decomposition of ethylene over iron and cobalt catalyst systems was investigated. The results indicated that at temperatures in the vicinity of 400 °C, the catalytic activity of both metals with respect to the formation of carbon nanofibers from the decomposition of ethylene was significantly enhanced by the presence of a critical amount of chlorine in the reactant mixture (Chambers and Baker 1997). It is well known that the chemisorption of sulfur on a metal surface can result in poisoning and premature catalyst deactivation (Rostrup-Nielsen 1984). However, there are reports in the literature that very low concentrations of sulfur can actually exert a promotional effect on the performance of a metal catalyst (Reyniers and Froment 1995). In this context it was found that when an ethylene/hydrogen reactant mixture containing about 10–50 ppm levels of hydrogen sulfide was passed over iron, cobalt, or nickel at 600 °C, there was a substantial increase in the yield of carbon nanofibers compared to that found in the absence of the additive molecules.

In summary, one can conclude that the incorporation of controlled amounts of certain gas-phase (sulfur, chlorine) or solid additives (copper, tin, silver) into the reaction system can dramatically enhance the

catalytic activity of the host metal towards carbon nanofiber formation. While geometric factors may play a dominant role in the modification in catalytic performance, one must also be cognizant of the fact that the introduction of the adatom can induce electronic perturbations in the surface of the host metal, which in turn will exert an impact on the adsorption characteristics of a hydrocarbon molecule.

4. Events Occurring at the Metal–Carbon Interface

The degree of crystalline perfection of the deposition carbon nanofiber is dictated by a number of factors including the chemical nature of the catalyst particle, the composition of the reactant gas, and the reaction temperature. It has been established that the graphitic nature of carbon nanofibers is controlled to a large degree by the wetting properties that exist between the metal and deposit, i.e., a strong interaction must exist between the two components. It has been demonstrated that in order for dissolved carbon to be precipitated in a highly crystalline form, there must be a registry between the interstitial spacing of the metal atoms at this interface and atomic spacing of carbon atoms in graphite (Yang and Chen 1985). Surface science studies have established that certain crystallographic faces of a metal favor precipitation of dissolved carbon in the form of graphite, whereas less ordered forms will be deposited from other faces (Goodman *et al.* 1980, Nakamura *et al.* 1989).

Investigations using controlled-atmosphere electron microscopy techniques have revealed that certain metals can readily undergo a spreading action along the edge regions of graphite under reducing conditions (Baker 1995). On the basis of these data it is possible to make predictions with regard to the structural perfection of nanofibers generated from a given catalyst system with ethylene/hydrogen at a temperature between 500 °C and 650 °C. Indeed, it is a detailed understanding of the properties exhibited by the two components at the interfacial region that enables one to catalytically engineer the growth characteristics of these novel materials.

In addition to controlling the degree of crystalline order exhibited by the nanofibers, the orientation of the crystallographic faces existing at the metal–carbon interface is responsible for imposing the particular geometric arrangement of the graphite platelets adopted by these structures (Rodriguez *et al.* 1995). Transmission electron microscopy studies have demonstrated that the nanofibers can exist in various conformations, some of which are presented in Fig. 2. In Figs. 2(a) and 2(b) the nanofibers have been generated via a bidirectional mode where the carbon precipitation process occurs from opposite faces of the catalyst particle, which remains embedded within the structure during the entire growth period. The
Figure 2

type of nanofiber shown in Fig. 2(c), however, is produced by a mode in which carbon precipitation occurs at the sides of the particle, which is located at the growing tip of the structure. These three types of structures share a number of common characteristics, including the fact that the width of the nanofibers is the same as that of the associated catalyst particle. A further feature is that the nanofibers are relatively straight, indicating that the carbon diffusion characteristics through the particle are symmetrical.

Figures 3 and 4 show the corresponding high-resolution micrographs and three-dimensional schematic renditions, respectively, of the carbon nanofiber structures presented in Fig. 2. Detailed examination reveals that the graphite platelets constituting the material shown in Fig. 4(b) are stacked in a direction that is perpendicular to the fiber axis, adopting the arrangement of a "deck of cards." This arrangement is to be contrasted with that presented in Fig. 4(c) where the graphite sheets are aligned parallel to the fiber axis, adopting the structure of a "multiwalled faceted nanotube." Inspection of the structure shown in Fig. 4(a) indicates that in this case the graphite platelets are at an angle to the fiber axis in a so-called "herring-bone" arrangement.

The unusual spiral form of nanofiber, highlighted in Fig. 5, is believed to originate from a perturbation in the diffusion characteristics of carbon species through the catalyst particle, brought about by the participation of either sulfur or phosphorus compounds which introduce an element of asymmetry into the system (Motojima *et al.* 1991, Owens *et al.* 1994). Such a condition could arise if the reconstruction of certain faces forced the particle to adopt an irregular shape during the formation of the nanofiber, or if adsorption of the adatoms occurred at certain faces of the particle and interfered with the carbon precipitation step, thus creating an anisotropic growth pattern.

5. Properties of Carbon Nanofibers

The unique configurations adopted by carbon nanofibers provide the material with a rare set of properties; a high electrical conductivity combined with a large fraction of active sites, that correspond to the exposed edge regions of the graphite platelets, are available for chemical and physical interaction with various species. Perhaps one of the most unexpected findings is that such ordered crystalline solids can exhibit high surface areas ($300–700\,m^2g^{-1}$), where the totality of the surface area is chemically active. From the physical point of view, carbon nanofibers vary from $5\,\mu m$ to $100\,\mu m$ in length and are $5–100\,nm$ in diameter.

A further factor to be taken into consideration is the functionality of the carbon nanofiber surface. When graphitic materials are in their pristine state

and free of surface oxygen groups they are hydrophobic in nature. Following normal activation procedures such materials exhibit a certain degree of hydrophilic character. It has been demonstrated that following treatment in an oxygen plasma, acidic groups were introduced onto the carbon surface, while nitrogen and ammonia plasmas produce basic functionalities (Esumi *et al.* 1989). The possibility of controlling the acid–base properties of the carbon nanofiber surface could have a direct impact on a variety of potential applications.

The information gathered to evaluate the mechanical properties of carbon nanofibers is very restricted. This is because of the difficulty involved in manipulating these microscopic structures. Despite this limitation it has been established indirectly that certain types of nanofibers possess very good mechanical properties. For example, the material can be used in liquid-phase reactions where it can withstand vigorous agitation without disintegrating and also provide improved transport properties over those found with more traditional adsorbates. Furthermore, because of their size dimensions, separation of the nanofibers from liquid-phase reactants and products make such structures desirable for catalytic and filtration systems. Motojima *et al.* (1991) devised a series of experiments to determine the elastic properties of coiled carbon nanofibers by performing transmission electron microscopy to record the observations and measurements. They fixed one end of the nanostructure to a piece of copper while the other end was pulled to extend the coiled structure, thus determining the extension ratio. This parameter was determined as a function of the original coil length and it was found that the structures studied could be 3.0 times extended elastically from its original length and 4.5 times semielastically.

A technique which involved the dispersion of the material in a solvent followed by precipitation onto lithographically defined gold contacts to make a "nanowire circuit" was used to determine the electrical resistivity of individual $10\,nm$ sized nanofibers (Whitesides and Weisbecker 1994). A resistivity of $9.5\,\Omega m$ was estimated for carbon condition along the fiber axis, which suggests that the materials could be useful for building nanoscale electronic devices.

6. Applications of Carbon Nanofibers

It is recognized that some exciting opportunities exist for exploiting the potential of carbon nanofibers in a variety of applications. Potential applications may include new technological devices that can possibly be used for energy storage or employed to clean the environment. For these particular applications, the surface area of the material and its adsorption properties are of great importance.

The unique blend of structural properties exhibited by certain types of carbon nanofibers, which are composed of an infinite number of extremely short and narrow pores, makes such materials ideal for trapping small organic molecules. This concept is based on the principle that a strong interaction is likely to be established between the organic impurity and the nonpolar basal regions of the graphite platelets constituting the nanofiber structure. However, adsorption of water will not be favored at these sites and, as a consequence, the material will function as a selective adsorption agent. Investigations (Fenelonov *et al.* 1995, Park *et al.* 1999) have demonstrated that this is a viable approach, from experiments in which the nanofiber adsorbate system was able to selectively remove alcohols from water in a much more efficient manner than that displayed by samples of high surface area active carbon. Furthermore, they found that the performance of the nanofibers could be improved when the materials were pretreated in 1 M hydrochloric acid.

The ability to tailor the structural characteristics of carbon nanofibers so that the product has the unusual dual properties of high surface area, normally associated with active carbon, and a high degree of crystalline perfection more typical of graphite, thus giving rise to high electrical conductivity, makes these

102

materials ideal for use as support media. The unusual arrangement of the surface carbon atoms encountered in these materials offer some fascinating methods to control the structure of supported metal particles and induce major changes in their catalytic performance. By following this same protocol it is possible to use the nanofibers as templates for the vapor deposition of metal oxides that are likely to grow in an epitaxial format on the substrate surface. A number of investigations have focused on the modifications in both particle morphology and catalytic performance brought about by supporting metal crystallites on carbon nanofibers (Rodriguez *et al.* 1994, Planeix *et al.* 1994, Hoogenraad *et al.* 1995, Chambers *et al.* 1998a, Park and Baker 1998). The exposed surfaces of some of these materials consist entirely of graphite edges that are separated by a distance of 0.335 nm and these features provide a template for the deposition of metal crystallites where the surface atoms adopt arrangements that are not generally encountered on other conventional support media, such as active carbon, silica, or γ-alumina.

Experiments performed with nickel particles supported on graphite nanofibers showed that these systems exhibited unusual properties with regard to the selectivity patterns obtained for the hydrogenation of olefins and diolefins when compared to the behavior found when the metal was dispersed on oxide carriers (Rodriguez *et al.* 1994, Chambers *et al.* 1998a, Park and Baker 1998). This enhancement in both activity and selectivity was attributed to the fact that the nickel crystallites were located on the edge sites of the nanofibers and, as a consequence, the arrangement of the metal atoms was governed by the interaction with the carbon atoms in these regions. Under such circumstances one might expect different crystallographic faces of nickel to be exposed to the reactant gas compared to those present when the metal was dispersed on less ordered materials. This claim was supported by the observations from high-resolution transmission electron microscopy examinations which revealed the existence of major differences in the morphological characteristics of metal particles supported on graphite nanofibers and γ-alumina. Close inspection of the metal particles supported on graphite nanofibers showed that they were preferentially aligned with respect to the fiber lattice. Furthermore, the hexagonal-shaped crystallites were very thin and flat, features consistent with the existence of a strong metal–support interaction.

The use of carbon nanofiber-supported nickel catalysts was extended to a reaction that is of technological importance, namely the selective hydrogenation of α, β-unsaturated aldehydes to the corresponding unsaturated alcohol (Salman *et al.* 1999). The results of these experiments, which were carried out over the range 75–150 °C, were compared with those obtained when the same metal loading was dispersed on γ-alumina. It was extremely encouraging

to find that at this upper temperature the activity and selectivity of the nanofiber-supported catalyst systems (78% crotyl alcohol) was significantly higher than the alumina-supported system (12% crotyl alcohol). This outstanding performance was attributed to a combination of factors, the unusual crystallographic orientation of nickel particles and the possibility that electronic perturbations were being induced in the metal from interactions with the electrically conductive nanofiber support media.

It is well known that advanced polymeric composites have several advantages (including high specific strength and energy absorption, low weight, styling flexibility, good noise/vibration/harshness characteristics, and excellent corrosion resistance) that make such materials ideal for fabrication of body parts for heavy vehicles. The high strength-to-weight ratio, combined with superior stiffness, has made carbon fibers the material of choice for high-performance composite structures. Carbon fibers have been used to reinforce several matrices, including polymers, metals, and ceramics. Unfortunately, these composite structures suffer from a number of shortcomings, including inadequate interlaminar shear properties and fiber pull-out. Several approaches have been used in an attempt to enhance the interfacial properties between the carbon fibers and the matrix; however, in many cases these treatments can induce severe damage to the fiber surface, which ultimately leads to a weakening of the structure.

An attempt was made to modify the chemical, physical, and mechanical properties of carbon fibers via the catalytic growth of carbon nanofibers on their surfaces (Downs and Baker 1991, 1995). In this work the emphasis was placed on establishing conditions for the optimum growth of carbon nanofibers without inducing a corresponding degradation in the mechanical properties of the parent fibers. Using this "whiskerization" protocol, tests demonstrated that it was possible to achieve an improvement of over 4.5 times in the interfacial shear strength of the fibers following the deposition of a critical amount of nanofibers.

In a further investigation it was shown that the incorporation of carbon nanofibers into various epoxy resins had a dramatic impact on the curing reaction; small amounts of the filler tended to retard the process, whereas large amounts of nanofibers exerted the opposite effect (Yin *et al.* 1993). Modifications in the curing characteristics were compared with those produced from the incorporation of carbon black into the same resins, and major improvements in both the mechanical and electrical properties of the composites were realized when large amounts of carbon nanofibers were present in the systems.

The failure to create a practical storage system has prevented hydrogen from reaching the commercial forefront as a transportation fuel. The ideal hydrogen storage unit should be lightweight, compact, relatively

inexpensive, safe, and reusable without the need for complex regeneration treatments. Four methods are currently being considered for hydrogen storage in commercial applications: (i) pressurized gas storage, (ii) liquefied hydrogen, (iii) selected metal hydrides, and (iv) refrigerated superactivated carbon. While the latter two approaches may offer advantages over the other technologies with regard to cost and safety aspects, they do have their own drawbacks. Metal hydrides are heavy, expensive, and release heat during the hydrogen absorption process. Active carbons are very effective adsorption agents for a variety of gases; however, interactions between the adsorbent and the solid are only of a physical nature, and as such, retention of hydrogen can only be achieved at cryogenic temperatures. It is clear that both storage and controlled release of hydrogen at moderate conditions of temperature and pressure are major issues that must be addressed if this technology is to be exploited commercially. The ideal solution would be an inexpensive, lightweight material capable of not only absorbing and retaining hydrogen at room temperature and moderate pressures, but also possessing the ability to release the gas at moderate temperatures. One type of material that fulfills these criteria is highly graphitic carbon nanofibers.

It has been demonstrated that when selected types of carbon nanofibers are pretreated under conditions whereby all adsorbed and absorbed gases are eliminated, then on subsequent exposure to hydrogen at moderate pressures, they are capable of absorbing and retaining up to 40% by weight of molecular hydrogen per gram of carbon at room temperature (Chambers *et al.* 1998b). The extraordinary hydrogen adsorption capacity exhibited by carbon nanofibers is attributed to the unique structural characteristics exhibited by these materials, which consist of an infinite number of graphite layers stacked at particular angles with respect to the fiber axis. Another important factor encountered with carbon nanofibers is that since the graphite platelets are held together by van der Waals forces and not by chemical bonds, the walls of the nanopores can readily undergo expansion to accommodate hydrogen in a multilayer fashion.

Carbon Nanotubes

Introduction

This article addresses the key issues on hand in carbon nanotube technology. It is apparent that carbon nanotubes work extremely well as field-emission sources and that the semiconducting variety of carbon nanotubes will be the ultimate ultraminiature field effect transistors that will be beneficial to a very large number of applications such as electronic devices and chemical sensors. The key challenges at present are to synthesize or separate carbon nanotubes according to their specific electronic properties so that they may be commercially viable for these envisaged applications. This article provides an overview of the rich variety of research and development in progress to attain these goals.

The discovery, nearly two decades ago, of the third ordered allotrope of carbon, referred to as buckyballs (or buckminsterfullerenes or C_{60}) by Kroto *et al.* (1985), opened the doors to the world of nanoscience and technology. It was this development that led to the discovery of other fascinating forms of nanocarbons, such as multiwalled carbon nanotubes by Iijima (1991) and, subsequently, the single-walled variant

almost simultaneously by Iijima and Ichihashi (1993) and Bethune *et al.* (1993). Since the 1990s, there has been extensive publication by a large number of researchers around the world in this field, and thus it has become extremely evident that the single-walled variant of carbon nanotubes (hereafter referred to as SWNTs) is an important component of the future of materials science. SWNTs can be considered as unique materials for several reasons: they are prototype one-dimensional quantum wires that are made up of one element (carbon), that are one atom in wall thickness and tens of atoms in circumference, with every atom on the surface of the tube. The theoretical as well as experimentally measured values of the mechanical properties of SWNTs, with elastic modulus and tensile strength calculated to be near 1000 and several tens of gigapascals (GPa), respectively, are comparable to those predicted for single sheets of graphite.

Perhaps the most exciting characteristics of SWNTs are their electronic properties, as reported by Avouris (2002), which depend exclusively on their diameter and chirality (the manner in which the single sheet of hexagonally arrayed carbon atoms is wound). The electronic structure and properties of SWNTs are based on those of a single layer of graphite and its own peculiar electronic structure, and can be broadly classified as being either metallic or semiconducting, which in turn can be further classified on the basis of individual tube diameters. The bandgap of a semiconducting tube (a critical attribute to be considered for nanoelectronic applications) is inversely proportional to the tube diameter. As described in this article, research on carbon nanotubes, with particular emphasis on SWNTs, clearly indicates that these materials are going to be key players in the arena of ''molecular electronics,'' in which the active part of the device is composed of either a single molecule or a few. However, several technical challenges need to be overcome before carbon nanotubes can be applied to electronic devices as commonly as silicon is nowadays. This article addresses some of these challenges and how the research community at the academic and industrial levels is attempting to overcome them.

1. Electronic Properties of SWNTs

The field of electronic properties of carbon nanotubes has perhaps been the most active area of research since their discovery in the early 1990s. Theoretical studies on the electronic properties of carbon nanotubes have been made using band structure calculations similar to those for planar single sheets of graphite, as described by Mintmire *et al.* (1992) and Saito *et al.* (1992). Considering the one-dimensional structural characteristics of nanotubes, the number of allowed electron states in the axial direction will be

large, whereas it would be significantly limited in the circumferential direction. In these studies, using conventional indices (n, m) to represent the chirality of the individual tubes, the electronic structure of the nanotube can be calculated on a basis analogous to that of a single sheet of graphite, with the additional imposition of the necessary boundary conditions due to the limits on the nanotube circumference. In terms of their electronic properties, carbon nanotubes can therefore be classified into two major groups—those with a moderate bandgap with $n - m \neq 3p$ (where n and m are the tube indices and p is an integer) and are electrically semiconducting, and those with a small bandgap that satisfy the relation $n - m = 3p$ and are electrically metallic in nature. These findings suggest that armchair (n, n) tubes would be metallic under all circumstances, and that zigzag (n, 0) and chiral (n, m) tubes would be metallic in one-third of the cases and semiconducting in the other two-thirds. It is also important to note that several other theoretical studies have demonstrated that "defect" structures on the tubes would lead to metal–semiconductor, semiconductor–semiconductor, and metal–metal junctions at the defect sites, which might themselves behave as nanoscale device elements, as demonstrated by Chico *et al.* (1996). Topological defects and atomic impurities in the tubes alter the local electronic density-of-states near the Fermi level, leading to localized variations in the dominant conductivity associated with the individual tube.

Recently, several research groups have attempted to measure the electrical properties of carbon nanotubes experimentally. The development of scanning tunneling microscopy (STM) and spectroscopy-based techniques has been particularly helpful in these experimental developments. The initial step of the experimental approach involves the dispersing of dilute suspensions of nanotubes onto patterned electrical contacts with the intention of contacting single nanotubes to two adjacent electrodes for electrical transport measurements. Considering that electrons in π-state control the electrical transport in nanotubes, the low-bias resistance of the nanotube for ballistic transport would be $h/4e^2$, which is ~ 6 kΩ. However, the two-point resistance of single-nanotube samples draped over platinum electrodes (or gold electrodes in other cases), which is shown in Fig. 1, was initially measured to be closer to 1 MΩ at room temperature, as reported by Tans *et al.* (1997). The key lesson from this initial experiment was that the contact resistance between the carbon nanotube and the metal electrode was a major factor in determining resistivity, and this was an issue that needed further consideration in future experiments. Also, the localized changing of the bond structure of the carbon atoms from sp^2-like to sp^3-like, when the nanotube was "draped" over the metal electrodes, led to significant resistivity enhancement; this was another serious technical issue to be addressed. But it was apparent from the initial
Figure 1

Reprinted by permission from Tans S J, Devoret M H, Dai H, Thess A, Smalley R E, Geerligs L J, Dekker C 1997 Individual single-wall carbon nanotubes as quantum wires. *Nature* **386**, 474–7 copyright 1997 Macmillan Publishers Ltd.

experimental analysis of electronic properties that carbon nanotubes behaved as coherent quantum wires and that the structure (chirality) was indeed a major factor in determining whether individual tubes were metallic or semiconducting (Wildöer *et al.* 1998). Recent experiments have also demonstrated that the conductivity of individual SWNTs depends significantly on adsorbed gases such as oxygen, making pure SWNTs extremely sensitive detectors for oxygen (Collins *et al.* 2000). These elegant experiments clearly confirmed the theoretical work on the electronic properties of carbon nanotubes, as did other experiments that confirmed that defect structures led to substantial enhancement in the resistivity of carbon nanotubes, as had been previously shown by Dai *et al.* (1996).

2. Dispersion and Separation of SWNT

Probably, the major concern for rendering SWNTs commercially viable for electronic devices is to be able to separate one tube from the next and to be able to classify them according to their electronic properties, such as whether they are metallic ballistic conductors or semiconductors. It would also be desirable to be able to separate the semiconducting nanotubes according to their respective chirality, which would be particularly important for nanoelectronic applications. Currently, SWNTs are synthesized by one of three different techniques—laser ablation, gas-phase catalytic growth from carbon monoxide (CO), or by chemical vapor deposition (CVD) from other hydrocarbon precursors, typically using nanometer-scale

transition metal catalysts mostly supported on oxides such as silica. The laser ablation and gas-phase catalytic growth from CO (referred to as HiPCO), techniques have been described in detail by Thess *et al.* (1996) and Nikolaev *et al.* (1999). Being a continuous flow process rather than a batch process, the HiPCO method offered the advantage of being able to be scaled up to produce SWNTs in kilogram quantities per day.

The processes described above, however, produced materials fraught with impurities, such as large amounts of disordered or glassy carbon in the case of the laser-ablation process or carbon-encapsulated catalyst iron particles adhering to the walls of the tubes in the HiPCO process. In either case, the tubes themselves were found to be a mixture of metallic and semiconducting types. In order to render SWNTs potentially useful for high-performance electronic devices such as field effect transistors or sensors, it is necessary to be able to obtain tubes that are mostly, or preferably, "only" semiconducting in electronic structure. The options available are processes that would enable high degrees of separation of the metallic tubes from the semiconducting ones. The ultimate "holy grail" would be a process or processes that selectively grow only semiconducting tubes (or preferably, semiconducting tubes with one chirality or a narrow set of chiralities) or only metallic tubes as the need may be. Analytical tools such as spectrofluorometric analysis in combination with resonance Raman scattering have already been demonstrated to map the chiralities of individual classes of SWNTs in a product, as illustrated by Bachilo *et al.* (2002) and reproduced in the on-line edition of the Encyclopedia of Materials: Science and Engineering, doi: 10.1016/B0-08-043152-6/00179-0.

3. Functionalization of Carbon Nanotubes to Enhance Selection and Separation

As-synthesized carbon nanotubes are highly polarizable, smooth-sided materials with attractive interactions of $\sim 0.5\,\mathrm{eV\,nm^{-1}}$ for tube-to-tube contact. At the dimensions of SWNTs, these cohesive forces are sizeable and cause the tubes to agglomerate into bundles. Inherently, these bundles are extremely difficult to separate into individual tubes for further manipulation or any potential uses of the SWNTs in other devices. Several types of functionalization schemes have been studied to potentially overcome these problems. Noncovalent functionalization, as for instance by the use of surfactants such as sodium dodecyl sulfate (SDS), leads to the identification of tube chiralities by fluorescence spectroscopy (O'Connell *et al.* 2002). Strategies for covalent functionalization of carbon nanotubes include defect creation or attachment of carboxylic acid groups to end-cap sites in order to provide local anchoring sites

for the functional groups, or direct covalent side-wall functionalization. The methodologies and resultant added groups attached to the walls of the carbon nanotubes have been reported by a number of researchers. The addition of preformed arene diazonium salts to micelle-coated nanotubes produces high levels of functionalization of aryl groups (estimated by Raman spectroscopy and thermogravimetric analyses to be as high as 10%) on the tube walls, as reported by Bahr *et al.* (2001). Functionalization of the tube walls at such levels causes the tubes to disperse well and stay dispersed in organic solvents. Figure 2 illustrates a transmission electron microscopic image of a single nanotube, its walls appearing rougher than typical nanotubes due to functionalization by aryl moieties. Other functionalization schemes that have been investigated are fluorination by Mickelson *et al.* (1998) and radical chemistry by Ying *et al.* (2003). A relatively lighter functionalization scheme was discussed by Georgakilas *et al.* (2002) involving a 1,3-dipolar cycloaddition of azomethyne ylide generated by the reaction of amino acid and aldehyde.

Recently, there have also been a number of both covalent and noncovalent functionalization chemistries that may be used to preferentially select metallic tubes over semiconducting tubes. The most striking one among these studies is the one reported by Zheng

et al. (2003), showing that single-stranded DNA molecules with specific sequences can self-assemble onto the highly ordered surfaces of SWNTs, which allows not only for the separation of metallic from semiconducting tubes but also for separation of semiconducting tubes based on individual diameters.

4. Device Fabrication

Of the various existing and potential applications involving carbon nanotubes, none appears to evoke so much interest or excitement as the use of single nanotubes (particularly single semiconducting SWNTs), as field effect transistors (FETs) at room temperature. What is driving this particular application/technology? Conventional semiconductor lithographic techniques are reaching their theoretical, practical, and possibly economic limits. The demand /value for continuing shrinkage of scale will probably keep growing even after conventional structures have reached these limits. From a technological standpoint, *n*-type FETs, where transport through the semiconducting SWNTs is dominated by electrons and not by holes, allow the fabrication of nanotube-based complementary logic devices and circuits. This can be achieved by converting the predominantly *p*-type SWNTs to *n*-type SWNTs by either alkali-metal doping or by annealing the device either in vacuum or in an inert atmosphere, which results in oxygen removal that subsequently alters the line-up of the valence bands at the electrode–nanotube junction (Derycke *et al.* 2002). Other efforts to develop this technology include lowering the contact resistance of the nanotube–electrode junction by "end-bonding" the nanotube to metals such as titanium (Martel *et al.* 2001), and altering the configuration of the gate electrodes to improve the overall electrical characteristics (Wind *et al.* 2002). Most recently, researchers in Infineon Technologies AG have successfully demonstrated the fabrication and operation of a sub-20 nm FET based on SWNTs (Seidel *et al.* 2005) using electron beam lithography with select e-beam resists. This device performs as well as much larger state-of-the-art silicon-based devices in many aspects with high on/off current ratios. A schematic of the process flow for this device and its current–voltage performance is illustrated in Fig. 3.

5. Advances in Field-emission Display Technology

The unique combination of the physical structure (high aspect ratio and nanometer-scale radius of curvature of the tip), mechanical properties such as stiffness and strength, and the chemical stability of the single graphite sheet that constitutes its surface makes the carbon nanotube a consummate field-emitting device. Several research groups have demonstrated that thin ropes of single-walled nanotubes are superb

field-emitting sources that show high emission properties (lower turn-on voltage and higher emissivity). The heart of such devices is the cathode, where the nanotubes serve as emission sources following appropriate fabrication techniques. In prototype demonstrations using a 4.5-inch diode-based flat panel display with ropes of single-walled tubes serving as emitting sources, researchers in the field-emitting display program at Samsung have demonstrated that the device can be turned on at low voltages (less than $1V\,\mu m^{-1}$), and the brightness measured on the green phosphor (ZnS:Cu, Al) of the screen was ~ 1800 candelas per square meter at $4V\,\mu m^{-1}$ (Choi *et al.* 1999). This development appears to be well on its way to commercialization with the recent demonstration of SWNT-based field emitters with gated structures, which allow the addressing of individual pixels and the subsequent development of video running image displays. The schematic of the field-emitting display

with SWNTs as emission sources with a gated structure and the flat panel display video image obtained from it are shown in Fig. 4. However, in the huge market for high-definition televisions, currently in excess of US $60 billion annually, carbon nanotube-based field-emission display televisions would have to compete against other existing and rapidly growing technologies such as plasma and liquid crystal displays. Several factors such as cost of manufacture, stability, power usage, and viewer-friendliness will ultimately determine the future of carbon nanotube-based field-emission technology in the long run.

6. Latest Advances in Synthesis Techniques

While it may appear that the research community at large is working on finding applications for carbon nanotubes, efforts to synthesize them with the desired structure or without impurities are still underway. Most recently, Li *et al.* (2004) have demonstrated a relatively low temperature (600 °C) plasma-enhanced CVD technique to produce SWNTs that are nearly 90% semiconductors. Analysis of this product by microscopy and Raman spectroscopy reveals that the nanotubes are of high quality, as illustrated in Fig. 5.
Figure 6

Copyright 2004 AAAS. Permission from AAAS is required for all other uses.

CVD, with the assistance of water, was also used recently to demonstrate that thick and aligned "forests" of SWNT can be grown where the catalysts can be easily separated from the tubes to provide carbon purities well in excess of 99% (Hata *et al.* 2004)—images of this new material are shown in Fig. 6. Although this latest offering has not yet been tested for any particular properties, it is easily conceivable that it could find use in a number of commercial applications.

Carbon–Carbon Composites

For many applications the ideal structural material would have high strength and stiffness and low

density. For high-temperature service, the material should also retain its mechanical properties at elevated temperature, be resistant to thermal shock, and be resistant to creep. Perhaps better than any material, carbon–carbon fulfills these requirements. Carbon–carbon is the most highly developed ceramic composite and consists of carbon fiber reinforcement of a carbon matrix as shown in Fig. 1. The fibers and matrix are evident in the scanning electron micrograph, and conical regions of matrix are seen in the optical micrographs.

Carbon–carbon is used as the friction material in aircraft brakes, nose cones of ballistic missiles, leading edges in high-performance aerospace vehicles such as the US Space Shuttle, and as turbine rotors and other high-temperature engine and rocket components. The range of applications has been broadened to include thermal management in electronic components and heat pipes where the very high thermal conductivity of certain carbon–carbon composites is advantageous. This article provides a brief history of carbon–carbon followed by a description
Figure 1
(a) Scanning electron, (b) optical polarized light, and (c) optical micrographs of carbon–carbon composite.

of fabrication processes. The influence of processing on the microstructure and properties of carbon–carbon are also briefly presented. Applications and cost of carbon–carbon are also reviewed. The reader is referred to several publications on carbon–carbon (Buckley and Edie 1993, Chung 1994, Fitzer and Manocha 1998, Savage 1993, Thomas 1993).

1. History of Carbon–Carbon

Graphite, the form of carbon having a hexagonal crystal structure, is an attractive material for applications at elevated temperatures in an inert atmosphere because of its high sublimation temperature, its retention of strength with increasing temperature, and its chemical inertness. However, the strength and fracture toughness of graphite are less than that desired for many structural applications. Reinforcement with strong carbon fibers, which became available in the late 1950s, improves both strength and toughness significantly.

Carbon composites were initially developed for the US Air Force space plane project and NASA's Apollo projects and received increased emphasis as a result of the US Space Shuttle program (Buckley and Edie 1993). Following this success, extensive work was performed on carbon–carbon both in the USA and Europe in the early 1970s, mainly for military applications (Warren and Williams 1972, Kotlensky 1971, 1973, Pierson 1967, Pierson *et al*. 1968, Granoff *et al*. 1973, Theis 1972, McAllister and Teverna 1972, Fitzer *et al*. 1978, Girard 1978). The original carbon composites used low-modulus rayon precursor fibers in the form of woven fabrics. The matrix was derived from the pyrolysis of phenolic and furan resins or was deposited via the chemical vapor infiltration (CVI) process which is described later. Good reviews are those of Kotlensky (1973) and Lackey and Starr (1990). Since the 1970s major developments have taken place in the production of high-modulus polyacrylonitrite (PAN) and pitch-derived fibers for use as reinforcements (Buckley and Edie 1993, Chung 1994, Fitzer and Manocha 1998).

2. Fabrication of Carbon–Carbon

Carbon–carbon composites are fabricated by starting with an array of carbon fibers referred to as the preform. The fibers typically fill about half of the preform volume. The remaining space is void until the carbon matrix is formed by either a liquid impregnation or gaseous infiltration process. The matrix holds the fiber array together and transfers mechanical loads experienced in service to the fibers.

2.1 Fiber and Preform Types

Many different types of carbon fibers are commercially available for use as the reinforcement constituent in carbon–carbons (Buckley and Edie 1993, Chung 1994). Mechanical properties such as tensile strength and physical properties such as thermal and electrical conductivity vary extensively from one fiber type to another. For example, PAN- and pitch-derived fibers are much stronger and have a higher elastic modulus than rayon-derived fiber. Even for a given fiber type, the properties and cost are strongly dependent on the highest temperature the fibers experience during processing. Higher temperatures encourage a greater percentage of the graphite-like crystals comprising the fiber to orient with their crystallographic *c*-axis perpendicular to the long axis of the fiber. Since the crystals are highly anisotropic, the properties of the fiber vary depending on the processing conditions. Increased preferred orientation of the crystals typically increases the elastic modulus as well as increases the anisotropy of the fiber. Broad ranges for tensile strength, elastic modulus, and fiber cost are, respectively, 1–5.7 GPa, 100–800 GPa, and US$2–50 per kilogram (Chung 1994). Fiber diameters are typically 7–10 µm but much smaller discontinuous fibers called "whiskers" may have a diameter less than 1 µm. For additional details on carbon fibers and whiskers see *Carbon Fibers**. Carbon whiskers produced by Applied Sciences, Inc. of Cedarville, Ohio have exceptional crystallinity as shown in Fig. 2. These whiskers have very high thermal conductivities, approaching that of diamond (Ting *et al*. 1995).

Preforms are typically comprised of carbon fibers in either continuous or chopped form. The fibers are
Figure 2
Highly crystalline, vapor-grown carbon whisker with basal planes oriented parallel to the surface of a central, less crystalline region.

often woven into cloth and preforms are readily fabricated by cutting and stacking the cloth layers. Adjacent layers are typically rotated 30° or 45° from one another so that fibers are oriented in several directions, although only 0–90° orientations are often used. Such two-dimensional preforms yield composites having high strength, elastic modulus, and conductivity in the plane of the component that is parallel to the cloth layers. Properties perpendicular to the lay-up plane are much inferior. Three-dimensional weaving and other textile processes can be used to orient some fibers in the transverse direction if the application requires more nearly isotropic properties.

Preforms are also regularly made by felting and slurry molding processes. The fibers or whiskers in such preforms do not all lie within one plane and thus the preforms are not as anisotropic as two-dimensional preforms. Previously the preforms for brakes were made by cloth lay-up, but cost considerations and the desire for improved properties in the transverse direction have led to the use of noncloth preforms. The latter typically have lower fiber contents than cloth lay-ups which may be as high as 60 vol.%. Several good descriptions of preform types are available (Buckley and Edie 1993, Fitzer and Manocha 1998).

2.2 Matrix via Liquid Impregnation

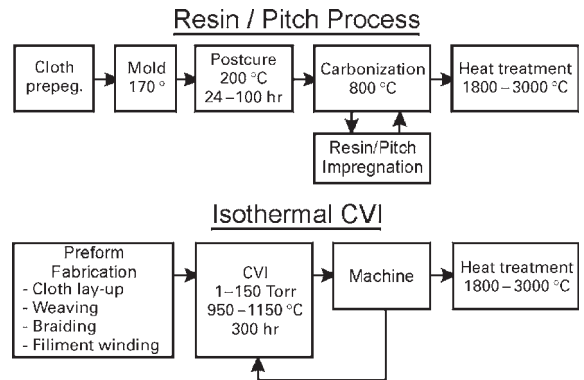
Carbon–carbon composites are fabricated using either the liquid impregnation method or CVI. In the former, the preform is impregnated with a polymer resin or coal tar or petroleum pitch which is then carbonized, i.e., heated in an oxygen-free atmosphere to cause volatilization of all elements (hydrogen, nitrogen, etc.) except carbon. Evacuation and pressurization may be used to assist flow of the liquid into the preform. Carbonization may also be performed at high pressure, such as in an autoclave. A subsequent higher temperature process step, called graphitization, which is conducted in the range 1500–3000 °C can be used to cause the carbon matrix to approach the crystal structure of graphite. A process diagram showing the steps involved is shown in Fig. 3. The resin and pitch shrink during carbonization, necessitating numerous cycles of impregnation and carbonization in order to obtain dense, i.e., low-porosity, composites. Sometimes components are initially densified using the impregnation process with CVI being used later to further reduce matrix porosity. A carbon matrix derived from pitch is more easily graphitized than when resin is used and thus pitch-derived composites are used for certain high-temperature and thermal management applications where thermal stability and/or high thermal conductivity are important. The CVI process can also yield a matrix that is readily graphitized. Carbon–carbon made by the CVI process has better structural properties


Figure 3
Processes for fabrication of carbon–carbon.
Figure 4

than material made by multiple impregnation–carbonization cycles since shrinkage does not occur, and is thus often preferred for critical applications (Kotlensky 1971).

2.3 Matrix via CVI

The CVI process for fabricating carbon–carbon begins by placing the carbon fiber preform in a furnace (Lackey and Starr 1990). Gaseous chemical vapor deposition (CVD) reagents that are flowing inside the furnace penetrate the pores of the preform and deposit a coating of solid carbon onto the fibers. Methane, propane, or other hydrocarbons, including mixtures, may be the active reagent. Diluent gases may be hydrogen, nitrogen, or argon. As this deposition process continues, the fibers get larger and consequently the spaces between the fibers become smaller. Eventually, the fiber coatings interlock and the fibers are held together by the coating. The carbon coating is the matrix which, along with the fibers, constitute the composite. The micrograph in Fig. 4

gives an insight into the process. The contour of fibers which have been coated with carbon are visible on the surface of the pore. The original cross-sections of several fibers are outlined in white.

A brief history of the CVI process is available (Lackey and Starr 1990). The CVI process for the deposition of carbon was first used to increase the density of graphite. Similar CVI processing is used to fabricate the highest-quality carbon–carbon. There are eight variants of the CVI process, depending on whether: (i) the reagents diffuse into or are forced to flow through the preform, (ii) the preform is isothermal or exposed to a temperature gradient, and (iii) the gas pressure is uniform or pulsed by cyclic evacuation and pressurization. In addition, the preform may be heated by one of several means including resistance, radiation, and induction.

Of the eight basic processes, primarily three have been used for fabrication of carbon–carbon. Industrially, large quantities of carbon–carbon for friction applications are made using the diffusion-isothermal process without pulsing. This process is often referred to as "isothermal CVI". Industrially, several thousand brake parts are placed in a furnace having a diameter of the order of 3 m. Hydrocarbon gases continually flow through the furnace which operates at temperatures in the range 950–1150 °C and pressures of 0.1–20 kPa (Kotlensky 1973). Typical values are 1100 °C and 0.6–6 kPa. Exact processing details, including processing time, are considered proprietary.

With the isothermal CVI process, deposition occurs preferentially onto fibers located at or near the external surface of the preform. As a result, the density of the completed component is less at the center of the preform. In order to minimize the density (porosity) gradient through the thickness of the component, the process variables are selected to retard the kinetics of carbon deposition relative to the diffusion of reagent. Increased uniformity is achieved by the use of lower temperatures, pressures, and reagent concentration even though processing times are lengthened. The infiltration time can be as long as three weeks. Since deposition occurs preferentially at the surface, a dense skin forms which hinders diffusion of reagents into the component. Typically, the infiltration process is interrupted after one and two weeks to permit removal of the dense surface region by machining. Alternatively, some manufacturers choose to adjust the process variables to further reduce the kinetics of the carbon deposition reaction. This increases the time required to complete infiltration but may permit the elimination of one of the machining steps. When the infiltration process is completed, the outer denser region of the component may also be machined away in order to produce a material having minimal variation in density through the thickness of the component. The final density of carbon–carbon used in aircraft brakes is in the range 1.70–1.85 g cm^{-3} (Tatarzycki and Webb 1992).

Another type of CVI process which has been used for many years to produce carbon–carbon nose cones for ballistic missiles also uses diffusion of the reagent, but a steep thermal gradient is present through the thickness of the preform (Kotlensky 1971). One surface of a carbon fiber preform, for example the inside surface of a nose cone as shown in Fig. 5, is in contact with a graphite susceptor which is heated inductively. Hydrocarbon reagents that are flowing through the reaction vessel diffuse through the cooler outer surface of the preform toward the hotter inner surface. When the reagents become suitably heated, they decompose, forming a carbon deposit on the fibers. This densifies the inner portion of the cone and increases its thermal conductivity so that the temperature gradient through the thickness of the cone slowly changes with time. Gradually, over a period of tens of hours, the deposition front moves toward the outer surface of the preform (Theis 1972, Kotlensky 1973). This inside-out deposition process prevents the formation of a dense surface skin and parts can be made more rapidly and without interrupting the process for machining.

A third CVI process uses forced flow of reagent plus a thermal gradient and is referred to as the forced flow–thermal gradient (FCVI) process (Lackey and Caputo 1986, Lackey and Starr 1990). In order to force reagent to flow through the preform, a special holder is required as shown in Fig. 6 (Lackey
Figure 5
Conical preform being densified by the diffusion–thermal gradient CVI process (after Buckley and Edie 1993).
Figure 6
Apparatus for forced flow–thermal gradient CVI.

Figure 7
Calculated and observed oxidation rates for carbon–carbon (after Luthra 1988).

1996). The process is most highly developed for disks and tubes. In either event, the holder also permits cooling of one surface and heating of the other. The reagent stream first contacts the cooler surface and exits the hotter surface. Opposing factors permit densification to proceed uniformly throughout the thickness of the component, as follows. Slower deposition kinetics at the cooler surface favors less deposition than at the hot surface, but this is balanced by the fact that the higher reagent concentration at the cooler surface favors more deposition. In other words, some of the hydrocarbon is consumed as the reagent stream flows through the preform toward the hotter surface. By using experimentation and process modeling, it is possible to choose temperatures, temperature gradient, pressure, and reagent concentration and flow rate so that components with minimal spatial variation in density can be fabricated in less than five hours (Lackey and Vaidyaraman 1999, Vaidyaraman *et al.* 1996a, 1996b).

The three major processes for fabricating carbon–carbon have various advantages and disadvantages. The isothermal CVI process excels in that a large number of irregularly shaped parts can be placed in a single large furnace. Even through the processing time is very long, the cost per part is competitive. For the FCVI process, a disadvantage is the special fixture required for each part to direct the reagent stream to flow through the preform. The short processing time is an advantage and there is more freedom to select processing conditions (temperature, pressure, and reagent concentration) that yield the desired microstructure, and therefore properties of the deposited matrix. The inside-out process has intermediate capabilities compared to the isothermal and FCVI processes.
3. Oxidation Protection

Carbon begins to oxidize at a measurable rate in air at 370 °C, and the rate of oxidation increases rapidly with increasing temperature. In order for oxidation to occur, oxygen must diffuse inward through the gas boundary layer surrounding the component and the reaction product (CO or CO_2) must diffuse outward. Thus, either diffusion or reaction kinetics at the interface may be the rate-limiting step. Calculated and observed rates of oxidation for uncoated, uninhibited carbon–carbon composites have been compared (Luthra 1988). Figure 7 shows that for temperatures above about 700 °C the calculated values for gas-phase diffusion compare favorably with the experimental data. At lower temperatures, the experimental results are similar to the rates calculated for a surface reaction limited process. Since the oxidation rate at higher temperatures is controlled by gas-phase diffusion, the thickness of the boundary layer has a large influence on the oxidation rate. The boundary layer thickness (δ) is, of course, dictated by the test or in-service hydrodynamics. The rather thick boundary layers (0.02 m and 0.05 m) indicated in Fig. 7 are for samples contained in a crucible. Flow across a

turbine blade would lead to a much thinner boundary layer. For a turbine blade, Luthra (1988) assumed a boundary layer thickness of 0.1 mm and calculated an oxidation rate of about $10^{-2}\,\mathrm{g\,cm^{-2}\,s^{-1}}$. Since acceptable rates are about $10^{-6}\,\mathrm{g\,cm^{-2}\,s^{-1}}$ and $10^{-8}\,\mathrm{g\,cm^{-2}\,s^{-1}}$ for short- and long-term exposures, it is clear that some means of retarding the oxidation of carbon–carbon is necessary for high-temperature applications in an oxidizing environment. This is an important aspect of carbon–carbon science and technology since failure of carbon–carbon components is often the result of oxidation of the matrix, fiber, or both. For this reason, oxidation protection approaches are described in some detail in this section.

3.1 Early Approaches

In 1934 the National Carbon Company patented a process for protecting carbon articles based on an inner layer of SiC and an outer glaze (glass) containing B_2O_3 (Johnson 1934). Glazes rich in P_2O_5 and SiO_2 were also mentioned in the patent. Many current patents are based on variations on this important theme. Throughout the 1940s and 1950s oxidation protection was sought for polycrystalline graphite to be used primarily as electrodes for melting metal or for furnace heating elements. In the 1960s oxidation- and erosion-resistant graphites were developed for reentry and rocket propulsion applications (Zeitsch 1967, Bortz 1971, Goldstein *et al.* 1966, Chown *et al.* 1963). These graphites contain boron, silicon, zirconium, and hafnium in the form of nonoxide ceramics, e.g., boron carbide. Oxidation produces a borate glass coating which is protective for periods of several hours at 1700 °C. Although primary protection by borate glasses can be expected for only limited times above ~ 1100 °C due to volatilization of B_2O_3, this early work demonstrated that incorporating boron into carbon articles was a valuable method for providing oxidation resistance.

The first effort to protect carbon–carbon composites from oxidation was conducted in the early 1970s for components to be used on the US Space Shuttle. These components were made of low-performance rayon-fiber-based composites (Rogers *et al.* 1975, 1976, Shuford 1984a). The coating system is composed of a SiC inner layer and an outer silicate glaze coating which contains SiC powder. A pack process in which the surface of the substrate reacts with silicon and SiO vapors is used to form the SiC layer. A silicon-rich coating is obtained, with the silicon particles being very small and finely dispersed. Coating thicknesses normally vary between 0.4 mm and 0.8 mm. Thicker coatings lead to decreased coating–substrate adherence and coatings over 2.5 mm thick are susceptible to spalling during heating. Glazing is performed with a commercial liquid silicate; cracks are sealed with silicon ethoxide (Shuford 1984a).

Protection of low-strength, low-elastic-modulus rayon-based composites is easier than protecting high-performance composites because the thermal expansion of the rayon-based material is about twice that of high-performance carbon–carbons. Thus, the thermal expansion mismatch is not as severe. Modifications of this coating system containing boron have been developed for high-performance (nonrayon) carbon–carbon composites (Shuford 1984b).

Many types of coatings, other than glasses or glass formers, have been developed for protecting carbon-bearing articles from oxidation. As early as 1963 SiC coatings made both by CVD and reaction of the substrate surface with silicon were investigated, as well as a variety of carbide (e.g., ZrC) and boride (e.g., ZrB_2) coatings made by reaction sintering (Chown *et al.* 1963). These results showed the potential of CVD SiC for providing protection up to ~ 1700 °C; ZrC and ZrB_2 provided protection for short times to 2200 °C.

In the mid-1960s the use of iridium coatings to protect graphite was explored. Early work demonstrated excellent protection for short times at 2000–2100 °C. Iridium has a melting point of 2440 °C, is rather impermeable to oxygen to 2100 °C, is nonreactive with carbon below 2280 °C, and is an effective barrier to carbon diffusion (Strife and Sheehan 1988). Disadvantages of iridium are its excessive erosion due to volatile oxide formation, possible lack of adherence to carbon–carbon, and a relatively high thermal expansion coefficient. It is also expensive.

3.2 Protection Schemes

Basically three approaches for protecting carbonaceous materials from oxidation have evolved:

(i) coating with a solid material, e.g., SiC, iridium, etc.;

(ii) coating with glass; and

(iii) adding constituents which truly inhibit chemical reaction of carbon with oxygen or which react to form glasses which retard the ingress of oxidant.

In practice, all three approaches are often used simultaneously since each by itself is unsatisfactory except at low temperatures. Most of the so-called inhibitors act by forming a glassy layer over internal and external surfaces rather than truly inhibiting reaction between carbon and oxygen. Boron is thought to have a truly inhibiting effect on the reaction of carbon and oxygen; also, B_2O_3 is a glass former. Thus boron-based inhibitors can retard oxidation by both mechanisms. In addition, some inhibitors retard oxidation simply by acting as oxygen getters.

While the US Space Shuttle rayon-based carbon–carbon is protected by a glass layer applied over a SiC layer, the state-of-the-art approach for protecting high-strength carbon–carbon materials reverses the order of the coatings. That is, first a layer of glass (or
Figure 8
Oxidation protection scheme for advanced carbon–carbon composites.

glass formers) is applied and this is covered with an outer coating which is usually SiC but may be Si_3N_4 or some other material. This approach is shown in Fig. 8. The outer layer (e.g., SiC) provides the primary barrier to oxygen, but on cooling from high temperature, this layer cracks because of tensile stresses generated by thermal expansion mismatch with the substrate. The coating shrinks more than the major faces of a two-dimensional carbon–carbon composite. An additional source of stress, which in some instances is additive, is any as-deposited stress in the SiC layer.

The purpose of the glass layer located between the outer coating and the substrate is to provide a glass with sufficient fluidity to fill the cracks in the outer coating. The glass also coats the fibers and composite matrix in order to provide some in-depth oxidation protection. Limiting chemical reactions (glass formation) between the glass layer and the outer coating or oxide scales (e.g., SiO_2) formed on the outer coating is very important. The outer coating must not be aggressively attacked and the resultant glass must have suitable viscosity to permit effective sealing of cracks to continue. If the viscosity is too low, the glass may be blown from the composite by hydrodynamic forces present in most engine and aerospace applications. Formation of high vapor pressure compounds is undesirable since this leads to loss of the coating.

Ideally, the outer coating should retard the ingress of oxygen, i.e., it should be nonporous, oxidation resistant, and have a small diffusion coefficient for oxygen and other oxidants. Further, the coating should have a thermal expansion coefficient which is near that of the carbon–carbon composite. Unfortunately, most ceramics and metals have expansion coefficients which far exceed that for carbon–carbon (Strife and Sheehan 1988). Assuming that the outer coating is not an oxide, it will gradually oxidize. It is desirable that a protective oxide scale should form,

i.e., the scale should have a low value for the diffusion of oxygen or gaseous reaction products. Scales of Al_2O_3, Cr_2O_3, and SiO_2 are noteworthy for their impermeability to oxygen. Although MgO is rather impermeable to oxygen, its large thermal expansion coefficient and the fact that its vapor pressure exceeds that of SiO_2 for temperatures below $\sim 1850°C$ make it unattractive. Its susceptibility to hydration is also undesirable.

The major disadvantage of BeO is its toxicity. The combined relatively low thermal expansion coefficients and good oxidation resistance have led to the extensive use of silicon-based ceramics (SiC and Si_3N_4) for the outer coating. It is also significant that SiO_2 scales have low oxygen diffusion coefficients and can be modified with other oxides to control glass viscosity. Various oxides, nitrides, carbides, and borides have been considered as protective coatings. Coatings containing multiple phases and graded coatings have also been considered. Thermal expansion mismatch often proves to be troublesome. Coatings for providing protection to carbon–carbon for several thousand hours at cyclical temperatures in excess of $\sim 1300°C$ are still under development.

4. Microstructure of Carbon–Carbon

The microstructures of both the fibers and matrix of carbon–carbon are important since they have a major influence on the mechanical, thermal, and electrical properties. Both the fibers and matrix can have a wide range of structures. The structures vary from amorphous to highly crystalline depending on the source of the material and the fabrication process, especially the maximum temperature used during processing. Important microstructural features include the degree of crystalline perfection, interlayer spacing, crystallite size, extent of preferred crystallographic orientation, and the quantity, shape, and orientation of pores. Extensive studies have created a large body of information on processing–microstructure–property interrelationships for carbon–carbon. Only a small fraction of that information can be summarized here. For further details see *Carbon Nanofibers*[*]; *Carbon Mesophase*[#]; and Fitzer and Manocha (1998), Thomas (1993), Chung (1994), Savage (1993), and Buckley and Edie (1993).

4.1 Fiber Microstructure

The microstructure, and therefore properties, of carbon fibers varies markedly depending on whether the precursor is rayon, pitch, PAN, or CVD reagents, and on processing details. An important structural feature is the type and extent of preferred crystallographic orientation of the basal planes of the graphite-like crystallites. In many fiber types, there is a preference for the basal plane to be parallel to the

long axis of the fiber with the *c*-axis oriented tangentially, radially, or randomly (Buckley and Edie 1993). The basal planes are often folded or crinkled, and ''onion-skin'' textures are common where the structure varies from the outside to the inside of a given fiber. Fibers with a large fraction of the basal planes parallel to the fiber length have high values for Young's modulus in the direction of the major axis of the fiber, since the bonds are strong within the basal planes.

The crystallite size parallel to the *c*-axis (L_c) and perpendicular to the *c*-axis (L_a) typically increases with increasing processing temperature. Typical values are in the range 2–20 nm. Fiber density typically increases with increasing processing temperature as a result of both a decrease in porosity and a decrease in the spacing between basal planes (d_{002}). The fiber structure influences not only the properties of the fiber but can also affect the properties of the carbon–carbon composite by influencing the adhesion between the fiber and matrix as well as influencing the crystallographic orientation of the matrix, especially near the fiber.

4.2 Matrix Microstructure

As with fibers, the matrix source (pitch, resin, CVI) and processing details control the microstructure of the matrix which, again like the fibers, can vary from amorphous to highly oriented graphite-like crystallites of varying density. Matrices obtained from thermosetting resins such as poly(furfuryl alcohol) and phenolics have minimum crystallinity which is not significantly enhanced by heating to typical graphitization temperatures.

Thermoplastic pitches attain their minimum viscosity at about 100–150 °C above their glass transition temperature. Low viscosity is advantageous for infiltration of the fiber preform. On further heating, volatilization of low molecular weight chemical species occurs along with polymerization and structural ordering of planar aromatic molecules. This liquid crystalline state is called a mesophase. Mesophase spheres about 0.1 µm in diameter form and subsequently coalesce on further heating. In the case of a pitch-derived matrix, the crystallinity in the final, solid carbon is spawned by the mesophase (Fitzer and Manocha 1998). The mesophase spheres deform and disk-like molecules of the liquid crystals tend to align parallel to the surfaces of fibers and fillers. This results in preferred crystallographic orientation near the fiber and filler. Within a bundle of fibers, this mechanism has a major influence on establishing the matrix microstructure. Further away from the fiber surfaces, the effect is reduced. The coalescence of the mesophase is retarded by the presence of particulate matter known as quinoline insolubles. These insolubles are found in coal tar pitches but not petroleum

pitches. Therefore, petroleum pitches yield more highly crystalline carbon matrices. Carbonization pressure and temperature also influence the degree of crystallinity. Further, the rate of heating is important in that it influences whether evolved gases have time to escape or whether they form bubbles that eventually result in porosity in the carbonized product. Shrinkage, which accompanies carbonization and graphitization, causes the solid carbon matrix to crack. Formation of closed pores, which cannot be filled by subsequent liquid or gaseous infiltration steps, is undesirable if a high-density product is sought. Multiple infiltration–carbonization–graphitization steps clearly alter matrix microstructure as do oxidation–stabilization steps. Further complication arises when thermosetting resins and pitches are both used to produce the matrix. Additional details are available in Fitzer and Manocha (1998). Cracks and pores, which may cover the size range from macroscopic to microscopic, generally have a detrimental effect on mechanical properties.

A carbon matrix derived from a thermosetting polymer reflects, to some extent, the structure of the parent polymer. Such carbons are of low density (1.4–1.6 g cm^{-3}) and are not very graphitizable even at 3000 °C. They possess minimal crystal structure consisting of very small areas of short-range, parallel graphitic layers which are highly wrinkled. These carbons are typically isotropic because of the lack of preferred orientation. The presence of mechanical stress during carbonization can alter the degree of crystallinity. Variations in fiber–matrix bonding caused by different fiber surface characteristics can alter the stress state in the matrix near the fiber–matrix interface and thus alter the matrix crystallinity (Fitzer and Manocha 1998). As a result, the matrix near a fiber may consist of aligned graphitic layers while far away from a fiber the matrix may be isotropic. Just as in fibers, the graphite-like planes can be kinked. The presence of particulate fillers also influences the matrix microstructure.

The matrix of carbon–carbon prepared using any of the CVI processes is very dependent on the process details and is often described as being comprised of carbon having a rough laminar, smooth laminar, or isotropic microstructure. Rough laminar (RL) identifies carbon that is very anisotropic, i.e., high degree of preferred orientation of the basal planes, and readily graphitized. It is thought to occur when the growth rate is low (Thomas 1993). The material is dense and has well-defined growth features as shown in Fig. 1.

Smooth laminar (SL) carbon possesses less preferred orientation than RL and is less graphitizable. Isotropic (ISO) carbon, as the name implies, is even less oriented and most difficult to graphitize. As might be expected for a highly oriented, anisotropic material, RL carbon has the highest density, thermal conductivity, and elastic modulus (Rellick 1994).

Table 1
Apparent crystallite size, L_c, of heat-treated carbon and extinction angles for different microstructures of graphitized CVI carbon matrix.

Microstructure	Apparent crystallite size, L_c (Å)	Extinction angle (°)
RL	310–460	$\geqslant 18$
SL	95–165	4–18
ISO	70–110	< 4

Techniques involving polarized light microscopy have been developed to rapidly identify the three types of material depending on the magnitude of the extinction angle as shown in Table 1 (Dupel *et al.* 1995).

Different sources are contradictory regarding identification of processing conditions that yield SL, RL, and ISO carbon deposits, and the present author does not believe it is possible to accurately generalize in any simple manner on this topic (Thomas 1993, pp. 91, 113, Fitzer and Manocha 1998, p. 151). For example, there is considerable disagreement as to whether low, intermediate, or high temperatures are conducive to the deposition of a particular microstructure. The disagreement is likely to be the result of complex interactions involving the processing variables as previously highlighted by Fisher (1993). That is, the influence on microstructure of one particular process variable, say temperature, is dependent on the levels of other process variables, such as pressure, flow rate, surface area, etc.

The processing variables of hydrocarbon type, concentration, flow rate, temperature, pressure, and preform architecture control in a complex manner the nature and residence time of numerous chemical species formed in the gas phase which, in turn, determines the microstructure of the deposited carbon matrix. Localized variations in structure can also occur as a result of the influence of the fiber surface. Also, deliberate or unavoidable changes in processing conditions during the course of infiltration/densification can alter the matrix structure. A thermodynamic microstructure model has been proposed that predicts the microstructure of the deposited carbon, which has been supported by experimental data in several different studies using isothermal and thermal gradient CVI (Lieberman 1972, Pierson *et al.* 1973, Pierson and Lieberman 1975, Lieberman and Noles 1973). The model has also been shown to be accurate for the FCVI process (Lewis *et al.* 1997). The model requires knowledge of the local temperature, pressure, and carbon-to-hydrogen ratio and is based on the assumption of equilibrium conditions in the gas phase before deposition of solid carbon. Regardless of the starting hydrocarbon, thermodynamic calculations show that under equilibrium conditions in the gas phase, methane (CH_4), hydrogen (H_2), benzene (C_6H_6), and acetylene (C_2H_2) are usually the most abundant gas species (Lieberman and Mark 1972). Gas chromatography results verified the calculations for thermal gradient CVI (Lieberman and Noles 1973). These results show that when methane and hydrogen are introduced into a furnace, the acetylene concentration initially increases, followed by an increase in benzene concentration. Carbon deposition is believed to result from the decomposition of both benzene and acetylene, although primarily from benzene. The Lieberman model does not attempt to identify the exact reaction mechanism for deposition. It simply uses the assumption that acetylene and benzene are important and that their relative concentrations determine the deposit microstructure. The value which is evaluated for the deposition conditions and used to predict the resulting microstructure is the gas-phase molar ratio, R, which is simply the equilibrium ratio C_2H_2/C_6H_6, i.e., the acetylene/benzene ratio. Experimental data show that as R increases, the microstructure changes from SL to RL to ISO. This is supported by the observation that deposited SL carbon is never seen directly adjacent to ISO carbon, and that a RL structure is always found between them. It has been observed experimentally that when R is below 5, the SL microstructure is obtained. When R is above 70, the ISO microstructure is obtained, and RL carbon is deposited for intermediate values (Lieberman 1972, Pierson *et al.* 1973).

Thermodynamic calculations show that the value of R has a strong dependence on temperature, pressure, and C/H ratios and perhaps accounts for the strong, complex influence these process variables have on the deposit microstructure. This model has been used to predict that it should be possible to use the FCVI process to fabricate carbon–carbon composites having the usually desired rough laminar matrix throughout the preform (Lewis *et al.* 1997). In this regard, the FCVI process offers considerable flexibility in controlling the matrix microstructure.

5. Properties

Fiber characteristics, preform architecture, the fiber–matrix interface, and the matrix macro- and microstructure control the properties of carbon–carbon. Addition of fillers, internal oxidation inhibitors, and an external oxidation protection coating also significantly influence mechanical, chemical, and physical properties of carbon–carbon. Obviously, a large number of material and process variables are involved, and caution must be exercised in specifying a particular carbon–carbon for a specific application.

5.1 Mechanical Properties

Most of the mechanical properties of carbon–carbon are very structure sensitive. This is particularly true of

tensile strength and fracture toughness. As a result, it is not possible to simply list reliable values for these properties. Instead, the mechanical properties depend on whether rayon-, pitch-, or PAN-based fibers are used and whether resin, pitch, or CVI processes are used to form the matrix. Even if one specifies the fiber precursor type and consolidation process, the properties can still vary over a very wide range depending on the details of fiber and matrix processing, including postconsolidation thermal treatment and the nature of any oxidation protective coatings. Unfortunately, even if all of these details are specified, day-to-day upsets in the long series of fabrication steps can significantly alter the mechanical properties. This variability makes it necessary to test a large number of samples in order to obtain a reliable measure of the mean and distribution of mechanical property values. This lack of reproducibility, coupled with borderline fracture toughness and oxidation resistance, often makes designers reluctant to specify carbon–carbon for high-temperature, oxidative environment structural applications.

Strength, elastic modulus, and fracture toughness of carbon are improved by reinforcement with carbon fibers. Not surprisingly, the improvement is dependent on the volume fraction of fibers oriented in the test direction. As a result, the properties of, for example, a two-dimensional carbon–carbon are highly anisotropic with superior properties occurring in the plane of the lay-up, i.e., the x–y plane. Properties in the transverse direction (z-axis) are decidedly inferior.

For a unidirectional composite where all the fibers are oriented in a single direction, the maximum possible tensile strength can be calculated from the rule of mixtures assuming that the fibers and matrix are intimately bonded:

$$\sigma_c = \sigma_f V_f + \sigma_m V_m$$

where σ_c is the tensile strength of the composite in the direction of the long axis of the fibers, σ_f is the fiber tensile strength, V_f is the volume fraction of fibers, and σ_m is the matrix tensile strength (Chawla 1993). The fibers are usually so strong that the contribution of the matrix to the strength of the composite can be neglected, i.e., the composite strength is proportional to the fiber content. The strength calculated using the above equation exceeds that of actual composites by a factor of about two or more due to fiber damage, incomplete transfer of load to the fibers, stress concentrations, etc. (Savage 1993, pp. 290–2). Figure 9 shows for a unidirectional carbon–carbon that the strength decreases markedly when the angle between the applied load and the fiber axis is increased.

The strength of two- and three-dimensional composites can be estimated by taking into account the fiber loading in the direction of interest. As above, the actual strength is considerably lower than the theoretical maximum, an additional cause being
Figure 9
Effect of angle between fiber axis and loading direction on the strength of a unidirectional carbon–carbon (after Savage 1993).

misaligned fibers due to crimping caused by the weaving process.

Again, for a unidirectional composite, the Young's modulus of the composite can be estimated by the following equation:

$$E_{cl} = E_f V_f + E_m V_m$$

where E_{cl} is the Young's modulus of the composite in the longitudinal direction, E_f and E_m are the Young's modulus of the fiber and matrix, and V_f and V_m are the volume fraction of fibers and matrix, respectively (Chawla 1993). The above equations are derived assuming that the fiber and matrix are rigidly bonded, which is not at all accurate. In fact, it is well known that in carbon–carbon and other ceramic matrix composites, if the bond is strong, the composite will be very brittle. Therefore, considerable effort is directed at achieving a fiber–matrix bond of weak to intermediate strength. This contributes to fiber–matrix debonding, crack deflection, and fiber pullout which, along with matrix cracking, are important phenomena that significantly influence composite mechanical properties. As a result, the mechanics of fiber–reinforced composites is a complex topic and field of study in itself (Chawla 1993, Reddy 1997, Agarwal and Broutman 1990).

Figure 10 shows stress–strain curves for a series of two-dimensional carbon–carbon composites densified via CVI using 10% propane at temperatures between 1100 °C and 1400 °C (Oh and Lee 1988). The variations in strength, elastic modulus, and fracture energy with infiltration temperature could be caused by alterations of the strength of the fiber–matrix bond and variable matrix microstructure and composite

density. Other process variables such as the hydrocarbon type and percentage of hydrocarbon, i.e., percentage of diluent, can have similar effects (Savage 1993, p. 298). Table 2 gives example mechanical property data for carbon–carbon made from pitch, PAN, and rayon fibers. Data for a grade of graphite are given for comparison.

Table 3 compares the mechanical properties of two resin-based carbon–carbon materials with that of a carbon–carbon having a CVI-derived matrix. Note

Figure 10
Room-temperature stress–strain curves for two-dimensional carbon–carbon prepared by CVI at 1100–1400 °C (after Oh and Lee 1988).

that values are given for the as-carbonized as well as the graphitized materials.

The strong influence of the fibers on the tensile strength of carbon–carbon is evident from examination of the data given in Table 4. Note that tensile strength is dependent on the quantity of fibers parallel to the loading direction. Also note the very low strength for the transverse direction. Compared to the other two, the three-dimensional composite is considerably more isotropic. It would also have increased strain tolerance, but maximum strength values are reduced.

It should be clear from the preceding discussion that the property values in Tables 2–4 are only representative and should be used with caution since processing details alter the values significantly. For a specific application, multiple pieces of material purchased from one or more vendors should be tested in an attempt to determine if the properties are suitable for the anticipated mechanical loading, including cyclic loading and environment. When materials such as graphite and carbon–carbon are selected for high-temperature applications, it is often because of the fact that these materials retain a significant fraction of their strength and stiffness at ultrahigh temperatures (~ 2500 °C) which are well above the maximum useful temperatures of other materials, including ceramics. The resistance to creep at high temperatures is excellent. Again, the exact influence of temperature on mechanical properties is dependent on the details of the manufacturing process. However, some carbon–carbons clearly show an increase in strength and stiffness as the temperature is raised to ~ 2000 °C (Thomas 1993). This may be the result of thermal expansion causing the closure of pre-existing cracks on heating or it may occur because the strength of some carbon fibers is known to increase with temperature. Other carbon–carbons show a minimum
Table 2
Mechanical properties of three carbon–carbon composites (A, B, C) and a graphite (G).

strength at $\sim 1000\,°C$ with higher strengths at lower and higher temperatures.

5.2 Thermal Conductivity

Some carbon–carbon composites have very high thermal conductivities. Since low density is important for some thermal management applications, a figure of merit defined as thermal conductivity divided by density may be used to rank materials. Table 5 shows such rankings, and it is apparent that carbon–carbon is much more suitable than traditional metals for many aerospace and electronic applications. This figure of merit is also pertinent for aircraft brakes. Carbon whiskers with thermal conductivities as high as $2500\,Wm^{-1}\,K^{-1}$ have been produced by vapor-growth techniques (Ting *et al*. 1995). Note in Table 5 that highly oriented CVD carbon is capable of a thermal conductivity very nearly as high as that of

diamond. A carbon–carbon composite containing these fibers in a high-conductivity CVI carbon matrix thus offers the potential of an exceptionally high thermal conductivity, lightweight material. The thermal conductivity will be a maximum in the direction of the whiskers. Carbon–carbon having a thermal conductivity of $1000\,Wm^{-1}\,K^{-1}$ has been prepared (Lake *et al*. 1990). The microstructure of a high-conductivity, vapor-grown carbon whisker is shown in the high-resolution transmission electron micrograph of Fig. 2. Both thermal and electrical conduction in a material having the hexagonal graphite-like crystal structure is highly anisotropic since conduction within the basal plane is many times larger than that perpendicular to this plane. A highly crystalline carbon fiber or matrix possessing extensive preferred orientation of the basal planes will have high conductivity within this plane. Figure 2 shows that the basal planes in the vapor-grown fiber are oriented parallel to the long axis of the fiber and thus conductivity is very high along the fiber axis. The thermal conductivity of crystalline carbons, including carbon–carbon, increases with an increase in temperature from absolute zero, reaches a maximum conductivity between $0\,°C$ and $500\,°C$, depending on the degree of crystallinity, and decreases with further increase in temperature (Savage 1993, p. 312). Higher graphitization temperatures clearly increase the thermal conductivity of carbon–carbon. The more easily graphitized RL carbon matrix structure yields higher conductivities than SL or ISO matrices. Pitch- and CVI-derived matrices yield higher conductivities than the less crystalline matrices derived from thermosetting resins.

5.3 Electrical Conductivity

The influence of processing on the electrical conductivity of carbon–carbon is similar to that previously described for thermal conductivity. That is, a

Table 5
Thermal conductivity and density of high-conductivity materials at 273 K.

Material	Thermal conductivity, K (W m^{-1} K^{-1})	Density, ρ (g cm^{-3})	Figure of merit, K/ρ
Carbon–carbon (in-plane)	~ 500[a]	2.0	250

CVD carbon (in-plane)	2500	2.2	1136
Aluminum	236	2.70	87
Copper	403	8.91	45
Gold	319	19.31	17
Silver	429	10.5	41

[a] Depends on fabrication process.

carbon–carbon containing highly crystalline fibers and matrix has higher electrical conductivity and thus high graphitization temperatures, and the use of pitch or CVI matrices enhance electrical conductivity. After an initial increase, electrical conductivity decreases with increasing temperature. As a reference point only, the following values at room temperature are given for the electrical resistivity of a two-dimensional carbon–carbon. Parallel to the fibers, the electrical resistivity was about 35 $\mu\Omega$ m and 10 $\mu\Omega$ m for heat treatment temperatures of 1200 °C and 2800 °C, respectively, while perpendicular to the laminate the corresponding values were 106 $\mu\Omega$ m and 70 $\mu\Omega$ m (Huettner 1990).

5.4 Thermal Expansion

The thermal expansion of graphites and carbon–carbon is very anisotropic because of the vast differences in thermal expansion for the directions parallel and perpendicular to the basal planes of the hexagonal crystal structure. On heating from room temperature, there is an expansion in the *c*-axis direction, i.e., perpendicular to the basal planes, and actually a contraction in the *a*-axis directions, i.e., within the basal planes. Since both the carbon fibers and most carbon–carbon matrices exhibit preferred orientation of the basal planes, carbon–carbon exhibits extensive thermal expansion anisotropy. For the temperature range 25–1200 °C, a carbon fiber, Amoco T-300, has average thermal expansion coefficients of 8.85×10^{-6} °C^{-1} and 0.93×10^{-6} °C^{-1} for the radial and axial directions, respectively (Ellenburg *et al.* 1994). The axial value is about one-tenth that of a typical oxide ceramic fiber such as alumina. This low axial thermal expansion is a major reason for carbon–carbon having low thermal expansion coefficients within the plane of laminates, i.e., in the plane of the fibers of a one- or two-dimensional composite. In this direction, the thermal expansion coefficient of carbon–carbon containing high-modulus fibers is in the range 0–1×10^{-6} °C^{-1}. In the transverse direction, the value is about 10×10^{-6} °C^{-1} (Thomas 1993, p. 208). The low expansion in the plane of the laminate severely complicates the application of an adherent external coating as discussed in Sect. 3.

6. Applications

Applications of carbon–carbon include military and commercial aircraft brakes, friction materials in clutches and synchronizers, leading edges of high-speed aircraft and re-entry vehicles such as the US Space Shuttle and intercontinental ballistic missiles, thermal management (heat sinks) in electronic devices, heat pipes, dimensionally stable space structures, molds for high-temperature forming of metals and glass, rocket nozzles, turbines, other heat engine components such as pistons and jet exhaust flaps, first walls in nuclear fusion reactors, corrosion-resistant containers, and various biomedical prostheses including hip and finger joints.

By far the largest application is for aircraft brakes. There are about 500 kg of carbon–carbon brakes in a typical commercial airliner. The low weight, high-temperature capability, high thermal conductivity, and desirable tribological properties of friction and wear rate are important. Carbon–carbon also has high internal friction, i.e., vibrations are readily dampened as a result of the presence of cracks and porosity. Vibration, which retards performance and can actually cause failure by fracture, is an important consideration for aircraft brakes.

The friction coefficient is another important property. It varies from more than 0.4 at taxi speeds to less than 0.1 for a rejected take-off. Moisture absorbed from the air and oxidation products formed during use can also influence the friction coefficient. Either pitch-or PAN-based fibers are used for brakes. A wide variety of preform types are used, including woven fabrics, short-length yarns, chopped fabrics, and knitted three-dimensional fabrics. Additional details regarding fabrication, design, and testing are available (Tatarzycki and Webb 1992).

7. Cost

Cost is a major consideration for commercial aircraft brakes. The competing material is primarily steel. Carbon–carbon has superior heat capacity and thermal conductivity and it is lighter. However, carbon–carbon is expensive. Fitzer (1994) has estimated the cost of carbon–carbon as about US$200 kg^{-1}. He further estimates that a little over 10% is associated with fiber and matrix raw material costs. The remaining costs are due to processing and presumably characterization. Savage (1993) states that because of the volume involved, aircraft brake materials are the cheapest carbon–carbon. He reports a price of £120 kg^{-1} for brake material, whereas a high-density, three-dimensional rocket nozzle may cost in excess of £1000 kg^{-1}. For a midprice-range (£300 kg^{-1}) carbon–carbon, he provides the breakdown of costs given in Table 6 (Savage 1993).

Ceramic Fibers from Polymer Precursors

High-strength, heat-resistant ceramic fibers can be produced from polymeric precursors by first spinning the precursor, and then transforming the polymer into a ceramic. This process is called the polymer precursor method.

The concept of the polymer precursor method was suggested by Chantrell and Popper (1964), and the synthesis of Si–C–N products from carbosilazane precursor was reported by Verbeek (1973). The polymer precursor ceramic fiber process was demonstrated by Yajima *et al.* (1975) with the development of a process for the production of SiC-based ceramic fibers by conversion of polycarbosilane. This type of fiber is produced by Nippon Carbon (NCK) under the trade name Nicalon. It is a continuous fiber with a diameter of about 15 μm. This fine fiber has a high tensile strength and has relatively high heat resistance. Another fine Si–Ti–C–O fiber from polytitanocarbosilane is produced by Ube Industries (UBE) under the trade name Tyranno. Besides Nicalon and Tyranno, a Si–C–N fiber from hydridopolysilazane (Legrow *et al.* 1987), a Si–N–O fiber from polycarbosilane (Okamura *et al.* 1987a), a high-purity Si_3N_4 fiber from perhydropolysilazane (Funayama *et al.* 1990), and a silicon carbonitride with high thermal stability (produced by Rhone-Poulenc under the trade name Fiberamic) have also been developed.

The SiC-based fiber Nicalon, produced by the thermal oxidation curing method (detailed below), has a high oxygen content and excess carbon, and is amorphous (Yajima *et al.* 1979). When Nicalon is heated above 1573 K, the fiber crystallizes into β-SiC, which is accompanied by the release of CO and SiO gases. The fiber shows severe degradation in tensile strength as a result of the structural destruction caused by the release of gases and the growth of SiC grains (Mah *et al.* 1984, Pysher *et al.* 1989, Laffon *et al.* 1989, Shimoo *et al.* 1990, 1994). A reduction in oxygen content is effective in improving the thermal stability of the SiC fiber. A curing method with electron beams has therefore been developed by Okamura *et al.* (1987b) in order to synthesize fibers with low oxygen content. When these fibers are converted from polycarbosilane to SiC under argon or nitrogen, the fiber obtained has excess carbon corresponding to a composition of about $SiC_{1.39}$; alternatively, if the conversion process is carried under hydrogen, the fiber has a near-stoichiometric composition of $SiC_{1.05}$ (Takeda *et al.* 1994). The resulting fibers are called Hi-Nicalon and Hi-Nicalon Type S, respectively. They have high heat resistance, the latter being excellent in this regard. By the heat treatment of Tyranno and its related Si–Al–C–O fiber, at higher temperatures in an inert atmosphere, sintered SiC fibers have also been produced. These are called Sylramic (Lipowitz *et al.* 1997) and SA (Ishikawa *et al.* 1998, Kumagawa *et al.* 1998) and exhibit excellent mechanical properties.

Other fiber systems can be produced using polymer precursors. For example, silicon carbide–silicon nitride ($Si_xN_yC_z$) fibers have been prepared by the pyrolysis of polycarbosilazane (Penn *et al.* 1983), silicon nitride fibers and various ceramic compositions containing the atomic species silicon, titanium, boron, nitrogen, and carbon have been prepared (Seyferth 1990), and Si–C–N filaments have been prepared from a new polycarbosilazane by melt spinning, γ-ray curing, and pyrolysis (Mocaer *et al.* 1993). However, the main engineering fibers derived by this route are based on silicon carbide. Nicalon and Tyranno are used as high-temperature fiber materials or as reinforcement fibers for polymer, metal, and ceramic matrix composites. More detail on the processing of these fibers is given in the following.

1. Synthesis of SiC Ceramic Fibers by the Polymer Precursor Method

Polycarbosilane (PCS) as a precursor polymer of SiC fibers is synthesized by the thermal conversion of polydimethylsilane. The molecular structure of PCS is planar, consisting of a ring-and-chain structure. PCS consists of two units, $Si(CH_3)_2CH_2$ and $Si(CH_3)HCH_2$, their unit ratio being almost the same (Hasegawa and Okamura 1986). The atomic ratio is $SiC_{1.93}H_{4.71}O_{0.01}$, oxygen being an impurity. The number average molecular weight is about 2023 and the melting point is 506 K. The SiC fiber processing sequence from PCS, shown in Fig. 1, comprises three main steps: PCS fiber spinning, fiber curing, and heat treatment of the cured fiber at high temperature.

The PCS is melt spun into a PCS fiber having a diameter of about 20 μm at about 583 K in N_2 gas. This PCS fiber is very fragile. It is therefore cured, in order to produce cross-links between polymer chains. This can be achieved by thermal oxidation in air at temperatures of 373–473 K or by electron beam (EB) irradiation, the dose rate varying from 2–5 kGys^{-1} up to a dose of 15 MGy in helium gas. In thermal oxidation, as the PCS fiber consists of more than 7 mass% of oxygen, the PCS fiber becomes infusible by cross-linkage with Si–O–Si bonds. Under EB irradiation, Si–H and –CH$_2$– or –CH$_3$– groups of the PCS fiber are cross-linked and polymerized directly as shown in Fig. 2. After irradiation curing, the PCS fiber is heated to about 700 K for 1–2 h in order to diminish the free radicals trapped in the PCS fiber by irradiation. Then, the cured PCS fiber becomes stable in air and it is insoluble in solvents such as water and infusible for heating. The radiation-cured PCS fiber consists of less than 1 mass% of oxygen (Okamura and Seguchi 1992).

Alternatively, the PCS fiber can be irradiated with an EB in air at room temperature. The dose is 1–4 MGy with a dose rate < 2 kGys^{-1}. The oxygen content in the PCS fiber increases with the dose and can be controlled from a few to 30 mass%. The PCS

fibers.

having a stoichiometric composition can be prepared.
This fiber is termed Hi-Nicalon-S.

2. Conversion Process of the Cured PCS Fibers to SiC Fibers

The conversion process of cured PCS fibers to SiC
fibers is explained on the basis of the analysis of gases
evolved during the heat treatment of cured PCS fibers
(Sugimoto *et al.* 1995a). The gas evolution process of
PCS fibers cured with EB irradiation, the radiation/
oxidation process, and the thermal oxidation process
are shown in Fig. 3.

In the case of the radiation-cured PCS fiber with
1.1 mass% of oxygen, H_2 and CH_4 are the major
gases, which begin to evolve at around 700 K
and increase to a maximum value at about 950 K.
CH_4 evolution stops at about 1200 K, but the H_2
continues until 1700 K. The evolution of H_2 and CH_4
at temperatures of 800–1200 K corresponds to de-
composition at the site of silicon atoms, i.e., Si–H
and Si–CH_3; H_2 gas evolution at temperatures of
1000–1700 K is due to decomposition at the carbon
atom sites in the PCS main chain (H–C–H). Above
1800 K, a small amount of CO gas is evolved.

fiber is then cured by heat treatment at about 600 K
for less than 1 h under vacuum after irradiation. This
radiation/oxidation curing process is induced by
cross-linking with oxygen bonding during the heat
treatment.

The PCS fibers cured by these methods are finally
heat treated in flowing argon or nitrogen at temper-
atures above 1473 K. This transforms the fragile as-
cured PCS fiber to a high tensile strength SiC or near-
SiC fiber. The SiC fiber obtained from the PCS fiber
cured by thermal oxidation or radiation/oxidation
(i.e., with oxygen cross-links) contains about
10 mass% oxygen, while the SiC fiber obtained from
the PCS fiber cured with radiation cross-linking by
EB irradiation contains about 1 mass% oxygen. The
former fiber is termed Nicalon while the latter is
called Hi-Nicalon. The Hi-Nicalon fiber has a carbon
to silicon ratio of 1.39, but by heat treatment in
flowing H_2 of radiation-cured PCS fiber, a SiC fiber

In the case of the radiation/oxidation-cured PCS fiber with 12 mass% of oxygen, CH_4 evolution is almost the same as with 1.1 mass% of oxygen. H_2 evolution at 800–1200 K decreases to about 1/2, and the evolution at 1200–1700 K is nearly the same. Much CO gas evolves above 1800 K. This is due to the increased oxygen content in the cured PCS fiber.

In the case of gas evolution from the thermal oxidation-cured PCS fiber with 13 mass% of oxygen, CH_4 evolution is almost the same as that for the two processes mentioned above, but the peak is higher by about 50%. H_2 evolution is similar to that found after radiation/oxidation. A large amount of CO gas evolves above 1700 K; the increased CO gas evolution gives rise to a light green color and fine SiC particles grow on the fiber surface.

The PCS fiber cured by radiation/oxidation or thermal oxidation contains less hydrogen, because the hydrogen is lost by the formation of H_2O in the process of both oxidation-curing processes. The oxygen reacts preferentially with silicon atoms and results in a small amount of Si–H as shown in Fig. 2. Therefore, H_2 evolution at 800–1200 K decreases for the PCS fiber cured with oxygen in comparison with radiation curing. CO gas evolution also depends on the oxygen content in the PCS fiber, and is produced according to

$$SiC_xO_y \rightarrow SiC(s) + SiO(g) + CO(g) \qquad (1)$$

SiO and CO gas evolution accelerates the grain growth of SiC.

The conversion process of PCS to SiC also proceeds through free radical mechanisms (Sugimoto *et al.* 1995b). Some atomic sites are trapped in the pyrolyzed PCS fiber as free radicals, and detected by the measurement of electron spin resonance (ESR). The radicals are produced abruptly above 800 K and increase sharply in concentration with increasing temperature. In the case of the PCS fiber with low oxygen, the radical concentration reaches a maximum at 900 K, then decreases and shows a second peak at about 1300 K, and decreases to zero at 1700 K. For the PCS fiber with 12 mass% oxygen the maximum concentration is at about 1400 K, and the radicals remain until rather higher temperature than the low oxygen-cured PCS fiber. The trapped radicals reflect the state of the conversion process from the cured PCS fiber to SiC fiber. The presence of radicals indicates that the conversion process is progressing until 1700 K. Therefore, stable SiC fibers can be formed by heat treatment above 1700 K especially after EB irradiation.

3. Properties of SiC Fibers

The tensile strength increases during the conversion of the cured PCS fibers to SiC ceramic fibers as

shown in Fig. 4. For the PCS fibers with 12 mass% oxygen and 13 oxygen, the synthesized SiC fibers reach maximum strength at 1600 K, and the strength decreases above this temperature. This decrease is due to the thermal decomposition described in Eqn. (1). By the generation of SiO and CO gases, the fiber morphology undergoes an extreme change, and the tensile strength rapidly decreases. For the PCS fiber with 1.1 mass% oxygen, the strength increases with the heat treatment temperature up to 1800 K. The SiC fiber formed from the PCS fiber with very low oxygen content of 0.4 mass% maintains its strength up to 2000 K. The Young's modulus (250 GPa) is maintained to 2100 K. By decreasing the oxygen content in PCS fibers with radiation curing, the fiber heat resistance is improved to 2000 K.

The thermal decomposition according to Eqn. (1) occurs in Tyranno fibers $(SiTi_{0.02}C_{1.37}O_{0.32})$ at temperatures above 1600 K. Large and loosely bonded SiC crystallites form, causing the fiber to become brittle. If, however, the fiber is heat treated with boron at high temperatures in an inert gas, the SiC grains in the fiber sinter together, thus eliminating porosity and resulting embrittlement. The chemical composition of this fiber is stoichiometric; this SiC fiber is called Sylramic. Another Tyranno-type fiber $(SiAl_{0.04}C_{1.47}O_{0.39})$ obtained from polyalunimocarbosilane is heat treated at temperatures above 1900 K in argon, and this, too, produces near-stoichiometric SiC sintered fibers. This SiC fiber is called Tyranno-SA. These sintered fibers have high tensile strength and high modulus. They show low creep rates, high thermal stability, and high oxidative resistance.

Several kinds of SiC fibers have been fabricated by the polymer precursor method, and their properties are shown in Table 1.
Figure 4
Tensile strength of SiC fibers produced by the heat treatment in argon from several kinds of cured PCS fibers. The tensile testing was carried out at room temperature.

4. Conclusion

In the development process of ceramic fibers by the polymer precursor method, SiC-based fibers have mainly been produced from polycarbosilanes. The first fibers fabricated were amorphous; low-oxygen fibers were then developed; and finally sintered fibers were created. The high-temperature properties of these fibers have progressively been improved, and sintered fibers have excellent high-temperature resistance. The precursor polymers of these fibers are mainly polycarbosilane polymers prepared by the thermal decomposition of polydimethylsilane. In the near future, in order to obtain high-quality fibers with a diameter of 5 μm and to establish a low-cost fabrication process, more effective polymers as starting materials need to be developed.

Ceramic Matrix Composites with Roughly Equiaxed Reinforcements: Microstructure and Mechanical Behavior

The main goal of ceramic matrix composites is to obtain ceramic-based materials with improved mechanical properties, especially toughness and creep resistance. For this purpose, several reinforcement mechanisms can be used (Fantozzi and Olagnon 1993): phase transformation, microcracking, crack deflection, crack bridging, and fiber or whisker reinforcement.

These mechanisms will first be briefly presented. Then the application of these mechanisms on particle, whisker, and platelet-reinforced composites will be described.

1. General Background on Reinforcement Mechanisms in Ceramics

1.1 Transformation Toughening

Increases in strength and toughness can be obtained in ceramics that undergo a stress-induced transformation (Green *et al.* 1989). The case of ceramics containing zirconia particles that present a tetragonal to monoclinic phase transformation is the most spectacular. By using an addition of Y_2O_3, CeO_2, and others, a metastable tetragonal solid solution can be obtained at room temperature. Under the effect of an applied stress, a martensitic tetragonal (t) to monoclinic (m) transformation takes place in the vicinity of the crack, associated with a volume increase and a shear strain which impede the crack opening and therefore lead to an increase of toughness. This increase, ΔK_c^t, is given by (Evans 1984):

$$\Delta K_c^t = \frac{\eta E e^T V h^{1/2}}{(1 - v)} \tag{1}$$

where η is a factor depending on the shape of the transformation zone around the crack, h its width, E the effective Young's modulus of the material, V the volume fraction of transformed particles, e^T the unconstrained transformation strain, and v is Poisson's ratio.

The zone width and the volume fraction of transformable particles depend on the microstructure and especially on the grain size of the material, via the critical stress for transformation σ_c. The higher the grain size is, the lower is σ_c, thus the higher is the volume fraction of transformed particles; however, when the grain size becomes higher than a critical size, d_c, spontaneous transformation occurs upon cooling and most grains are already transformed before crack propagation.

1.2 Microcracking

When the size of the particles is greater than the critical size d_c, microcracking arises, which leads to a decrease in the strength of the material (Evans 1984). However if the particle size is smaller than the critical size, micro-cracks need additional stress to be induced that can be provided by the applied load. For an efficient reinforcement, the microcracking must be confined in a process zone in front of the crack tip. The particle size must be as close as possible to the critical size to induce significant toughening.

1.3 Crack Deflection

Cracks can be deviated either by the stress fields present around particles or by hard particles of higher resistance. This mechanism leads to a nonplanar crack, subjected to a mixed fracture mode. The

analysis has been carried out for spherical, rod, and disc shaped particles for isotropic composite materials (Evans 1984). In the case of discs and rods, the influence of the aspect ratio has been investigated. High deflection and therefore high toughening are obtained with rods with a high aspect ratio for a volume fraction of about 10–20%.

This analysis has also been extended to the case of rods randomly oriented in planes in order to simulate transverse isotropic whisker-like composites. A more significant reinforcement can be obtained by crack deflection for this more specific case.

1.4 Crack Bridging

Such a reinforcement occurs when a crack meets a reinforcement particle without breaking it. The unbroken ligament exerts a bridging stress on the crack surfaces that counteracts the cracks opening and thus reduces the stress intensity factor (Becher and Rose 1994).

The toughening reinforcement is given by:

$$\Delta K_c^b = 2\left(\frac{V_f \sigma \mu u_c}{1 - v}\right)^{1/2} \tag{2}$$

where V_f is the volume fraction of ligaments, σ the closing stress applied to the ligaments, μ the shear modulus, and u_c the crack opening at the end of the bridging zone.

The reinforcement depends on ligament density and the stress exerted by the ligaments, as well as on the crack opening. The reinforcement must exhibit a high strength in order to exert the highest possible stress and must be of large dimension in order to bridge over a large crack opening.

1.5 Whisker Reinforcement

The analysis of toughening by whisker reinforcement has been reviewed by Becher and Rose (1994). They consider uniaxially aligned whiskers. The analysis of reinforcement by whiskers is close to that developed for crack bridging. However, debonding of the whisker–matrix interface, and consequent friction at the interface, are generally taken into account. When whisker–matrix interface debonding occurs, the bridging stress supported by the whisker is reduced and a large bridging zone appears.

The energy dissipated by friction is given by:

$$\Delta G^f = \frac{V_f(\sigma_f^w)^3 r}{GE^w \tau_o} \tag{3}$$

where σ_f^w, E^w, r, and V_f are, respectively, the strength, the Young's modulus, the radius, and the volume fraction of whiskers, and τ_o is the interfacial shear stress.

The fracture energy increases as the interfacial shear stress decreases, i.e., when more interface debonding occurs. Furthermore, after whisker failure, whisker pullout can contribute to additional toughening.

In the case of short fibers, the same dependence of the fracture energy is observed: low fiber–matrix adhesion and high fiber strength are needed in order to obtain matrix microcracking and fiber pullout with friction and energy absorption.

2. Mechanical Properties of Zirconia-toughened Composites

As shown in Sect. 1.1, the fracture toughness increase is due to the t→m transformation of zirconia particles and needs the retention of t-ZrO$_2$. This retention can be obtained by using several types of microstructures (Claussen 1984). In all cases, the grain size of zirconia particles must be lower than the critical size d_c required for the spontaneous t→m. Zirconia can be found in the form of tetragonal zirconia polycrystal (TZP) stabilized in the tetragonal symmetry by an addition of different oxides, e.g., cerium (Ce–TZP) or yttrium (Y–TZP) oxides. Zirconia can also exist in the form of tetragonal precipitates in a cubic matrix. An example is that of magnesia partially stabilized zirconia (Mg–PSZ). Zirconia particles can also be dispersed in a ceramic matrix other than ZrO$_2$: these materials are called ZrO$_2$-dispersed ceramics. An example of such a composite is the ZrO$_2$-toughened alumina (ZTA) of which a microstructure is shown in Fig. 1.
Figure 1
Microstructure of a zirconia (10 vol.%)-toughened alumina (ZTA). Zirconia appears as the bright phase in back-scattered scanning electron microscope observation.

2.1 Effect of Size and Amount of Zirconia Particles on Toughening

Toughness improvement is related to the tetragonal particle size. In the case of PSZ, the precipitate size depends on the ageing conditions after sintering and solution treatment. A dramatic drop-off in toughness occurs when the precipitate size is just above the critical size d_c: the t→m transformation becomes spontaneous during cooling and the amount of tetragonal precipitates available for transformation decreases. Figure 1 represents a ZTA composite where the zirconia grain size has been optimized in size (below d_c) and distribution (as narrow as possible) in order to obtain the largest amount of transformation toughening (Chevalier *et al.* 2000).

Equation (1) predicts that the toughness increment due to the t→m transformation depends on the volume fraction of transforming particles. This is actually observed (Becher and Rose 1994) when care is taken to control the tetragonal particles content. If during processing, monoclinic particles or stable (nontransforming) particles are obtained, the transformation toughening contribution decreases. Hence, fracture toughness presents a maximum with increasing volume fraction of zirconia particles. The maximum occurs at higher volume fraction with smaller particle size. This behavior is due to local tensile thermal stresses which provoke spontaneously transformation of the zirconia particles during cooling, decreasing the tetragonal phase content. Maximum toughness occurs for a volume fraction of particles corresponding to thermal stresses (which increase with the volume fraction of ZrO_2) reaching the critical stress σ_c. In this case, another contribution to toughening due to ZrO_2 particles that have spontaneously transformed is microcracking in the stress field around the monoclinic particles. Fracture energy (G_c) values for different pressureless sintered (PS) or hot-pressed (HP) ZTA compositions have been measured (Fantozzi and Orange 1986) (Table 1). For PS composites, G_c is nearly constant up to 15 vol.% ZrO_2 whereas, for HP materials, G_c shows a maximum near 10 vol.% ZrO_2.

The observed increase in G_c in PS materials and to 10% ZrO_2 in HP materials can be attributed mainly to the stress-induced transformation-toughening mechanism as indicated by the relative amount to tetragonal phase Qr and as predicted by Eqn. (1).

Above 15 vol.% pure ZrO_2, the relative amount of tetragonal phase is considerably reduced and microcracking toughening becomes the effective mechanism. However, the microcracking toughening is not as energy dissipative as transformation toughening, thus toughness is lower.

2.2 Effect of Solute Content and Temperature

With stabilizing agent additions, the initial tetragonal phase content increases (Table 1), which is reflected by an increase of the critical size d_c. Consequently, the stress-induced phase transformation toughening effect becomes preponderant over microcracking toughening and the fracture energy increases up to 2 mol.% Y_2O_3. For higher Y_2O_3 content, the critical stress σ_c required to initiate the transformation increases and the tetragonal phase becomes too stable to induce transformation toughening (G_c decreases).

Because the critical stress σ_c increases with yttria content and the thermal stresses augment with the volume fraction of ZrO_2, the volume fraction of particles corresponding to maximum toughness increases also as a function of yttria content.

Fracture toughness decreases as temperature increases, σ_c increases. The reinforcement becomes negligible when temperature reaches about 600 °C, the critical temperature at which the t→m transformation is no longer effective.

When the preponderant toughening mechanism is microcracking (e.g., the composite A20Z without stabilizing addition, in Table 1), toughening becomes independent of temperature.

Table 1
Fracture energy of ZTA ceramics.

Source: Fantozzi *et al.* (2000).

Zirconia particles have also been added to reinforce other ceramic matrices. The preceding general features can be applied; however toughening mechanisms are more complex (Green *et al.* 1989).

2.3 Creep and Fatigue Behaviors of Zirconia-toughened Composites

The creep behavior of zirconia-reinforced ceramics has been described recently by Fantozzi *et al.* (2000). The addition of zirconia particles does not improve the creep resistance, creep being essentially controlled by grain boundary sliding (GBS) in the matrix.

The static fatigue behavior of ZTA composites was studied at room temperature (Chevalier *et al.* 2000). Figure 2 shows the slow crack growth behavior of an alumina reinforced under static loading. For comparison, the results obtained for alumina- and yttria-stabilized polycrystalline tetragonal zirconia (3Y–TZP) are also included.

Crack propagation is controlled by stress corrosion by water at the crack tip. Clearly, the slow crack growth resistance is increased for the ZTA composite, because the overall V–K_I (crack velocity versus stress intensity factor) curve is shifted towards high stress intensity factors for the composite. A threshold K_{IO} below which no propagation occurs is observed in the three ceramics. The threshold K_{IO} is higher for the alumina composite compared to alumina or TZP. This result is very significant, e.g., for bio-ceramics applications, where the resistance to slow crack growth is detrimental.

Cyclic loading promotes crack growth rate and leads to a decrease of the threshold stress. The fatigue behavior can be described as stress corrosion propagation associated with toughening degradation (as shown by Chevalier *et al.* 1999). Several toughening mechanisms can intervene (transformation toughening, bridging, microcracking). Similar observations have been made on PSZ composites by Dauskardt *et al.* (1990).
3. Properties of Whisker Composites

Whiskers (W) being strongly anisotropic, different composite textures can be observed depending on the processing route used to produce the composite. The reduction of densification induced by the whiskers has led to the use of hot pressing (HP), which produces a microstructure in which the whiskers are randomly oriented within a plane. This is also the case when the slip-casting route is used. Isotropic bodies can be obtained by powder preparation followed with pressureless or hot isostatic pressing.

The structural anisotropy can be observed on the microstructure and by toughness and strength measurements. An increase of both toughness and strength of about 50% has been measured in SiC(W)–Al$_2$O$_3$ composites when the crack plane was perpendicular to the whisker plane (Becher and Wei 1984). Whiskers have been incorporated in alumina, silicon nitride and to a lesser extent in mullite, zirconia, glass, or other matrices (Bradley *et al.* 1988).

3.1 SiC(W)–Alumina Composites

Spectacular reinforcements by whiskers have been obtained in the case of alumina, with concomitant increases of both toughness and strength, Fig. 3. Toughness values higher than 10 Mpam$^{1/2}$ have been recorded for 20–30 vol.% whisker content. Such composites have been made with small diameter whiskers (0.3–0.6 μm). The achievement of a similar strengthening depends on the whisker dispersion in the matrix and on the densification of the composite. In order to reach theoretical density, the composites are generally hot pressed. Figure 3 shows the evolution of both

Figure 2
Crack velocity versus stress intensity factor K_I in alumina, zirconia (Y–TZP), and ZTA (10 vol.%ZrO$_2$) (after Chevalier *et al.* 2000).
Figure 3
Fracture toughness and flexural strength of whisker-reinforced alumina as a function of whisker content.

toughness and flexural strength of alumina matrix composites with the SiC(W) addition.

As predicted by Eqn. (3), higher toughening is obtained with increasing whisker diameter, strength, and volume content, and with decreasing the frictional interfacial shear stress.

However, owing to the thermal expansion mismatch of SiC and Al_2O_3, too large a whisker diameter induces matrix microcracking, reducing strength. Optimum results have been obtained with whisker diameters lower than $1\,\mu m$ (Fantozzi and Olagnon 1993).

The main toughening mechanisms are crack deflection and crack bridging. Reinforcement is observed up to about $1000\,^\circ C$.

3.2 SiC(W)–Other Matrices Composites

Whiskers have been incorporated in silicium nitride, mullite, zirconia, and glass (Becher and Rose 1994). In the case of a Si_3N_4 matrix, the results were disappointing: the reinforcement is less significant than for alumina. This is due to the different microstructures observed for Si_3N_4: equiaxed or elongated grains depending on the sintering conditions and sintering aids. Toughness values of about $10\,MPam^{1/2}$ have been observed. For other matrices, the toughness increase is lower.

In order to improve toughness further, various toughening processes can be combined: whisker reinforcement, transformation toughening, and matrix microstructural-grain size effect. Either additive or coupled contributions can be obtained and multiple toughening mechanisms provide significant increase in fracture resistance: values of $10\,MPam^{1/2}$ have been observed for mullite reinforced by $20\,vol.\%$ of SiC(W) and $20\,vol.\%$ of t-ZrO_2 and toughness higher than $13\,MPam^{1/2}$ has been achieved for ZTA reinforced with $20\,vol.\%$ of SiC(W).

3.3 Creep Behavior

Most creep studies of these materials have been performed on whisker-reinforced alumina but other matrices such as Si_3N_4, ZrO_2, and mullite have also been studied (Fantozzi *et al.* 2000).

The creep rate of alumina is reduced by the additional SiC(W) as shown by Fig. 4. This decrease depends significantly on the whisker content, size and shape, on the presence of densification additives, and on the matrix grain size. The steady state creep rates of the alumina composites are two orders of magnitude lower than that of monolithic alumina. GBS, accommodated by diffusion processes, is the dominant mechanism responsible for the creep behavior of the composites. The addition of whiskers limits GBS, the whiskers acting as hard intergranular particles. For high whisker content ($\geqslant 30\,vol.\%$), creep resistance is
Figure 4
Stress dependence of the steady creep rate in flexure of alumina (1) and $20\,vol.\%$ SiC (W) composite (2) at $1473\,K$.

degraded, creep cavitation being enhanced. Similar enhancement in creep resistance is observed for mullite. However, reinforced Si_3N_4, ZTA, or ZrO_2 do not show improvement in creep resistance.

4. Particle and Platelet Reinforced Composites

Under this classification, only particles or platelets experiencing no transformation are considered.

The concept is similar to that of whisker composites, but with lower potential toughening. However, this type of composites has the advantage of being processed by conventional methods. The development of such composites was primarily focused on tribological applications with a double target: improving both toughness and hardness.

The reinforcement of alumina by SiC, TiC, BN, and TiN; of silicon carbide by TiB_2, TiC, and AlN; and of silicon nitride by SiC and TiC has been investigated (Fantozzi and Olagnon 1993).

The residual stress due to thermal mismatch is an important parameter controlling toughening. When the thermal expansion coefficient of particles is lower than that of the matrix, composites are likely to experience micro-crack toughening whereas in the contrary case, toughening will be mostly due to crack–particle interaction.

A good example of toughening by microcracking has been observed in SiC–Al_2O_3 composites: a maximum in toughness occurs as a function of the particle contents. Highest toughening is obtained with the smallest particles but a strength degradation is observed for large-sized particles, due to the formation of large cracks.

In the case of Si_3N_4 reinforced with SiC, the highest fracture energy has been obtained with the coarse particles, crack deflection being responsible for toughening without microcracking.

135

Thus, no general law between the toughness and the particle size can be stated since values observed strongly depend on the toughening mechanism. The reinforcement by particles can lead to values of 5–6 MPam$^{1/2}$ for toughness.

Platelets of SiC or Al_2O_3 have been incorporated into Si_3N_4, alumina, mullite, and TZP matrices. Toughening is due to crack deflection and crack bridging, with some pullout. In the case of Si_3N_4, spectacular toughening has been observed with 30% SiC platelets (14 MPam$^{1/2}$), but this was accompanied by a strength reduction. A special mention must be made with regard to nanocomposites (Niihara 1991). The reinforcing nano-sized particles are either inter- or intragranular. Indeed, room temperature and high temperature strengths are significantly improved in nanocomposites, although fracture toughness is only modestly increased. The particles bridging and the decrease of flaw sizes could be the essential strengthening mechanisms.

The creep behavior of particle or platelet reinforced composites has been studied for different matrices (alumina, mullite, Si_3N_4) (Fantozzi *et al.* 2000). In the case of alumina composites, the increase of creep resistance is lower than that observed with the whisker composites (one order of magnitude). On the other hand, alumina/silicon carbide nanocomposites present an excellent creep resistance: the creep rate is reduced by two to three orders of magnitude in comparison with alumina. The SiC nanoparticles hinder GBS and provoke a large improvement in creep resistance.

Improvement of creep resistance in other matrices for particle or platelet composites is also observed but is generally low. However, excellent creep resistance is obtained for mullite–zirconia composites and Si_3N_4 composites.

5. Conclusion

Monolithic ceramics can be toughened with roughly equiaxed reinforcements primarily to increase toughness, strength, creep resistance, and fatigue behavior. A wide variety of approaches can be used to reinforce ceramics: toughness values can be increased from 2–4 MPam$^{1/2}$ for monolithic ceramics to about 15 MPam$^{1/2}$ for composites with an optimized microstructure.

Ceramic Matrix Composites: Applications

This article provides a short guide to the application of ceramic matrix composites (CMCs). Its purpose is to give the reader an appreciation for the broad range of potential for CMCs via illustrations of programs that have remained largely in the research and development phase, but which have demonstrated the directions for future applications.

The applications of CMCs are based on the fact that ceramics are key to meeting the "everyday" needs of society as well as enabling high-performance, futuristic concepts. Encompassing such a diverse range of materials as pottery, cements, high-temperature refractories and their coatings, and glasses, these materials are integral to our everyday lives.

Some of the well-known problems with ceramic materials, however, are that they are frequently fragile, lack toughness, and can fracture readily upon impact. Much of the technological history of ceramics has been devoted to overcoming these problems and notable successes are clearly evident. The highly impact-resistant window glasses found in automobiles and the use of steel rods to reinforce concrete are examples that are relied on every day.

1. General Application Requirements

As described in *Ceramic Matrix Composites: Matrices and Processing** and *Ceramic Matrix Composites with Roughly Equiaxed Reinforcements: Microstructure and Mechanical Behavior**, CMCs are a class of materials that address the issue of toughness by the incorporation of particles, fibers, and interfaces to inhibit the growth of cracks. The broad fields of building/construction, industrial equipment, and aerospace can all benefit significantly from the development of CMCs. The key attributes for successful application in these sectors can be summarized as follows:

Environmental durability. First and foremost, CMCs must exhibit the important environmental durability typical of ceramics. Polymers decompose and burn and metals corrode and melt under conditions that have little or no effect on many ceramics. This simple fact, combined with the relative low density of ceramics, ensures that CMCs will be well received in many potential applications, if they are durable and cost effective.

Strength combined with toughness. As described in *Continuous Parallel Fiber Composites: Fracture** and *Ceramic Matrix Composites with Roughly Equiaxed Reinforcements: Microstructure and Mechanical Behavior**, CMCs possess the unique capability of providing a combination of both strength and toughness (crack growth resistance) well in excess of traditional, monolithic ceramics. Because of the brittle nature of fracture in monolithic ceramics, toughness is the most important quality of CMCs. It is exemplified by the ability of CMCs to crack and deform locally, without causing total structural failure. This is necessary to provide reliability in the event that damage occurs during use or if loading in service exceeds the intended design limits.

Cost effectiveness. Finally, affordability must be achieved. In the development of CMCs this has been approached in two ways. First, CMCs are generally more costly than their unreinforced ceramic counterparts; however, CMC potential performance advantages and longer lives can "earn" this higher cost. Second, by virtue of the unique, new fabrication processes enabled by the structure of CMCs, it may be possible to manufacture very special new shapes or articles not even possible in ceramics. The following examples illustrate this concept.

2. Applications

2.1 Construction Industry Applications

The use of fibrous additives in brittle materials to facilitate their fabrication and use in construction applications is one of the oldest technologies known. The biblical reference to the use of straw in the manufacture of brick (Exodus 5:6) is a well-known example as is the more contemporary use of asbestos fibers in the manufacture of plasters and cements for domestic use. The application of cellulose fiber-reinforced plasters (papier-mâché) in Europe in the 1800s is an example of this technology being applied in decorative and practical ways. A comprehensive reference to the many ways in which reinforced cementatious materials can be created and used can be found in Hanant (1978).

Another example of achieving both toughening and strengthening is the use in Japan of small percentages (1–3 vol.%) of discontinuous carbon fibers in cement. The loosely bonded carbon fibers alter the fracture morphology to permit multiple microcracking and change the deformation behavior. This change in fracture characteristic causes the effective toughness of this material to become very high and difficult to quantify because cracks are diverted from their original path (i.e., no longer self-similar). Even at these very low volume percentages of fiber, the ability to alter the fracture mode can cause significant increases in reliability and structural strength. This technology has been so successful that it has led to the development of a lightweight concrete used in the construction of large buildings (Fig. 1).

Figure 1
A 37 story building in Tokyo that has a carbon fiber-reinforced cement exterior. The low weight is achieved by adding large percentages of lightweight fly ash to the cement along with 2% chopped carbon fibers to increase toughness and strength.

2.2 Aerospace Applications

The impetus provided by potential aerospace applications has clearly been the key driver since the 1970s for the development of new types of CMCs. This has been a global effort with very large national teams leading the way. In Europe, Asia, and the USA there have been focused government-funded programs to apply ceramic composites to conventional gas turbine engine technology. The advantages sought have been lighter weight, improved durability, and greater efficiency as compared to metals-based designs.

(*a*) *Military fighter programs.* An example of a successful application is the European development of military aircraft components using a SiC matrix reinforced with either carbon or silicon carbide fibers. These composites are manufactured using the chemical vapor infiltration (CVI) process, as described in *Ceramic Matrix Composites: Matrices and Processing** and elsewhere (Naslain 1999). The application of these composites to the exhaust nozzles of high-performance military engines (Fig. 2) achieves mass savings of up to 60% compared with the more traditional metal components in service (Spriet and Habarou 1996).

(*b*) *Japan's Advanced Material Gas Generator Research and Development (AMG) project.* Japan, the country in which SiC-type fibers have reached their highest state of commercial development, also has major national programs to apply ceramic composites to gas turbines. Most notable is the AMG project, initiated in 1993, which involves the combined efforts of 14 major Japanese companies (Hiromatsu *et al.* 1995). The ambitious goals of this program include a 50% reduction in engine weight, a 20% improvement in fuel consumption efficiency, and a 75% decrease in the emission of nitrous oxides. The program has resulted in several key demonstrations of CMC performance. One example is a large CMC combustor liner, which operated without failure under conditions in which the gas temperature reached 1600 °C (Nishio 1998). Another example is a complex, rotating CMC gas turbine engine component known as a "blisk," a term to indicate that it consists of a series of blades (gas turbine airfoils) that are integrally embedded in a disk (Fig. 3). This significant transformation from metals-based gas turbine technology is attributable to the use of continuous fibers to make both the blades and the disk. The integration of these elements is accomplished via integral weaving of the entire structure, followed by composite densification to achieve the final shape (Nojima *et al.* 1999).

(*c*) *Supersonic commercial flight.* While the engine applications discussed above have clearly demonstrated the possibility for improvements in performance, it is the future concepts of supersonic commercial flight that capture the imagination and demonstrate the possibilities that CMCs can provide. A notable example of this is the national initiative in high-speed research in the USA. This effort is focused on the development of the technology to enable the creation of a 300 passenger civilian transportation aircraft that can travel 8000 km with a cruise speed of Mach 2.4. This would permit travel between Los Angeles and Tokyo in 4 hours, compared to the 10 hours of the late 1990s. An overview of this program

can be found at the website www.lerc.nasa.gov/
WWW/HSR/HSROver.html. The ability of CMCs
to be formed into large, lightweight structural ele-
ments that can perform at high temperatures is key to
the success of this aircraft and its ability to meet
environmental requirements. Large CMC combustor
liners (for reduced nitrous oxide emission) and nozzle
acoustic liners (for reduced noise) have been success-
fully developed and tested under realistic engine
conditions. Details of how CMCs have been used
in these structures can be found at the website
www.lerc.nasa.gov/www/hsr/epm.html.

This program has achieved significant milestones
in the demonstration of durability and fabricability
of complex structures. The impetus was curtailed
when the US government decided to slow the pace of
high-speed civil transport development; however, the
materials technologies developed in this program will
be used in other, more immediate applications in the
gas turbine and industrial arenas.

2.3 Industrial Applications

While the aerospace industry has provided the tech-
nological basis for high-temperature CMCs, the cost
of such CMC materials still remains high. Much
larger volumes of production must be developed to
bring costs down. Industrial applications for CMCs
offer this opportunity.

The already widespread use of ceramics in many
industrial applications provides a fertile basis for the
future large-volume use of CMCs. A good source of
information regarding existing ceramic applications
is the American Ceramic Society (www.acers.org).
The technical requirements to be successful in indus-
trial applications (Frietag and Richerson 1998) are no
less complex than those for aerospace applications.
However, in an industrial environment prone to
rough handling and occasional unanticipated dam-
age, the fragile nature of ceramics frequently limits
their applicability. This provides the opportunity for

tough CMCs to enable application. As in the case of
the construction industry, the need for achieving
benefits while keeping the cost low is paramount.

A program dedicated to this expansion of CMC
use into the industrial sector is the US Department of
Energy-funded Continuous Fiber Reinforced Ce-
ramic Composites (CFCC) program. Led by the US
Oak Ridge National Laboratories, this program
(www.ms.ornl.gov/programs/energyeff/cfcc/default/
htm) addresses a broad range of applications, many
of which are summarized in Table 1.

2.4 Space-based Applications

CMCs also find application where very specific prop-
erties can be developed via the creation of unique
combinations of materials and microstructures. One
such example is the development of dimensionally
stable composites for space-based satellite applica-
tions. In this very special case, the development
of a combination of dimensional stability, toughness,
and thermal conductivity results in a material suited
to the fabrication of both space structures and also
mirrors. The latter are particularly demanding
and are manufactured via the use of specialty glasses
that require very tedious and expensive hot forming
and machining operations to achieve their final,
lightweight dimensions. In contrast, the incorpora-
tion of carbon fibers into a glass matrix can achieve
similar levels of dimensional stability, with much
higher thermal conductivity and stiffness and a
significant reduction in weight. The mirrors shown
in Fig. 4 are comprised of chopped carbon fibers
in a borosilicate glass matrix. They have a thermal
expansion coefficient of less than $0.1\,ppm\,°C^{-1}$ from
$-150\,°C$ to $+100\,°C$. Tests on board NASA's
Long Duration Exposure Facility (LDEF) satellite
have also demonstrated the extreme resistance of
carbon fiber-reinforced glass composites to the effects
of atomic oxygen (AO) degradation (Tredway and
Prewo 1991).

Table 1
Industrial applications of CMCs under development.

Industrial application	CMC material type
Self lubricating diesel valve guides	Carbon fiber-reinforced silicon nitride produced via hot isostatic pressing
Tubular radiant burners and heat exchangers	Silicon carbide-type fiber-reinforced silicon carbide produced via chemical vapor infiltration
Hot gas filters and heat-treating furnace fan blades	Silicon carbide-type fiber-reinforced silicon carbide produced via chemical vapor infiltration
Immersion heating tubes for aluminum metal processing	Silicon carbide-type fiber-reinforced bonded silicon carbide

Figure 4
Mirrors for space-based optical applications.
Manufactured with carbon fiber-reinforced glass, they
exhibit extreme dimensional stability and highly
polished surfaces.

3. Conclusion

The applications described in this article, along with many others achieved in a global community of national programs and companies, provide a robust basis for CMC technology readiness. The future realization of large-scale applications requires three things to happen. First, the need for CMCs must be shown conclusively; it must be demonstrated that metals and polymers alone will not suffice. Environmental requirements for cleaner and more efficient combustion will surely contribute to this clarification. Second, confidence in CMC production and performance must be established further. No serious applications will emerge without user confidence in the CMC suppliers and the performance of the resultant materials. Finally, CMCs must be affordable. The existent, well-recognized maturity and economic success of polymer matrix composites provides an excellent example that CMCs can follow.

Ceramic Matrix Composites: Matrices and Processing

Ceramic matrix composites (CMCs) generally consist of ceramic fibers or whiskers in a ceramic matrix. CMCs are designed to overcome the main drawback of monolithic ceramics, namely their brittleness. They are referred to as inverse composites, which is to say that the failure strain of the matrix is lower than the failure strain of the fibers, whereas it is the reverse in most polymer or metal matrix composites. Hence, under load it is the matrix which fails first. In order to prevent an early failure of the brittle fibers when the matrix starts to microcrack, the fiber/matrix (FM) bonding should be controlled during processing. CMCs are tough materials and display a high failure stress when the FM bonding is not too strong or too weak, which is usually achieved through the use of a fiber coating referred to as the interphase (Chawla 1993, Warren 1992, Mazdiyasni 1990). The fabrication of CMCs requires specific processing techniques. Gas- or liquid-phase routes (or a combination of both), in which the interphase and the matrix are formed around the fibers from gaseous or liquid precursors, are usually preferred.

CMCs are used as thermostructural materials under severe service conditions, e.g., high temperatures under load and in corrosive atmospheres, such as combustion gases. The most commonly used CMCs are nonoxide CMCs, namely carbon/carbon (C/C), carbon/silicon carbide (C/SiC), and silicon carbide/silicon carbide (SiC/SiC), the fibers being specified first.

1. Structure

There are three constituents in a CMC: a fiber (or whisker reinforcement), a matrix, and generally an interphase. The nature, volume fraction, and arrangement of the constituents depend on a number of considerations including the function of the part to be fabricated, the service conditions, and the cost.

Both oxide and nonoxide fibers are used in practice. Refractory oxide fibers, such as alumina-based fibers, display a high resistance to oxidizing atmospheres and are insulating materials. However, their strength retention and creep resistance at high temperatures are poor due to grain growth. The most attractive oxide fibers are those made of a mixture of alumina and mullite ($3Al_2O_3$, $2SiO_2$), their service temperature limit being 1000–1100 °C. Nonoxide fibers include carbon and SiC-based fibers. With respect to oxide fibers, they exhibit a lower density and much better strength retention and creep resistance at high temperatures. The failure strength of carbon fibers increases with increasing temperature up to 1500–2000 °C and that of the best SiC fibers is still significant at 1400–1500 °C. Depending on their composition and microstructure, they are either conducting or insulating. Unfortunately all of them react with oxygen, above 500 °C for carbon fibers and above 800 °C for SiC fibers. The fiber arrangement depends on the load pattern. It is rarely unidirectional (1D) but rather multidirectional (nD, with $n \geqslant 2$). In this latter case, which is very common in CMCs, the starting material is a fiber preform, i.e., a self-standing porous body made of fibers (continuous or short) and having roughly the shape and size of the part to be fabricated (Bunsell and Berger 1999).

The interphase has a key role in a CMC although its volume fraction is extremely low. It is actually a thin coating (less than 1µm) deposited on the fibers or formed *in situ* during composite processing. It has three main functions: load transfer, crack deflection (the so-called mechanical fuse function), and diffusion barrier (in reactive FM systems). The best interphase materials might be those with a layered crystal structure (such as pyrocarbon (PyC) or hexagonal boron nitride (BN)) or a layered microstructure (such as (PyC–SiC)$_n$ multilayers, with $n = 5$–20) (Fig. 1(a)), the layers being oriented parallel to the fiber surface to promote crack deflection (Naslain 1998).

A variety of ceramic matrices are used. Silica-based glass–ceramics, i.e., ceramics made of a mixture of a crystalline refractory phase and a glass phase have been extensively studied (Mazdiyasni 1990). The most common are LAS, MAS, MLAS, CAS, and BMAS, with $L = Li_2O$, $A = Al_2O_3$, $S = SiO_2$, $M = MgO$, $C = CaO$, and $B = BaO$. All of them have two important advantages. First, before being ceramed, they are glasses which soften upon heating and display relatively low viscosities at high temperatures. This property is actually used to embed the fibers by hot pressing. Second, they exhibit a high resistance to corrosive media. However, the occurrence of residual glassy phase in the ceramed state lowers their creep resistance. Alumina and mullite, the latter having a better creep resistance than the former, are also used. However, their lack of plasticity at high temperatures is an important disadvantage in terms of CMC processing.

(a)

(b)
Figure 1
(a) Multilayered interphase and (b) self-healing matrix infiltrated in a fiber preform by P-CVI (courtesy of S. Bertrand and F. Lamouroux *et al.*).

Nonoxide matrices comprise mainly carbon, silicon carbide, and silicon nitride. Carbon matrices display a variety of properties depending on their microtexture. Pyrocarbon can be isotropic, nongraphitizing, and insulating on the one hand, or strongly anisotropic (laminar), graphitizable through heat treatment at very high temperatures (2500–3000 °C), and highly conducting (such as the so-called rough laminar used for C/C brake systems) on the other hand. Carbon is extremely refractory (≈ 3600 °C), light (1.8–2.1 g cm^{-3}), and biocompatible (C/C composites are used in prosthetic devices) (Savage 1993). Silicon carbide is less refractory (≈ 2500 °C) and its density slightly higher (3.2 g cm^{-3}). It is extremely hard and, more interestingly, its reaction with oxygen results in the formation of a protective layer of silica explaining why SiC ceramics can be used up to about 1500 °C in oxidizing atmospheres. Beyond this limit and/or at low oxygen partial pressure, the oxidation of SiC yields gaseous silicon monoxide (SiO) with no longer any protective effect. SiC matrices can actually be pure SiC or mixtures of SiC with free silicon or free carbon. When free silicon is present, the service temperature limit is lowered to ~ 1410 °C. The occurrence of free carbon does not alter the refractoriness of SiC matrices. Silicon nitride matrices have properties close to those of SiC matrices; however, they are less thermally stable and exhibit lower conductivities.

When selecting a given fiber–interphase–matrix system, several considerations should be taken into account. First, the constituents should be compatible. The coefficients of thermal expansion (CTEs) of the fiber, α_f, and the matrix, α_m, should be roughly the same. If $\alpha_m > \alpha_f^R$ (the radial CTE of the fibers), the matrix clamps the fibers after cooling from processing to ambient temperature, resulting in strong FM bonding and a brittle character. Conversely, if $\alpha_m < \alpha_f^R$, the FM interface may spontaneously debond during cooling. The matrix should also be chemically compatible with the fibers. FM reactions may alter the strength of the pristine fibers and/or change the FM bonding. As an example, SiC fibers react with silica-based glass–ceramic matrices and a suitable interphase, such as a BN–SiC dual interphase, has to be used. To avoid these problems, the fibers and the matrix often have relatively close compositions in actual CMCs.

CMCs should also be compatible with their service atmospheres. Mostly, these service atmospheres are oxidizing (air or combustion gases) whereas the best CMC constituents are nonoxides, a somewhat paradoxical situation. To solve this key problem, two routes have been suggested: (a) the use of oxidation inhibitors and protective coatings and (b) the design of self-healing interphases and matrices. The addition of boron or phosphorous compounds (inhibitors) to carbon matrices decreases significantly their oxidation rate. Multilayered coatings containing glass formers (such as silicon or boron carbides) are also used to slow down the in-depth diffusion of oxygen in C/C composites. The concept of multilayered self-healing interphases (Fig. 1(a)) and matrices (Fig. 1(b)) has been developed for advanced SiC matrix composites, with a dramatic increase in their lifetime in oxidizing atmosphere at high temperatures and under cyclic loading (Lamouroux *et al.* 1999). Here, the interphase and/or the matrix, deposited according to a gas-phase route, are multilayered, involving crack arrester layers (such as PyC or BN) and glass former layers (such as B–C, Si–C, or Si–B–C compounds). When a microcrack is formed, oxygen diffusing along that crack reacts with the boron- or silicon-bearing species, yielding a low-viscosity glass which fills the crack and slows down oxygen diffusion. Under such conditions, the composite behaves somewhat as a smart material. It displays high mechanical performance with a lifetime long enough for applications under oxidizing atmospheres (e.g., in engines) (Naslain 1999).

2. Processing Routes

Most ceramic matrices being hard, refractory, and displaying no (or little) plasticity within a broad temperature range, the brittle fibers are preferentially embedded in a liquid or gaseous precursor of the matrix which is transformed into a ceramic matrix via chemical reactions or annealing treatments (Mazdiyasni 1990, Naslain 1999, Warren 1992).

2.1 Liquid-phase Routes

(*a*) *Reactive melt infiltration* (*RMI*). RMI processes can be used when one of the elements constituting the ceramic matrix displays a low (or relatively low) melting point and readily wets the fibers. Such is the case for aluminum alloys (m.p. ≈ 650 °C) and even silicon (m.p. $= 1410$ °C). The former can yield an alumina matrix by reaction with an oxidizing atmosphere and the latter a silicon carbide matrix through a chemical reaction with a carbonaceous fiber preform.

In the so-called DIMOX process (from a company called Lanxide, DE, USA), the molten element, aluminum, reacts with the atmosphere, e.g., air, as it climbs by capillary forces in the preform pore network, yielding an alumina matrix. The alumina matrix grows according to a complex mechanism involving the dissolution of oxygen and the precipitation of alumina, in which magnesium (present in the alloy) plays a key role. A layer of magnesia is formed at the metal surface which actually prevents the formation of a dense protective scale of alumina that would otherwise stop the in-depth diffusion of oxygen. The process being run at about 1200 °C, a variety of fibers, including Si–C–O Nicalon fibers (from Nippon Carbon), can be used. The process can be extended to

nitride matrices (such as aluminum nitride and even silicon nitride) if it is conducted in a nitrogen atmosphere (Mazdiyasni 1990, Urquhart 1991).

In the so-called SILCOMP (from General Electric) and related processes, a ceramic fiber preform is first consolidated with carbon, e.g., according to the PIP process (see below). Then it is impregnated with liquid silicon at about 1450 °C (Fig. 2). Liquid silicon spontaneously wets carbon and hence climbs by capillary forces in the preform pore network, reacting with the pore wall, i.e., carbon, to give the SiC matrix (Mazdiyasni 1990, Luthra *et al.* 1993). Since the process is run at high temperatures, only fibers with a high thermal stability, namely carbon or oxygen-free SiC fibers, can be used.

Both processes are relatively rapid and yield near-net-shape composites. Conversely, liquid aluminum and silicon being corrosive, the fibers have to be precoated. Dual BN–SiC coatings deposited from gaseous precursors (see Sect. 2.3) have been successfully used in Nicalon/alumina and Hi-Nicalon/SiC composites. The BN sublayer acts as mechanical fuse (crack deflection function) and the SiC sublayer as diffusion barrier. Further, some residual free aluminum or silicon is usually present in the matrix as the result of an incomplete chemical reaction, which lowers the mechanical properties at high temperatures. Residual aluminum can actually be removed by wicking (thus yielding some open porosity) whereas residual silicon can be entrapped in the SiC matrix as a refractory silicide when necessary.

(*b*) *Polymer impregnation and pyrolysis* (*PIP*). In the PIP process, a porous fiber preform is first impregnated with a liquid organic (or organometallic) precursor of the matrix. After curing by heating, irradiation, or chemical reaction, the material is pyrolyzed at medium temperatures (700–1000 °C). When necessary, the composite is further submitted to a heat treatment (2500–3000 °C for carbon) to stabilize its microstructure and optimize its properties (Fitzer and Manocha 1998, Mazdiyasni 1990, Savage 1993). The liquid precursor is used either in the molten state or in solution. Examples of commonly used precursors are thermosetting polymers (e.g., polyphenolics) or mesophase pitch for carbon, polycarbosilanes for SiC, and polycarbosilazanes for Si–C–N matrices. The liquid phase should display a low enough viscosity and wet the fibers (in the impregnation step).

Further, the precursor should have a high ceramic yield, typically 70–85 wt.% (in the pyrolysis step). Even under such conditions a weight loss and shrinkage of the matrix occur during the pyrolysis due to the formation of gaseous species. This drawback can be overcome by loading the liquid phase with an inert filler (such as a fine powder of the ceramic matrix) and/or by repeating several times ($n = 4$–10) the impregnation–curing–pyrolysis sequence, hence increasing processing time and labor cost at the plant level. Further, organometallic liquid precursors are often sensitive to moisture. The PIP process relies on relatively simple technologies.
Figure 2
Principle of RMI processing of Si–SiC matrix composites (courtesy of K. Luthra).

(*c*) *Slurry impregnation and hot pressing* (*SIHP*). The SIHP process can be used to fabricate a variety of oxide and nonoxide matrix composites. In a first step, a fiber tow (or a fiber tape) is impregnated with a slurry, i.e., a stable suspension of matrix powder in a liquid containing a fugitive organic binder and various additives. The wet continuous material is taken up on a drum, yielding after drying a green composite prepreg somewhat similar to those employed for producing polymer matrix composites. After cutting and stacking, the prepreg layer assembly is heated to eliminate the fugitive binder and hot pressed yielding a dense matrix composite (Mazdiyasni 1990).

Two requirements should be fulfilled. First, the fibers should be stable under the hot-pressing conditions; hence, the fiber choice is limited to the most stable ceramic fibers, such as the oxygen-free SiC fibers. Second, the matrix should soften enough and flow during hot pressing to embed the fibers, supposing that some liquid phase is formed. This is typically the case for glass and glass–ceramic silica-based matrices, as already mentioned, the hot-pressing temperature being 1200–1400 °C. For such matrices, a heat treatment (the ceramization step) is usually performed after hot pressing, to transform partly or totally the glassy matrix into the related stable crystalline phase(s). Specific sintering additives, which form a small amount of liquid phase at the sintering temperature, have to be added to the slurry, for refractory covalent nonoxide matrices (such as SiC and Si_3N_4), hot pressing being performed at much higher temperatures (up to ~ 1800 °C), with some risk of fiber degradation. Some organic or organometallic liquid precursors (e.g., PCS for SiC) can also be added to the slurry. An important advantage of CMCs fabricated according to the SIHP process lies in their low residual porosity.

2.2 Vapor-phase Routes

In vapor-phase routes, also referred to as chemical vapor infiltration (CVI), the interphase and the matrix are successively deposited within the pore network of a fiber preform from gaseous precursors. The chemical reactions involved in the deposition process have to be activated. This is achieved by heating the fiber preform to moderate temperatures (typically 900–1100 °C) either in cold- or hot-wall reactors, the latter being usually preferred. CVI is closely related to chemical vapor deposition (CVD), a process commonly used in material engineering to form thin films, thick coatings, or filaments. Both processes have the same chemical basis but are run under different temperature (*T*), pressure (*P*), and gas flow rate (*Q*) conditions. In CVD, deposition mainly occurs on the external surface of the substrate, whereas in CVI it takes place within the pores of the substrate, the deposition process being used to embed the fibers in

the ceramic matrix, i.e., to densify the fiber preforms (Warren 1992).

Two different phenomena are involved in CVI: (a) chemical reactions occurring either in the gas phase or on the fiber surface with formation of the deposit and (b) mass transfer of the gaseous reactants and products outside the preforms and in their pore networks. As an example, carbon, silicon carbide, boron nitride, and alumina can be deposited according to the following overall equations (Naslain and Langlais 1986):

$$CH_4(g) \rightarrow C(s) + 2H_2(g) \tag{1}$$

$$C_3H_8(g) \rightarrow 3C(s) + 4H_2(g) \tag{1a}$$

$$CH_3SiCl_3(g) \overset{H_2}{\rightarrow} SiC(s) + 3HCl(g) \tag{2}$$

$$BX_3(g) + NH_3(g) \rightarrow BN(s) + 3HX(g) \quad \text{with} \quad X = F, Cl \tag{3}$$

$$2AlCl_3(g) + 3CO_2(g) + 3H_2(g) \rightarrow$$
$$Al_2O_3(s) + 3CO(g) + 6HCl(g) \tag{4}$$
Actually, the chemical mechanisms are much more complex and often involve intermediate gaseous species, the gas phase undergoing a maturation process as it diffuses in the pores. Mass transfer of the gaseous species occurs by convection and/or diffusion depending on *T–P–Q* conditions. Generally speaking, a key requirement in CVI is that the pores should remain open up to the end of the densification process.

(*a*) *Isothermal/isobaric CVI* (*I-CVI*). In I-CVI, the fiber preforms are set in the isothermal zone of a hot-wall deposition chamber (Fig. 3). The gaseous precursor flows outside the preforms by convection and inside the preforms by diffusion. In order to avoid an early sealing of the pores entrance by the deposit, deposition is performed at relatively low temperatures (to lower reaction rates) and under reduced pressures (to favor the diffusion of the gaseous species in the pores). Hence, the deposition yield and deposition rate are low. When necessary, the densification process is stopped and the preform surface machined in order to reopen the porosity or to enlarge the pore entrance (deposition occurring preferentially near the pore entrance) (Naslain and Langlais 1986, Savage 1993, Warren 1992).

(*b*) *Temperature/pressure gradient CVI* (*F-CVI*). The F-CVI process (the "F" signifying "forced") has been designed to increase the deposition rate and to shorten the densification time via the use of temperature and pressure gradients applied to the
Figure 3
Principle of I-CVI processing of 2D fiber/SiC matrix composites (courtesy of Woodhead Publishers).

fiber preform in opposite directions. The reactant species are injected in the fiber preform through its cold face (where almost no deposition occurs), under pressure, whereas the porosity is rapidly filled near the opposite hot face (where the deposition rate is high). As deposition proceeds, a densification front moves from the hot face to the cold face (whose temperature progressively increases if the deposit is conducting, this being the case for both pyrocarbon and SiC), while the unreacted precursor and reaction products are extracted by pumping first through the hot face of the sample then through its lateral face(s). Under such conditions, the densification time is significantly shortened (Mazdiyasni 1990).

(*c*) *Pressure-pulsed CVI* (*P-CVI*). In P-CVI, the furnace and the fiber preform pore network are first evacuated by pumping. Then the reactants are injected in a very short time in the reactor and inside the preforms. Deposition occurs during a given time, referred to as the residence time. This sequence of events is repeated in time, the opening and closing of the gas flow valves being operated automatically. One of the advantages of P-CVI lies in the fact that the fiber preform pore network is periodically fed with fresh reactants whereas the reaction products (which often act as reaction inhibitors) are periodically evacuated. Second, when the residence time is low enough (typically a few seconds), the deposit thickness per pulse can become extremely small (of the order of 1nm or less). Hence, if the composition of the precursor is periodically changed, P-CVI yields multilayered

ceramic deposits. As an example, if one switches periodically from propane (Eqn. (1)) to methyltrichlorosilane/hydrogen (Eqn. (2)), a multilayered (PyC–SiC)$_n$ interphase can be deposited *in situ* on the fibers surface (Fig. 1(a)) (Naslain 1998).

(*d*) *Film boiling*. In the film boiling (or calefaction) process, a self-standing fiber preform, inductively heated with a susceptor, is directly immersed in a boiling liquid precursor, e.g., cyclohexane for pyrocarbon matrices. Assuming an axisymmetrical configuration, i.e., a cylindrical preform with a hole at the center in which the susceptor is set, a steep temperature gradient is generated radially in the preform. Further, precursor mass transfer in the preform, diphasic in character, is extremely efficient. As in the F-CVI process, a densification front moves vs. time from the preform hot surface (that near the susceptor) to the surface in contact with the boiling precursor. Densification times of the order of one day have been reported (David *et al.* 1999).

(*e*) *Advantages and drawbacks*. CVI processes are run at relatively low temperatures and hence are less damaging to the brittle fibers. They also yield interphases and matrices with high microstructural quality and excellent mechanical properties. Further, some of these processes are extremely flexible and all yield near-net-shape materials. However, CVI processes require important investments for volume production and the resulting CMC parts exhibit some residual

open porosity. This residual porosity is not a problem from a mechanical standpoint since CMCs are tough materials; however, the occurrence of open residual porosity (that does not exist in composites fabricated according to some of the liquid-phase routes, e.g., the RMI process for SiC–Si matrix composites) favors the in-depth diffusion of oxygen in service conditions, which can be a drawback in nonoxide CMCs unless the materials are self-healing.

I-CVI has been already transferred to the plant level for the fabrication of C/C brake disks or C/SiC jet engine parts. Its main advantage is its high flexibility, a large number of preforms (which may have different sizes and shapes) able to be treated simultaneously. Even when intermediate surface machining of the partly densified preforms is performed, there is still much less handling than in, say, the PIP process. The flexibility of the process mitigates the fact that the densification times are relatively long. I-CVI is the preferred process for the volume production of CMC parts.

Both F-CVI and film boiling are attractive processes since densification times can be reduced by almost one order of magnitude with respect to I-CVI; however, their flexibility is much lower. In F-CVI, a specific fixturing has to be used for each fiber preform to establish the temperature/pressure gradients. As a result, this process is not suitable for the densification of preforms of complex shapes. In a similar manner, the use of a susceptor per preform (or pile of preforms) somewhat limits the flexibility of the film boiling process. To summarize, both processes may be advantageous when limited series of parts, with a relatively simple shape, have to be fabricated and delivered in a short time.

P-CVI is still an experimental process. It has a flexibility similar to that of conventional I-CVI but it requires more complex facilities. Although its use may result in shorter densification times, its main advantage lies in the fact that it is extremely suitable for the infiltration of highly engineered multilayered ceramics (interphases and matrices) in porous fiber preforms (Fig. 1).

2.3 Solid-state Routes

Solid-state routes, which are in principle closely related to the powder processing of multiphase ceramics, are limited to CMCs with short fiber reinforcements, such as whiskers (Mazdiyasni 1990). The starting material is a homogeneous powdered mixture of the fibers and the matrix, with appropriate additives (e.g., fugitive binder, sintering aids, stabilizers, etc.). It is often prepared by ball-milling in a protective liquid medium. After drying, the powder mixture is poured into the die of a press and sintered by uniaxial hot pressing. It can also be cold pressed, encapsulated in a suitable material (a metal or a glass), and

sintered isostatically. During the ball-milling and hot-pressing steps some fragmentation of the brittle fibers usually occurs, leading to a decrease of the fiber aspect ratio and reinforcing capability. Further, the presence of the short fibers often renders the sintering of the powder matrix still more difficult (sintering of covalent carbides and nitrides, such as SiC and Si_3N_4, being known to be intrinsically difficult and to necessitate sintering additives), requiring high temperatures and pressures. Hence, only very stable fibers can be used (short carbon fibers or SiC whiskers). Finally, composites fabricated with short fibers according to solid-state routes display mechanical properties which are much lower than those of the related composites processed from continuous fibers.

SiC whiskers have been used in alumina-based or silicon nitride matrices, e.g., for producing cutting-tool inserts and other wear-resistant items, with an increase in toughness, hardness, and lifetime. It is important to note that the use of whiskers of small size raises health problems somewhat similar to those reported for asbestos fibers, which actually limit the development of these composites.

3. Concluding Remarks

The development of low-cost, high-performance CMCs relies on available fibers and it supposes an optimization of both the FM interfacial zone and the matrix itself. Some progress has been achieved in the field of ceramic fibers. As an example, oxygen-free SiC fibers and quasistoichiometric SiC fibers display a higher thermal stability than their Si–C–O counterparts. Hence, they are compatible with a variety of processing techniques including the high-temperature processes. However, available oxide fibers are not stable enough from a microstructural standpoint.

A key point in terms of material design is to improve the durability of nonoxide CMCs in oxidizing atmospheres. Taking the example of SiC/SiC composites, a promising approach is to replace the pyrocarbon interphase by boron nitride or multilayered $(PyC–SiC)_n$ or $(BN-SiC)_n$ interphases and the SiC matrix by self-healing multilayered matrices. In terms of processing, rapid densification techniques (such as RMI or film boiling) are becoming available beside well-established routes (such as CVI) which could still be improved. Even if these processes display less flexibility, they may be appropriate for specific matrix compositions and/or specific application areas.

Ceramic Nanocomposites with Organic Phases, Optics of

Since the 1970s there has been considerable progress in the sol–gel technique for the manufacture of glasses, glass-ceramics and ceramics. This method has been successfully used for a variety of products ranging from bulk glasses (Kirkbir *et al.* 1996) to optical fibers (Susa *et al.* 1982), to special coatings, ultra-pure powders and multifunctional materials. Also, the sol–gel processed transparent porous matrix offers an exciting potential as a host matrix for doping optically active organic molecules (Nogues and Moreshead 1990). This matrix exhibits many properties of inorganic glasses as well as some unique characteristics that can lead to novel developments in photonics. Avnir *et al.* (1984, 1985) demonstrated for the first time that organic molecules can be added to the sol–gel matrix and thin films. Since then, many groups around the world have introduced organic materials into a variety of inorganic matrices via the sol–gel process. Sol–gel processed materials have been used in the areas of solid-state lasers and in platforms for chemical and biosensors (Braun *et al.* 1990, Narang *et al.* 1993). The sol–gel technique has also been used to fabricate nonlinear optically active composites for applications in optical telecommunications (Burzynski and Prasad 1994). Organically modified and sol–gel processed materials were shown to exhibit excellent nonlinear optical χ^2 and χ^3 properties. The sol–gel method also provides a more convenient route to prepare luminescent glass optical fibers doped with rare earth ions (Wu *et al.* 1993, 1994), waveguides (Bahtat *et al.* 1994, Benatsou *et al.* 1997), and lasers (Thomas *et al.* 1992).

To date, there are only a few sol–gel-derived materials that meet the materials quality required for fabricating devices. One of the major problems has been to produce useful bulk materials with controlled doping (organic and inorganic) at the nanoscale. Another problem has been the fabrication of a low-loss optical fiber with active species incorporated within it.

This article briefly discusses different sol–gel approaches, which have shown promising results in producing useful materials for photonics. They include (i) rare earth doped glasses, (ii) multiphasic nanostructured composites, which combine the merits of the inorganic glass and an organic polymer, and (iii) optical fibers with active molecules incorporated within the fiber matrix and dispersed homogeneously for sensing or lasing applications. Selected examples are given of the preparation processes and applications based on the past and current results obtained primarily in the authors' laboratory (see also *Reactive Ceramic Nanocomposites with Organic and Bio-organic Phases**).

1. Sol–Gel Processed Materials

1.1 Sol–Gel Process

Sol–gel processing involves the hydrolysis of a metal alkoxide, followed by a cascade of condensation and polycondensation reactions. More detailed information pertaining to the chemistry of sol–gel processing can be found in several books and review articles (Brinker and Scherer 1990, Hench and West 1990).

A sol is a dispersed system where the dispersed phase, consisting either of solids, discrete "globules" or oligomers in the form of chains, is present in a liquid dispersion medium. The medium can be water or any other liquid. A gel is a stiff mass of a continuous phase, more like a viscous liquid. The sol can be prepared by controlled hydrolysis and polycondensation reactions of alkoxides, which then form the network of the resultant glasses.

The most commonly used precursor materials for the silica sol formation are tetramethylorthosilicate (TMOS) and tetraethylorthosilicate (TEOS). The basic reactions of a sol–gel system undergoing concurrent

hydrolysis and condensation are:

$$nSi(OR)_4 + 4nH_2O \rightarrow nSi(OH)_4 + 4nROH \quad (1)$$

$$nSi(OH)_4 \Rightarrow nSiO_2 + 2nH_2O \quad (2)$$
Gelation occurs when the growing polymers cross-link to form an extensive three-dimensional network. Because of the sharp increase in viscosity accompanying gelation, it may be considered a rapid solidification process. In other words, its structure at a given state of polymerization is essentially "frozen in" at the gel point. Aging under conditions in which appreciable polymer solubility occurs (e.g., high water and high pH) can result in extensive restructuring of the gel. The strength of the wet gel increases with aging, which reduces the chance of cracking during drying.

A promising class of sol–gel-derived materials is the organic–inorganic hybrid materials which combine the merits of an inorganic glass and an organic polymer. A novel way to prepare high optical quality nanocomposite monoliths with desirable mechanical behavior is by forming a rigid glass monolith matrix with controlled porosity through the sol–gel process. Then, an organic monomer is diffused into the open pores and polymerized inside. Pope *et al.* (1989) pioneered this method.

1.2 Sol–Gel Silica Glasses and Composites

The silica skeleton of a composite glass is prepared by hydrolyzing silicon ethoxides with an acid or a base followed by heat treatment. The resulting product is a highly porous monolith with a wide range of pores that can be controlled by manipulating different process parameters. The porous monoliths are either densified thermally to make silica glasses or they can be impregnated with an organic phase resulting in composite glasses. More detailed preparation procedures for silica and composite glasses are explained below.

The silica glasses doped with rare earth ions were prepared according to the procedure described elsewhere (Biswas *et al.* 1999). Briefly, TEOS was hydrolyzed with a $0.1\,M\,NH_4OH$ solution. The molar ratio of $TEOS:H_2O$ was 1:10. The mixture was magnetically stirred to obtain a clear homogenous solution (sol). The sol was cast into a polystyrene Petri dish and covered with a thin polyethylene film. The sol transformed into a gel within 24 hours at room temperature. The gels were aged and dried at 45 °C for 2 weeks and finally heat treated at 1000 °C to form a rigid porous silica matrix with a pore volume of 60% and an average pore size of 100 Å (measured using nitrogen adsorption isotherms and calculated by the BET method).

The porous silica gels were soaked with a different dopant salt solution for 12 hours. Simple chemical treatments (Maeda *et al.* 1990) were used to immobilize the dopant ions in the pores to ensure uniform ion distribution in the bulk of the final glasses. After removal from the solutions, the gels were dried at 50 °C for 12 hours and then heat treated at ~1150 °C for 1 hour to convert into dense pore and bubble free glasses.

The fabrication of the composite glass was done following the method described by Gvishi *et al.* (1995a, 1997). Highly porous silica-gel bulk glasses were prepared by a two-step hydrolysis sol–gel process (Pope *et al.* 1989). The procedure starts with a precursor solution, which contained TEOS and ethanol in the molar ratio 1:4. After one hour of pre-hydrolysis, water (molar ratio 4) and HNO_3 (molar ratio 0.06) were added to complete the hydrolysis. This step was followed by the addition of HF (molar ratio 0.8) to achieve fast gelation. The solution was then covered with a lid having small orifices to allow the solvents to escape and was kept for aging at 40 °C for 1–3 weeks. The bulk gels were then partially densified by slow heating (60 °C/hour) from room temperature to 500 °C. These gels had an initial surface area of about $850\,m^2\,g^{-1}$, a pore volume of 68%, and an average pore size of 46 Å. These bulk glasses (dimensions $10\,mm \times 5\,mm \times 1$–$5\,mm$) were immersed in a methylmethacrylate (MMA) monomer solution for 10–15 min. The MMA-dye solution diffused into the sol–gel-derived glass pores and was polymerized therein using benzoyl peroxide (2%) as the initiator. The MMA-dye-doped bulks were re-immersed in a MMA-dye solution, which at this stage was initiated for full polymerization with benzoyl peroxide (0.5%), and kept in a sealed container at 40 °C until the polymerization process was completed (a few days). After the completion of the polymerization process, the samples were withdrawn, cleaned with chloroform, and polished to obtain parallel-piped slabs with clear smooth surfaces.

1.3 Sol–Gel-derived Fibers

The process of drawing continuous fibers using the sol–gel technique has been studied extensively. Under specific preparation conditions, fibers up to 1 m in length can be pulled from the sol by hand or using a spinning apparatus.

A stock sol–gel solution was prepared by stepwise mixing of tetraethoxysilane, water, ethanol, and hydrochloric acid in molar ratio of 1:1.5:1.9:0.01, respectively. The ethanol solution used in the above step contained the dye to be entrapped within the sol–gel matrix. The dye-doped sol–gel solution was placed in a beaker, sealed with aluminum foil, and stored in an oven at 40 °C for gelation (several days). Just before gelation (indicated by the high viscosity of the sol), sol–gel-derived uniform continuous fibers were drawn. The fibers were kept for aging and drying under ambient conditions for a few weeks. They were cut to a specific length without any polishing of

the fiber ends. The average attenuation loss was $60 \, dBm^{-1}$ from the organically doped sol–gel-derived fiber. However, in each fiber there are several sections with losses as low as $10 \, dB \, m^{-1}$ (Narang *et al.* 1996).

The potential of the dye-doped sol–gel-derived optical fibers has been studied by doping with fluorescein, a well-known pH sensitive fluorescent probe (Narang *et al.* 1996) for chemical fiber sensing and with rhodamine-6G, a well-known laser dye, as a fiber laser medium (MacCraith *et al.* 1991, Drexhage 1990).

2. Applications of Sol–Gel Glasses, Composites, and Fibers

2.1 Sol–Gel Processed Rare Earth Doped Glasses

Silica glasses doped with rare earth ions are potential materials for solid-state fiber lasers and amplifiers, memory devices, switches, sensors, etc. Early work on silica glasses reveals that silica can be doped with rare earth ions to a maximum concentration of 0.1 mol.% by a conventional melt technique.

Interest in high-powered laser glasses of rare earth ions in a silica matrix, due to its favorable thermal and mechanical properties, has prompted several researchers to increase the solubility of rare earth ions in silica glasses through various techniques. Pope and Mackenzie (1988) first suggested that the sol–gel method could be effectively used to obtain relatively large concentrations of neodymium in a silica host as compared to that obtained by conventional melting or plasma torch CVD techniques. The works of others (Moreshead *et al.* 1990) have focused on the development of bulk neodymium-doped sol–gel silica glasses for laser applications. Among the other rare earth ions, Er^{3+} (Zhou *et al.* 1997), and Eu^{3+} (Nogami and Abe 1996) have been studied most extensively. However, their success was severely restricted by the fact that the rare earth ions tend to have a nonuniform distribution and form clusters (Lee *et al.* 1994) in the bulk, which reduces the fluorescence efficiency and lifetime. The presence of a large number of hydroxyl groups (Fujiyama *et al.* 1991) in gel glasses also degrades the emission properties of the rare earth ions. In order to prepare device-quality silica glasses doped with rare earth ions, hydroxyl quenching and ion clustering must be eliminated. Nevertheless, laser emission has been observed in a neodymium-doped sol–gel glass (Thomas *et al.* 1992).

It was shown that the Al^{3+} co-doping prevents the clustering of rare earth ions (for the atomic ratio of Al^{3+} to Nd^{3+} greater than 10) and disperses them homogeneously in the SiO_2 glass matrix (Arai *et al.* 1986). Therefore, it overcomes the concentration quenching problem in sol–gel-derived rare earth doped glasses. However, the addition of alumina was found to promote hydroxyl quenching by retaining more hydroxyl groups in the glass (Lochhead and

Bray 1995). Several other methods have been proposed to reduce rare earth ion clustering, including using acetate precursors (Chakrabarti *et al.* 1994), ion encapsulation by chelating ligands and co-doping with other metallic ions (Costa *et al.* 1996).

Hydroxyl-free silica glasses by the sol–gel method can be realized by treating the gels with either CCl_4 (Phalippou *et al.* 1984) or Cl_2 (Satoh *et al.* 1997) at high temperature. However, this process is not suitable for rare earth doped gels because of the volatile nature of the chloride byproduct. Another proposed method to reduce the hydroxyl group is by doping the gel with an index lowering element, such as fluorine (Rabinovich *et al.* 1986).

Rare earth (RE) ions are generally incorporated into a glass in their trivalent state. However, some of the RE ions can exist in a divalent state as well. These divalent RE ions show very strong emission because of the dipole-allowed electronic transition. Sm^{2+} and Eu^{2+} doped glasses have attracted a great deal of attention for applications in memory devices and as phosphor materials. The broad emission of Eu^{2+} ions is host sensitive. Depending on the host matrix, Eu^{2+} ions could emit from the UV to the red region of the electromagnetic spectrum.

Divalent rare earth ion doped porous gel glasses can be prepared by heating the gel in the presence of a H_2–N_2 gas mixture (Nogami *et al.* 1998) at a relatively high temperature. The Eu^{3+} ions were also shown to be readily reduced to Eu^{2+} in a silica xerogel at room temperature by a "surface assisted reduction" (Zaitoun *et al.* 1998). In another approach, *in situ* formation of hydrogen in a mixed zirconium propoxide and siloxane (Cordoncillo *et al.* 1998) was found to reduce the Eu^{3+} ions at room temperature.

Recently, it was shown that the Eu^{3+} ions were spontaneously reduced in the sol–gel matrix during densification (Biswas *et al.* 1999). The optical absorption spectrum in the 200–500 nm range of the Eu–Al co-doped glasses densified at 1125 °C in air is shown in Fig. 1. The spectrum shows a broad peak around 266 nm that is attributed to a transition of the Eu^{2+} ions from $4f^7$ to $4f^65d$ (t_g). The emission and the excitation spectra of the Eu–Al co-doped sample at 1125 °C are shown in Fig. 2. The emission shows a broad intense peak at 435 nm. A qualitative measurement based on the emission intensity and the absorption coefficient of these glasses shows that a maximum 85% of the Eu^{3+} ions were converted to Eu^{2+} ions. Figure 3 shows the excitation spectra for the $^5D_0 \rightarrow {^7F_2}$ transition of Eu^{3+} ions (614 nm) in the densified silica and in the Al^{3+} co-doped silica matrices. The sharp lines observed between 200 and 500 nm are assigned to the *f–f* transitions of the Eu^{3+} ions in the glasses. However, a broad band with a peak at 300 nm is observed only in the aluminium co-doped sample that contains both Eu^{2+} and Eu^{3+} ions. The excited Eu^{2+} ions in the $4f^65d$ (e_g) level can

relax to the ground state by transferring energy to the Eu^{3+} ions which, in turn, are excited to the $^5D_2$ level.

2.2 Multiphasic Nanostructured Composites

Sol–gel derived composite glasses, due to their excellent optical quality, play an important role in photonics applications such as lasing, optical power limiting, nonlinear optical response, etc. (He *et al.* 1995, Gvishi *et al.* 1995a, 1995b). The multiple impregnation method can be used to dope two (or more) different optically active materials, with each existing in different phases of the matrix (the inorganic silica phase, the organic polymer phase, and the interfacial phase).

The basic idea of the multiphasic nanostructured composite is illustrated in Fig. 4. The inorganic phase (phase #1) is doped with inorganic species that can survive the heat treatment. The pores can be doped with organic functional molecules through impregnation of the solution, or by using a melt or vapor-phase infiltration. After draining out the solvent and drying, the dopant organic molecules form a phase (phase #2) on the surface of the pores. Finally, the pores are filled with an index-matched polymer by *in situ* polymerization of a monomer, such as methyl-methacrylate. Another active organic species can also be introduced in the polymer phase (phase #3). The

resultant monoliths, thus prepared, are suitable for many applications in photonics.

(*a*) *Solid-state dye laser*. Laser emission via a one-photon excitation process (He *et al*. 1994) or a two-photon excitation process (Zhao *et al*. 1995, He *et al*. 1996) from dye doped solid matrices has been reported. These composite glasses exhibit excellent slope efficiencies (up to 39%). The success of a solid-state dye laser depends mainly on its photostability and mechanical properties. Sol–gel derived composite glasses offer better photostability, optical quality, and mechanical stability as compared to other organic matrices. Solid-state dye lasers could be useful for applications where only low laser output is required, e.g., photodynamic therapy (PDT), medical diagnostics of tissues using laser-induced fluorescence (LIF), and photodynamic purification of blood from viruses.

The sections below present the results obtained in our laboratory on (i) multiexcitation pumping (one- and two-photon excitation) of a dye-doped composite glass and (ii) multidye laser—a multiphasic nanostructure composite glass monolith containing two different laser dyes.

(*b*) *One- and two-photon pumped dye laser*. Sol–gel composite glasses doped with ASPD in the interfacial surfaces have been prepared according to the procedure discussed above. Lasing experiments were carried out by one-photon excitation pumping. The laser output spectrum of the composite glass doped with ASPI ($\sim 3.1 \times 10^{-3}$ M), pumped with a frequency-doubled Nd:YAG laser is shown in Fig. 5. The output exhibits a peak at ~ 593 nm with a full width at half maxima (FWHM) of 2 nm (Zhao *et al*. 1996).

Figure 6 shows the output energy vs. input pump energy for ASPD in the composite glass (Zhao *et al*. 1996) pumped with a frequency-doubled Nd:YAG laser (532 nm). The observed threshold was 0.244 mJ/pulse for the composite glass doped with $\sim 3.1 \times 10^{-3}$ M ASPI. Maximum lasing slope efficiencies of $\sim 9\%$ in the composite glass was observed under one-photon excitation. From calculations, it was found that there was no evidence for additional losses, such as excited-state absorption, which were observed for red perylimide dye-doped composite glass (Gvishi *et al*. 1993).

ASPI also exhibits a strong two-photon absorption at 1.06 μm followed by red fluorescence. Using an appropriate optical cavity and longitudinal pumping with an intense IR beam, up-converted visible lasing was obtained from ASPI-doped composite glasses. Two-photon lasing was first demonstrated in a polymer matrix (He *et al*. 1996) and subsequently in composite glass and composite vycor glass (Zhao *et al*. 1995). The lasing efficiency was found to be very high ($\sim 3.5\%$) as opposed to the expectation based on the
Figure 5
Lasing output vs. wavelength for the ASPD composite glass. The composite glass was transverse pumped with an 8 ns pulsed-frequency-doubled Nd:YAG laser at 532 nm and at a 1 Hz repetition rate.
Figure 6
The output energy vs. input energy, under excitation with a frequency-doubled Nd:YAG laser (532 nm) for ASPD in composite glass.

assumption that two-photon absorption is not an efficient process. For a dye-doped polymer, the lasing lifetime in terms of pulse number was more than 4×10^4 pulses at a 2 Hz repetition rate and with a pump energy of 1.3 mJ. Since, it has been demonstrated that the photostability of a sol–gel composite glass matrix is much higher than those of a polymer host (three orders of magnitude) under one-photon excitation; one can expect the same under two-photon pumping. It was found that the composite glasses could stand a flux power of 400 MW cm^{-2} with 10 ns pulses without damage (Zhao *et al*. 1995, He *et al*. 1996).

(*c*) *Multidye laser*. The multidye solid-state composite glasses for tunable laser operation contain ASPI in the interfacial phase and R6G in the polymer phase of the matrix. The details of the fabrication process of the glasses is reported elsewhere (Ruland *et al.* 1996). Lasing was observed across the region of the individual dyes.

Figure 7 presents the lasing tunability of a multiphasic composite glass containing both dyes. Lasing tunability of the two composite glasses containing each dye separately is also shown in the same figure for a reference. The FWHM of the tunability spectra for the ASPI composite glass is ~ 21 nm and that for R6G is ~ 12 nm. However, a composite glass containing both dyes is ~ 37 nm. From this data it is evident that the laser emission from the composite glass containing both dyes is tunable across the range of both dyes (560–610 nm), whereas in the solution state the R6G emission is quenched. It was assumed that the quenching in the solution state is a result of Förster energy transfer. Therefore, due to the extremely large ratio between the specific surface area and the pore volume, which is $\sim 8.5 \times 10^6$, it is possible to separate the two dye molecules (which reside in different phases) to a distance where the Förster energy transfer is no longer effective. This result illustrates the fascinating possibilities embodied in the multiphasic composite glasses for fabricating multifunctional devices for photonics.

2.3 Organically Doped Fibers

(*a*) *Micron-scale chemical and biosensor fibers*. Micrometer- and submicrometer-scale fiber optic

sensing was first demonstrated by Tan *et al.* (1992). Here, micrometer-scale chemical and biosensor fiber applications are presented using a fluorescein-doped sol–gel-derived fiber, where the fluorescein is doped in the sol–gel matrix. Fluorescein has previously been doped within the sol–gel-derived monoliths and thin films as a pH sensitive dye (Reisfeld *et al.* 1987, MacCraith *et al.* 1991). The fluorescence quantum yield of fluorescein is pH dependent; increasing with increasing pH. The effect of pH on the fluorescence intensity by exposing the fluorescein-doped sol–gel-derived fiber ($20 \pm 3 \,\mu$m) to ammonia and HCl vapors was investigated in our laboratory. The bulk of the instrumentation and the setup of the measurements were described before.

Figure 8 presents the change (increase) in fluorescence intensity of the fluorescein-doped sol–gel-derived fiber by exposing the fiber to ammonia and HCl vapors (Narang *et al.* 1996). A 50% increase in the fluorescence intensity was observed when it was exposed to ammonia vapors. A 45% decrease in the

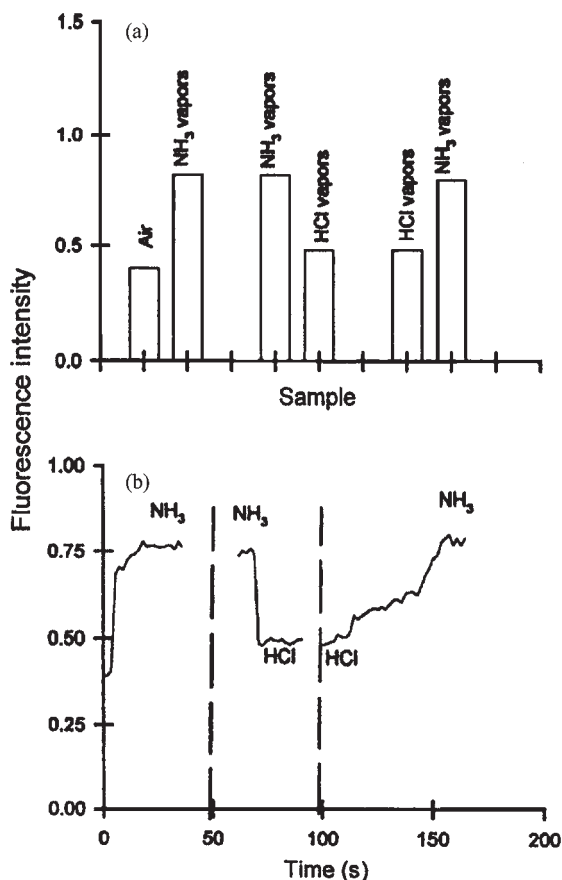
Figure 7
Lasing tunability of Rhodamine-6G composite glass (♦), ASPD composite glass (■), and the multiphasic composite glass containing both Rhodamine-6G and ASPD (▲). The composite glasses were transversely pumped with an 8 ns pulsed frequency-doubled Nd:YAG laser at 532 nm operating at a 1 Hz repetition rate, using a grating as the back reflector.


Figure 8
Change in emission intensity of sol–gel derived fluorescein-doped fiber under HCl or NH₃ exposure.
Figure 9
Slope efficiency of sol–gel derived Rodamine-6G doped fiber (length = 1 cm, diameter = 150 μm) laser pumped at 532 nm with a 8 ns pulsed frequency-doubled Nd:YAG laser.

fluorescence intensity was noted when the same fiber was treated with HCl vapors. The results indicate that a fluorescein-doped sol–gel-derived fiber could be used as a pH sensor. The response time of the fluorescein-doped sol–gel-derived fiber to ammonia and HCl vapors was observed to be 1–2 s (panel B), which was increased by an order of magnitude by further recycling. This method can be used to fabricate optical fiber based micron-scale sensors to detect *in situ* environmental changes. An improved response time is expected by using a smaller diameter fiber, as was achieved in the case of a pyranine-doped sol–gel-derived micropipette by Samuel *et al.* (1994).

(*b*) *Solid-state dye-doped fiber laser*. A solid-state fiber laser was demonstrated in our laboratory using R6G-doped sol–gel-derived fiber. R6G, a commercially available laser dye, exhibits very high lasing efficiency and solubility properties but low photostability.

An amplification of 10 was achieved in the cavity lasing compared to a single-pass super-radiance intensity (amplified emission under the conditions of a blocked back mirror). The lasing intensity was extremely sensitive to the alignment of the cavity component, due to the delicate coupling requirement into a micron-size fiber. Therefore, thick fibers (5.5 cm or 1 cm long, 150 μm in thickness) (Gvishi *et al.* 1996) were used for laser demonstration. Figure 9 presents

the measured laser output–pump input intensity relationship for R6G ($\sim 10^{-4}$ M) doped sol–gel fiber (1 cm long, 150 μm in thickness), when pumped with an 8 ns pulse at a 1 Hz repetition rate (Gvishi *et al.* 1996). The observed lasing slope efficiency was $\sim 2.8\%$. A much higher slope efficiency can be achieved by improving coupling into the fiber (by polishing the fiber ends), decreasing fiber optical loss, optimizing concentration-length relationship (preventing aggregation effect), and improving the cavity design.

With appropriate improvements in preparation and laser design, this device can be fabricated and operated as a single-mode dye-doped fiber laser. By replacing the back mirror with a grating, tunable laser action is expected.

3. Summary

Over the years, rapid progress has been observed in the field of sol–gel-derived materials for photonics. The present article focuses on specific applications of the sol–gel process, with emphasis mainly on rare earth doped glasses, a multidye solid state tunable laser, micrometer-scale chemical and biosensor fibers, and a solid-state dye-doped fiber laser.

Ceramic-modified High-temperature Polymers

Property enhancement through hybridization in the area of thermally stable polymers and ceramics is important for many applications in the electronics and aerospace industries. Preparation of such ceramers through the sol–gel process (Brinker 1988) allows systems to be designed that combine superior thermal stability, high refractive index, low thermal expansion coefficient, and a wide range of permittivity for ceramics, and to provide the toughness and crack deflection properties of polymers (Mark *et al.* 1995, Mark 1996). One of the challenges to obtaining significant improvements in these classes of polymers, however, is due to the fact that many of these polymers either possess superb thermal and mechanical properties to begin with or they are insoluble and infusible in organic solvents.

The unreactivity of such polymers that qualifies them as high-temperature, high-performance materials generally causes poor interfacial bonding between the polymers and the ceramic phases. As a consequence the molecular level combination of the two different components necessary to optimize the property combination may be difficult to achieve. Relatively few of the materials synthesized using these polymers have been exploited commercially. A brief account of the different strategies that have been used to combine thermally resistant polymers and ceramic phases using this process shall be discussed in this review.

The progress in heat-resistant polymers has been governed by the opposing requirements of thermal stability and processability. The structural requirement needed to attain high thermal stability means using the strongest chemical bonds in the polymer chain and resonance stabilization, and ensuring that these are no easy paths for rearrangement reactions. Polybonding is often utilized. Ring structures that have normal bond angles are preferred but to ease processability, thermally less stable flexible linking groups often have to be introduced between rings. Those having the least effect on stability are –COO–, –CONH–S–, –SO$_2$–, –O–, –CF$_2$–, and –C(CF$_3$)$_2$–.

Many thermally stable polymers, for example, polyesters, polyphosphazenes, aramids, and those containing heterocyclic rings: polyimides, polybenzoxazoles, polybenzobisthiazoles, and polybenzimidazoles have been used to combine with the inorganic components via the sol gel process. Silica is the ceramic phase most commonly generated in this sol–gel route to composites, but other ceramics such as titania (TiO_2), alumina (Al_2O_3), and zirconia (ZrO_2) have also been used. A combination of two or more oxides may also be used, as one type of oxide may improve one set of properties while the other improves different ones.

Morphology and phase separation control is critical in the generation of such hybrid materials. This problem has been solved by adding a coupling agent, functionalizing the oligomer or polymer chain ends, selecting polymers with appropriate backbone structures, or by using copolymers possessing functional groups that can interact with the growing inorganic oxide network. The relation between the structure of multiphase materials and their properties has been reviewed by many authors although there are severe limitations to theoretical models describing these parameters. In general the deformational behavior in such systems depends on the nature of the components, the volume fraction, size, shape, and orientation of the filler, and the state of adhesion between the filler and polymer matrix.

Radiation scattering, NMR, and other state-of-the-art techniques have been used to characterize these parameters. Generally these materials exhibit greater stiffness and hardness, although toughness is reduced. Highly transparent films, coatings and membranes have been produced using different means to control morphology. Preparation and properties of ceramers from some thermally resistant polymers are now described. Additional information is given in *Polymer–Ceramic Nanocomposites: Polymer Overview**.

1. Polyimides

The polyimides (PI) have become widely used as high performance polymers owing to their excellent thermal stability and toughness. However the thermal expansion coefficient (TCE), mechanical and dielectric properties, and so on, need to be strictly controlled for their application as circuit-printing films and semiconductor-coating materials in the microelectronics industry, and as adhesives in the aerospace industry. Several studies (Chujo 1996, Mascia 1995) have been carried out on the preparation of polyimide–metal oxide hybrid materials for this purpose through the sol–gel process. These materials have usually been produced by mixing solutions of pyromellitic dianhydride (PMDA), oxydianiline (ODA), and a metal oxide precursor, for example, tetraethoxysilane (TEOS), carrying out the hydrolysis and

polycondensation of TEOS followed by an imidization process at high temperatures. Thin films were found to be transparent at low silica levels but were opaque at higher ones.

Despite the expected strong interactions through hydrogen bonds between the polyamic acid, the precursor for the PI, and hydroxyl groups from the silica phase, it was rather difficult to prevent phase separation. These systems have been compatiblized (Wang *et al.* 1994) with the selective use of thermally stable organically substituted alkoxysilanes, for example, aminophenyltrimethoxysilane, (aminoethylaminomethyl)-phenethyltrimethoxysilane, or 1-trimethoxysilyl-2-(*m,p*-chloromethyl)phenylethane, which undergo hydrolysis and polycondensation along with TEOS to form silica or polymeric silicates, while the groups at their other ends (such as the amino or chloro) provide secondary bonds with the PI chain.

Mascia and Kioul (1995) and Menoyo *et al.* (1998) have reported the use of glycidyl and isocyanate-type trialkoxysilanes to "couple" a polyamic acid to the silicate network prior to the condensation reactions for the formation of ceramer. By partial replacement of TEOS with dimethyldiethoxysilane and by varying the mixing conditions, morphologies ranging from interpenetrating networks to finely dispersed particles were obtained.

These results illustrate the role of the interconnected silica-rich particle within the polyimide-rich matrix in depressing the α-relaxations and reducing the TCE accordingly by an extent substantially greater than expected from the usual additivity rule.

Nandi *et al* (1991) used the concept of "site isolation" to reduce the silica particle size. Constraining phase separation between the polymer and inorganic clusters to a smaller scale provides optically transparent materials with improved properties. Masa-aki *et al.* (1992) introduced functional groups into the polymer backbone using ethoxysilylated diamines in place of ODA which provided bonding sites for the silica. The silica particle size was found to decrease and the modulus to increase as the number of bonding sites increased. Habib (2000) partially replaced ODA with 2,2-bis(3-amino-4-hydroxyphenyl)methane, a diamine monomer that has two pendant hydroxyl groups to develop extensive bonding between the PI and the silica network. Transparent hybrid films containing 70 wt.% of silica were obtained.

The relationships between various mechanical properties and the silica content are given in Fig. 1 The tensile modulus increased with an increase in silica content. Unlike the unbonded system where the tensile strength decreases with an increase in silica level these ceramers show slight increases and then retention of tensile strength up to much higher (25 .wt%) silica content. Extensive chemical bonding between the inorganic network and the polymer backbone solves the stress transfer problem thus
Figure 1

reinforcing the hybrid films. The dynamical mechanical behavior of hybrid films also indicates (Fig. 2) the role of the bonded silica network in increasing the storage modulus and depressing substantially the α-relaxations. The SEM (scanning electron microscopy) micrograph of the unbonded ceramers (Fig. 3) shows sharp boundaries between the component phases, which become diffused in bonded ceramers (Fig. 4) showing interconnectivity between the phases. The thermal decomposition temperatures exhibited by these ceramers were at ∼ 550 °C.
Figure 3

Ree *et al.* (1995) prepared PI nanocomposite films for use in fabrication of microelectronic devices by solution blending of polyamic acid and silica aerogels, and subsequently processing the PI film by conventional methods. The optical and dielectric properties were improved, whereas the interfacial stress and thermal expansion coefficient were significantly degraded by a large disturbance in the polymer chain in-plane orientation caused by silica aerogels despite their low thermal expansivity. This indicates that in the rigid type of polymer composites, the orientation of polymer chains still has an important effect on the physical properties. Nano-composite membranes based on PI and titania, and silica components with a higher permeability coefficient

and significant improvement in preselectivity, have also been prepared using the sol–gel process. The dielectric constant was lowered substantially.

The sorption and permeation data for gases such as O_2, CO_2, H_2 and CH_4 have been correlated (Hu *et al.* 1997) to the morphology of the composite structure. Transparent PI films with large nonlinear optical (NLO) coefficient moieties have also been prepared (Jeng *et al.* 1992) where the linked alkoxysilane dyes and the polyimide form a semi-interpenetrating polymer network resulting in a substantial increase in the α-relaxation temperature and superb thermal stability of the poled order. The poled film of this PI-inorganic composite showed a large second-order NLO effect and excellent temporal stability, over 168 h at 120 °C.

2. Polyaramids

Ahmad and co-workers, (Ahmad and Mark 1998, Ahmad *et al.* 1997a, 1997b, 1998) have synthesized various types of aramid–silica composites. These aramids have been prepared from a terephthaloyl chloride and a mixture of *para*- and *meta*-phenylene diamines, with the former acting to stiffen the chains and the latter to provide some flexibility and tractability. In those hybrid materials where the aramid chains were not chemically bonded to the silica network, no significant increase in the mechanical strength of the polymer was observed. In another system, end-capping the aramid chains with aminophenyltrimethoxysilane developed chemical bonding between the aramid chains and the silica network. By end-linking the polymer chains with the silica network, transparency of the films improved greatly. The tensile strength was found to go through a maximum, whereas the elongation at break decreased and the tensile modulus increased with increasing silica content.

Interconnectivity of the two phases is thought to be the reason for improvements in mechanical properties. Increases in silica content beyond 10 wt.% in the matrix, however, caused a decrease in the tensile strength. Interfacial bonding through end-linking of the polymer chain can be achieved only up to a limit in linear polymers, because the higher the molecular weight of the polymer, the fewer the chain ends and the more limited the bonding capabilities of the chain. In some related materials, the average functionality of the monomer was increased in the synthesis simultaneously of linear–nonlinear polyaramid chains, which could be bonded into the inorganic network at more than just the two ends. Such chains have been prepared by the addition of benzenetricarbonyl chloride and terephthaloyl chloride (TPC) in a two-step process in which the TPC was first reacted with the diamines, with addition of the trifunctional monomer delayed until near the end of the reaction.

The linear parts of the chains give the desired strong intermolecular bonding, while the nonlinear chain ends provide more bonding points and thus better adhesion with the inorganic network. The introduction of silica raises the modulus, but the toughness and elongation to break are greatly reduced. The bonding between such polymers and *in situ* generated silica significantly reduce water absorption, and this improves the mechanical and dielectric properties of the matrix, particularly under humid conditions.

3. Polybenzoxazoles

The successful use of pendant functional groups in benzoxazole copolymers to provide chemical bonding between the polymer chain and the silica network has been made to produce thermally stable transparent ceramers. The copolymers were prepared by the polycondensation reaction of 4,4′-(2,2,2-trifluoro-1-(trifluoromethyl)ethylidene)bis(2-aminophenol) with a mixture of 4,4′-dicarboxybiphenyl ether and 5 hydroxyisophthalic acid or 5-phosphonoisophthalic acid. The tensile strength was found to depend on the nature of copolymer and the number of segments containing pendant functional groups in the chain; it increased with initial increase in the silica content and then decreased. The mechanical strength of the copolymer containing phospho acid groups was lower than those containing the hydroxyl groups (Chen *et al.* 1995).

4. Polyphosphazenes

The sol–gel synthesis of hybrid materials based on poly [bis ((methoxyethoxy) ethoxy) phosphazene] (MEEP) and silica has been reported. MEEP bears ethylene oxide oligomers as phosphorus side groups, which impart metal coordination ability to the polymer thus making it an ionic conductor. The low T_g of -71°C, has however limited the industrial development of MEEP. Chemical bonding of MEEP to a rigid inorganic network through the sol–gel process has been carried out (Guglielmi *et al.* 1996). Investigations on the thermal, mechanical, and electroconductive properties of the composite materials showed that these matrices presented improved mechanical and thermal features with respect to those of the original phosphazene. Abrasion-resistant transparent and antistatic MEEP–silica coatings have also been reported. Those prepared by the sol–gel process have been spin-coated on substrates and cured at ambient temperature or with moderate heating. The coating exhibits relatively steady conductivity with change in humidity, good transparency, toughness, hardness, and flexibility (Coltrain *et al.* 1990).

5. Polyesters

Transparent protective coatings from hydroxy-terminated polyesters and silica hybrids via the sol–gel process have been synthesized and evaluated for their performance on prefinish construction steel and aluminum. The interaction between the inorganic and organic domains occurs via hydroxyl end groups of polyesters and hydroxyl groups of silanols. These coatings combine flexibility, that is, upon deformation of the metal substrate after coating, with increased scratch resistance. The composition and molecular weight of the organic polymer, the ratio of the organic versus inorganic components, the cross-link density of the phases, solvents, catalysts, and curing conditions are some of the important parameters that control protein resistance of such coatings. Increases in Konig hardness and T_g was observed as the amount of inorganic component was increased (Frings *et al.* 1997).

6. Concluding Remarks

The inherent advantage of the sol–gel process and compatiblization of the organic and inorganic phases using organically substituted alkoxysilanes allows tailoring and improvement in materials properties. Many applications are still in the early stage of development, but transparent films, coatings, and membranes with high performance properties have been prepared and are being used in industry.

Ceramics and Glasses, Sol–Gel Synthesis of

The sol–gel process represents an elegant chemical route that can be used for the low-temperature synthesis of single- or multiple-component ceramic materials (including glasses) in the form of thin solid films, ultrafine powders, high surface area porous materials, dense abrasive minerals, and continuous ceramic and glass fibers. The sol–gel process involves the preparation of a precursor mix (a sol or a solution), which is ultimately converted into a final product via a stage that may involve drying, chemical reactions, gelation of the precursors, and curing (often using heat). The major advantages associated with the sol–gel processes include lower processing temperatures, high levels of purity, control of dopant concentrations, and the ability to synthesize multi-component compositions in different product forms.

For some applications the cost of the starting materials used in sol–gel processing may be relatively high, yet it is used commercially for the preparation of continuous ceramic fibers, abrasive minerals, optical fibers, ceramic powders, and thin films. This article first describes and clarifies the different terms used in the area of sol–gel processing. This is followed by an overview of the sol–gel process that includes a description of the precursors used and the chemical reactions involved. In the final section an attempt is made to capture and highlight some of the applications of the sol–gel process.

1. Terminology

The term *sol* refers to a dispersion of colloidal particles of one phase in a fluid medium. For example, when colloidal particles are suspended in air, water, or an organic liquid, the terms aerosol, hydrosol, and organosol, respectively, are used. The particles in a sol, by definition, are colloidal, i.e., at room temperature they remain dispersed by virtue of Brownian motion. This usually requires the average particle size to be less than 1000 nm (1 μm). In practice, in the sols used in sol–gel processing, the average particle size of precursors used can consist of somewhat larger particles (a few micrometers in diameter) and, as is explained below, *solutions* can also be used. An important and fundamental distinction between a *sol* and a *solution* is that a true solution is thermodynamically stable. A sol, however, is a dispersion and is therefore thermodynamically unstable. The term *gel* is defined here as a material consisting of a three-dimensional network of a solid phase interwoven with an entrapped and immobilized continuous liquid phase. The sol–gel process has also sometimes been referred to as the *solution sol–gel* (SSG) process. This term is more appropriate if the precursors comprise a true solution that undergoes chemical reactions that lead to formation of a sol of colloidal species, which in turn transform into a gel.

The terms *colloidal sol–gel* and *polymeric* (*alkoxide*) *sol–gel* are used to describe sol–gel processes in which dispersions of ultrafine particles of ceramics or solutions of metal alkoxides (or other chemicals) are used, respectively. The terms *sol precipitation* or *chemical*

precipitation have been used to describe chemical processes in which ultrafine particles of a ceramic material are formed by chemical reactions occurring in a solution of precursors. Ceramic powders can also be formed from curing of a gel obtained from colloidal or polymeric alkoxide precursors. The term *metalorganic decomposition* (MOD) has also been sometimes used interchangeably with the term *sol–gel*. MOD is actually a solution decomposition process and is similar to the spray pyrolysis process. Typically in MOD, long hydrocarbon chain metalorganic precursors are dissolved in organic solvents and the resulting solutions are then thermally decomposed to form thin films or powders. This article describes colloidal and polymeric sol–gel processes used for the synthesis of thin films, continuous fibers, powders, and large vitreous silica monoliths.

2. Overview of the Sol–Gel Process

In sol–gel processing of ceramics and glasses, chemical precursors such as solid colloidal particles and/ or solutions of inorganic or organic compounds of metals are used to form a precursor mix, which is usually a sol of ceramic particles or a solution containing other dissolved chemicals (Fig. 1(a)). Colloidal precursors are often preferred for larger volume applications since they allow much higher levels (up to $\sim 50\,\mathrm{wt.\%}$) of solids loading. Polymeric alkoxide precursors are more suited for thin-film deposition applications. The precursor mix is then formed into the desired shape such as thin films (Fig. 1(b)), ultrafine particles/powders, a bulk gel (Fig. 1(c)), or continuous fibers (Fig. 1(d)).

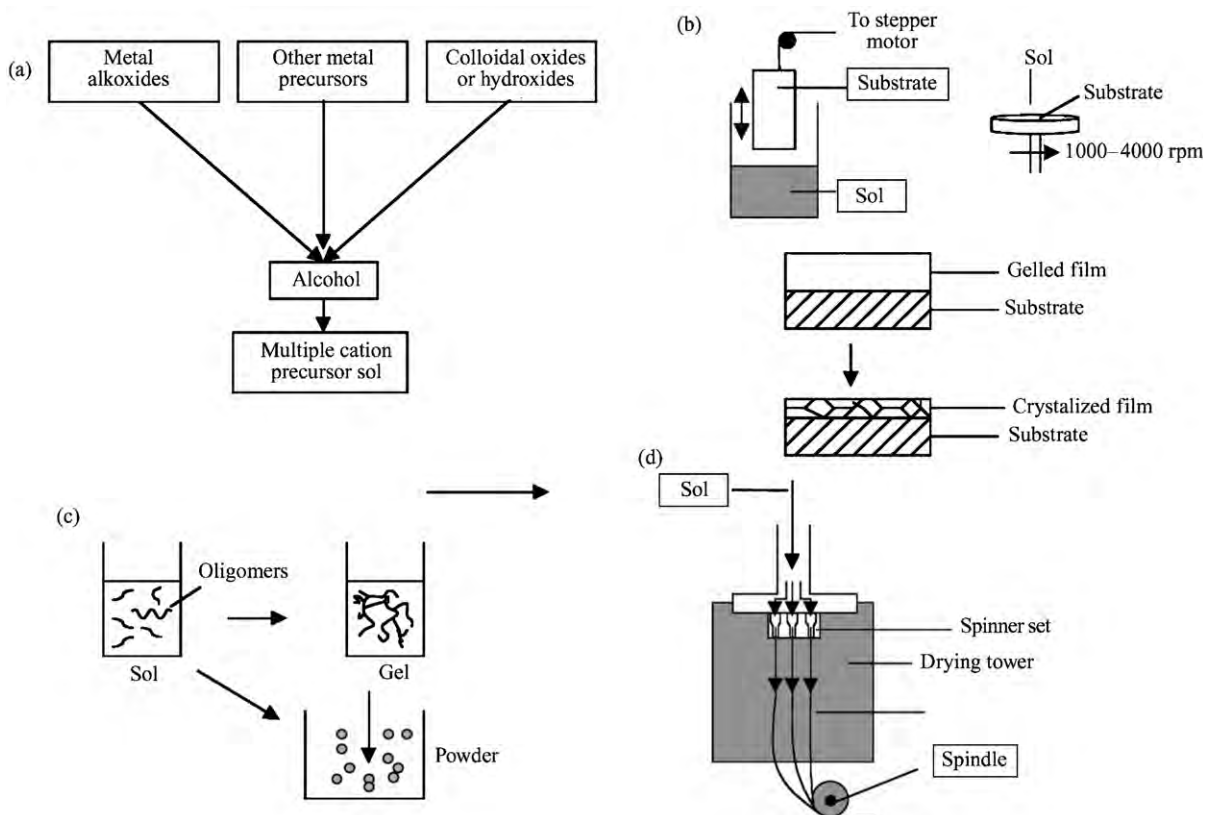
During this conversion the precursor mix transforms into a more solid-like material as a result of evaporation of the solvent, dehydration, and chemical cross-linking between the solid particles or dissolved precursors. The sol-derived "wet" thin film, gel, powder, or fiber is then cured to yield a final product. The curing process may involve simple drying (including drying under supercritical conditions), calcination, and sintering steps. During the curing step, the precursors may react with each other to form chemical bonds that are characteristic of a ceramic or a glass. For example, a colloidal silica sol or a silicon alkoxide dissolved in an alcohol may be used


Figure 1
Overview of the sol–gel process and some of applications for the synthesis of bulk gels, powders, thin films, and fibers.

to create an essentially inorganic silica (SiO_2) thin film or a silica fiber. The transformation of a sol or solution into an essentially inorganic crystalline ceramic or glass, via a gel-like intermediate, can be often accomplished at temperatures that are significantly lower that those necessary in "traditional" processing. This is because the precursors used are intermixed at a molecular level and can react through chemical pathways to form a network of chemical bonds that are characteristic of completely inorganic materials. Therefore, in sol–gel processing high processing temperatures, used typically to induce long-range diffusion of atoms, are often not needed. Temperatures used in the curing step may range from $\sim 300\,°C$ to $1500\,°C$, depending on the composition of the material being prepared. The concept of using *seeds* or *templates* (Hong and Messing 1999), nucleating agents as well as heterometallic precursors, has also been shown to be useful in lowering the temperatures needed for formation and densification of the desired phases. This lowering of the synthesis and processing temperatures is one of the most important advantages of using the sol–gel process for the synthesis of ceramics and glasses.

The chemical nature of the sol–gel process provides additional advantages. Since the degree of mixing of two or more phases is dictated by the nature of the chemical precursors (molecular vs. colloidal), the sol–gel process, by proper design, can be used to prepare thermodynamically stable as well as metastable phases of materials. This chemical control of the degree of homogeneity of the precursors also allows the controlled introduction of selected dopants into the sol–gel ceramic material. Finally, another key advantage of the sol–gel process is that since mostly synthetic precursors are used rather than naturally occurring minerals, the purity of sol–gel-derived fibers, powders, and thin films can be exceptionally high.

3. Precursors for the Sol–Gel Process

In sol–gel processing, metal alkoxides ($M(OR)_n$; M^{n+} = metal cation of valence n and OR = alkoxy group) or other metalorganic chemicals and/or colloidal metal oxides or hydroxides can be used as precursors. The metalorganic precursors are characterized by the presence of M–O bonds and are different from organometallic precursors, which are characterized by the presence of M–C bonds. For example, for the preparation of silica (SiO_2) films, an alkoxide of silicon, e.g., tetraethylorthosilicate ($Si(OC_2H_5)_4$), dissolved in an alcohol or a colloidal silica sol can be used as the starting material. Alkoxides of many individual metals are available commercially. Many metal alkoxides, especially those that are liquids, can be obtained in exceptionally high levels of purity ($>99.99\%$, metals, basis). This

purity, combined with the volatile nature of certain metal alkoxides, enables these precursors to be used not only in the sol–gel process but also in processes such as chemical vapor deposition (CVD). In certain cases it is also possible to use heterometallic alkoxides. Such heteroalkoxides have been used to advantage in the synthesis of binary oxides such as mullite ($3Al_2O_3 \cdot 2SiO_2$) and spinel ($MgO \cdot Al_2O_3$).

Precursors such as acetylacetonates and acetates or metal alkoxides molecularly modified with these functionalities have also been used for the sol–gel synthesis of ceramics. These precursors are useful for metals whose alkoxides are either insoluble (e.g., some of the group 2 elements) or extremely reactive (e.g., group 1 elements). Metal nitrates have also been used but are not preferred since they tend to crystallize during the subsequent drying steps. Precursors such as metal chlorides may be used but contamination owing to remnant anions may not be acceptable. Partially neutralized, soluble salts known as "basic" metal salts are also employed as sol–gel precursors. Basic metal salt solutions generally are comprised of complex mixtures of polynuclear metal cations (as in the case of aluminum, zirconium, titanium, iron, chromium, and beryllium) and concentrated basic metal salt mixtures have been used to produce ceramic metal oxide fibers. Sols of colloidal particles of silica, alumina, titania, and other materials are also available commercially.

4. Chemistry of the Sol–Gel Process

The chemical basis for the *polymeric sol–gel* process is similar to the well-known polymerization process. Alkoxide molecules exist as low molecular weight species, usually monomers or small oligomers, depending on the particular alkoxides used, the solvent, and other factors. The polymerization of these species occurs via hydrolysis of the M–OR moiety and polycondensation reactions involving the resulting M–OH group. Water acts as the "initiator" and is usually externally added. Water can also be generated *in situ* by condensation reactions such as the formation of esters by the condensation of carboxylic acids and alcohols. Acids or bases are used as catalysts for these reactions. The initial viscosity of the sol derived from polymeric precursors is rather low and in many cases is similar to that of water ($\sim 1\,mPas$). If the polycondensation reactions are allowed to occur to a significant extent, the original sol can transform into a gel.

The reaction of metal alkoxides with water is known as the hydrolysis reaction:

$$M(OR)_x + xH_2O \rightarrow M(OH)_x + xROH \qquad (1)$$
Note that Eqn. (1) represents a complete hydroxy–alkoxy exchange, i.e., all the alkoxy groups have been

shown to be replaced by hydroxy groups. This may or may not occur depending on the relative concentration of water and other conditions. The partial hydrolysis can be represented by

$$M(OR)_x + yH_2O \rightarrow M(OH)_y(OR)_{x-y} + yROH \quad (2)$$

One of the implications of the hydrolysis reaction is that proper care must be taken in handling, packaging, and using metal alkoxides. Even traces of moisture are often sufficient to cause prehydrolysis and undesirable precipitation of hydroxides.

The next step is the following condensation reactions:

$$M-OR + M-OH \rightarrow M-O-M + R-OH \quad (3)$$

$$M-OH + M-OH \rightarrow M-O-M + H-OH \quad (4)$$
In Eqns. (3) and (4) the remaining functionalities on the metal cations are not shown. Notice that Eqn. (4) also can be used to describe network formation between hydroxyl-functional, colloidal metal oxide precursors. For example, colloidal silica particles can undergo gelation through reactions such as that shown in Eqn. (4). The products of condensation reactions may be alcohol, water, or both, depending on the alkoxide used. Thus metal–oxygen–metal (M–O–M) bonds can form during the condensation reactions that occur using either alkoxide or colloidal oxide precursors. These reactions ultimately lead to the formation of a network consisting of metal–oxygen bonds. An important feature of these reactions is that they can occur at low temperatures ($\sim < 100\,°C$). This is one of the reasons that metal alkoxides and colloidal oxide particulates represent the precursors of choice for gel processing of oxide ceramics and glasses. Cross-condensation reactions, i.e., reactions between species from two or more cations, are also possible:

$$M^1(OR) + M^2(OH) \rightarrow M^1-O-M^2 + R-OH \quad (5)$$

$$M^1(OH) + M^2(OH) \rightarrow M^1-O-M^2 + H-OH \quad (6)$$
Again, note that Eqn. (6) can also represent linking of colloidal particles of different precursors, e.g., colloidal silica and colloidal alumina. In principle, a solution containing different alkoxides could be used to construct a network of many cations. In practice, however, differential hydrolysis and polycondensation rates of different alkoxides pose a problem. Also, owing to the insolubility or other factors (such as extreme reactivity, cost, etc.) certain metals may be introduced in the form of other precursors that do not exhibit hydrolysis and polycondensation reactions. Different approaches including prehydrolysis of the more slowly reacting metal alkoxides as well

as stabilization of highly reactive metal alkoxides by the molecular modification process have been developed to tackle this important problem (Phulé and Khairulla 1990).

5. Applications of the Sol–Gel Process

The historical routes and applications of the sol–gel process for synthesis of ceramic materials and glasses have been traced to the archives dating back to the sixteenth century and perhaps even before (Wood and Dislich 1995). Although the term "sol–gel" was to be coined later, technology identical to that now known as sol–gel was used to produce adsorbents, catalysts, and ceramic coatings in the period 1920–1950. Roy (1956) reported on the use of this process for a controlled chemical synthesis of multicomponent minerals. In the early 1960s the sol–gel process found application in the preparation of thorium oxide and uranium dioxide microspheres used in the nuclear industry and it was during this period that sol–gel was given its name. Since the early years of the sol–gel process, considerable technological development has occurred in this area. Noteworthy examples of commercial applications of sol–gel technology include, but are not limited to, the areas of optical fibers, refractory and reinforcing ceramic fibers, abrasive minerals, and ceramic and ceramic-like coatings.

The first practicable sol–gel process for making high-quality silica optical fibers was reported by researchers at Lucent Technology (MacChesney et al. 1999). More specifically, in this application the sol–gel process is used for the production of large overcladding silica tubes. The material from these tubes ultimately results in about 90% of the mass of the fiber and this application requires exceptionally pure silica glass. The sol–gel process developed for optical fiber production is different from the schematic shown in Fig. 1(d). Researchers have used colloidal silica (Degussa OX-50, surface area $50\,m^2\,g^{-1}$) that is dispersed in an aqueous solution of tetramethylammonium hydroxide, a polymer, and a lubricant. The stabilized sol of silica particles is centrifuged to remove impurity particles and de-aired in vacuum.

An ester such as methyl formate is added to the sol (to lower the pH) and then the sol is pumped into a mold to form the so-called overcladding tubes. Gelation occurs within 10 minutes, following which the gel body is removed and dried in a controlled atmosphere. Dry tubes are heated first to remove residual water and volatile organics and then heating in a chlorine-containing atmosphere is also used to remove hydroxyl ions, transition metal impurities, and refractory particles. This is followed by sintering at 1500–1550 °C to produce a vitreous cylinder. Optical fiber preforms are then fabricated by collapsing the tube over a vapor-deposited core rod. High-quality optical fibers

are then drawn from such optical fiber performs. The mass of such overcladding tubes that can be prepared using the sol–gel process approaches 20 kg.

Other examples of commercial applications of the sol–gel process include the development of the Nextel fibers and Cubitron abrasive grains. Nextel fibers are prepared by extruding, drying, and firing a concentrated sol containing a basic aluminum salt mixture along with additives such as colloidal silica, organic polymers, and, in some cases, a boron oxide precursor. In general, the Nextel fibers are polycrystalline, transparent, and can be woven or braided for different engineering applications. Nextel 312 fibers based on a ceramic consisting of 62% Al_2O_3, 14% B_2O_3, and 24% SiO_2, are processed using a colloidal sol–gel process. Nextel 610 fibers are high-modulus, α-alumina ceramic fibers having an exceedingly fine grain size (average grain size less than 2000 nm). In the production of these fibers nucleating agents are used to reduce the average grain size. A micrograph of α-alumina fine-grained fibers produced with the use of nucleating agents is shown in Fig. 2(a). For comparison, a micrograph of the relatively coarse-grained and porous microstructure of fibers prepared without using nucleating agents is shown in Fig. 2(b). Such sol–gel-derived ceramic fibers and products made using these (Fig. 3) find applications in ceramic fiber-reinforced metal matrix composites and in reinforcing ceramics and plastics.

While sol–gel processes have been used for many years to produce porous ceramic materials that have been used as adsorbents and catalyst supports, in the 1970s researchers at 3M began to develop technologies to form dense and tough ceramic materials via the sol–gel approach. This effort resulted in the development of a number of sol–gel-derived abrasive

minerals, including materials based on α-alumina–spinel mixtures, superfine-grained aluminas, and alumina–rare earth aluminates. The synthesis of these materials involves first forming a concentrated sol of nanocrystals of aluminum oxyhydroxide, boehmite.

The boehmite that is used is a synthetic product that is formed via hydrolysis of an aluminum alkoxide generated by the oxidation of aluminum metal by alcohol at elevated pressure and temperature. The concentrated boehmite sol is gelled either by raising the ionic strength of the sol or by heating. Modifying agents such as phase-forming precursors or nucleating agents for enhancing the formation of α-alumina can be added to the sol prior to gelation. To form the ceramic abrasive grain, the boehmite gel is dried, crushed to size, calcined, and fired to full density. High-performance abrasive grains of this general type are manufactured and distributed worldwide on a very large scale by 3M Company.

In many familiar applications, sol–gel-derived products play an important role that is often not readily recognized. For example, precipitated silicas are used as a filler material in the manufacture of automobile tires. Other products such as paints and toothpastes also often make use of colloidal silica particles. Some of the other applications of sol–gel-derived products include antireflective (AR) coatings, spin-on glasses for dielectric planarization, ferroelectric thin films, electrochromic coatings, and thin layers of transparent oxide conductors. Also of interest is the area of sol–gel-like processes for polysiloxane–silica coatings on clear plastics for improving abrasion resistance of ophthalmic products such as eyeglasses and contact lenses.

Much effort in the area of sol–gel processing has been devoted to the synthesis and processing of oxide

ceramics and glasses. However, the gel synthesis of nonoxide ceramics (nitrides, sulfides, carbides, etc.) has also received considerable attention. For more detailed information on the sol–gel process the reader is referred to the bibliography below. Internet sites such as at http//www.solgel.com may also yield useful and updated information.

Ceramics: Whisker Toughening

Whiskers of ceramic materials, with their potential high strength coupled with high stiffness, refractoriness, and low theoretical density, originally were considered as agents for reinforcing metallic alloys in the early 1960s. In the early 1980s, significant breakthroughs were made in reinforcing ceramics with ceramic-based whiskers. The first successful development involved an aluminum oxide matrix reinforced with microscopic single-crystal silicon carbide whiskers (Becher and Wei 1984). The whiskers used are typically less than 1 μm in diameter—much smaller than a human hair ($\geqslant 30\,\mu$m in diameter). The whiskers serve to toughen the ceramic, acting much like rebar does in concrete or nails used to hold two pieces of wood together. To do this the whiskers must remain intact as a crack advances through the composite and they must bridge across the crack, serving to hold the crack together until they eventually fracture

Table 1
Mechanical properties of fine-grained (2 μm) alumina composites.

	Flexure strength (MPa)			Fracture toughness (MPa m$^{1/2}$)		
Temperature (°C)	22	1000	1200	22	1000	1200
With no reinforcement	≤ 550			≤ 3		
With 10 vol.% SiC whiskers	600			6		
With 20 vol.% SiC whiskers	800	775	550	8.4	8.1	10

or are pulled out of the matrix. For this to occur, the interface between a whisker and the ceramic matrix must separate (debond) before the whisker can fracture, as the goal is for the crack front to go around the whiskers rather than through them. A number of factors influence the properties of whisker-reinforced ceramics including the size (length, diameter, and aspect ratio) and morphology (e.g., straightness, surface smoothness) of the whiskers, and matrix characteristics and processing parameters (Becher *et al.* 1988, Becher 1991, Homeny *et al.* 1986).

Whisker-reinforced alumina (WRA) composites quickly found application in high-speed machining of metallic alloys (Smith 1986) where their wear and fracture resistance allowed for higher precision machining and lower requirements for lubrication (reducing waste by lowering requirements for solvent cleaning). WRA cutting tools are used in high-speed machining operations involving hard materials such as nickel-based superalloys used in turbine engines. Other applications include machining of fiberglass epoxy composites (e.g., instrument boards), and in woodworking and construction (e.g., longer service life with resistance to wear and corrosive attack associated with modern particle and chipboard materials). Attempts to use whisker reinforcement of other ceramics have not been as successful; however, whisker-reinforced silicon nitride composites (Campbell *et al.* 1990, Sajgalik and Dusza 1989) have been developed and are used in similar machining applications. The known annual worldwide sales of WRA components are reported to have a total value in excess of US$50 million. Some of the properties that contribute to the application of WRA composites are summarized below. The reader is referred to the bibliography for further information.

1. Properties of SiC WRA Composites

With careful selection of the SiC whiskers and the processing conditions, WRA composites, in comparison to nonreinforced alumina ceramics, can exhibit substantial increases in fracture toughness and fracture strength (Becher and Wei 1984, Becher *et al.* 1988, Becher 1991), which are also retained as the test temperature is increased (Becher and Tiegs 1988). Furthermore, the improvements are also found in
Figure 1
Resistance of alumina to creep at elevated temperatures increases significantly with the addition (e.g., 10 and 20 vol.%) of SiC whiskers. Increasing the grain size (*G*) of the alumina matrix (see Lin and Becher 1990, 1991) can enhance this further.

thermal shock resistance (Tiegs and Becher 1987, Becher and Warwick 1993), crack growth resistance when exposed to both static and cyclic loading (Becher *et al.* 1990, Dauskardt *et al.* 1993, Han and Suresh 1989), and creep resistance (Lin and Becher 1990, 1991) in SiC WRAs. Examples of some of the improvements in fracture strengths and toughnesses that have been achieved are listed in Table 1.

An added attractive feature is the greater creep resistance of WRA composites, as shown in Fig. 1. The creep resistance in air is limited by a weakening effect caused by oxidation of the SiC whiskers to form SiO_2, which reacts with alumina to form a glass. Because this is a thermally activated process, WRA composites are typically quite oxidation resistant until temperatures are in excess of 1100 °C and this oxidation-driven reaction can also be limited by
Figure 2
Thermal shock resistance is substantially increased by whisker reinforcement. Even sections that are several millimeters thick do not undergo strength losses after quenching from several hundred degrees centigrade into a boiling water bath (Becher and Warwick 1993).

lowering the SiC content. The combination of crack growth (Becher *et al.* 1990, Dauskardt *et al.* 1993, Han and Suresh 1989) and creep resistance contribute to the superior performance of WRA composites in high-speed machining of superalloys where high temperatures in the alloy at the tool tip are needed to enhance the cutting speed and surface finish.

Ceramics that have low thermal conductivity are susceptible to failure when rapidly cooled or heated (i.e., thermally shocked) as a result of the low toughness and strength and high Young's modulus. A convenient measure of the degree of thermal shock resistance is reflected in the temperature from which a sample is quenched into a liquid held at a fixed temperature that results in a recognizable loss in strength. This is known as the critical (quenching) temperature (ΔT_c). As a result of heat transfer effects during the quenching process, ceramics are more readily damaged as the smallest dimension of the sample increases. Alumina ceramics are no exception; however, the addition of SiC whiskers, which increases both the toughness, strength, and thermal conductivity, is found also to result in a far greater thermal shock resistance as the sample size increases (Fig. 2).

Cermets and Hardmetals

The word "cermet" is a term that designates a material made of the combination of a metallic alloy and a ceramic. A wide range of materials is covered by this definition. In agreement with common use, it is more appropriate to define as cermets those ceramic–metal composites that contain a predominant ceramic phase (carbides, nitrides, borides, silicides, oxides, and eventually ceramics deriving from the metalloids silicon and carbon) bonded with a metal alloy. This definition allows cermets to be classed between metal matrix composites (see *Metal Matrix Composites: Matrices and Processing**) and ceramic matrix composites (see *Ceramic Matrix Composites: Matrices and Processing**). In both ceramic and metal matrix composites, a ceramic phase is added as reinforcement to a metallic or ceramic base material. In cermets, the metallic phase is, in most cases, added in order to improve toughness while maintaining ceramic-like properties: cermets are generally hard, refractory, and chemically resistant.

1. Classification

As in the present definition, cermets contain a dominant ceramic phase; these materials can be classified according to their refractory component, even if some of the properties of the composite may be quite different from those of the ceramic.

1.1 Hardmetals

When the term "hardmetal" was introduced (Schwarzkopf and Kieffer 1953), it was attributed to ceramics constituted of carbides, nitrides, borides, and silicides of the metals in the fourth to sixth groups of the periodic table of elements. Particular characteristics of these ceramics are relatively high electrical and thermal conductivities due to the metallic character of the chemical bonds. Their mechanical properties, such as hardness and brittleness, are typical of ceramics. In practice, most materials of commercial use that contain hardmetal ceramics are made with a metal binder, and the term "hardmetal" is now generally used to designate cermets based on these hardmetal ceramics.

The hardmetals that have had by far the largest commercial success are those used for the manufacturing of cutting tools. These materials are essentially based on the combination of tungsten carbide (WC), titanium carbide (TiC), or titanium carbonitride (TiCN), which constitute the majority of the ceramic phase, with an alloy dominated by one or more elements of the iron group: iron, nickel, cobalt. In the machining industry, the hardmetals that contain a dominant WC phase are generally named "cemented carbides" since their discovery by Schröter in 1922. The designation "cermet" has been historically reserved for TiC-based hardmetals, to specify the ceramic character (lower electrical conductivity) of TiC in comparison with WC. Among cemented carbides, those based on the system WC–Co are the most widespread, while the most used system among TiC-based cermets is TiC_xN_{1-x}–Mo–Ni.

The success of WC- and TiC-based hardmetals is due to their exceptional mechanical properties and to the favorable thermodynamic conditions in the processing of these materials by liquid-phase sintering. Carbides and nitrides of the hardmetals group are more stable than carbides and nitrides of the ferrous metals. Therefore, during sintering, the basic constituents of the cermet are not modified (apart from some potential exchange of metal ions between carbides and nitrides). The material thus behaves essentially like a binary alloy (Holleck and Kleykamp 1981) composed of well-defined metallic and ceramic phases. Moreover, partial dissolution of these carbides or nitrides into the metal produces a low melting point eutectic having a high solubility of the hard phase in the liquid metal. These conditions

are very favorable for liquid-phase sintering (see Sect. 3).

Many other cermets based on hardmetal ceramics have been developed and tested for high-temperature applications, as wear parts, and in chemically aggressive environments. Their advantage compared to cutting tool hardmetals, which are also widely applied to wear parts, is often restricted, however, to special applications. A description of the main systems involving borides and silicides together with their industrial applications is given in Sect. 3.

1.2 Other Relevant Carbides and Nitrides

The hardest ceramics are found among nitride and carbide compounds of metalloid elements. Silicon carbide (SiC), silicon nitride (Si_3N_4), boron carbide (B_4C), cubic boron nitride (cBN), and diamond are the most important among these. Their use is, however, practically limited to metal matrix composites where these ceramics provide reinforcement or fulfill an abrasive function. The differences of elastic modulus and thermal expansion from metals, combined with a weakening of the ceramic grain boundary adhesion by products of reaction with metals, often make cermets based on these hard ceramics of little practical interest. Another compound that should be added to this class for its chemical characteristics is AlN. Due to good wetting by molten metals such as aluminum or nickel, cermets based on AlN can be produced by liquid-phase sintering. AlN is a good electrical insulator but has a very high thermal conductivity. Cermets based on the Al–AlN system are used in integrated circuits.

1.3 Oxide Cermets

Oxides used in industrial ceramics, such as Al_2O_3, ZrO_2, and SiO_2, are poorly wetted by most metals, with which they also tend to react at high temperature to form complex oxides. The processing of oxide cermets is therefore somewhat difficult (see Sect. 2). The high resistance to chemicals and the refractory character of oxide ceramics has, however, stimulated research efforts towards the engineering of cermets mainly aimed at improving the low mechanical and thermal shock resistance of the ceramic oxide.

2. Processing

Most cermet fabrication processes are based on powder metallurgy (PM) techniques. The metal and ceramic powders are mixed and then milled in ball mills or attritors. During the milling operation, a wetting organic lubricant is added in order to agglomerate the powder, prevent oxidation, and lubricate particle sliding. Organic lubricants may be polyglycols or paraffin wax dissolved in hexane, acetone, or

alcohols. The purpose of the milling step is to obtain a homogeneous distribution of the ceramic grain size and to cover the ceramic powders with the metal, which facilitates the sintering. The slurry obtained after milling is then dried to remove the solvent. Spray drying is the most used technique for this purpose. After this operation the powder takes the aspect of spherical granules with a typical diameter of 0.1–0.5 mm.

Forming of the parts is achieved by powder compaction. The most used method for relatively simple shapes is cold pressing. Cold isostatic pressing, PM injection molding, or slip casting can be used for complex shapes.

After the cold processing steps, fully dense cermets are obtained by high-temperature PM processes. The most used method is sintering. This is generally carried out in batch ovens under vacuum, inert gas, or hydrogen. The choice between solid- and liquid-phase sintering depends on the particular ceramic–metal system. Liquid-phase sintering is well adapted to the systems used for hardmetal cutting tools described in Sect. 1.1. The densification, enhanced by the presence of a liquid phase, involves three stages: rearrangement of particles, solution-precipitation, and grain coarsening (German 1996). Rearrangement requires good wetting so that the capillary forces can promote the collapse of the powder structure. Solution-precipitation requires adequate solubility of the hard phase in the liquid phase. The ceramic grain coarsening must be controlled so as to achieve a homogeneous structure. All these requirements are generally met in the hardmetal families used for cutting tools. A typical sintering cycle for these hardmetals involves two or three steps where temperature, pressure, and sintering atmosphere are changed. First, the remainder of the organic lubricant is removed during the sintering cycle at 700–800 °C under vacuum. The true sintering step occurs at temperatures above the liquidus temperature of the ceramic–metal system. Typical temperatures for hardmetals are between 1350 °C and 1500 °C. The sintering step may be followed by hot isostatic pressing (HIP), which allows for elimination of residual porosity. This operation is efficient only on closed pores, which requires the achievement of a density greater than 95% after the pressureless sintering step. Solid-state sintering processes, such as warm extrusion and powder rolling, are used to form wires or slabs.

During the sintering process the microstructure, the morphology, and the phase partition of the cermets are built. In hardmetals, the ceramic phase composed of the carbides and/or nitrides partially dissolves in the binder and reprecipitates, producing the final shape and structure of the ceramic grains. In cemented carbides, the growth anisotropy of WC produces well-faceted single crystals (Fig. 1(a)) while most hardmetal carbides and nitrides like TiC have a NaCl cubic structure and produce round-shaped particles (Fig. 1(b)). The solubility of the other metallic elements in WC being very small, WC appears always pure, whatever the ceramic composition. However, the case of WC is special: hardmetal carbides, nitrides, and borides have a high reciprocal solubility and may exchange metal ions or carbon with nitrogen. Figure 1(b) shows, for example, a cermet sintered from TiCN, Mo_2C, and nickel powders. The ceramic grains assume a typical core–shell morphology. The core corresponds to the undissolved particles, while the shell is produced upon sintering by reaction and precipitation from the liquid phase of cubic Ti(Mo)C (Andrén *et al.* 1994). The shell and the core have identical crystal orientations.

Upon sintering, the ceramic particles join together in order to minimize the surface energy (German 1996) producing a continuous network. Depending on the binder content and on the dihedral angle (Wray 1976), the binder can also form an interconnected network. The connectivity of these two networks greatly influences the properties of the composite. In particular, the metal binder, which is in a constrained state in the network, exhibits features that are very different from those of the same but free metal. One example is that of cobalt, which in the hardmetals does not transform from the f.c.c. to the hexagonal structure (Exner 1979). In the metastable constrained state at room temperature, it can exhibit a highly strain-hardened structure with hardness comparable to that of the ceramic (Sigl and Fischmeister 1988); however, when constraints are released, e.g., by fracture, the cobalt can deform with a high toughening effect. The mechanical properties of the metal binder are also affected by solute impurities or precipitates deriving from the elements contained in the original ceramic powders.

Liquid-phase sintering is the most effective and economical production process when good wetting and solubility of the hard phase in the liquid are obtained; however, these conditions are not met in most metal–ceramic couples. Different techniques of pressure-assisted sintering, such as hot uniaxial or isostatic pressing, may then be adopted in order to obtain poreless materials in nonwetting systems like oxide cermets. These techniques may be applied also at relatively low temperatures in order to prevent undesired reactions between phases. Another processing technique that may be applied to cermets is infiltration of a ceramic matrix by molten metal. The excessive shrinkage that is associated with liquid-phase sintering may be avoided by this technique and accurate dimensions in complex shapes may be obtained. Infiltration is effective in wetting systems where the metal alloy can penetrate the preform by capillary forces. Pressure-assisted infiltration, which is widely used in metal matrix composite fabrication, can be used in nonwetting systems; however, it may be more difficult to apply this process in cermets due to the high volume content of the ceramic matrix.
Figure 1
Grain structure of (a) WC–18 vol.% Co cemented carbide and (b) TiCN–6.2 vol.% Mo_2C–6.3 vol.% Ni cermet where typical core–rim structure can be observed.

Infiltration may also be applied to obtain graded cermets (see *Functionally Graded Materials**). Reactive synthesis techniques may be particularly attractive in making cermets. In most cases the sintering is achieved by an exothermic reaction between constituent powders. For example, TiAl–TiB_2 cermets have been produced by igniting a blend of titanium, aluminum, and boron (see XD process). Infiltration may also be associated with reactive synthesis. Systems like Al_2O_3–SiC–Al or ZrB_2–ZrC–Zr have been produced by infiltrating a carbide preform with a reactive metal in an oxidizing atmosphere.

3. Properties and Applications

3.1 Hardmetals for Cutting and Wear Applications

The improvement of the mechanical properties that can be obtained by combining metal with ceramic is particularly effective in the hardmetals for cutting tools, where an optimum combination of hardness and toughness is desired. From the commercial point of view, cutting tools represent the most widespread application of cermets in general. It is estimated that 65% of the total world production of tungsten is devoted to the fabrication of cemented carbides for cutting tools.

Since the beginning of cutting tool manufacturing, launched by the Krupp company in 1927 under the trademark Widia (wie Diamant), the WC–Co alloys have shown exceptional properties in cutting aluminum and cast iron. Their properties have since been enhanced successively with TiC and TaC additions to improve their resistance to oxidation and to retard diffusion into the tool edge (from elements like iron or nickel while machining steels), and with VC or Cr_2C_3 added to control the ceramic grain growth during sintering. Cemented carbides are still unsurpassed in room-temperature mechanical properties, showing a toughness (K_{IC}) of 10–24 MPa $m^{1/2}$ and corresponding Vickers hardness (roughly inversely proportional to toughness) in the range 2000–1100 H_v30 (Warren and Johannesson 1984). However, many cutting applications require a high working temperature; hence toughness and hardness are not the only parameters that define the quality of cutting tool materials. Their mechanical behavior at high temperature plays a fundamental role in defining their domain of application (Mari *et al.* 1999).

Generally, the softening of the metal phase with increasing temperature results in a decrease of the yield stress of the material. As the ceramic matrix constitutes the dominant phase in the material and forms a continuously bound skeleton, the deformation of the metal phase cannot produce extended cermet strain until the ceramic skeleton deforms. Plastic deformation of the ceramic grains is generally rather small, even in cubic carbides and nitrides where dislocations can glide in several high-density planes, as in f.c.c. metals. Above 1000 °C, grain boundary sliding of the carbides may however occur, leading to extensive plastic deformation. This phenomenon is particularly evident in cobalt-bonded cemented carbides. For this reason the TiC cermets, mostly used in the TiCN–Mo–Ni base compositions, find an important place in high-speed cutting applications where working temperatures can go beyond 1000 °C. Even if, just looking at the hardness and the toughness range (H_v = 1400–1750, K_{IC} = 7–12 MPa m$^{1/2}$ (Warren and Johannesson 1984)), these materials seem to perform less well than WC–Co, their refractory character proves extremely important to prevent wear while cutting.

It must be mentioned that in order to improve their chemical resistance to oxidation and to diffusion of external elements, most cutting tools are coated with refractory ceramics. The coating consists of a multi-layered structure composed of TiC, Al_2O_3, and an external layer of TiN that gives a characteristic golden color to the cutting inserts.

3.2 Oxide Cermets

The development of oxide cermets is still limited despite a consistent research effort. The poor resistance of oxides to thermal shock and fracture could be improved by the presence of a tough metal binder; however, when a dominant oxide phase is present, the toughening effect of the metal is often too low. This is due, in many cases, to poor bonding at the metal/oxide interfaces. However, oxide cermets show some clear advantages when oxidation or chemical resistance are required, and also for high-temperature applications.

Al_2O_3 is used in combination with nickel, Ni_3Al, or chromium binders, or with TiC and a nickel alloy binder. These cermets are used for wear parts working at high temperature. Zr_2O–Ti or ZrO_2–Mo composites are used for wear and chemical applications. Its high thermal shock resistance and low thermal conductivity make ZrO_2 a good candidate as an insulator. ZrO_2–Mo cermets are used in thermocouple sheaths and extrusion dies in steel foundry technology. An interesting application of ZrO_2 in cermets is in the fabrication of anodes in solid oxide fuel cells made of yttria-stabilized ZrO_2–Ni cermets. These electrodes must be gas permeable, so the cermets contain 30% porosity. They are made by sintering a NiO–ZrO_2 ceramic in which the NiO is directly reduced during the first operation of the fuel cell. Another interesting application is the toughening of high T_c oxide superconductors (e.g., $YBa_2Cu_3O_7$) with a silver binder. These cermets are either hot extruded or made by reaction synthesis using Ag_2O as a silver precursor.

3.3 Borides

Borides have better chemical stability than carbides and may be used in applications that require extreme heat and corrosion resistance. Their brittleness, with strength hardly above 200 MPa makes their toughening with a metal binder very attractive. For example, adding 8% nickel to a TiB_2 matrix produces an increase of the flexural strength from 200 MPa to 700 MPa. TiB_2, ZrB_2, CrB_2, and MoB_2 combined with iron, nickel, chromium, or molybdenum binders are used as dies or crucibles with reactive metals like copper, bronze, lead, and zinc.

3.4 Silicides

Metallic silicides have found little commercial use due to their extreme brittleness. $MoSi_2$ is mostly used in heating elements due to its outstanding oxidation resistance combined with a favorable electrical resistance. $MoSi_2$-based cermets made with small amounts of nickel, cobalt, or silver as binder show a certain improvement of the toughness compared to the pure ceramic.

4. Summary

Cermets are constituted of a ceramic matrix bonded by a metallic binder. The metal improves the toughness and the thermal shock resistance of the ceramic. Two major groups of cermets can be defined: the hardmetals, which are based on carbides, nitrides, borides, and silicides of the fourth to sixth element groups, and the oxide cermets. Among hardmetals, the cemented carbides based on WC–Co–Ni and the TiC–Co–Ni cermets are used for the fabrication of cutting tools; these materials constitute the large majority of commercial cermets principally because they feature an optimum compromise between toughness and hardness. Cermets are mainly used in wear components, for chemical-resistant and high-temperature applications, and as insulators.

Clay-based Polymer Nanocomposites

A clay comprises silicate layers having a 1 nm thick planar structure. It has been shown that the silicate layers can be dispersed at the molecular level (nanometer level) in a polymer matrix with the polymer existing between the silicate layers (two-dimensional space). Polymer and clay nanocomposite materials produced in this manner are called polymer–clay hybrid materials. In this article some materials of this type are described, in categories based on synthetic methods. Five methods of synthesis of clay-based polymer nanocomposites will be described on the basis of the relationship between an ammonium cation-exchanged clay and monomer (or polymer). The methods are: (i) monomer intercalation, (ii) monomer modification, (iii) co-vulcanization, (iv) common solvent, and (v) polymer intercalation.

1. Classification of Producing Polymer–Clay Hybrid Material According to the Synthetic Method Employed

1.1 Monomer Intercalation Method

A polymerization producing nylon 6 is the ring-opening polymerization of ε-caprolactam. It can occur in the presence of clay after ε-caprolactam is intercalated into clay galleries, the silicate layers being dispersed uniformly in the nylon 6 matrix. We found that organophilic clay which had been ion-exchanged with 12-aminododecanoic acid was swollen by molten ε-caprolactam (basal spacing being expanded from 1.7 nm to 3.5 nm) (Usuki *et al*. 1993a). In the clay galleries the ε-caprolactam was polymerized, and the silicate layers were dispersed in the nylon 6 to give a nylon 6 clay hybrid (NCH) (Usuki *et al*. 1993b). This is the first example of an industrial clay-based polymer nanocomposite. Figure 1 shows a schematic representation of the polymerization.

The modulus of NCH increased to 1.5 times that of nylon 6, the heat distortion temperature increased to 140 °C from 65 °C, and the gas barrier effect was doubled at a low loading (2 wt.%) of clay (Kojima *et al*. 1993b).

There is another example, in which ε-caprolacton is polymerized in the clay galleries in the same manner. In this case, the gas permeability decreased to about 20% under 4.8 vol.% (12 wt.%) clay addition (Messersmith and Giannelis 1995). There is yet another example of an epoxy resin clay nanocomposite. In this case, the tensile strength and modulus
Figure 1
Schematic diagram of polymerization to NCH.

increased drastically on 2–20 wt.% clay addition (Lan and Pinnavaia 1994).

1.2 Monomer Modification Method

In one example, a quaternary ammonium salt of dimethylaminoacrylamide (Q) was ion-bonded to silicate layers, and ethyl acrylate (EA) and acrylic acid (Aa) were copolymerized in the clay galleries. The ratio between EA and Aa was 10:1 (mole ratio). Each of the four kinds of acrylic resin–clay hybrid were polymerized. The clay content was 1, 3, 5, and 8 wt.% on the basis of solid acrylic resin. A suspension above 3 wt.% clay addition acted as pseudoplastic fluid (Tables 1 and 2 give details of compositions). The acrylic resin clay hybrid films cross-linked by melamine were transparent, and the gas permeability of their film (Fig. 2) decreased to about 50% on 3 wt.% clay addition (Usuki *et al.* 1995).

There are also some other reports of acrylic resin–clay hybrids. A poly(methyl methacrylate) clay hybrid was synthesized using a modified organophilic clay in the same manner (Biasci *et al.* 1994), and by emulsion polymerization (Choo and Jang 1996). Figure 3 shows a schematic representation of this polymerization method.

1.3 Co-vulcanization

The basal spacing of organophilic clay ion-bonding nitrile rubber (NBR) oligomer with telechelic amino groups was expanded 0.5 nm from its initial spacing

(1.0 nm) (Moet *et al.* 1994). After this, high molecular weight NBR was kneaded with this organophilic clay and vulcanized with sulfur. It produced an NBR clay hybrid consisting of dispersed clay and co-vulcanized high molecular weight NBR and NBR oligomer (Fukumori *et al.* 1991). Its permeability to hydrogen and water decreased to 70% on adding 3.9 vol.% clay (Kojima *et al.* 1993a). Figure 4 shows a schematic representation of this production method.

1.4 Common Solvent Method

In the case of synthesis of polyimides, the polymerization solvent for the polyamic acid precursor of polyimide is usually dimethyl acetamide (DMAC). We found that a clay ion-exchanged dodecyl ammonium ion could be dispersed in DMAC homogeneously. The solution of this organophilic clay and DMAC was added to a DMAC solution of polyamic acid. The film was cast from a homogeneous mixture of clay and polyamic acid, and was heated at 300 °C to get the desired polyimide clay hybrid film. The permeability of water decreased to 50% on adding 2.0 wt.% clay (Yano *et al.* 1993). It was confirmed that the permeability of carbon dioxide also decreased by half (Lan *et al.* 1994). Figure 5 shows a schematic representation of this method.

1.5 Polymer Intercalation Method

Polypropylene (PP) clay hybrids could not be synthesized easily because PP is hydrophobic and has

poor miscibility with clay silicates. Dioctadecyldimethyl ammonium ion was used as a modifier for the clay and a polyolefin oligomer was used so that the clay became more compatible. Organophilic clay, polyolefin oligomer, and PP were blended using an extruder at 200 °C. It was confirmed by transmission electron microscopy that the clay was dispersed in a monolayer state in the PP matrix. Thus PP was directly intercalated into the clay gallery (Usuki *et al.* 1997). Figure 6 shows a schematic representation of this polymerization.

There is also a direct-intercalation process in which PP is modified using maleic anhydride, followed by melt compounding (Kawasumi *et al.* 1997). It is a useful process from an industrial standpoint. There are also some studies showing that polymer is intercalated directly into the clay galleries. There is a report that intercalation of nylon into clay galleries was successful (Takemura *et al.* 1996). The clay silicates may not have been dispersed uniformly, judging by the physical properties exhibited.

2. Functional Clay Hybrids

The examples described above involved organic polymer clay hybrids which are aimed at high performance structural polymer materials with high strength, high modulus, and high gas barrier properties. This hybrid technique should also be applicable to various other types of materials, including low molar mass compounds. This section presents one of the unique attempts to obtain novel hybrid materials based on a low molar mass liquid crystal and organized clay mineral (liquid crystal clay composite, LCC). Clay exchanged with 4-cyano-(4′-biphenyloxy)undecyl ammonium ion was used to enhance the miscibility between clay and the liquid crystal. The LCC (clay content 1.25 wt.%) cell displayed a reversible and bistable electro-optical effect based on light scattering which could be controlled by changing the frequency of an electric field (Kawasumi *et al.* 1996). Figure 7 shows a typical change in the light transmittance of the LCC (clay content 1.25 wt.%) when the cells were subjected to electric fields.
Figure 7
Light transmittance of LCC.

This new material would be a potential candidate for advanced applications such as a light controlling glasses, high information display devices which do not require active addressing devices, erasable optical storage devices, and so on.

3. Possible Future Subjects

The above examples illustrate the synthesis methods and the properties of clay-based nanocomposites including polymers and liquid crystals. A modification of the clay surface plays a principal part in the technology. Other modifications of monomer and/or polymer, or an addition of adequate compatibilizer for organic materials and clay could open a new methodology of clay nanocomposite production. Future subjects are considered to be:

(i) Clay-based nanocomposite technology involving polymer alloys.

(ii) Investigations of clay-based nanocomposites involving new properties such as transparency, recyclability, fire retardation (Gilman and Kashiwagi 1997), and biodegradation.

(iii) Identification of the most suitable clay manufacturing technique for each polymer.

Composite Dental Materials: Wear

The use of light-cured composite resins for restoring posterior stress-bearing cavities has increased significantly in recent years. These materials feature the advantage of good esthetics for posterior restorations and are able to bond to tooth structures (see Bayne *et al.* 1989, Lutz *et al.* 1984, Manhart *et al.* 2000, Roulet 1988). New methods for diagnosis and treatment, such as Diagnodent (KaVo) and caries detectors (Cavex), Sonicsys (KaVo), micropreparation

(Komet), and air abrasion have ensured that composite resins are the materials of choice in the concept of minimal invasive dentistry (Degrange and Roulet 1997). As an alternative to amalgam, the early attempts to place composites in posterior teeth had only limited success because of inadequate material properties. Inadequate resistance to wear, resulting in a loss of anatomic form under masticatory abrasion and attrition, fracture within the body of the restoration and margins, and marginal leakage due to polymerization shrinkage were often cited as being the most common causes of failure in posterior composite restorations (Manhart *et al.* 2000). Improvements in the properties of the materials together with their positive clinical performances encourage continuously the use of posterior composite resins as a viable alternative to amalgam (see Bayne *et al.* 1989, Degrange and Roulet 1997, Lutz *et al.* 1984, Manhart *et al.* 2000, Roulet 1988).

Because it is natural tooth tissues that are being replaced, human enamel and dentin should be used as the physiological standards with which to compare composite resins, especially in the posterior region. The goal of restorative dentistry should be to make highly wear-resistant occluding surfaces that do not cause wear on the opposing structures (Lambrechts *et al.* 1989, Lambrechts *et al.* 1991, Willems *et al.* 1993a).

1. Description

1.1 Mechanisms

Wear of dental composites includes diverse phenomena such as adhesion, abrasion, attrition, chemical degradation, and fatigue, to mention the most common (Lim *et al.* 2002). In reality, the various mechanisms usually act simultaneously and/or sequentially and often influence each other in a very complex way, resulting in the general tendency of wear processes to be very difficult to predict (Pallav 1996).

Abrasion in the dental literature is caused mainly by frictional surface interactions with toothbrush and paste, food bolus, and fluid components during chewing. This form of wear is considered an important mechanism of occlusal material loss with composites (Krejci *et al.* 1990). Attrition is caused by direct contact of sharp roughness asperities of the antagonist, which should at least be some 50% harder than the wearing substrate for substantial wear to occur. Attrition may cause substantial changes in surface texture (roughness, smear layer, etc.). Additional, chemical wear is an underestimated wear mechanism. All kinds of chemical influences on wear processes are possible, such as degradation of silane couplings in composites and possible softening of resin material by food or saliva constituents. Surface fatigue is a wear phenomenon that occurs in moving contacts and/or at cyclic load variations. Due

to common dental geometry, stress concentrates slightly below the surface. Because of this, a network of subsurface cracks is created. One of the characteristics of surface fatigue is the incubation period (McKinney and Wu 1982, Lambrechts *et al.* 1987, Juvinall and Marshek 1991). The cracks are very likely to grow and connect at their roots, through stress concentration (Truong and Tyas 1988) until, at the end of the onset period, the damaged area no longer offers enough support for the superficial layer, which will then rapidly delaminate, leaving an extremely rough surface (Lambrechts *et al.* 1985).

Another important wear mechanism is adhesive wear. High adhesive shear stresses tear platelet-shaped wear particles out of the surface(s), which may, sometimes permanently, remain attached to the antagonistic surface, which in mild cases reduces the wear rate and in severe cases can increase the wear rate.

The wear process of dental composites is complicated by the fact that the filler and matrix consist of fundamentally different materials, the relative influence of which varies greatly with the wear type. With abrasion, the relatively soft matrix allows the digging out of filler particles, while with direct contact, attrition and adhesive wear are located at the peaks of protruding particles. If, however, the filler is also relatively soft, then the antagonist may be smoothed by material transfer and in this way, wear may be reduced (Pallav 1996).

1.2 Types of Wear

Wear of composite resins takes place at the occlusal surface and at the proximal interface. In literature, there is a difference between wear at contact free occlusal areas (CFOA) and wear at the occlusal contact area (OCA) (Lambrechts *et al.* 1987).

In the chewing cycle, opposing dentition traps a layer of food and grinds it as the teeth move past one another. The excursion of food particles produces wear of the tooth structure and restorative materials through three-body abrasion. This is considered the main wear mechanism active in the contact-free area, resulting in generalized loss of form (Lutz *et al.* 1984). The chewing forces produced during this phase have been modeled in the range of 10–20 N (De Gee *et al.* 1986, De Gee and Pallav 1994, Sakaguchi *et al.* 1986). At the end of the chewing cycle, the sliding motion stops as the teeth reach centric occlusion. The chewing force is heightened within the range of 50–150 N (Bates *et al.* 1975), and tooth surfaces come into more direct contact. This produces localized two-body abrasion wear or attrition at sites termed OCAs (Lutz *et al.* 1984). Wear on the OCAs was found to be approximately 2.5 times greater than that on the CFOAs (Roulet 1988).

Proximal surfaces are subjected to compressive and sliding forces during function as well. As a result,

interproximal wear of posterior resin composite restorations can be significantly greater than that of unrestored surfaces (Cunningham *et al.* 1990, Wang *et al.* 1989). The periodontal status and its related tooth mobility determine the degree of sliding and related wear.

1.3 Influencing Factors

Generally, wear can be related to either material or clinical factors. Material factors relate to the resin composite's particle size, shape and hardness, the filler content, the interparticle spacing, the filler distribution, and degree of conversion. Additionally, the silane coupling, the nature of the matrix, and the surface hardness play an important role in the composite materials wear resistance (Hilton 2000, Suzuki *et al.* 1995, Venhoven *et al.* 1996). Since the process of three-body abrasion involves the cutting away of a soft material by a hard abrasive, it seems reasonable that adding hard inorganic filler particles to a soft resin matrix should enhance the material's overall resistance to abrasion (Leinfelder 1988). An important factor is particle size. In the range of current composites a smaller particle size is desirable. It appears that there is a critical value of filler particle size (1.2–1.5 μm), under which the food fibers are not able to penetrate the interparticle space, so the erosive capability of the erosive medium will be reduced (Venhoven *et al.* 1996). *In vitro* wear tests indicated that composites containing the smallest (0.2 μm) spherical particles exhibited substantially higher wear resistance compared to larger filler paricles (Suzuki *et al.* 1995). However, the mean particle size does not adequately describe the filler system. In particular, the proportion of the largest fillers dominates the wear behavior (Degrange and Roulet 1997). An additional aspect to be considered is particle brittleness. Under high stress, brittle particles will easily fracture and cause rapid abrasion of the material itself, but less antagonistic engagement (Lambrechts *et al.* 1991).

Besides the addition of filler particles to the matrix of the composite, filler–matrix-interactions appear to have great effect on increasing the wear resistance of the composite resins. Apparently, the ability for a resin composite to resist abrasive action is an interaction of the different mechanical factors. Clinical studies have shown less heavily filled composites (<60% filled by volume) to exhibit unacceptable wear (Willems *et al.* 1993b, 1993c). However, the results from clinical studies indicate that no direct relationship exists between filler content and abrasion resistance since wear tribology is multifactorial and complex. Also, *in vivo* wear measuring techniques are often unable to unravel the complicating biological factors. Because of their generally lower filler content, (30–50%), microfilled composites are more subjected to attrition and marginal breakdown, especially adjacent to OCAs (Manhart *et al.* 2000, Collins *et al.* 1998). However, they are more resistant to abrasion because of their smoother surface, decreased interparticle spacing, and decreased friction to food particles.

Bayne *et al.* (1992) suggested that, in a microfilled composite, very little (<6.0 vol.%) microfiller was required theoretically to provide matrix protection. Pallav *et al.* (1989) reported that an optimum microfiller level was approximately 15 vol.% to achieve the good wear resistance for small-particle hybrid composites, if the fillers were distributed well. As filler volume increased, wear was reduced regardless of filler treatment. Wear resistance of microfilled composites was significantly enhanced by filler volume with an increase from 25 vol.% to 30 vol.%.

Besides the filler type and filler volume fraction, the interparticle spacing and filler distribution influences the physical properties and wear behavior of dental composite materials (Degrange and Roulet 1997, Bayne *et al.* 1992, Mitchem and Gronas 1990, Ferracane and Condon 1999).

From Jørgensen's findings (Jørgensen and Asmusson 1978, Jørgensen *et al.* 1979), it may be concluded that the use of finer particles for a fixed volume fraction of filler results in decreased interparticle spacing and reduced wear. Filler particles situated very close protect the softer resin matrix from abrasives, thus reducing wear. Based on research (Jørgensen and Asmussen 1978, Jørgensen *et al.* 1979) and clinical research data available today, it appears that the critical interparticle spacing for dental composites is around 0.1–0.2 μm.

In addition to interparticle spacing, another key factor in wear of composites is good stress-transfer ability (Söderholm and Shang 1993, Calais and Söderholm 1998). Such a stress transfer can be enhanced by either improving the bond between the filler and the matrix, or by increasing the filler surface area (Degrange and Roulet 1997). Silane coupling agents are thought to play a major role in enhancing the adhesion of the interface between the inorganic filler and the organic resin. The silane used in most dental composites is γ-methacryloxypropyl-trimethoxysilane, which can bond to inorganic silica surfaces and organic polymers (Söderholm and Shang 1993). Another advantage of the use of a coupling agent in dental composites is that it, at least to some extent, protects the filler against hydrolytic degradation. Condon and Ferracane (1997) and Beatty *et al.* (1998) reported that wear resistance decreased linearly as the percentage of silane-treated silicate glass fillers in experimental hybrid composites was reduced.

There is an advantage gained by the reinforcement of the resin matrix with well-bonded microfillers, which protect the matrix and interfere with crack propagation at higher filler levels (Mohsen and Craig

1995). It is important to keep microfillers well dispersed to achieve the full effect of protection (Bayne *et al.* 1992). Particles in which silane molecules have condensed may form clusters that are not penetrated by the resin monomer.

Filler particle clustering ought to be one of the detrimental factors to performance of particle-reinforced composites. According to Söderholm (1985), the silane coupling agent tends to form aggregates on the filler surface. Aggregates of filler particles and silane coupling, however, do not form a very stable bond between filler and resin. Mohsen and Craig (1995) suggested that dispersion of the filler in the monomer mixtures involved wettability of the filler surface by the monomer, dispersion of the particles, and stabilization. The degree of agglomeration decreased slightly with an increase of the filler content. This may be a result of the increasing amount of filler that is available to break down the filler agglomerates by grinding against one another during mixing. Bayne *et al.* (1992) calculated the minimum and maximum interagglomerate spacing. They presumed that agglomerates were 0.5–1.0 μm in diameter with 1000 microfiller particles being involved, and particles in the agglomerate were assumed to be closely packed. To achieve the full effect of protection, they concluded that the critical filler fraction should be in the range of 35–48 vol.%. In addition, contamination of the filler might disturb silanization and reduce filler–matrix coupling. Therefore, Shirai *et al.* (2000) proposed the use of sodium peroxodisulfate in a presilanization filler decontamination step in the process for the production of resin composites (Yoshida *et al.* 2002, Shirai *et al.* 2000).

Wear was found to reduce significantly as the degree of cure was increased (Ferracane *et al.* 1997). The excellent correlation between degree of conversion of the polymer matrix and abrasive wear for experimental composites verifies that, for a given filler composition, abrasive wear is dependent upon the properties of the polymer network. It is expected that the increased cure produced by the longer curing times causes the polymer network to be more highly cross-linked, and, therefore, more resistant to the forces of abrasion. It should be noted that the baseline depths are also related to the curing time, because the composites with lower conversion are less abrasion-resistant and are polished to a greater depth during the finishing sequence. The heat-cure process enhances the fracture toughness of the microfill composite, which results in an enhanced resistance to marginal breakdown (Ferracane and Condon 1992). Study results imply that maximum wear resistance requires that the composite should be cured to its maximum amount (Ferracane *et al.* 1997).

However, in addition the strength of the resin matrix must be considered. A weak, incoherent matrix can invoke phenomena such as plucking out of filler particles and thus reduce the abrasive capacity.

Studies have revealed that matrix composition is a significant factor affecting the wear rate. The superior resistance of UEDMA/TEGDMA resin can be related to its higher degree of conversion (Condon and Ferracane 1996, Söderholm and Shang 1993). In laboratory evaluations, the UEDMA/TEGDMA had a conversion rate of 70% while the BisGMA/ TEGDMA had a conversion rate of 55% (Söderholm *et al.* 2001).

It is noteworthy that long-term exposure to water after 3 yr caused a DPMA-based matrix to undergo substantially greater degradation than an UDMA-based matrix (Beatty *et al.* 1993).

The BisGMA resin compound is susceptible to chemical softening, which reduces the surface hardness of the composites and enhances the occlusal wear rate (McKinney and Wu 1982). The mixing of certain incompatible resins such as BisGMA and UDMA can cause agglomeration if the resins are not stirred well (Lambrechts and Vanherle 1983). Thus, good mixing is very important to avoid filler agglomeration and an inhomogeneous resin phase.

The chemical environment is one aspect of the oral environment which could have an appreciable influence on the *in vivo* degradation of composite resins. The resin matrix can be softened and fillers can be leached out when composites are exposed to certain chemicals/food simulating liquids (Yap *et al.* 2002).

Apparently the toughness of the resin matrix is an important factor since urethane-based materials are the most abrasion resistant (Beatty *et al.* 1998). The intrinsic surface roughness of composite resins must be equal to or lower than the surface roughness of human enamel on enamel-to-enamel occlusal contact areas (Ra = 0.64 μm) (Lambrechts *et al.* 1991). Roughness determines the biological strength of composite resins. The nanoindentation hardness value of the filler particles (2.91–8.84 GPa) must not be higher than that of the hydroxyapatite crystals of human enamel (3.39 GPa) (Willems *et al.* 1993a). However, an ultrafine filler size will reduce the impact of the filler hardness.

Whenever filler particles protrude and are large and extremely hard, there can be high antagonistic wear rates that would cause catastrophic loss of tooth substance in time (Lambrechts *et al.* 1987). Therefore, if there is a mismatch between the filler hardness and surface roughness of the composite and that of enamel, there is a danger that the enamel will be worn down. During mastication, composite filler particles may scratch and abrade the antagonistic enamel. The vertical dimension will thus decrease if premolar and molar regions are treated with such restorative material.

A smooth surface provides reduced frictional wear at the occlusal contact area. This smoothness will benefit the composite wear as well as the antagonistic enamel wear (Lambrechts *et al.* 1988).

Wear resistance tends to increase as cavity size decreases. The restorations placed should be as small as

possible in order to benefit from the strong support of, and a full protection by, the surrounding natural tooth structure. It was also found that more wear occurred with larger-sized restorations (Roulet 1988).

Tribology or wear science plays an important role. The width of various parts of the restoration is of influence in three ways. First, at the central part of the fossa the erosive activity increases with the distance from the center. This implies that the average wear rate at a restored area in the central part increases with the width of the restoration. Second, the greater (wider) the restored part of a tooth's occlusal surface, the more occlusal contacts are, statistically, on the restored part, and the more a developing height loss will be compensated for by repositioning (natural eruption) of the teeth. Because of this, the wear rate will decrease less with developing height loss. Third, imagine a cusp and fossa with three equal escape ways. If one of its escape ways contains a wider restoration, then its flow resistance will decrease more with height loss than that of the other two. Because of this, gradually more food will escape at the wider restoration and less will flow out at the other two. For the height loss versus time means that, although the wear rate decreases at all the three escape ways, it will decrease less at the wider restoration and more at the other two (Pallav 1996).

Another factor determining the wear process is the dimension of the occlusal contact area. Krejci *et al.* (1991) found that composite wore significantly less with increased OCA dimensions for a constant load. When considering an OCA with restricted dimensions, the chewing stresses will cause more local composite damage because the occlusal forces will be spread over a tiny contact area. Increasing the OCA will diminish composite wear (Krejci *et al.* 1991, Willems *et al.* 1993c).

2. Measuring Methods

Several systems have been described for the assessment of changes in anatomical form of composites and major discrepancies have been shown between the *in vivo* and *in vitro* wear rates of posterior composites (Roulet *et al.* 1987). Attempts to correlate *in vitro* results with a long-term *in vivo* situation have not been very successful (Sakaguchi *et al.* 1986, Taylor *et al.* 1994). Also the complex *in vivo* wear behavior cannot be predicted from physical and mechanical testing alone. Therefore, long-term quantitative *in vivo* wear measurements are still essential to determine the clinical performance of new posterior composite materials. Clinical evaluations are generally the most widely accepted measures of composite performance. However, clinical trials are both expensive and time-consuming. In addition, the lack of control over important variables such as chewing force, dietary intake, or environmental factors in

in vivo studies limits their contribution to the tribology of dental materials (Taylor *et al.* 1994). It is important that any machine which attempts to characterize composite wear behavior reproduces both of these types of wear—abrasion and attrition (Condon and Ferracane 1997). The OHSU oral wear simulator developed by Condon and Ferracane (1996) has demonstrated its ability to produce clinically relevant wear results. It has the ability to generate wear simultaneously through the two dominant oral wear mechanisms of abrasion and attrition, while also allowing for the measurement of opposing enamel wear attrition (Condon and Ferracane 1997). Other oral wear simulators are the Munich Artificial Mouth, the ACTA oral wear simulator, and the Artificial Mouth from Minnesota (Manhart *et al.* 2000, Mehl *et al.* 1997, Pallav 1996, Sakaguchi *et al.* 1986). Experience with a denture model has verified that similar abrasive wear of composites occurs as in dentate patients (Condon and Ferracane 1996, Mitchem and Gronas 1990, Söderholm 1985).

The results from *in vitro* and *in vivo* wear tests can be measured in several ways. *In vivo* wear can be evaluated in a direct way, using clinical performance scales like the US Public Health Service criteria (Cvar and Ryge 1971). Clinical wear performance can also be measured in an indirect way, using the same techniques as for *in vitro* wear measurements. The *in vivo* wear can be measured by the use of replicas (Lambrechts *et al.* 1991, Manhart *et al.* 2000, Söderholm *et al.* 2001). The most common measuring method is profilometry (Condon and Ferracane 1997, Ferracane and Condon 1999, Ferracane *et al.* 1997, Lutz *et al.* 1984, Söderholm *et al.* 1992). The distinct wear step between enamel and composite can be visualized by means of scanning electron photomicrographs (Willems *et al.* 1993b).

Other possible methods of determining the wear on replicas are the use of a 3D-measuring technique, a scanning microscope or a 3D-laser scanning measurement method (Lambrechts *et al.* 1984, Mehl *et al.* 1997, Söderholm *et al.* 1992, Yoshida *et al.* 2002). Figure 1 is an excellent example of wear measurement by means of a 3D-laser scanner.

An *in vitro* investigation found that there were no significant differences in consistency between the microscopic measure and the laser measure (Söderholm *et al.* 2001). It seems reasonable to suggest that the digital laser scanning method gives depth values comparable to microscopic evaluation, but because of its ability to register the entire surface area, this technique has certain advantages in clinical wear evaluations of dental materials over the microscopic evaluation method (Yoshida *et al.* 2002).

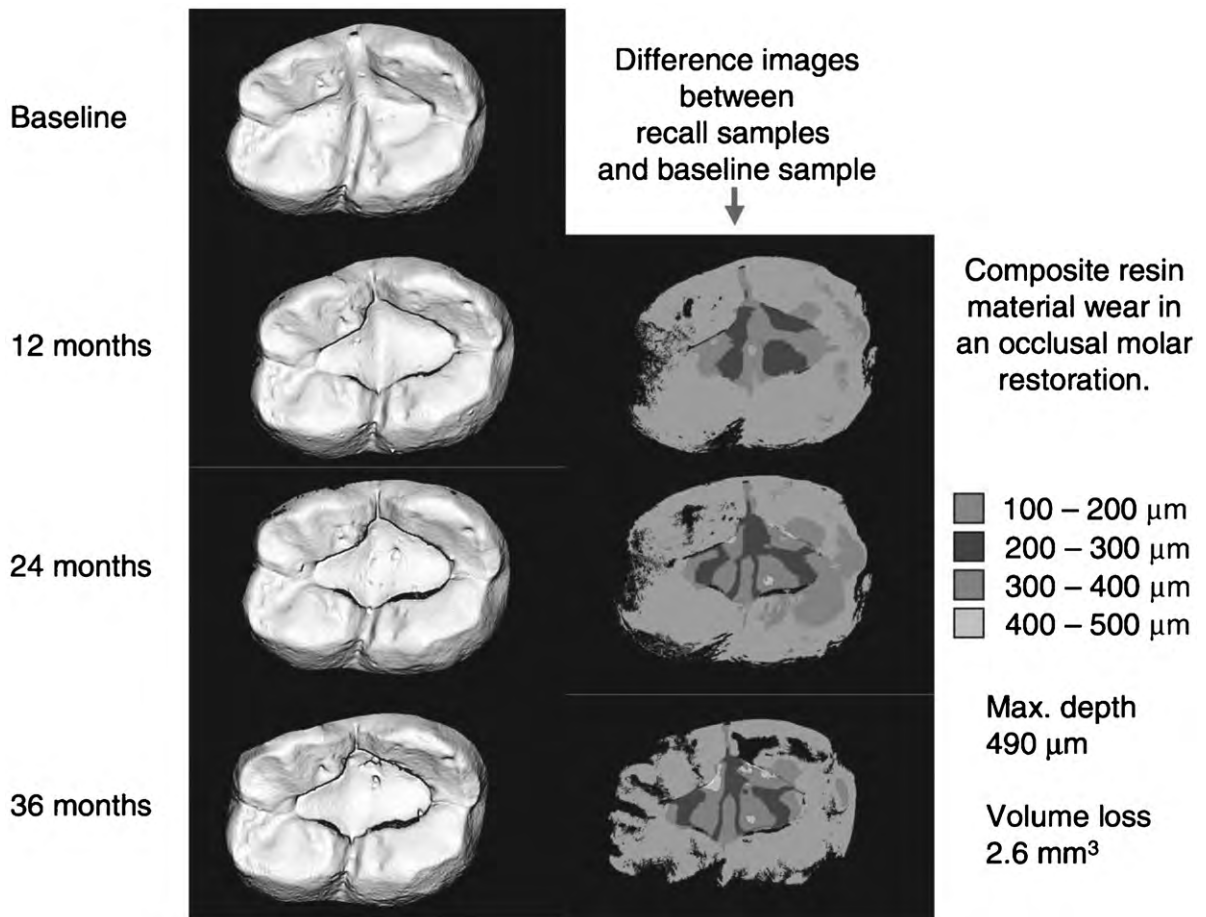
The mass of data generated about the various competing products is very confusing, and ranking the different materials according to their laboratory results does not necessarily reflect their clinical performance (Lambrechts *et al.* 1987). This is not


Figure 1
Composite resin material wear in an occlusal molar restoration. Difference images between recall samples and baseline sample measured by means of Laser Scan 3D-Pro, Willytec, Munich, Germany.

surprising, since the phenomenon of wear is very complex and multifactorial (Braem *et al*. 1986). Therefore, long-term quantitative *in vivo* wear measurements are still essential to determine the clinical performance of new posterior composite resin materials (Willems *et al*. 1993a).

3. Wear Rates

Wear rates of dental composite resins should be in the range of *in vivo* enamel wear. Söderholm *et al*. (2001) found that the *in vivo* attritional enamel wear rate in molars was about 39 μm month^{-1} and that the average wear rate on contact-free surfaces was about 9.2 μm month^{-1} with the microscopic measurement technique and 8.5 μm month^{-1} with the laser scanner over a 36-month period.

The wear performance of modern composites is comparable to amalgam and enamel with abrasion wear rates from ~ 5 μm to ~ 100 μm per year (Lambrechts *et al*. 1997, Wendt and Leinfelder 1992). Results differ among evaluators because of operator variations, patient variations, and last but not least important, the wear evaluation method (Söderholm *et al*. 1992). The relatively high standard deviations in the results are inherent to *in vivo* studies (Lambrechts *et al*. 1989). The *in vivo* results reveal that the loss of substance is consistently greater in the OCAs than in the CFCAs. Willems *et al*. (1993b) evaluated the wear of five posterior composites at the OCAs and CFOAs in Class II cavities over a 3-yr period with an accurate 3D-measuring technique. A clinical evaluation was also performed. The ultra-fine compact-filled composites showed acceptable OCA-wear rates ranging

from 110 µm to 149 µm after 3 yr. This is very similar to the OCA-wear rate of human enamel on molars, which is about 122 µm after 3 yr. The fine compact-filled composite had an unacceptable OCA-wear value of 242 µm after 3 yr. The *ultrafine midway-filled composite* showed an exceptionally high CFOA-wear rate of 151 µm after 3 yr, which gave the impression of it being gradually washed out of the cavity.

The nonlinear wear behavior has been previously discussed by Leinfelder (1988) and may be a result of reduced occlusal stresses as the surface of the composite wears down from the cavosurface margin and becomes somewhat protected by the cavity walls.

For material selection it is only relevant how much time it takes a material to wear to a predefined maximum height loss in comparison to other materials. It has been proposed to convert nonlinear (clinical) height loss data to a linear parameter, introduced as wear life, which is defined as the time it would take a material in a standard restoration to reach a maximum acceptable amount of height loss (Pallav 1996). This wear life should be comparable to the wear life of human enamel.

4. New Technology

In 1998, the first restorative material based on the ormocer technology (Definite [Degussa Agn, Hanau, Germany]) was marketed. Multifunction urethane and tioether(meth)acrylate alkoxysilanes as sol-gel precursors have been developed for synthesis of inorganic–organic copolymer ormocer composites as the dental restorative materials. Ormocers (acronym for organically modified ceramics) are characterized by novel inorganic–organic copolymers in the formulation that allow the modification of mechanical parameters in a wide range (Hickel *et al.* 1998, Manhart *et al.* 2000). According to Xu *et al.* (1999), contact damage resistance of resin composites can be substantially improved by reinforcement by ceramic whiskers fused with silica glass particles. Rudell *et al.* (2002) investigated the use of prepolymerized fused-fiber filler modified composite particles (PP-FFMC). They found that these PP-FFMC particles were better incorporated and resistant to plucking-out of the surface. A current trend in composite technology is toward the use of homogeneously distributed nanoparticles with approved resin matrix protection and reduced surface friction.

Other new filler technology is the use of irregular, spherical or porous filler particles (Luo *et al.* 1998). The significance of these technological developments on *in vivo* wear resistance is still under investigation, but an alternative enamel substitute is thought to be very near at the beginning of the twenty-first century.

5. Conclusion

The ultrafine compact-filled composite resins are very promising materials for posterior use. They have a Young's modulus of elasticity that is higher than that of dentin and have a high content of inorganic particles. They also display good Vickers hardness values compared to dentin and relatively high compressive strength values; these suggest that they are able to support occlusal stresses. Furthermore, their surface roughness ranges from 0.48 µm to 0.71 µm, values very similar to that of enamel. The ultrafine compact-filled composite resins are the materials of choice for restoring posterior cavities at the beginning of the twenty-first century, offering stress-bearing restorations.

The microfilled composite that possesses the highest percent of inorganic filler, the best homogeneous dispersion of filler, and the strongest chemical bond between filler and resin matrix should have the best wear resistance, but not necessary the best fatigue resistance (Lim *et al.* 2002, Willems *et al.* 1993a). A posterior composite resin should also have a good "packability," clinical handling, and possibilities of repair.

Composite Materials, Microstructural Design of

Any two materials could, in principle, be combined to make a composite (Fig. 1), and they might be mixed in many geometries (Fig. 2). This article summarizes a scheme for identifying the component materials that could be used to make composites with potentially attractive properties. Three concepts are used. The first is that of performance indices, which isolate the combination of material properties that maximize
Figure 1
The material classes from which composites are made.
Figure 2
Unidirectional fibrous composites, laminated composites, chopped-fiber and particulate composites.

performance; the second is that of materials-selection charts, onto which both material properties and performance indices can be plotted; and the third is the use of bounds to define the envelope of properties accessible to a given composite system (Ashby 1993).

1. Indices, Selection Charts, and Property Bounds

A performance index is a property or group of properties that measures the effectiveness of a material in performing a given function (Ashby 1999). The best material for a light, stiff tie (a tensile member) is that with the greatest specific stiffness, E/ρ, but it is not always so straightforward. The lightest beam (a member loaded in bending) with a prescribed stiffness is that made of the material with the greatest value of $E^{1/2}/\rho$; the best springs are those made of materials with the highest values of σ_f^2/E, where σ_f is the yield or fracture stress; the precision device that is least distorted by heat is that made of the material with the highest value of λ/α, where λ is the thermal conductivity and α is the expansion coefficient. The performance indices are $E^{1/2}/\rho$, σ_f^2/E and λ/α. The best choice of material is that with the largest value of the appropriate index. The indices provide a set of pointers; they direct the composite-developer towards material combinations that, potentially, offer something new.

The indices, frequently, combine two or more properties. This suggests the idea of constructing charts on which one property is plotted against another in such a way that both the properties and their combinations can be examined. Figure 3 illustrates this. The axes are Young's modulus E and density ρ. The scales are logarithmic, and span a range so wide that almost all engineering materials are included. The index E/ρ appears on these axes as a family of parallel lines of slope 1; the index $E^{1/2}/\rho$ appears as a family of slope 2. Other charts give optimal selection via other indices. Charts and indices have been fully described by Ashby (1999).

On a macroscopic scale a composite behaves like a homogenous solid with its own set of thermomechanical properties. Calculating these precisely is difficult. It is much easier to bracket them by bounds or limits: upper and lower values between which the properties lie. For most properties, this can be done accurately enough to identify interesting possibilities.

Seven mechanical and thermal properties are of primary interest in assessing the potential of a new composite: density, modulus, strength, toughness, thermal conductivity, expansion coefficient, and heat capacity (Table 1); others, like fracture toughness and thermal diffusivity, are calculated from them. In this section we assemble bounds or limits for material properties. The term "bound" will be used to describe a rigorous boundary, one that the value of the property *cannot*—subject to certain assumptions—exceed or fall below. However, it is not always possible to derive bounds; then the best that can be done is to derive "limits" outside which it is *unlikely* that the value of the property will lie. In what follows, density and specific heat are calculated exactly; moduli, thermal expansion, thermal conductivity and diffusivity are bracketed by bounds, but strength and toughness can only be enclosed by limits. As far as possible, all are based on micromechanical modeling; their origins have been detailed by Hull (1981), Kelly and Macmillan (1986), Chamis (1987), and Ashby (1993). The important point is that the bounds or limits bracket the properties of all arrangements of matrix and reinforcement shown in Fig. 2; by using them we escape from the need to model individual geometries.

1.1 Density

When a volume fraction f of a reinforcement r (density ρ_r) is mixed with a volume fraction $(1-f)$ of a matrix m (density ρ_m) to form a composite with no residual porosity or void-space, the composite density
Figure 3
A schematic selection chart: modulus E is plotted against density ρ.

Table 1
Design limiting properties.

Property	Symbol and usual units
Density	ρ (Mg m^{-3})
Young's modulus	E (GPA)
Strength	σ_f (MPa, sometimes GPa)
Toughness; or fracture toughness	J_{1c} (kJ m^{-2}); K_{1c} (MPa m$^{1/2}$)
Linear thermal expansion coefficient	α (K^{-1})
Specific heat	C_p (J kg^{-1} K^{-1})
Thermal conductivity	λ (W m^{-1} K^{-1})
Thermal diffusivity	a (m^2 s^{-1})

is given exactly by a rule of mixtures (an arithmetic mean, weighted by volume fraction)

$$\rho_r = f\rho_r + (1-f)\rho_m \tag{1}$$

1.2 Modulus

The modulus of a composite is bracketed by the well-known Voigt and Reuss bounds:

$$E_r = fE_r + (1-f)E_m \tag{2}$$

and

$$E_r = \frac{E_m E_r}{fE_m + (1+f)E_r} \tag{3}$$

Here E_r is the Young's modulus of the reinforcement and E_m that of the matrix. Tighter bounds exist, but Eqns. (2) and (3) are sufficient for our purpose.

1.3 Strength

The upper bound is, as with modulus, a rule of mixtures

$$(\sigma_f)_u = f(\sigma_f)_r + (1-f)(\sigma_f)_m \tag{4}$$

where $(\sigma_f)_m$ is the strength of the matrix and $(\sigma_f)_r$ is that of the reinforcement. A lower limit is the yield strength of the matrix enhanced slightly by the plastic constraint imposed by the reinforcement

$$(\sigma_f)_1 = (\sigma_f)_m 1 + \frac{1}{16}\left(\frac{f^{1/2}}{1-f^{1/2}}\right) \tag{5}$$

The bounds are wide, but they still allow important conclusions to be reached.

1.4 Specific Heat

The specific heats of solids at constant pressure, C_p, are almost the same as those at constant volume, C_v. If they were identical, the heat capacity per unit volume of a composite would, like the density, be given exactly by a rule-of-mixtures

$$\rho C_p = f\rho_r(C_p)_r + (1-f)\rho_m(C_p)_m \tag{6}$$

where $(C_p)_r$ is the specific heat of the reinforcement and $(C_p)_m$ is that of the matrix.

1.5 Thermal Expansion Coefficient

We use the approximate lower bounds of Levin

$$\alpha_L = \frac{E_r \alpha f + E_m \alpha_m(1-f)}{E_r f + E_m(1-f)} \tag{7}$$

and the upper bound of Schapery

$$\alpha_u = f\alpha_r(1+v_r) + (1-f)\alpha_m(1+v_m)$$
$$- \alpha_L[fv_r + (1-f)v_m] \tag{8}$$

where α_r and α_m are the two expansion coefficients and v_r and v_m the Poisson's ratios.

1.6 Thermal Conductivity

A composite containing parallel continuous fibers has a conductivity, parallel to the fibers, given by a rule-of-mixtures

$$\lambda_u = f\lambda_r + (1-f)\lambda_m \tag{9}$$

This is an upper bound; in any other direction the conductivity is lower. The transverse conductivity of a parallel-fiber composite (again assuming good bonding and thermal contact) lies near the lower bound first derived by Maxwell

$$\lambda_L = \left(\frac{\lambda_r + 2\lambda_m - 2f(\lambda_m - \lambda_r)}{\lambda_r + 2\lambda_m + f(\lambda_m - \lambda_r)}\right) \tag{10}$$

Particulate composites, too, have a conductivity near this bound. Details are given by Ashby (1993), in which bounds and limits for thermal diffusivity, toughness, and fracture toughness are also discussed.

2. Applications: The Potential of Composite Systems

The last step is that of combining the indices, the charts and the bounds to design composites for specific applications. Two examples are developed, but it will be clear that the method is a general one, and can be extended further.

2.1 Composite Design for Stiffness at Minimum Weight

Consider, first, design of a composite for a light, stiff, beam of fixed section-shape, to be loaded in bending. The efficiency is measured by the index $M = E^{1/2}/\rho$. Imagine, as an example, that the beam is at present made of an aluminum alloy and that the alloy could be stiffened by incorporating particles or fibers of beryllium (Be) or of alumina (Al_2O_3) in it. Both are much stiffer than aluminum—that is, they have higher moduli.

Figure 4 is a small part of the $E-\rho$ chart introduced in the last section. Three groups of materials are shown: aluminum and its alloys; beryllium; and a range of aluminas. Composites made from them have densities given exactly by Eqn. (1), and moduli that are bracketed by the bounds of Eqns. (2) and (3). Both of these moduli depend on volume fraction of
Figure 4
Part of a modulus–density space, showing aluminum alloys, beryllium and alumina. The moduli of the Al–Be and the Al–Al$_2$O$_3$ composites are bracketed by the bounds of Eqns. (1), (2), and (3). The Al–Be composite offers much greater gains in M than the Al$_2$O$_3$ composite.

Figure 5
A part of expansion coefficient–thermal conductivity space, showing aluminum alloys, boron nitride and silicon carbide. The properties of Al–BN and Al–SiC composites are bracketed by the bounds described by Eqns. (7)–(10). The Al–SiC composites have better values of the index M (which increases towards the bottom right) than the Al–BN composites.

reinforcement, and through this, on density. Upper and lower bounds for the modulus–density relationship can thus be plotted on the $E-\rho$ chart using volume fraction f as a parameter, as shown in Fig. 4. Any composite made by combining aluminum with beryllium will have a modulus that lies somewhere in the Al–Be envelope; any made of aluminum and alumina will have a modulus contained in the envelope for Al–Al$_2$O$_3$. Fibrous reinforcement gives a longitudinal modulus (that parallel to the fibers) near the upper bound; particulate reinforcement or transversely loaded fibers give moduli near the lower one.

Superimposed on Fig. 4 is a grid showing the performance indices M—the quantity we wish to maximize. The bound-envelope for Al–Be composites extends almost normal to the grid, while that for Al–Al$_2$O$_3$ is, initially, parallel to the M grid: 30% of particulate Al$_2$O$_3$ gives almost no gain in M. The underlying reason is clear: both beryllium and Al$_2$O$_3$ increase the modulus, but only beryllium decreases the density; both indices are more sensitive to density than to modulus.

2.2 Composite Design for Specific Thermal Properties

Thermo-mechanical design involves the specific heat, C_p, the thermal expansion, α, the conductivity, λ, and

the thermal diffusivity, $\alpha = \lambda(\rho C_p)^{-1}$. These composite properties are bounded by Eqns. (6)–(10). They are involved in a number of performance indices. One is the criterion for minimizing thermal distortion $M-\lambda/\alpha$.

Figure 5 shows a small part of the $\lambda-\alpha$ materials selection chart, with a grid of lines of the index M superimposed on it. Three groups of materials are shown, aluminum alloys, boron nitride (BN), and silicon carbide (SiC). The thermal properties of Al–BN and Al–SiC are bracketed by lines that show the bounding equations. The plot reveals immediately that SiC reinforcement in aluminum increases performance (as measured by M); reinforcement with BN decreases it. By systematically testing alternative combinations of material and reinforcement in this way, the pair that offers the greatest potential gain in performance can be identified.

3. Summary and Conclusions

Developing a new composite is a long and expensive business. It is helpful, before starting, to have an idea of what its strengths and weaknesses might be and where its applications might lie. This article outlines a procedure for doing this. It combines the ideas of performance indices, materials selection charts and bounds or limits for composite properties to identify

the composites which, potentially, have attractive combinations of mechanical and thermal properties. Two examples of the method are given in the text. The same approach can be applied to a wide range of thermal and mechanical applications.

Composite Materials: Environmental Effects

Composite materials must, as with all materials, resist chemical attack by their service environment. The characteristics of the reinforcements and of the matrix materials can be altered by the absorption of agents, by various mechanisms of corrosive attack, or by the temperatures at which the materials are used.

With composite materials these problems can be amplified because their behavior depends not only on the characteristics of their components, which are the reinforcements and the matrix materials, but also, and often most critically, on the quality of the interfaces between the components. It is the interface that determines load transfer in resin and metal matrix composites, and its controlled failure is a major factor in determining the toughness of ceramic matrix composites. Often the interfaces are vulnerable to outside effects and provide preferential channels for the ingress of agents which can modify the interactions between the fibers and the matrix. In this way composites sometimes may be dramatically deteriorated and their properties reduced by the environment in which they are used, even though both matrix and reinforcement offer good environmental resistance.

In the case of resin matrix composites, the most serious concern for their environmental aging is the effect of water, as the presence of water molecules at the fiber–matrix interface can lead to the failure of the chemical bonds assuring the adhesion of the fibers to the matrix. Such a failure is irreversible and strikes at the basic mechanism of fiber reinforcement since it removes the ability of the matrix to transfer load to the fibers. This is made worse as the water at the interface acts as a lubricant. Furthermore, water is everywhere: applications for which the composite must be immersed in water obviously raise the question of its effects, but water is also in the air in the form of water vapor. Resin matrix composites will absorb water to a lesser or greater extent and although measures such as painting can hinder its penetration, eventually the composite will either come to an equilibrium with its environment or will be degraded by it.

It is therefore necessary to understand and to be able to calculate the rate of diffusion of water in these materials as a function of water concentration and temperature, as the process is thermoactivated. Water also has the effect of a lubricant at the molecular level on the bulk structure of the resin which is revealed most strikingly by a fall in glass transition temperature, T_g, as absorption proceeds. In some resin systems this can lead to dramatic falls in T_g so that at the beginning of exposure the composite may be well below T_g but as water is absorbed T_g falls below the ambient temperature and as a consequence the physical behavior of the matrix is greatly changed. This effect can be totally or partially reversible. Water can also provoke the hydrolysis of the resin leading to a deterioration of the matrix and hence of the composite. In the case of thermoplastic matrix composites, this can lead to an increase in crystallinity and progressive embrittlement of the matrix. In some high-temperature resin systems, oxidation of the polymer matrix can also be a source of degradation.

In the case of metal matrix composites it is often the interaction between the fibers and matrix during composite manufacture which can be the cause of deterioration of the material by corrosion. Also, when their reinforcement can conduct electricity (notably carbon fibers), metal matrix composites can be subject to rapid corrosive attack of one of their phases when water is present and the two types

of materials possess markedly different electron energy levels.

Ceramic matrix composites rely on the interface to act as a mechanical fuse which fails when a crack approaches and so blunts further propagation. Even when the crack passes around the fiber the failure of the interface over a substantial distance provides an important mechanism for absorbing energy and so contributes to the overall toughness of the composite. The interface in such composites is controlled so as to facilitate this debonding process. Their use at high temperatures in air, however, can cause major changes to the interfaces, which make the interfaces strong and, in turn, the composite brittle so that any crack provokes fiber failure and interfacial debonding does not occur. In this case, the increased toughness of the ceramic matrix composite with respect to the monolithic ceramic is lost. In addition, the fibers themselves evolve at high temperatures so that they may lose strength and begin to creep.

1. Water Diffusion in Polymer Composites

Diffusion laws have generally been applied to the modeling of simple water uptake, and it has been shown that Fick's law can be applied to carbon-fiber-reinforced epoxy resin subjected to humid environments (Shen and Springer 1976). Water is considered to remain in a single free phase driven to penetrate the resin by the water concentration gradient. Other studies have indicated, however, that non-Fickian processes do occur which can complicate the understanding of the role of the water and which may lead to irreversible changes in mechanical properties (Dewimille and Bunsell 1982). In particular, water ingress can occur by capillary action along the fiber–matrix interface, and some resin systems can be dissolved by water.

Water penetration can cause swelling and plasticization of the resin. Composite structures consisting of several layers of differing types of fiber layup, often with a thick resin or gel coat, can suffer from water being trapped in a particular layer or at the interface between layers. This effect may be irreversible because of osmosis, and blistering may result (Marine *et al.* 1988). This is a particular problem with glass-fiber-reinforced boats for which considerable efforts are made, by a judicious choice of resin materials and manufacturing techniques, to avoid this type of damage. In addition to changes in mechanical properties, modification of other physical characteristics may occur, such as changes in dielectric properties.

1.1 Diffusion Models

(*a*) *Fick's law and single-phase diffusion.* Fick's law assumes that the water remains in a single free phase which is driven to penetrate the material by the water

concentration gradient (Crank 1956), dc/dx, so that the water uptake as a function of time is given by:

$$\frac{\partial c}{\partial t} = \frac{d}{dx}\left(D\frac{dc}{dx}\right) \tag{1}$$

where D is a diffusion coefficient considered to be constant in the direction of diffusion, x, so that Eqn. (1) can be rewritten as:

$$\frac{\partial c}{\partial t} = D_x\frac{d^2 c}{dx^2} \tag{2}$$

It has been shown (Crank 1956) that for an infinitely large plate of thickness h the mass of water, M_t, absorbed in time t across a unit surface area as a percentage of the mass of water absorbed at saturation, M_∞, is given by:

$$\frac{M_t}{M_\infty} = 1 - \frac{8}{\pi^2}\sum_{n=0}^{\infty}\frac{1}{(2n+1)^2}\exp\left[-D(2n+1)^2\pi^2 t/h^2\right] \tag{3}$$

This equation has been simplified by Shen and Springer (1976) to show that the initial absorption is given by:

$$\frac{M_t}{M_\infty} = \frac{4}{h}\left(\frac{Dt}{\pi}\right)^{1/2} \tag{4}$$

The initial linear relationship of M_t/M_∞ as a function of the square root of time is to be noted, and so water uptake is usually plotted as M_t/M_∞ vs. square root of time. Figure 1 shows the classical Fickian behavior of a glass-fiber-reinforced epoxy resin at two temperatures and at different values of relative humidity. The composite reaches equilibrium with its environment and saturates. It can be seen that the saturation levels are independent of temperature but do depend on relative humidity. Figure 2 shows that the diffusivity, D, obeys a thermoactivated Arrhenius-type relationship and is independent of relative humidity. This behavior indicates that the water is absorbed by the resin and is linked to it by hydrogen bonds.
Figure 1
Absorption curves obtained under different conditions of temperature and relative humidity with glass-fiber-reinforced DGEBA epoxy resin, showing classical Fickian absorption.
Figure 2
Thermoactivated diffusion into a glass-fiber-reinforced DGEBA epoxy resin, obeying an Arrhenius relationship with temperature. E is the activation energy.

Under most conditions water can penetrate into the material in several directions. In general, the co-efficient of diffusivity varies with the direction so that edge effects can become important and should be considered in any analysis of the water uptake of structures which present more than one surface to water diffusion.

For a unidirectional specimen, two diffusion coefficients must be considered accounting for penetration normal ($D_\perp$) and parallel ($D_\parallel$) to the fibers. A third coefficient (D_r) for the unreinforced resin also exists.

(b) *The Langmuir model of diffusion*. In some cases the simple Fickian model proves inadequate, such as when two plateaus in the absorption curve of mass of water absorbed vs. square root of time are observed or where it is found that the absorption depends on the specimen thickness. It is then sometimes useful to consider a more complex model of the Langmuir type in which the water is considered to be in two phases, one free to diffuse and the other trapped in the absorbing medium. This model has been treated by Crank (1956). In addition to the two parameters D and M_∞ used in the simple free-phase diffusion model, the two-phase model introduces two other parameters: α, the probability of a trapped water molecule being released and γ, the probability of a free water molecule being trapped.

The analysis of this situation results in the following simplified equation which describes the rate of water uptake from both sides in a plate of thickness $2l$:

$$\frac{M_t}{M_\infty} = 1 - \frac{\gamma}{\gamma + \alpha}e^{-\alpha t} - \frac{8}{\pi^2}\frac{\alpha}{\gamma + \alpha}e^{-\gamma t}\sum_{n=1}^{\infty}\frac{1}{(2n-1)^2}e^{-(\pi/2)^2 Dt}$$

$$(5)$$
Figure 3
Two-phase diffusion as a function of square root of time, as described by the Langmuir model, showing the influence of specimen thickness. $\delta = (h/\pi)(\alpha/D)^{1/2}$, $\delta_1 = 0.05$, $\delta_2 = 0.2$, and $\delta_3 = 0.5$, where h is the specimen thickness. The dashed curve follows Fick's law ($\alpha/(\alpha + \gamma) = M'/M_x = 0.8 \rightarrow \alpha/\gamma = 4$).

Figure 3 shows how Eqn. (5) describes the uptake of water into plates of differing thicknesses, h. It should be noted that the Langmuir model reduces to the simple Fickian model when $\gamma = 0$.

In passing to a two-phase model it is assumed that the absorbed water is in two states. The free phase having a concentration $n(t)$ water molecules per unit volume can diffuse in the resin, but can be linked or trapped in the resin with a probability γ, and the combined phase with concentration $N(t)$ able to break free with a probability α. At saturation:

$$n_\infty\gamma = N_\infty\alpha \qquad (6)$$

i.e., there is an equilibrium between those water molecules being trapped and those being freed.

The physical processes involved in water absorption by the composite are certainly more complex than the processes considered in the Langmuir model but because of its additional flexibility the model is applicable to a wider range of cases.

1.2 Physicochemical Aspects of Absorption in Resin Matrix Composites

Most polymers absorb water to a greater or lesser degree so that, even in the absence of defects or preferential routes for water uptake such as are provided by poor fiber–matrix adhesion, resin matrix composites will absorb water in humid environments. Water diffusion occurs in most resins by hydrogen bonds being formed between the water and the molecular structure of the resin.

Epoxy resins are the most widely used resins in high-performance composite structures. They are

mixed with a hardener, which can be of several types, to produce a cross-linked structure which provides many sites for hydrogen bonding for the water molecules, such as hydroxyl groups (O–H), phenol groups (O–C), amine groups (N–O), and sulfone groups (O–S). Figure 4 shows the sites available in a commonly used epoxy consisting of a bisphenol-A epoxy resin cross-linked with a dicyandiamide hardener. The hydrolysis of epoxy resins is in itself a cause of degradation and is not by any means limited to this class of matrix materials. Certain fibers, such as those of glass, can be damaged by prolonged exposure to water which arrives at the interface. Glasses are made up of silica in which are dispersed metallic oxides including those of the alkali metals. These latter non-silicate constituents represent microheterogeneities which are hygroscopic and hydrolyzable. The absorption of water by glass is therefore characterized by the hydration of these oxides. The most common form of glass fiber is E-glass, which contains only small amounts of alkali metal oxides and so is resistant to damage by water.

However, the presence of water at the glass-fiber surface may lower its surface energy and promote crack growth. Water trapped at the interface may also allow components of the resin to go into solution and if an acidic environment is formed the fiber can be degraded. Organic fibers such as the aramid family can absorb considerable quantities of water and although this does not lead to a deterioration of fiber properties, the resulting swelling of the fiber may be a cause of composite degradation. The size, or coating, put onto many fibers to protect them from abrasion and to ensure bonding with the matrix also serves to protect them and the composite from damage from water absorption by eliminating sites at which the water can accumulate. However, this is not always adequate.

(a) Influence of the resin matrix on composite degradation. Degradation of glass fibers embedded in an epoxy matrix depends greatly on the type of hardener used to cross-link the resin. Figure 1 shows the
classical Fickian behavior of a glass-fiber-reinforced bisphenol-A epoxy cross-linked with a diamine hardener. The saturated composite reveals a somewhat increased tenacity owing to a softening of the matrix which is accompanied by a fall in glass transition temperature (Bonniau and Bunsell 1981, Springer 1982). Damage does occur under severe conditions (90 °C, 100% relative humidity for two weeks) and appears as a progressive whitening of the material with no detectable weight gain. This is probably due to microcracking which begins at the surface.

A change to a dicyandiamide hardener produces, however, a significant change in water-uptake kinetics, and this behavior can only be explained by the two-phase model of absorption. Saturation is attained after considerably longer exposure than with the diamine-hardened resin, but after equilibrium is reached both composites behave in a similar manner.

The use of an anhydride as the cross-linking agent, which is extremely common, produces a composite which, in water that is warmer than about 40 °C, degrades quite rapidly. Saturation is not achieved and severe weight loss after drying is observed, owing to leaching of the resin into the water. An excess of the anhydride from the cross-linking process combines with the water to produce an acid which degrades the composite. The correct choice of hardener in these epoxy composites is therefore extremely important if they are to be used in warm, humid conditions.

The glass transition temperature, T_g, of organic matrix composites is lowered on water uptake. In the case of thermosetting resins such as epoxes, this decrease can be as much as 30 °C and is even more in the case of glass-fiber-reinforced polyamide, as shown in Fig. 5.

Figure 4
Sites available for water molecules to be combined by hydrogen bonding onto the molecular structure of a DGEBA epoxy resin cross-linked with a dicyandiamide hardener.
Figure 5
Glass transition temperature of glass-fiber-reinforced nylon decreasing dramatically with water uptake. The composite is immersed in water at 90 °C and T_g is measured using a differential scanning calorimeter.

Families of resins able to withstand higher temperatures than the epoxy resins have been developed and in general are less susceptible to water uptake. Prolonged exposure of these resins to hot water can, however, lead to irreversible changes. Polystyrylpyridine (PSP) reinforced with carbon fibers can operate at 250 °C for 1000 hours. Prolonged exposure to humid conditions, e.g., 70 °C and 100% relative humidity, reveals an apparent initial Fickian absorption leading to saturation. Longer exposures lead, however, to further water uptake and the creation of microcracks as well as the hydrolysis of the polymer matrix. Thermal cycling from 70 °C to 150 °C in the presence of water increases water absorption owing to the water being vaporized and forcing microcracks further open. Cycling to 250 °C leads to a more marked worsening of properties owing to greater damage exacerbated by oxidation of the resin. The effects of water on other high-temperature resins, such as PMR-15 and Avimid-N which are rated to be used above 300 °C when dry, are to produce a fall in T_g of around 100 °C during hygrothermal cycling.

1.3 Mechanical Degradation owing to Water Absorption in Resin Matrix Composites

As mentioned above, water penetration into resin matrix composites can lead to changes in mechanical properties. A softening of the matrix is commonly observed which in some cases can be beneficial, inducing a greater toughness. However, changes are usually associated with deterioration in properties such as strength or modulus. These changes can appear to be reversible as, upon drying, the composite may regain most of its lost properties. Figure 6 illustrates this for a unidirectional glass-reinforced epoxy subjected to three-point bending. It can be seen that drying the specimen almost reversed the effects seen at saturation. A second cycle in humid conditions usually reveals that water penetration occurs much more quickly and property loss is much more rapid than in the first cycle. This behavior is because of the destruction of the chemical bonding at the interface by the presence of water. Upon drying, load transfer between fiber and matrix is assured by frictional forces which may largely compensate for the loss of chemical bonding. A second exposure to humidity results in rapid water uptake as the water can quickly penetrate the composite along the fiber–matrix interfaces and, acting as a lubricant, rapidly results in loss of mechanical properties.

2. Corrosion of Metal Matrix Composites (MMCs)

Fiber- or particle-reinforced metals are made in much smaller volumes than polymer composites but are of interest for applications that require higher operating
Figure 6
Load–deflection curves obtained with notched three-point bending tests on a unidirectional glass-fiber-reinforced epoxy resin: (a) initial state, (b) after 96 hours in boiling water, and (c) after 96 hours in boiling water followed by drying.

temperatures. In addition, MMCs do not suffer from outgassing of water vapor or solvents, which cause major problems in space applications, as do resin composites. They can be made with very low coefficients of thermal expansion by balancing the properties of the reinforcements and those of the matrix. Such composites can also provide a means of increasing the stiffness of light alloys and of making abrasion-resistant materials. However, the manufacture of MMCs usually involves a stage when the reinforcements are in contact with the molten matrix material. This can lead to chemical interactions and the degradation of the reinforcements, and also to the formation of compounds of intrinsically low resistance to the environment.

The interfacial reaction product Al_4C_3 is a notable example, this compound being water soluble. Another issue with MMCs arises from the fact that the matrix is a conductive metal. If the reinforcement can also conduct current, galvanic couples can form between matrix and reinforcement if these have very different electron energy levels. This has been extensively reviewed by Hihara and Latanision (1994). They propose that corrosion of MMCs in the presence of water and air can be an electrochemical process involving anodic (oxidation) and cathodic (reduction) reactions. This can be written as the dissolution of the metal, M, by the anodic reaction:

$$M \rightarrow M^{n+} + ne^-$$

For the reaction to proceed the electrons released by the anodic reaction must be consumed by a cathodic reaction. In an aqueous environment such reactions

can be by oxygen and proton reduction:

$$O_2 + 4e^- + 2H_2O \rightarrow 4OH^-$$

and

$$2H^+ + 2e^- \rightarrow H_2$$
The former reaction requires the presence of oxygen whereas the latter can occur in both aerated environments and in the absence of oxygen. In some cases the oxidation process can lead to the creation of a passive layer on the metal which can eventually inhibit further corrosion, although this protection can be breached if aggressive anions, particularly chlorides, are present. This can result in very severe pitting or dissolution of the metal.

Corrosion by galvanic processes is the major concern in carbon-fiber-reinforced aluminum and magnesium. The fibers, which are electrical conductors, act as relatively inert electrodes for both proton and oxygen reduction. Attempts to limit this behavior by coating the carbon fibers by a variety of materials, such as SiC, B_4C, TiC, and TiB_2, increase the costs of manufacture but work by increasing the electrical resistance between the fiber and the matrix. The protection of the carbon fibers used in such composites may also be necessary as contact between the reinforcements and the molten aluminum leads to the formation of aluminum carbide (Al_4C_3) and decreases in fiber strength. In addition, as mentioned above, the carbide that is formed hydrolyses in damp environments, producing methane (CH_4) and aluminum hydroxide. For some marine applications resin coatings of polyurethane, chlorinated rubber, and epoxy on the outside of the composite have been shown to be effective in preventing this type of corrosion.

Silicon carbide, as particles, fibers, or whiskers, is generally less prone to cause corrosion than carbon fibers; however, it can suffer from galvanic corrosion in aerated chloride-rich environments but this can be controlled using resin coatings.

3. Ceramic Matrix Composites (CMCs)

CMCs offer the possibility of structural materials capable of operating at temperatures above 1200 °C in air. The relationship between the fibers and the matrix material is not that found in most composites. The primary role of the fibers is to provide a mechanism to impede crack propagation in the matrix. This is because, although ceramics can withstand high temperatures, they are hard and brittle polycrystalline structures, which usually contain many defects that can initiate crack propagation owing to thermal or mechanical shock. Ceramics do not possess mechanisms for accommodating such shocks so that once a crack is initiated it propagates catastrophically and causes failure of the structure. Introducing fibers into the ceramic provides mechanisms that can absorb the

energy of crack propagation. These mechanisms are crack blunting by debonding of the fiber–matrix interface, fiber bridging of cracks in the matrix, and fiber pull-out. These processes rely on there being an interface acting as a mechanical fuse that fails when a crack approaches. In this way CMCs can accumulate multicracking without the structure failing so that they can be used as structural materials, whereas the unreinforced ceramic cannot (Bunsell and Berger 1999).

The most widely studied family of CMCs is composed of β-silicon carbide-based fibers with diameters between 8 μm and 15 μm embedded in a SiC matrix. The fiber–matrix interface is usually controlled by making the surface of the fibers rich in carbon. At room temperature the stress field ahead of a crack in the matrix induces the debonding of the interface with the resulting consequence of an increase in tenacity. Observation of the failure surface reveals extensive fiber pull-out. Use of these CMCs in air at temperatures around 700 °C, however, reveals a dramatic fall in tenacity and no fiber pull-out. Under these conditions, the carbon interphase is oxidized by the oxygen in the air at the interfacial region along the cracks or at surfaces where the interface is revealed. Oxidation proceeds along the interface creating tubular channels and resulting in the oxidation of the fiber surface to create silica (Frety and Boussuge 1990). This silica is produced by the oxidation of nanometer-sized grains of SiC in the fibers. Fibers other than those originally used have near-stoichiometric compositions and as a result have larger SiC grains which are less prone to oxidation, so that overall resistance to degradation is improved. The result of the formation of silica at the interface is to create a strong and brittle bond between the matrix and the fibers, so that instead of debonding when a crack reaches the vicinity of a fiber it passes through it causing it to break with no fiber pull-out (Frety *et al*. 1992). As the mechanisms for absorbing energy have been removed from the composite its tenacity is greatly reduced. The formation of the silica can block the interfacial channels created by the oxidation of the carbon so limiting the degradation. Raising the CMC to temperatures above 1200 °C produces a softening of the silica at the fiber–matrix interface and toughness is increased as debonding and fiber pull-out again become possible.

These composites are produced for applications at very high temperatures in air. First-generation SiC-based fibers begin to lose strength and creep above 1100 °C. This is because of the presence of a disordered phase in the fiber structure which allows creep to occur easily. Temperatures above 1200 °C cause the decomposition of this phase and of the fiber. These problems led to fibers being produced with larger grain sizes which are much more stable. The latest generation of SiC fibers has compositions close to stoichiometry and can retain their properties to

around 1400 °C in short-term tests. Eventually these fibers will, however, suffer from oxidation of the SiC and such composites are limited in higher temperature use by this phenomenon.

The development of CMCs made from fibers and matrix materials which are both oxides offers a solution to the limitations of SiC-based fibers. Most oxide fibers are based on alumina, often associated with amorphous mullite. Such fibers suffer from rapid creep at temperatures above 1000 °C and lose their strength by grain boundary weakening above 1100 °C. Fibers produced by 3M under the name Nextel 720 have a two-phase composition of α-alumina and mullite and show good resistance to creep with an upper limit of around 1500 °C. However, the fibers are susceptible to degradation above 1200 °C in the presence of alkaline elements which form silicate phases having low melting points and which consequently promote elemental diffusion in the fibers leading to grain growth and loss of strength.

These issues related to the corrosion resistance of CMCs at elevated temperatures, illustrated above with selected examples, are quite ubiquitous and represent a major issue in their development. The most usual fiber–matrix interfaces that have been developed to toughen these composites by interfacial debonding are based on carbon or boron nitride, both of which have poor resistance to oxidation. This presents a major limitation in their engineering viability (Tressler 1999). Consequently, alternative interfacial phases are being explored such as multilayers which are analogous to the structure of shells of mollusks. Layers in these phases can be of SiC and pyrolytic carbon and, although the carbon is still susceptible to oxidation, the crack deflection behavior that they provide and the increased resistance to oxidation owing to the SiC show possible means of resolving this type of degradation (Naslain *et al.* 1998).

4. Conclusion

Composites of all types can be degraded by the environment in which they are used. This degradation often occurs at the fiber–matrix interface which determines many of the characteristics of this type of material. The environmental resistance of composites varies depending on the material class:

- in polymer matrix composites, water ingress into the composite represents a major issue;
- with MMCs, the presence of matrix/reinforcement reaction products and the possibility of galvanic couple formation between matrix and reinforcement are important issues; and
- with CMCs, the engineering of interfaces which can both toughen the composite by crack deflection and resist attack by oxygen remains a major challenge.

A judicious choice of components and processing conditions, careful engineering of the interface

structure, and an understanding of the chemistry underlying the degradation can limit these effects.

Composites for Biomedical Applications

Implants, and the materials they are made from, have to be biocompatible. Biocompatibility is defined as compatibility of a technical system with the recipient living tissue. One can distinguish between surface and structural compatibility of an implant (Wintermantel *et al.* 1996). Surface compatibility is understood as the chemical, physical, biological, and morphological suitability of the implant surface properties, aiming at clinically desired interactions with the surrounding tissue. Structural compatibility is the optimal adaptation to the mechanical behavior of the hosting tissue, and refers to the mechanical properties of the

implant material, such as stiffness and strength. Optimal interaction between biomaterial and host is reached when both surface and structural compatibility requirements are fulfilled.

Many human tissues are anisotropic and reveal a structure similar to that of composite materials. This similarity has been realized, and consequently attempts have been made to use fiber-reinforced composites to replace parts of the human body. Load-bearing implants for bone replacement and fixation made of fiber-reinforced polymers (FRPs) are currently being developed because they offer several advantages over metal implant materials (Wintermantel and Mayer 1995):

- stiffness, strength, and anisotropy can be adapted to the biological requirements over a large range, thus offering optimized structural biocompatibility. Stress shielding can be disabled by adapting the stiffness of the implant material and therefore minimizing strain mismatch between it and bone tissue;

- the absence of metal ions prevents allergic reactions;

- adjusting of x-ray transparency is possible by adding a contrast medium to the polymeric matrix; and

- FRPs cause no artifacts in MRI (magnetic resonance imaging) and CT (computer tomography) relevant to diagnostic interpretation.

Dental composites, on the other hand, make use of reinforcing components, e.g., fibers and particulate filler, mainly to improve their mechanical stability and wear resistance. However, the same basic criteria of biocompatibility, as well as specific advantages of polymer composites towards metallic restoration materials, remain relevant.

1. Fiber-reinforced Implants

Despite the advantages mentioned above, particularly in terms of structural compatibility with bone and other human tissues, composite implants are still mostly at the developmental stage. Competition by alternative materials such as biocompatible metal alloys remains strong, and several critical issues remain to be resolved fully before composite implants can enter in a big way this particularly stringent and competitive application area market segment.

Typical examples of ongoing research in the field of load-bearing implants made of FRPs are hip prostheses, osteosynthesis devices, and intervertebral disk implants. Design, processing, characterization, and clinical application of FRP hip prostheses have been investigated by many researchers (reviewed by Wintermantel and Mayer 1995). The general conclusion of these studies is that stiffness and anisotropy of composite prostheses can be well adapted to cortical bone, thus minimizing strain mismatch and stress

shielding effects. The required fatigue strength and surface compatibility considerations, potentially requiring coating of FRP prostheses, are however still a matter of investigation. Some new approaches making use of modified injection molding techniques have also been introduced.

Bone fixation using FRPs has been found to be advantageous because of their low stiffness, thus promoting the formation of external callus, which increases fracture strength after healing (McKibbin 1989). Textile composites, e.g., knitted fabric reinforced composite (KFRC), allow new net-shape processing techniques to be introduced (Mayer and Wintermantel 1998). The textile architecture removes the sensitive interlaminar layers, which induced failure of laminated bone plates. Furthermore, it has been found that formed-in holes increase the fiber density and, therefore, the strength in the critical area around the holes. Further improvements regarding mechanical stability and productivity are achieved using new net-shape flow processes. Their application to bone screws and internal fixation devices is presented below in more detail.

Encouraging studies with intervertebral disk cages consisting of carbon fiber-reinforced polymers (Ciappetta *et al*. 1997) have also been performed. This has led to market introduction of these composite implants.

As with any other material in service, FRPs are subjected to the influence of their environment. The function of the composite part must be fulfilled during its entire lifetime. Certain biomedical applications, e.g., load-bearing implants, are intended to remain in the human body for several decades, where they are exposed to electrolytes.

Unlike metals, FRPs are composed of at least two phases, which introduces different considerations concerning their environmental sensitivity. First, the polymer matrix absorbs moisture, which induces swelling and, in turn, internal stresses. Second, these materials include fiber/matrix interfaces. The mechanical behavior of FRPs, as anisotropic, inhomogeneous materials, is very complex and is a function of the synergistic properties of fiber, matrix, fiber/matrix interface, and of geometric properties such as distribution and orientation of the reinforcement. With regard to environmental degradation, the most critical properties that have to be considered are the interface characteristics. The fiber/matrix interface, as an adhesive bond, is potentially sensitive to moisture degradation. Strength and failure behavior are significantly influenced by the interface, because it is the location of stress transfer.

Many polymeric matrices (Wintermantel and Mayer 1995), such as polysulfone, polyamides, and polyesters, or even epoxy resins, have been applied as matrix materials in preclinical implant development studies. Since elemental carbon is known to have an excellent biocompatibility, carbon–carbon composite

(CCC) systems have also been investigated for implant applications, e.g., heart valves, osteosynthesis devices, and hip endoprostheses stems (Savage 1993). Mainly complex fiber architectures such as three-dimensional textiles are used as reinforcing systems. CCC-implants have to be coated by bioactive coatings such as hydroxyapatite or tricalciumphosphate and because of this they have shown good bone bonding properties. However, the high manufacturing costs were still considered as one of their major drawbacks impeding market introduction at the start of the twenty-first century.

Polyetheretherketone (PEEK) is at the center of interest since this thermoplastic, high-temperature, polymer shows an excellent resistance to most inorganic and organic solvents, to hygrothermal aging, and to radiation. Among the available thermoplastic polymer composite systems, PEEK-carbon fiber composites are among the most intensively investigated systems (Wintermantel and Mayer 1995). Investigations including exposure to physiological solutions and to environments at $37\,^{\circ}C$ were performed for the evaluation of CF/PEEK in biomedical applications. Summarizing the studies performed on the *in vitro* degradation behavior of CF/PEEK, it is noted that the results are partly in conflict. Some studies report a significant influence on flexural, impact, and interface strengths of CF/PEEK, while other authors note no effects under the same environmental exposure parameters. If effects on mechanical properties were observed, it is generally accepted that only matrix and matrix-dominated properties are affected. Thus, if the occurring stresses in the implant can be carried predominately by the fibers due to appropriate fiber orientation and implant design, one can expect a good long-term stability of the implant in the intracorporeal environment.

Pure PEEK and CF/PEEK have shown no *in vitro* cytotoxicity and have behaved in general comparably to polyethylene (Williams *et al.* 1987). *In vivo* tests indicated nonspecific foreign body reactions around PEEK implants, which are comparable to those of other approved polymeric implants. Carbon fibers could eventually affect the biocompatibility of CF/PEEK implants if fiber particles are released from the implant surface. Therefore, fully matrix covered surfaces have to be achieved, by applying net-shape molding processes for manufacturing of implants and by avoiding any kind of cutting processes. Nevertheless, one has to consider that fretting between implant surface and surrounding tissue will cause the formation of particles if the polymeric surface is not covered by an abrasion-resistant layer, e.g., a spray-coated layer of hydroxyapatite or CVD coatings such as amorphous diamond-like carbon.

Beyond issues related to biocompatibility of composite materials, a specific challenge is in the processing of composite implants. Composite materials show a strong dependence of their microstructure and quality on the specifics of the process by which they are produced (see *Polymer Matrix Composites: Matrices and Processing**). Improvements in the quality and performance of composite implants can, therefore, be achieved by improved and tailored processing. Two examples from current research in the authors' laboratory are given as illustrations of this point.

1.1 Composite Squeeze Forming (CSF)

By using biocompatible, carbon fiber-reinforced PEEK processed with a new composite squeeze forming (CSF) technique, one can optimize the mechanical properties of implants with regard to stress-shielding and fracture fixation stability, with good process flexibility in composite design and cost-effective manufacturing (Wintermantel *et al.* 1998). This process has been used to produce screws, while internal fixation plates have been produced using a variant of the process, called oscillation CSF. This process provides more homogeneous mechanical properties and reinforces sensitive areas, e.g., the countersunk hole. The imaging contrast behavior for x-ray based systems was optimized using various types of metal filaments incorporated in the composite in the range of 0.5–1.0 vol.%. The design concept of the internal fixation system aims at the lowest possible irritation of the fractured site. This was achieved through a hybrid design featuring characteristics of bone plate as well as internal fixators. Bone screws made by transfer CSF achieved tensile strength of 400 MPa and bending strength of 700–1000 MPa. Fixation plates manufactured by oscillation CSF had maximum bending moments of 14 Nm, thus equaling their counterparts made of commercially pure (CP)-Titanium (13 Nm). Figure 1 illustrates the synergistic effect of process and component shape optimization on the fatigue properties of the screw being applied in the mechanically most critical case of nonunion of transvertebral fixation. It is seen that through process and design improvements, composite implant performance can be rendered competitive with that of metallic screws.

1.2 Injection Molding

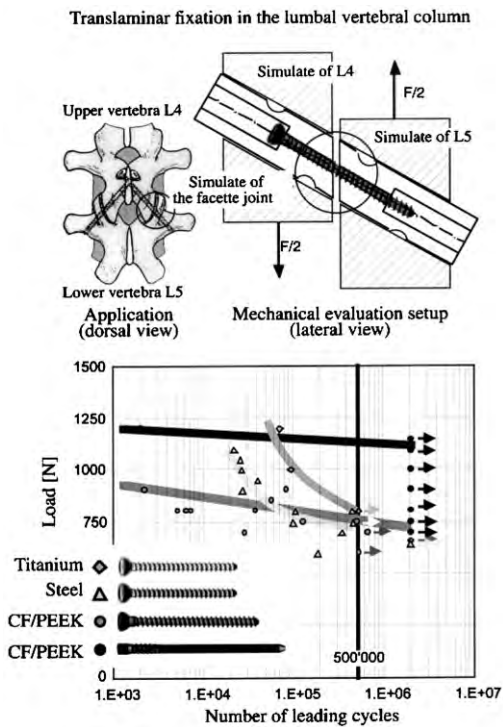
As an example of a highly loaded implant, an anisotropic hip endoprosthesis stem can be used to demonstrate the potential of the combination of an optimized material based on injection molded short carbon fiber-reinforced PEEK with a new processing technique (Semadeni *et al.* 1998). For this application, the fiber content must be high. However, with increasing fiber content one observes a pronounced deterioration of the fibers after processing, down to a residual length of 50 μm at 68 wt.%. Analysis of the influence of fiber content and length on the structure–properties


Figure 1
Fatigue properties of titanium and carbon fiber-reinforced bone screws illustrating the synergistic effect of process and design optimization. The load case is mainly transversal shear and short bending is indicated in the sketch.

	Conventional injection molding	Push through injection molding
tensile strength:	350 MPa	650 MPa
compression strength:	375 MPa	680 MPa
shear strength:	60 MPa	100 MPa

Figure 2
Influence of the processing technique and fiber content on the specific mechanical properties of the prosthesis in its critical cross-section: comparison of a conventionally injection molded prosthesis (left, 30 wt.% fiber content) with a push-through molded prosthesis (right, 50 wt.% fiber content). Strength values take reference to the ISO-7206-4 standard for distal fixation of stems.

relations in the investigated tensile test specimens revealed that the highest mechanical strength (700 MPa) is achieved at 50 wt.% fiber. Above this value, structural inhomogeneities, e.g., domains and localized vortices, are strength limiting. Conventional injection molding and push–pull molding were compared to new processing techniques, i.e., push-out and push-through molding. The working principle of these new injection molding processes is the maintenance of a continuous flow in the part during consolidation, thereby providing process-integrated control over the fiber orientation distribution. The evaluation of this specific potential in comparison to push–pull molding and conventional injection molding indicates that the new technique provides additional mechanical performance if fiber content and fiber length are increased and when the process is applied to bulky parts, such as the hip endoprosthesis stem. Compared to commercially available carbon fiber-reinforced PEEK (Victrex 450CA30) processed by conventional injection molding, the combination of the optimized material (APC2/IM7, 50 wt.% fiber content) with push-through injection molding allows to increase the modulus and

strength by 171% and 80%, respectively. This can be closely related to the homogeneity of the consolidation, the fiber orientation distribution, which exhibits a process-induced extension of the highly oriented surface layer, and, finally, the increase in residual fiber length (500 μm instead of 100 μm), see Fig. 2. Clinically even more relevant, a ratio of fatigue to static strength of 0.69 is obtained.

These two examples indicate the importance of processing towards the development of competitive composite implant technology.

2. Dental Composites

Auto- and light-cured composites are used for direct and indirect restorations in dentistry. Initially, composites were bonded to enamel only (Buonocore 1955). Since bonding to dentin was established, composites became a standard restorative material in western industrial nations (Lutz *et al.* 1993). Dental composites generally comprise three phases: (i) an organic phase, the matrix; (ii) a dispersed phase, the fillers, e.g.,

195

particles or fibers; and (iii) coupling agents, the interfacial phase (Vanherle and Smith 1985). A concise review covering more than 300 publications in the field of dental restoration materials, which includes dental composites, is given by Whitters *et al.* (1999).

The common monomers are based on diacrylates of the formula M–R–M or oligoacrylate of formula M–R–M (n) are used. R is the skeleton of the molecule and M is the methacrylic group –O–CO–C(CH$_3$)=CH$_2$, which includes a double bond for polymerization. The most important representatives for R are polycarbonate, polyurethane, and polysiloxane, the latter and most recent also known as ormoceres.

Polymers are built up more or less completely in homo- or co-polymerization, network formation and interlinking. High conversion rates of double bonds after polymerization are desired for complete polymerization. Unreacted double bonds can result in material softening and higher water absorption, which can lead to an unwanted change of color and, even more important, can cause leaching of toxic components and degradation of mechanical properties. Activated double bonds with free radicals on free surfaces are useful for co-polymerization between composite-layers. The residual monomer content should be kept to a minimum, because of its allergic and toxicologic potential.

2.1 Filler Systems

The available particulate filler systems can be subdivided according to filler size and properties:

(*a*) *Microfillers and microfiller-complexes.* SiO$_2$-microfillers of sizes ranging from 5 nm to 1000 nm with an average of about 200 nm have the problem of large active free surfaces, which makes their incorporation into the matrix difficult, limiting possible filler contents in the material. The technical solution is the use of larger and/or spherical microfillers of 200–300 nm in diameter, or the use of microfiller complexes. Splintered pre-polymerized microfiller complexes are made by incorporating microfillers into an organic resin matrix and milling the cured mixture into particles of diameter near 1 µm. The surface of these complexes is not very reactive to the matrix. Naturally or artificially agglomerated microfiller complexes are also 1 µm in diameter and almost purely inorganic. Their surface might be mechanically retentive. Spherical pre-polymerized complexes are made by mixing matrix and microfiller, forming spheres of about 1 µm in diameter. Complex size distributions allow extremely dense packing at convenient viscosity. Bonding to the matrix is rather weak.

(*b*) *Solid and porous macrofillers.* Solid macrofillers are prepared by grinding or crushing of inorganic materials like quartz, glass, borosilicate, or ceramics to sizes ideally in the range 0.8–2 µm. Heavy-metal glasses provide clinically desired radioopacity. Porous macrofillers are prepared by etching or sintering solid fillers of diameter up to 20 µm and 30 µm. Traditional macrofillers can be silanated or impregnated with monomer.

(*c*) *Fibrous fillers.* Besides glass and silica fibers, various fiber systems, e.g., carbon fibers, silicon nitride, all being in the range of 5–10 µm in diameter and 60–100 µm in length, are being investigated. Silicon nitride whiskers (diameter 0.4 µm, length 5 µm) have been introduced, which are roughened with fused silica to enhance the interfacial bonding to the polymeric matrix. Due to their high aspect ratio fibrous filler induce anisotropy in the composite and rather high residual stresses in the cured resin.

Also in dental composites, the interfacial properties are of key importance for the long-term performance of the material. A good interfacial phase can be achieved by silanating or silicating of the inorganic fillers or by co-polymerization between the matrix and combined organic and inorganic fillers. All current versions of interface adhesion are still sensitive to chemical disintegration. Additionally, mechanical interlocking is attempted with natural and artificial agglomerated microfiller complexes and splintered pre-polymerized microfiller complexes. The highest degree of interlocking is achieved in porous macrofillers.

2.2 Classification and Clinical Performance of Dental Composites

The types of fillers previously described represent the backbone of the classification of composites (Lutz and Phillips 1983).

(*a*) *Homogeneous microfilled composites.* Homogeneous microfilled composites are constructed from a matrix and microfillers of a diameter of 400 nm. They feature low filler content, have a low elastic modulus, and are not radioopaque. Their surface is smooth, easy to polish, and shiny. Wear of the restoration and of the antagonistic teeth is low. However, it is deformable and has a low form stability.

(*b*) *Inhomogeneous microfilled composites.* Inhomogeneous microfilled composites are constructed from a matrix, microfillers, and microfiller complexes. They feature moderate filler content, have a low elastic modulus, and their radioopacity is acceptable. Their surface is also smooth, easy to polish, and shiny. Wear of the restoration and the antagonists is low, but it is deformable and has a low form stability. This confines their use to non stress-bearing restorations.

(*c*) *Traditional composites*. Traditional composites are constructed from a matrix and solid and/or porous fillers. They feature high filler content and high hardness, their Young's modulus is dentin-like, and their radioopacity is good. Depending on the degree of milling, the surface is rough to nearly smooth. Depending on size and distribution of the fillers, wear of the restoration and antagonists is low to high.

(*d*) *Hybrid composites*. Hybrid composites are constructed from a matrix, microfillers, traditional fillers, and rarely from glass fibers. Depending on the size of the traditional fillers, these can be divided into coarse and fine hybrid composites. They are always highly filled, their Young's modulus is dentin-like, and the radioopacity is good. In coarse hybrid composites the traditional fillers are about 3–5 μm and their characteristics are comparable to those of traditional composites. In fine hybrid composites the size of the traditional fillers is 2 μm. The surface is nearly smooth, acceptable to polish, and wear of the restoration and the antagonists can be equal to those of human enamel. The stability of the restoration is good.

2.3 Prospects

Dental composites are hydrophobic in relation to human dental tissues. To achieve bonding to enamel and dentin, a surface pretreatment is necessary. They are still sensitive to humidity during processing in the oral cavity. The shrinkage of modern dental composite materials amounts to 2–3 vol.%. During polymerization the shrinkage forces can reach 3–7 MPa with peaks of 30 MPa. For these reasons, an advanced operative technique is necessary. A shrinkage-free composite with a good wetting ability is highly desired to simplify the operative technique and is the object of ongoing research.

Glass and Kevlar continuous fiber-reinforced thermoplastics are being developed for specific applications, e.g., prosthodontic frameworks and orthodontic retainers, however, these still require considerable improvement of the interfacial stability. To explore possible enhancement of the mechanical properties of resin composites, strong electric fields are investigated inducing an alignment of filler particles and, thus, increasing the mechanical properties of filler-reinforced systems.

The hydrolytic sensitivity of the available systems compromising mechanical strength and fracture toughness remains an unsolved problem that has to be approached.

3. Conclusion

Composite materials are attractive in biomaterial applications because these can mimic natural load transmitting structures, e.g., bone, anisotropic reinforcements for osteosynthesis and for hip endoprosthesis stems. It is possible to process carbon fibers and thermoplastic matrices into composites which fulfill the following requirements:

(i) optimized interface and interphase designs for long term mechanical stability;

(ii) mimicking bone anisotropy with three dimensional reinforcement architecture due to appropriate processing; and

(iii) cost-effective industrial manufacturing induced by net shape processing.

Dental composites are now well established, yet undergo a continuous development aiming at reduction of shrinkage and wear as well as improvement of mechanical long term stability. Since amalgams have still to be considered as a strong benchmark and since composites are still relatively new to implant applications further developments are required. These are in progress integrating the advances in nanocomposites and thermoplastic high performance polymers.

Composites for Sensors and Actuators

Composite materials by nature have the advantage of allowing the combination of significantly different types of material. This has principally been used to integrate reinforcing fibers with a passive load-bearing functionality, which carry load along selected and optimized paths. This allows one mainly to avoid fatigue problems and to optimize strength and weight of structural components. Composites can, however, also integrate reinforcing elements that feature other functionalities than load-bearing ones, such as sensing and/or actuation. Resulting materials and structures are known as *adaptive, intelligent*, or *smart*.

Smart materials and structures—briefly expressed—are materials and structures with built-in sensing and/or actuation functions, which contain sensors and actuators linked via a controller. The level of intimacy of coupling between the material and its active elements can range from a classical mechanical coupling of two structures (such as is found in many mechanical structures) down to the level of molecular design. As such, "smart" composites represent a convenient intermediate level of coupling, which allows one to conveniently design and develop a smart material to be applied in a smart structure.

The reasons for developing smart materials and structures are various. These range from a desire to sense the material condition in service (e.g., damage, loads, shape, temperature, pressure, etc.) to design materials capable of adaptive actuation (e.g., changing deformation, shape, stiffness, inner stresses, temperature, color, etc.). Controllers may be built into the composite itself, but so far these have been situated outside the material in the vast majority of cases. The matrix material of such composites is mainly polymer resin; however, metal or concrete matrices have also been considered.

Electromagnetic composites represent another type of smart composite allowing one to modify dielectric permittivity, magnetic permeability, and electric resistivity, which is used for stealth applications. These composites are a combination of multilayered structures, or feature dispersed particles in a matrix. The particles used for passive absorbers are typically graphite powder/fibers, aluminum particles, iron whiskers, or nickel flakes. Active absorbers only absorb electromagnetic energy through integrated semiconductor diodes or other electronic devices when being triggered externally. Further embedded materials can be photosensitive (e.g., fiber optics), pyrosensitive (e.g., silver iodide, Ni–Cr filaments), or voltage/current sensitive arrays of elements, which can be designed for either narrow- or broad-band frequency selection.

With respect to different frequency bands (radio frequency to microwaves), further active roles for "smart" materials can be designed. Examples include phantom materials (absorbing composites simulating human bone tissue and body fluid), electromagnetic shielding (lossy dielectric layers), quasioptic composites consisting of rare-earth materials and ferrites, composite dielectrics (which are two-phase mixtures of low- and high-permittivity components such as polystyrene and barium titanate), chiral composites which include particulates of asymmetric shape allowing the cross-coupling of electric and magnetic effects, and electrochemical composites such as porous carbon impregnated with hydrophobic agents used for fuel cells.

Techniques related to nanoscale materials and composites are atomic and molecular layer manipulation with a focus on semiconductors.

1. Sensor, Actuator, and Control Options

1.1 Sensor Options

Components already existing in a classical structural composite may be used as sensors. An example is carbon fibers, of which variations in the electrical resistance can be used for monitoring damage such as delaminations, or matrix or fiber cracking. A wider application can be seen with fiber optical sensors being attached to, or integrated into, conventional structural composites. Polyimide-clad Bragg grating sensors are the most popular type of such composites. Another option is to make use of piezoelectric materials, available as both ceramics and polymers. These emit a voltage when subjected to stress, and can be shaped to any size and form and adapted onto, or integrated into, the composite. Furthermore, piezoelectric elements can additionally work as actuators when a voltage is applied. Finally, the relationship between electrical resistance and strain of shape memory alloys (SMAs) is another option allowing one to use a classical actuation element as a sensor as well.

1.2 Actuator Options

Piezoelectric materials, usually ceramics (e.g., lead–zirconate–titanate, PZT), are highly favored as actuators owing to their high precision and very rapid response; however, piezoelectric actuators can only work under dynamic loading conditions. Patches or even fibers can be integrated into, or bonded onto, the composite. Deflections achieved are relatively small and may be used for influencing structural damping behavior. Larger deflections need to be achieved through leverage mechanisms. Brittleness of the piezoelectric ceramics, manifested as low allowable strain, must be considered in these applications. Magnetostrictive materials have similar or even slightly better properties as actuators when compared to piezoelectric materials; here the electrical field is replaced by a magnetic field.

SMAs allow one to recover large deformations as a result of a transformation process between martensite and austenite and work at frequencies of about 3 Hz at maximum. Their change in Young's modulus by a factor of three between martensite and austenite allows one to influence damping properties. Transformation is, however, mainly achieved at temperatures less than 60 °C, which limits their applications.

The shape memory effect is also observed for specific classes of polymers (e.g., polyurethane of the polyester polyole series) but polymeric materials produce about two orders of magnitude less in force when compared to more conventional metallic SMAs. Density is much lower ($0.9–1.1 \, \mathrm{g \, cm^{-3}}$ vs. $6–8 \, \mathrm{g \, cm^{-3}}$) and deformation significantly higher (250–800% vs. 6–8%). More information on these materials can be obtained from the literature (e.g., Otsuka and Wayman 1998).

Other types of polymeric composite worth mentioning are ionic polymer–metal composites (IPMCs). These are mainly used as artificial muscles based on charged polyelectrolyte membranes such as collagen or fibrous protein, poly(acrylic acid) (PAA), and poly(vinyl chloride) (PVC). IPMCs show large deformation ($>10\%$) in the presence of low applied voltage (4–7 V) and operate best in a humid environment, but can also be made as self-contained encapsulated actuators to operate in dry environments. Their density is similar to that of the polymers mentioned above but the reaction time is of the order of a microsecond to a second, and thus these are faster. More details are given in Shahinpoor *et al.* (1998).

Electrorheological (ER) fluids are used in order to influence the damping characteristics of materials. These consist of a dielectric liquid (e.g., oil), polarizable particles (e.g., cornstarch), and water as an activator. Through application of an electrical field their rheological properties (e.g., viscosity) are changed. In a zero-field environment the particles are randomly distributed. In an electrical field, however, the particles line up according to the field lines, which then leads to the more rigid behavior of the fluid.

1.3 Control Options

The classical procedures of feedforward and feedback control are used for smart structures as well. Owing to the possibly large number of sensors and actuators to be handled, artificial neural networks have gained broad interest as a means for pattern recognition and novelty detection. Genetic algorithms and wavelet transforms are further procedures that allow for automated determination of optimum solutions and advanced sensor signal processing, respectively.

2. Design and Manufacturing

2.1 General Considerations

A major consideration is the compatibility between the sensing/actuation and the host materials. The stiffness ratio between these different materials is a significant parameter. If the actuation or sensing material is too soft, then it will be difficult to transfer the actuation to the host material for actuation, or to the sensing material for sensing designs. A value for this stiffness ratio between 0.5 and 2 is a good design rule of thumb. Another important issue is the quality of the interface between the different materials, because this must have the ability to transfer significant shear stresses. Otherwise the sensing/actuation elements work rather as artificial delaminations. Poor interface stress transfer can also result from chemical incompatibility, or from increased temperature generated by heating of the actuation element.

Size, shape, and quantity of the sensing/actuation elements need to be considered with regard to any notch effects these elements may cause when being integrated into the composite (Warkentin and Crawley 1991). Depending on the application, a large number of widely dispersed small elements may be more useful than one bulky element placed at one location only. The location and thus the number of sensing/actuation elements also very much depend on the geometry and function of the component and structure considered. Optimum design of the smart composite can therefore often very much rely on global component design.

Smart composites are not manufactured on an industrial scale basis, nor are such materials yet qualified according to industrial standards. The vast majority of activity on "smart" composites and structures is still at a research and development stage. There are, however, practical applications for which research and development of such composites has achieved relatively advanced levels, and in which their use is generating significant interest. A few of these cases are described below.

2.2 Fiber Optics

Optical fibers are among the most frequently used sensing elements in "smart composites." These are preferably embedded in the composite (Fig. 1), because this generates a more reliable sensor signal output; however, there are techniques that allow surface attachment while maintaining sensor output quality. The smaller the diameter of the optical fiber, the better is its integration into the composite, with diameters $\leqslant 125\,\mu$m being ideal. Larger diameters are feasible; however, one needs to take into account the formation of resin-rich zones around the fiber. These zones are especially likely if the optical fibers are embedded at an angle to the adjacent ply directions. Very thin optical fibers may, however, lead to positioning problems during processing owing to electrostatic forces. Cleaning of the optical fibers with acetone helps to improve adhesion significantly. One advantage of the use of optical fibers as sensors is that structural integrity is not compromised, since the volume fraction of optical fibers usually required is small compared to the volume fraction of the reinforcing fibers. Another advantage of fiber optic sensors is their very low weight and volume and their immunity to electromagnetic interference.

Critical locations of fracture in the resulting composites are the intersections where the optical fiber comes out of the material, as well as optical fiber terminations and connections. A solution to this makes use of locally cocured synthetic rubber implants that are put around the fiber at these intersections. Adjacent to these are connectors, which are conventional optical fiber plugs incorporating a ceramic precision ferrule. Special techniques have been developed to integrate these connectors into the composite. Results of some initial studies are reported in Green *et al.* (2000).

2.3 Piezoelectric Materials

Piezoelectric sensors are kept small (a few millimeters in diameter and less than 1 mm thick). Examples are "smart layers" (http://www.acellent.net) made of dielectric films with an embedded network of distributed piezoceramic elements, manufactured by a process similar to a circuit printing technique. The layer can either be integrated into the prepreg composite, or it can be bonded onto its surface without compromising the strength of the composite.

The use of piezoelectric elements as actuators (Fig. 2(a)) requires elements of relatively large size, such as $10\,\text{mm} \times 4\,\text{mm} \times 0.1\,\text{mm}$. Special cutouts have to be prepared in the prepreg material in order to integrate such actuation devices. Considerable care
Figure 1
Fiber optic sensor in a quasi-isotropic laminate (courtesy of M. Trutzel, DaimlerChrysler R&T).
Figure 2
(a) Piezoelectric wafers laminated into a composite (courtesy of H. Zaglauer, U. Herold-Schmidt, F. Dürr, DaimlerChrysler R&T). (b) Piezoelectric fiber concept for integration into composites (courtesy of H. Schönecker *et al.*, Fraunhofer-Institute, IKTS, Dresden, Germany).

is required regarding the selection of the appropriate bonding technique to avoid any detrimental effect to the composite. A compressive prestress on the piezoelectric element can help to improve its performance. When integrating the piezoelectric elements care is also required in order to limit the influence of heat being generated by these actuators when operating at higher frequencies and possibly as an actuator

cluster. Special conductive layers for heat transfer help to alleviate this problem.

Piezoelectric fibers (Fig. 2(b)) can be integrated like conventional fibers and allow one to avoid any cutouts in the prepregs. A problem, however, exists in producing the required electrical field; this has been solved by developing an interdigitated electrode pattern that is put on the top and bottom of a layer of

piezoelectric fibers. This new type of prepreg can then be included into the stacking sequence during composite production.

Other types of piezoelectric elements used as actuators are 1–3 piezoelectric actuator composites. This type of composite consists of a series of piezoelectric rods surrounded by a soft matrix. The rods are manufactured by an injection molding process and are directed vertically to the plane of the composite, which is also the direction of polarization. This allows one to make the best use of sensing and actuation capabilities of the piezoelectric elements, as long as deformations are required in the thickness direction of a plate.

To overcome the problem of high brittleness of piezoelectric ceramics, piezoelectric rubbers and paints have been developed based on the principle that a piezoelectric material is milled into a very fine particulate-sized powder, mixed to a rubber or epoxy resin, and then polarized to obtain again the piezoelectric effect. This allows one easily to shape these types of sensors and actuators. However, a reduction in the sensing and actuation effect is observed when compared to the original piezoelectric material.

2.4 SMAs

State-of-the-art integration of SMA elements—mainly wires with films as an option—into a composite material requires a frame with a comb at its ends where the SMA wire is continuously looped around (Fig. 3). The ends of the frame in the SMA fiber direction are then pulled, which allows one to produce a desired prestress and prestrain on the wires. The whole system is then stacked with the other prepregs and cured, producing a SMA reinforced composite. Appropriate surface treatment of the wires plays a major role in allowing shear stresses to be transferred; however, this should not compromise strength. Techniques of weaving SMA wires into prepregs and even designing complete preforms are a further step being explored. An important issue is that of heat generated by the SMA when going through larger deformations and higher frequencies, and which needs to be transferred from the interface between the SMA and host materials.

SMAs may also be plasma sprayed or sputtered as very thin coatings of arbitrary shape on either the composite surface or the prepreg surface prior to composite consolidation. These developments are, however, still at a very early stage. Another novel approach is the integration of SMA particles into a metal matrix, which leads to an arrest effect on crack propagation.

2.5 ER Fluids

ER fluids by definition can only be filled in cavities between composite plates and rubber seals along the thickness axis. CFRP plates are advantageous because they can be used directly as electrodes owing to their electrical conductivity.

2.6 Electrochromatic Effects

Electrochromatic windows allow one to change light transmission as a result of applied voltage. The window consists of a sandwiched cross-section including two transparent electrodes, two electrochromatic layers, and an electrolytic polymer layer. A small current of 1–2 V imposed by the electrodes on the system allows an exchange of ions between the two electrochromatic layers owing to a chemical process and leads to darkening of these layers. Reversing the direction of the current allows one to reverse the darkening process.

2.7 Manufacturing Methods

Manufacturing of composites for sensors and actuators requires care because the sensors, actuators, and wiring must not be affected by mechanical, thermal, or chemical reactions during processing. This is with respect to their properties as well as location within the composite. Adequate care may be achieved through individual hand laying and bonding; however, this is the most costly process. Initial research activities are under way to integrate active fibers such as the ones made of SMA or piezoelectric materials using automatic methods. Automated fiber and tape laying are alternatives but these techniques still need to be adapted to the specifics of these new composites. One approach is a filament winding/tape laying technique with directed energy heating through a laser to synthesize a composite structure layer by layer. Finally, coating techniques represent another promising area where homogeneous material qualities have, however, to be guaranteed. Other low-cost manufacturing processes that have been proposed include extrusion processes for polymer materials designed such that optical fibers or films of piezoelectric materials can be included in the material.

3. Applications

3.1 Sensing

Monitoring of loads is a big issue for determining used structural life in components. The sensing elements that are mainly considered are fiber optics and piezoelectric elements, the latter being useful for vibrational loads of frequencies > 10 Hz. A related issue is damage monitoring, which includes detection of barely visible delaminations, or of localized fiber and matrix fracture resulting from overloads such as impacts. Here fiber optic sensors are mainly used for monitoring damage-inducing loads while the
Figure 3
Manufacturing of SMA-reinforced composites. Frame for prestraining SMA fibers (top), stacking and curing process (bottom) (courtesy of V. Michaud, R. Gotthardt *et al.*, EPFL Lausanne, Switzerland).

piezoelectric elements can even be used as actuators by sending into the material a chosen (e.g., ultrasonic) signal which is then recorded by another sensor. Nondestructive testing thus becomes an integral part of the composite material. Another option specific for carbon fiber-reinforced composites is to monitor electrical resistance. This can be achieved by simply contacting the carbon fibers with an adequate current generating and sensing device across the composite. Fiber optics and piezoelectric sensors are also well suited for monitoring the curing process during composite processing. Finally, one can mention electromagnetic sensing, which can be conducted using specially designed composites, and is classically known for radars in aerospace and general defense applications, but is becoming increasingly popular with ground traffic control as well.

3.2 Actuation

Apart from introducing ultrasonic signals, shape control, vibration damping, and electromagnetic antennas are further significant applications of "smart" composites. Shape control originally comes from a desire to adapt the shape of fluid dynamic profiles according to different operational conditions by changing their camber or twisting rotorblades. Shape control can, however, also be desired in order to generate or control the grips of arms such as those used for robots. Applications can also be seen in the medical field, such as stents or valves. The actuators mainly considered are ones that make use of SMAs and, for some specific applications such as microrobots with very low forces, also shape memory polymers. For vibration damping applications, improved passive damping can be achieved by integrating SMAs into the composite, with the side effect that the dynamic properties of the SMA can be changed by heating. SMA-reinforced composites are also used because of their improved impact resistance when compared to the standard composite. Active damping can be added to other functionalities by using piezoelectric elements and/or ER fluids. Much effort is focused on active constrained layer damping using sandwiched structures consisting of the parent structure, a viscoelastic layer, a constraining layer, and a

PZT actuator. The actuator is then able to distribute more efficiently its damping energy through the constrained layer over a wider area. Specific applications are seen with turboengines as well as in aircraft generating noise. 1–3 piezoelectric composites represent another solution used as hydrophones for acoustic damping. Actuation is also seen with electromagnetic wave-absorbing composites for antennas, which are used to send out well-defined signals but can be converted to materials that are electromechanically invisible with regard to stealth applications.

4. Conclusion

Although composites with sensors and actuators are generally not available "off the shelf," their design as well as their potential applications are already well understood to a large extent. Full-scale experimental verification in an application-oriented environment will allow one to identify and hopefully close any remaining gaps. Specification, qualification, and manufacturing procedures can then be established that may have an impact on further improvement of available sensor and actuator materials.

Composites, Joining of

Composite materials, be they metal matrix composites (MMCs), polymer matrix composites (PMCs), or ceramic matrix composites (CMCs), are joined by the same procedures that are well-known for joining isotropic materials such as metals or polymers. This is to be expected since the process of transferring loads between joined components sets up stress patterns which are more dependent on the component/joint configuration than on the material used to fabricate the article.

Of course, composites often display directionality of mechanical properties, especially those fabricated from long or continuous fibers and used in laminated form e.g., graphite fiber-reinforced epoxies used in aerospace applications (see *Polymer Matrix Composites with Roughly Equiaxed Reinforcements: Microstructure and Mechanical Behavior**; *Ceramic Matrix Composites with Roughly Equiaxed Reinforcements: Microstructure and Mechanical Behavior**; *Metal Matrix Composites with Roughly Equiaxed Reinforcements: Microstructure and Mechanical Behavior**, *Laminates: Physical and Mechanical Behavior**; *Polymer Matrix Composites: Applications**; *Metal Matrix Composites: Applications**; *Ceramic Matrix Composites: Applications**). Such directionality, which usually results in low strength through the thickness of plate-like constructions, causes particular problems and the emphasis when designing load-carrying joints is on minimizing the stresses in these weak directions.

1. Joint Configurations

1.1 Standard Configurations

The type of joint most often encountered is the lap joint, which has the four basic forms shown in Fig. 1; single lap, double lap, stepped lap, and scarf. Such joints are mainly used between fiber-reinforced plastic (FRP) laminates, but in the stepped and scarf forms could be between an FRP laminate and a metal plate.

Flange joints are also commonly encountered, although there is a shortage of generally available
Figure 1
Lap joint configurations for in-plane loading.

information. Such joints would be used to join sections of pipes (tubes), cylinders (e.g., turbojet casings), or the (usually flat) panels that form the sides of containers, for holding water, etc. Tubular components can also be joined by cylindrical forms of the flat lap joints.

1.2 Special Configurations

Nonstandard configurations are reserved for particular applications, e.g., wedge joints are used for securing turbine blades or propeller blades to the turbine disc or propeller hub, respectively. As the rotational speed of the device increases so does the corresponding radial force on the blade and the constraint afforded by the wedge produces an ever tightening joint. The same principle is encountered in the wedge grips of tensile testing machines.

Another special configuration, which has been used for securing helicopter rotor blades to the rotor hub,
is the "race track" or "wrapped" joint. Here, continuous fibers are positioned around the hole (Fig. 2) in which the securing pin is located, the forces on the joint being such as to load the fibers in tension, an ideal uni-axial stress state.

2. Load Transfer

The purpose of a structural joint is to transfer load from one side of a joint to the other. In so doing a complex state of stress, which varies throughout the joint, will be set up. The main points can be illustrated by reference to the single cover joint (end-to-end single lap joints) shown in Fig. 3. The load in plate A has to be transferred to plate B via cover plate C. As a consequence the joining medium (adhesive in Fig. 3(b)) will deform in shear, with maximum stresses occurring at the ends of the overlaps. Because the line of action of the force in A and B is not aligned with that in C, overall bending, as shown in Fig. 3(c) will occur. The ends of the overlaps will move apart, setting up through-thickness tensile (so-called, "peel") stress in the joining medium and the plates. It is these stresses mentioned above that are likely to be the cause of failure in FRP laminates.

With flange joints the usual consideration is to maintain a leak-proof configuration by ensuring that the mating faces of the flanges do not separate. Such issues are well understood from many decades of joining steel pipes. With composites, the usual problem is to prevent failure either at the corner of the flange due to the gross bending, or due to the connecting fasteners pulling through the material (Godwin *et al.* 1986).

Figure 2
"Wrapped" joint.
Figure 3
Load transfer across a single cover joint.

3. Joining Polymer Matrix Composites

Polymer matrix composites (PMCs), or FRPs, constitute the bulk of the commercial market (see *Polymer Matrix Composites: Applications**). The majority of FRPs will have a thermosetting matrix and their popularity is due to their ease of processing. These materials are normally used in the form of laminates, with continuous or long fibers, and hence joints are usually of lap configuration. FRPs with thermoplastic matrices are also gaining popularity, although these are more commonly produced with short fibers by processes such as injection molding and hence, rather than being plate-like, will have a bulk form. Joining procedures are then similar to those used for bulk isotropic materials, or for MMCs (see Sect. 4).

Recently introduced materials for aerospace use includes laminates of aluminum alloy sheets bonded to sheets of aramid fiber/epoxy (ARALL) or to sheets of glass fiber/epoxy (GLARE) (Wu *et al.* 1992). Such hybrid laminates would be joined in the same way as conventional FRP laminates.

3.1 Adhesive Bonding

Adhesive bonding (or gluing) is used to join (pre)-cured laminates. A layer of adhesive is inserted between the laminates in the joint region and allowed to cure. So-called "cobonding" is a similar procedure, but here the joint is between uncured laminates, and the adhesive and matrix cure in the same operation. Slightly different, but producing identical configurations, is "cocuring" when there is no additional adhesive layer between parts and the matrix resin acts as the glue during the cure process.

The bonding procedure is perfectly straightforward and well-understood (Matthews 1994). However, care is needed to prepare the mating surfaces by removing all traces of mold release agent, or other contaminant, from the composite. If the composite is to be bonded to a metal then the latter will also need pretreatment to remove grease, etc., and any surface oxide layer (for aluminum and titanium). Adhesives are normally epoxy resin, but could be acrylic, phenolic, or polyurethane. They come in liquid, paste or film form and cure at room temperature, $120\,^\circ\text{C}$ or $170\,^\circ\text{C}$.

Of the standard configurations the single lap is the weakest, followed by the double lap, then the stepped lap, with the scarf being the strongest joint (Matthews 1994). Essentially this is due to the eccentricity of load paths being greatest for the single lap and zero for the scarf. Indeed, by making the angle sufficiently small, it is possible to make a scarf joint stronger than the material being joined (efficiency of 100%). The only drawback is the need to maintain a "knife edge" at the corner of the scarf and this is difficult to produce, and avoid being broken off, in

wide joints (i.e., items bigger than laboratory test specimens). The stepped joint is difficult and costly to fabricate and so would only be used in the most demanding applications.

The performance of single and double lap joints is enhanced by increasing the length of the overlap region. Further improvements can be brought about by tapering the thickness (being a minimum at the overlap end) of the laminate. Performance is also enhanced by using a ductile adhesive and having the largest possible in-plane stiffness of the laminate, consistent with other structural constraints (Hart-Smith 1972).

Typical applications of bonded FRP joints include: secondary and tertiary (control surfaces, fairings) as well as primary (tail plane-to-fuselage) aircraft structures (Anon 1990, Hoskin and Baker 1986), the chassis of Formula 1 race cars, satellite structures, ship hulls, the doors of truck cabs, suspension bridge decks, and indeed any situation where a smooth profile is desirable and/or drilling holes for fasteners is not feasible (Phillips 1989).

3.2 Mechanical Fastening

Mechanically fastened joints are used in aircraft (e.g., spar-to-skin joints in wings), ships (frame-to-hull joints), and race cars (engine-to-chassis joints). In the aircraft case they are a necessary feature of the overall assembly process (Anon 1990). Mechanical fastening is a suitable procedure when bonding is either difficult (e.g., with thermoplastics) or its durability is questionable. Mechanical fasteners are ideal if disassembly is required, and could be an acceptable approach for (temporary) repair. Of course, fasteners are heavy so a weight penalty will be incurred.

Typical fasteners are screws (only used for the most lightly loaded joints), rivets (limited to laminates no thicker than 6 mm), and bolts (Matthews 1994). The latter produce the strongest joints. Of course, it is necessary to drill holes in the laminate to receive the fasteners, and these holes will give rise to stress concentrations, which inevitably limit the strength of the joint. Drilling the holes requires diamond or carbide tipped bits and controlled feed rates to prevent ply separation on the back face of the laminate.

Mechanical fasteners are mainly used for single lap joints (rivets and bolts), double lap joints (bolts), and, of course, for flanges (bolts). The fiber/matrix combination is very important; carbon (graphite) fiber/epoxy (CFRP) gives the strongest joints, followed by glass fiber/epoxy (GFRP), with "Kevlar" fiber/epoxy (KFRP) being the weakest. A joint with optimum dimensions containing one fully tightened bolt could have an efficiency of around 40% (Hart-Smith 1987). The obvious way to overcome this low performance is to increase the thickness of the laminate in the region of the joint.

Other parameters that can influence performance are the dimensions of the joint, i.e., the fastener diameter, thickness of the laminate, distance of the hole center from the end of the joint, and width of the joint (for one fastener) or the pitch between fasteners for an array of fasteners (Matthews 1994).

3.3 Welding

Because of their low surface energy, thermoplastic matrix composites (TPMCs) are difficult to bond, although with appropriate pretreatment, such as corona discharge, bond strengths are equivalent to those obtained with thermosets (Kinloch *et al*. 1992). The welding process involves melting of the matrix polymer alone and/or an intermediate layer of unreinforced polymer. The general characteristics of welded joints will be similar to those of bonded joints.

The processes that have been considered include: hot plate, vibration, ultrasonic, resistive implant and induction welding (Wise 1992), and, more recently, microwave welding. Induction welding appears to have the most potential for large-scale use and has been employed successfully to fabricate wing components on Airbus airliners (Clements 2000). With all these processes it is possible to weld small specimens, the difficulty is in applying the procedures to real components when large areas have to be heated and consolidated.

4. Joining Metal Matrix Composites

Although not so widely used as PMCs, MMCs have been employed in some key areas, and are becoming more popular (see *Metal Matrix Composites: Applications**). Applications include: automotive drive shafts, valves, pistons, cylinder liners and brake discs; mountain bike frames and golf clubs; struts in space craft; electronic instrument racks; and yacht fittings (Ellis 1994, Koczak *et al*. 1993).

MMCs are normally reinforced by particles or short fibers and hence do not display the anisotropy seen with long fiber reinforcement. They could, clearly, be joined by mechanical fastening or adhesive bonding (provided the latter is compatible with the operation temperature).

However, the main attraction is to be able to use conventional metallurgical techniques such as fusion, forging, and brazing. It is important to ensure that the joining process does not react adversely with the MMC so that properties are reduced in the joint region. The matrix metal is a key determinant of performance, in the latter respect; aluminum (Al) is the most commonly encountered, but titanium (Ti), magnesium (Mg), and other metals have been used (Koczak *et al*. 1993).

4.1 Fusion Welding

During welding the matrix will be above its melting point, but the reinforcement (typically silicon carbide, SiC, or alumina, Al_2O_3) will remain solid. The defects normally found when welding unreinforced alloys, such as solidification cracking, may still be encountered with MMCs, but with the latter additional problems occur, i.e., the higher viscosity of MMC melts; segregation on solidification; reinforcement/matrix interactions; evolution of occluded gases (Ellis 1994).

There are several processes available for fusion welding of MMCs: tungsten inert gas (TIG), metal inert gas (MIG), electron beam (EB), laser beam (LB), resistance, capacitor discharge, plasma (Ellis 1994). TIG and MIG processes should be used when weld fillers are needed. EB and LB methods are attractive because they have short thermal cycles and low heat input.

4.2 Forging and Solid State Welding

Since melting is largely absent, solid state processes avoid the problems encountered with fusion welding of MMCs.

Diffusion bonding is one main category. In this approach the components are held under load at elevated (below melting) temperature in a protective atmosphere or vacuum. Solid phase diffusion bonding (SPDB) is one variant of the process, although transient liquid phase diffusion bonding (TLPDB) is a more successful approach.

Friction welding is another solid state joining process. Friction is created by moving one part against the other, or by a separate tool, using rotary (stir welding), linear, or orbital motion. After sufficient time has elapsed the motion is stopped and the parts brought together under load for the forging stage of the weld. Drive shafts are joined by friction welding. With some MMCs the particulate or fibrous reinforcement close to the bond line may be fragmented.

4.3 Brazing

Since brazing does not involve melting of the matrix, problems of matrix/reinforcement reactions and reinforcement destruction are reduced. Dissimilar materials can be joined by brazing and heat induced distortion is minimized.

5. Joining Ceramic Matrix Composites

CMCs are used in high temperature applications such as turbine blades, piston engine valves, and turbo charger components. It may be necessary to join CMCs to themselves or to a metal (Fernie *et al*. 1991). A particular problem is the brittleness of CMCs, which means that tensile stresses in the joint

must be kept to an absolute minimum. The use of mechanical fasteners is normally not feasible, because of the associated stress concentrations, and the difficulty of making holes in such hard materials.

One approach is to use shrink fitting, in which differences in thermal contraction (on cooling from elevated temperature) are exploited to form a tight joint. This method is used in the automotive industry to produce spark plugs (which have an alumina insulator).

Friction welding has also been used to join CMCs to metals, as have SPDB and TLPDB. Brazing can also be used, although this may be difficult because ceramics are not easily wetted by the braze metals. Finally it is possible to join CMCs using ceramic adhesives. However, such materials have very low toughness so joint strengths are generally low.

6. Concluding Remarks

All forms of composite can be satisfactorily joined. Adhesive bonding and mechanical fastening are the main methods for PMCs, and these are now mature technologies with well-established design rules.

MMCs can be joined by a variety of methods, but care is needed to avoid unwanted reactions, particularly with fusion processes, and destruction of the reinforcement in the joint region. CMCs are the most difficult type of composite to join and development is needed. Shrink fitting can give an acceptable joint in the right circumstances.

Composites, Microstructure of: Quantitative Description

The inner morphology of materials is generally set at a scale that requires the use of microscopes for observation. Two modes of observation exist in microscopy: transmission microscopy, which requires that the material be transparent, and reflection microscopy, which is often used with composite materials since most are generally quite opaque to light or electron beams. In the vast majority of cases, what is obtained from a microscope is a two-dimensional picture, representing a thin slice (in transmission microscopy) or a planar cut (in reflection) through a three-dimensional structure. Understanding the nature of, and quantifying, the inner microstructure of materials therefore is largely centered around the question of "guessing" and quantifying three-dimensional structures from these two-dimensional images. With composites, such "guessing" is aided by the fact that the shape of the reinforcement is to some extent known; however, although more easily achieved in composites, quantification of microstructures nonetheless remains challenging.

1. Specimen Preparation and Image Acquisition

Depending on the scale of the microstructure and the characteristics of the material, optical or scanning electron microscopes will be most often used. Observation by optical microscopy is limited by the optical resolution ($0.3\,\mu m$ for the best lenses). To a lesser extent, observation is also limited in terms of the size

of the frame of measurements exploitable from the metrological point of view. Vignetting or geometrical distorsions will appear if the frame is too large.

The scanning electron microscope (SEM) enables work at higher magnification. It possesses several modes, the most classical being back-scattered electron imaging, secondary electron imaging, x-ray elemental mapping, and more recently grain orientation imaging by electron back-channelling analysis. One can obtain many images of the same area using these different observation modes, which can be very useful for the segmentation step described below. Therefore one often works with multimodal images (in optical microscopy a color image is considered as multimodal).

Quantitative and automatic investigation of microstructures requires significant care during specimen preparation. Surface planarity and the absence of scratches or other artefacts potentially introduced during the polishing step are important, as is the choice of any chemical or thermal etching procedure used to enhance certain features of the microstructure. The success of quantitative microstructural analysis is strongly dependent on initial sample preparation, which is often the most important step in the procedure.

2. Principles of Image Processing and Analysis

Different methods can be used to treat images. There are methods derived from signal processing (Rosenfeld 1986, Gonzalez and Wintz 1987, Pratt 1991), methods constructed from mathematical morphology analysis (Serra 1982, Coster and Chermant 1985, 1989, Dougherty 1992), and also, to a lesser extent, methods based on pattern recognition and artificial intelligence.

2.1 Image Filtering

Filtering allows elimination of noise, to simplify images, and to facilitate the segmentation procedure (see below). Filters can be classified according to their properties into three categories: linear filters that use the convolution product or Fast Fourier Transform (FFT) (Rosenfeld 1986, Gonzalez and Wintz 1987, Pratt 1991), morphological filters (Serra 1982, Coster and Chermant 1985, 1989) based on the mathematical morphology operators, and rank filters (Kunt *et al*. 1993), which are constructed from the distribution of pixels in a given neighborhood.

Image acquisition systems give images that can be noisy. Generally the noise corresponds to frequencies higher than the signal containing the information. One uses low-pass filters to eliminate such noise; such filters can be of three types: (i) mean linear filters (weighted or not); (ii) opening, closing and their combination (low pass morphological filters); and (iii) median and/or rank filters of the same order.

The contours of objects delineate important transitions in the image; hence, these correspond to high frequency signals. To emphasize these contours, high-pass filters must be used. These come in several types: linear gradient filters (Sobel, Prewitt, etc.), morphological gradient filters (residual of a dilation or an erosion) and Laplacian filters (morphological or linear filter).

2.2 Extraction of Phases or Objects

Most often, on images of microstructures the attribute that allows one set of objects to be distinguished from another is the grey tone level or the color. This is why segmentation by thresholding is generally used to delineate objects in the microstructure. The result of this type of procedure is generally a binary image in which the objects have pixels set equal to 1 while background pixels equal 0. This thresholding operation can be performed either manually or automatically. Other methods can also be used: region growing or contour tracking; these are detailed below.

(*a*) *Manual thresholding*. In manual thresholding, one first chooses an upper and a lower threshold. Objects with a grey tone level within the interval stretching between these thresholds are then extracted from the image. Visual comparison with the original image is used to adjust the threshold levels.

(*b*) *Thresholding from the histogram analysis*. Manual thresholding presents the disadvantage that it depends on the operator, which raises problems of reproducibility and reliability. An automatic thresholding procedure solves these problems, but the choice of the method turns out to be difficult. Nearly all automatic methods are based on histogram analysis (Coster and Chermant 1985, 1989) and can be sorted according to their algorithms, which fall into classes very close to those used in statistical data analysis. One can quote examples such as thresholding by maximization of entropy (Pun 1981, Kapur *et al*. 1985), moment preserving (Tsai 1985), or interclass variance (Otsu 1979).

(*c*) *Thresholding from contours*. In contour thresholding, one uses information derived from object contours. To this end, one has to determine a threshold, which allows detection of a maximum of contours having high contrast and a minimum of contours with low contrast. The first category uses derivative methods (morphological gradient or not, second derivative, Laplacians or optimum filtering: Deriche (1987)). All these methods use thresholding as the last step to eliminate low-gradient transitions. The operators used to detect outlines consist of a threshold adjusted by striking a compromise between

the pertinent information and the noise. It is therefore necessary to close incomplete contours afterwards. Three main approaches are used to this end: graph exploration, which searches for the best path between two extremities, the use of neuron networks, and the method of snake contours (Kass and Witkin 1987).

(*d*) *Thresholding from regions*. Two strategies can be used for thresholding from regions: either the growth or the division of regions can be used. A region is defined as a homogeneous zone (defined by texture, grey tone level, color, etc.). Pixel gathering is performed according to a double criterion of adjacence (neighboring at the pixel level) and homogeneity (Lowitz 1983, Chassery and Garbay 1984).

In mathematical morphology the watershed method (Beucher and Meyer 1993) constitutes the main method of segmentation by region growing. The image in grey tone levels is assimilated to a relief made up of crest lines, peaks and valleys. From the minima (markers) of that relief, watersheds are reconstructed. When two catchment basins meet, one obtains the watershed line, which segments the image into several regions. The efficiency of such segmentation is principally linked to the choice of the markers and to the filtering operations involved.

2.3 Binary Image Processing

The binary images obtained after such threshold or segmentation steps can still be modified, again to eliminate noise or artefacts, to separate objects, or to simplify and extract features. Mathematical morphology is the privileged processing tool used to this end. Among the several operators available, the most frequently used are: hole filling, noise elimination by opening–reconstruction, and separation of objects by the watershed technique.

2.4 Last Step: Measurement or Classification

The last step of image processing and analysis consists of either a quantitative description of the microstructure using parameters or functions (vectors) derived from the treated image, or a classification of its different features. To this end, one must take into account the general constraints that limit what one can achieve in quantitative microstructural analysis of materials.

3. Constraints of Image Analysis in Material Science

3.1 Statistics

A first general limitation of image analysis is that the area that is sampled is but a small portion of the material from which it is extracted. An important constraint that therefore arises is that of the statistical representativity of the local area that is examined. This factor can, for example, place significant limitations on as simple an image analysis task as the measurement of volume fraction reinforcement in composites.

This issue of statistical representativity of the data gathered is compounded by the fact that to access specific features of the microstructure, a sufficiently high magnification must be used. As all the images are numerically treated, one must in particular be sure that small details represent lines on the pictures that correspond to a minimum of about 20 pixels. In most cases, the choice of the frame size is intimately linked to the magnification. Theoretically one can increase the frame size at constant magnification, using oculars with large optical field, for example. But under these conditions, aberrations mentioned above can become important; hence, one often resorts to fusion of images taken by contiguous views. In the most delicate cases, a compromise between sufficient magnification and statistical representativity must be made.

To guide this compromise, one can use the covariance function method, which tests for data representativity (Serra 1982, Coster and Chermant 1985, 1989). This is easily obtained from mathematical morphological analysis after erosion by a bipoint method as outlined below. The covariance function (Matheron 1965) is calculated as the probability that a random point x and that point $x + h$, obtained by translation of x by a vector $\vec{h}$, both belong to the same phase (single covariance) or to two specific phases (crossed covariance of multiphase materials). When h equals 0, the phase volume fraction, V_V (A), is obtained from the single covariance, and the value obtained for the crossed covariance between the phases A and B, C(A, B, h), is zero. In all cases, the slope at the origin informs on the specific surface area of the phase. In the case of a random and stationary structure, the single covariance also tends towards the square of V_V (A) for a large distance h. In the case of crossed covariance, C(A, B, h), the asymptote is given by V_V (A) $\cdot$ V_V (B). If the frame size is not sufficient or if the structure possesses a drift over high length scales, this phenomenon is not observed.

3.2 Geometry

A second limitation in experimental analysis was mentioned in the introduction, namely that microstructural data are generally gathered from two-dimensional sections cut through a three-dimensional material. Unfortunately, there is no general method of knowing or quantifying all features of a three-dimensional microstructure using data gathered on one or a few two-dimensional cuts. To this end, one therefore must make specific hypotheses concerning

the nature of the microstructure before using two-dimensional data in constructing the three-dimensional microstructure. In composites, this can be facilitated by prior knowledge of the shape of the reinforcement (fibers, equiaxed particles, spheres, etc.); however, even in these materials this is not a simple question. One method of circumventing this problem is to gather information from a succession of closely spaced planes and build a three-dimensional picture by interpolation (e.g., Li *et al.* 1999). This is, however, an extremely time-intensive procedure; hence, such serial sectioning is very limited in terms of the volume that can be analyzed and, in turn, in terms of the statistical representativity of the data gathered.

When the magnification and the size of the frame of measurements are adequately chosen, one has to try to determine the number of frames to be analyzed to obtain a representative classification or a correct estimate of the measured parameters. Two strategies are possible. First, one supposes that the structure is perfectly stationary even at short dimension scale. In this case, one can determine the minimum number of frames, considering that each parameter measured on a given frame is a random variable that follows a given probability law (normal log, Student law, etc.). Therefore the confidence interval as a function of the number of frames can be measured.

The spatial variability of parameters is not taken into account by such classical statistical methods. With the geostatistic methods (Matheron 1965) the variable is associated with its position: then it is called a regionalized variable and the tool used to analyze its statistical behavior is the variogram, $(\gamma(h) = E(f(x) - f(x+h))^2$, where E is the expectation of the square deviation of the variable measured at x and $(x+h)$. The variogram starts from zero and tends towards an asymptotic value when the frames of analysis become independent. To obtain a variogram it is necessary to implement regularly spaced analysis frames.

4. Quantification of Microstructures

Principal criteria of quantification of a microstructure are the phase ratio, the phase size, its state of dispersion, shape, and anisotropy. The relevance of all of these parameters in composites is evident in the examples shown in Fig. 1.

4.1 Stereological Parameters

Stereological parameters (DeHoff and Rhines 1968, Underwood 1970, Coster and Chermant 1985, 1989) are mean magnitude microstructural parameters that correspond to the space in which they are defined. There exists $n+1$ such parameters in n dimensional space. Among these, n stereological parameters correspond to parameters of the lower spaces. Three-dimensional stereological parameters are the volumic fraction of phase X, $V_V(X)$, its specific surface area, $S_V(X)$, the integer of mean curvature per unit volume, $M_V(X)$, and the connectivity number, $N_V(X)$. In two dimensions these are the surface fraction, $A_A(X)$, the specific perimeter, $L_A(X)$, and the connectivity number (number of objects less the number of holes) per unit surface, $N_A(X)$. In a single dimension, these are the linear fraction, $L_L(X)$, and the connectivity number (number of segments) per unit length, $N_L(X)$. In zero dimensional space, there is the point fraction belonging to phase X, $P_P(X)$. These parameters are related by the following stereological relationships:

$$V_V(X) = A_A(X) = L_L(X) = P_P(X)$$
$$S_V(X) = \pi L_A(X) = 4N_L(X)$$
$$M_V(X) = 2\pi N_A(X)$$

These basic stereological parameters allow calculation of derivated parameters such as the mean free path (mean chord), the mean curvature, the mean surface or the contiguity of a phase. The only hypothesis required for validity of all these relations is that the data set must be stationary random.

4.2 Granulometric Measurements

Composite materials generally consist of a large number of isolated reinforcing phase elements such as fibers or particles contained in a continuous matrix. From basic relationships two mean size criteria can be derived to characterize isolated reinforcing phase elements: their mean chord length $\bar{L}_1 = V_V(X)/N_L(X)$ and their mean surface area $\bar{A}_A = V_V(X)/N_A(X)$. These parameters can be completed by granulometric analysis, which leads to the definition of many other possible size parameters. Two strategies are possible to this end. If the phases are granular, individual analysis can be performed by measuring each grain. In that case, many size parameters exist: the diameter of the equivalent circle, the Feret diameters, etc. In the case of an interconnected (matrix) phase, pertinent granulometry may be measured by morphological opening (Serra 1982, Coster and Chermant 1985, 1989). The size parameter is that of the structuring element. It must be noticed that the linear granulometries with the P(l) function obtained from an erosion by a segment is a very powerful tool leading to the measurement of many morphological parameters.

4.3 Phase Dispersion

When a phase is more or less dispersed in a matrix, it becomes of interest to quantify the level of dispersion.
Figure 1
(a) Granular composite; (b) short or chopped fiber; (c) continuous fiber composite; (d) woven fiber composite.

For this purpose one uses the distance function (cartography of the point distances of the matrix from the phase) or the distribution of the nearest neighbors. This covariance function has previously been used to determine if the frame of measurements is large enough. This function can also be used to identify evidence of particle attraction, repulsion, or periodicity, as illustrated in Fig. 2.

4.4 Anisotropy Characterization

To characterize three-dimensional anisotropy, several plane sections (generally orthogonal) must necessarily

be analyzed. The choice for the plane orientation depends on *a priori* knowledge of the microstructure. This anisotropy could be described using parameters calculated from stereological quantities defined above (Underwood 1970). The covariance function can also be used to this end; one advantage of this tool is that the orientation of vector $\vec{h}$ can be used to quantify orientation-dependent characteristics of the microstructure.

In polar coordinates, two types of roses can also be plotted to characterize microstructural anisotropy: the rose of directions and of intercepts (Underwood 1970, Coster and Chermant 1985, 1989). The rose of directions is the probability of having a contour

(a)

(b)

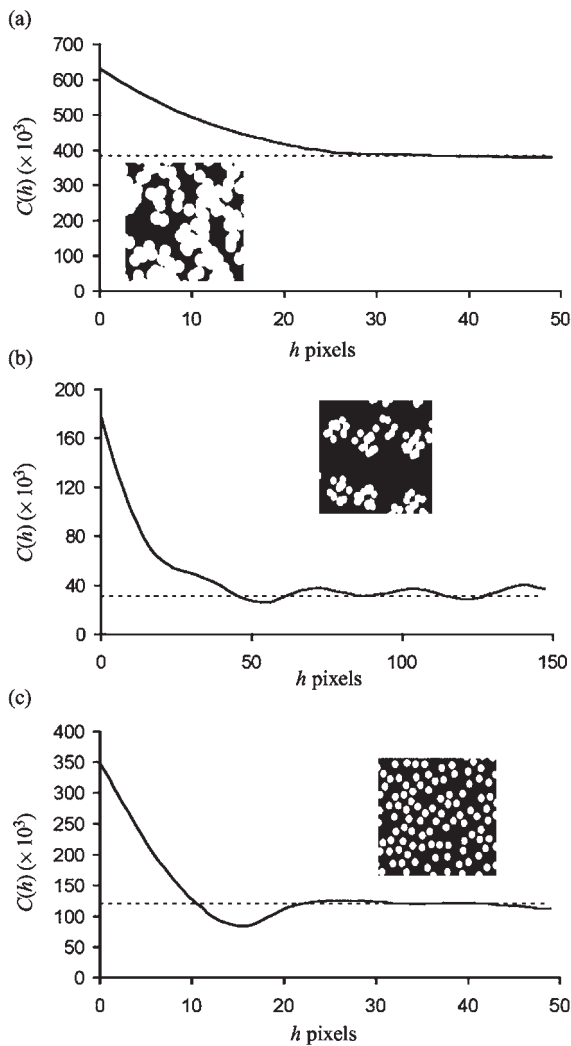
(c)


Figure 2
(a) Covariance on a Boolean (random) model; (b) covariance on a cluster (interparticle attraction) model; (c) covariance on a hardcore (interparticle repulsion) model.

oriented along direction α. The rose of intercepts is the projection distribution of the contours in direction α as a function of this angle.

4.5 Shape Analysis

The analysis of shape can only be applied to objects having a well-defined geometry; in composites, this can often be said of the reinforcement. Shape analysis possesses no stereological character, meaning that relevant variables are not simply linked with

stereological parameters defined above. For random microstructures, parameters describing the shape are generally dimensionless, since these must be invariant with the magnification. Hence, these are often ratios of two size parameters either measured on an object (for example length/radius for fibers, known as their "aspect ratio"), or ratios of one parameter measured on an object to another measured on its convex envelope (for example surface area of the object/surface area of its convex envelope). Other types of parameters can be used: these can be calculated from the spatial position of pixels belonging to the object (e.g., moments) (Chermant and Coster 1991).

5. Modeling and Interpretation

As mentioned above, a full description of a three-dimensional microstructure from two-dimensional cuts is *a priori* impossible. In particular, the number of objects per unit volume, and the distance or the distance distribution of objects constituting dispersed phases in a matrix, cannot be assessed from two-dimensional cuts without making assumptions.

One approach in analysis of composite microstructures is therefore to (i) generate "typical" microstructures of the material at hand, and (ii) to compare this model microstructure with that of the material at hand, somewhat as is practiced in high resolution electron microscopy. If good agreement between model and experimental microstructural data is found, one can draw conclusions concerning the material microstructure using the model.

Due to the more or less random aspect of composite microstructures, probabilistic models appear to be in general well adapted (Serra 1982, Jeulin 1997). Practically all models used to this end are based on a point by point Poisson process. Such probabilistic models can be divided in three categories: space partition, Boolean models and sequential models. The Boolean models are necessarily at least two-phased; the others can be mono- or polyphased.

The best-known space partition model is the Voronoi partition (e.g., Li *et al.* 1999). From a Poisson distribution of points, the influence zone of each point is constructed by drawing lines (in two dimensions) or planes (in three dimensions) equidistant from pairs of neighboring points. A mosaic made of polygons in two dimensions or polyhedra in three dimensions is then obtained. A variant of this model is the Johnson–Mehl model, where points are generated, not via a Poisson process, but by a process comprising nucleation and growth at a constant rate, polygon or polyhedral boundaries being located where growing grains impinge. Unfortunately, such Voronoi partitioning of space does not feature good stereological properties, such that a three-dimensional simulation intersected by a plane must be used to compare the model with two-dimensional

213

microstructural data. Another model of partition is the Poisson mosaic: it is constructed from the intersection of Poisson lines in $\mathbb{R}^2$ or Poisson planes in $\mathbb{R}^3$. In that case the model is stereological.

Boolean models can also be constructed from Poisson points. A primary grain replaces each point and the union of the primary grains corresponds to the Boolean model. The primary grains can take different shapes: monosized spheres, spheres of diameter following a given distribution, polyhedra of known or variable shape, random polyhedra. This model is stereological and three-dimensional parameters can be estimated from plane sections of the material. The parameters are, in that case, the Poisson density and the characteristics of the primary grains (volume, surface area, distribution).

As with Boolean models, sequential models are constructed from a point generation process followed by assignation to each point of grains of chosen shape. However, unlike Boolean models, sequential models are function of time: so the free space and previous grains are covered by new primary grains.

Since composites are made of a reinforcement phase more or less dispersed or agglomerated in a matrix, microstructures will differ according to the reinforcement state of dispersion. With equiaxed reinforcements, several corresponding "granular" model microstructures can be used. The most simple comprises the Boolean scheme issued from a Poisson process, and other schemes incorporating the influence of point to point attraction or repulsion. Figure 1(a) was generated via such a process. Fiber composite microstructures come in various different classes: fibers can be short or continuous, and their orientation can be random or ordered along one, or several directions in woven fiber composites. The case of random fiber structures can be schematically represented by a Boolean scheme of short fibers or by thick Poisson lines for continuous fibers.

The strategy used for analysis depends on the desired characteristics of the model microstructure. In any case, stereological parameters of the material microstructure must be estimated using the methods outlined above, taking into consideration any anisotropy characteristics that may be relevant. Moreover the dispersion state of reinforcing phases should always be analyzed, using the covariance function. Then, these characteristics can be compared with those of model microstructures; for example, covariance plots from a Boolean model show the influence of inter-particle attraction or repulsion on microstructural parameters (Fig. 2). In Fig. 2(a), in the absence of attractive or repulsive effects, a continuous decrease of the covariance towards a constant asymptotic value is observed. In Fig. 2(b), one can see an attractive effect causing the formation of clusters, which translates into oscillations of the covariance around the asymptote at large values of h. Finally, a curve extending at large distances below the asymptote

provides evidence of interparticle repulsion (Fig. 2(c)), which can be quantified in the model.

Fiber composites can also be subdivided according to the state dispersion of the fibers; in practice, this translates into the difference between random dispersion or woven structures. Random fiber dispersions can be more or less represented by probabilistic models. In the case of short fibers, a Boolean model is generally suitable (Fig. 1(b)). For continuous fiber composites, thick Poisson lines are better adapted (Fig. 1(c)). A drawback of these relatively simple models is that the fibers are superimposed; increased sophistication in how fiber location is computed can of course eliminate this drawback.

With woven composites (Fig. 1(d)), knowledge of the fabrication process gives significant *a priori* information guiding the choice of orientation with regard to the cloth orientation of the plane sections to be considered in analysis. Due to the high anisotropy of such materials, transforming two-dimensional to three-dimensional information can be challenging. It is then better to analyse only sections and not to aim for derivation of three-dimensional stereological parameters other than the volumic ratio. Sections locally perpendicular to yarns can thus be used to gather information concerning fiber distribution or matrix and pore networks. The covariance function can also provide information on the periodicity or nonperiodicity of the fiber architecture.

6. Conclusion

Quantification of microstructures is now a task that can be readily accomplished with the use of computerized analysis of two-dimensional sections through materials. Significant challenges nonetheless exist: sampling must be statistically significant, and the derivation of three-dimensional parameters from two-dimensional pictures is not trivial. Because composite materials in the majority of cases consist of a reinforcement of known geometry dispersed within a continuous matrix, these are particularly amenable to microstructure quantification; general approaches used to this end are outlined in this review.

Composites, Physical Properties of

The aim when designing a composite material is to combine the virtues of two or more quite different materials. The extent to which this is achieved depends on the coupling between them. In this article the elastic and physical properties of composites are examined. In this context, predictive models are essential tools because they delineate the properties achievable for a given coupling and thus provide a benchmark against which real composites can be compared. They are also important because they enable the designer to try out different couplings prior to undertaking costly fabrication of new systems.

Models have been especially successful in predicting physical properties (e.g., stiffness, thermal and electrical conductivity, etc.) because, unlike properties such as toughness, they tend to depend on volume average quantities. That toughness is not a volume average quantity is exemplified by the observation that a tough ceramic composite can be made by combining two brittle ceramic materials by careful control of the interfaces. As a result, most physical properties can be modeled fairly accurately on the basis of reinforcement volume fraction, aspect ratio, and orientation data without the need for detailed microstructural information. Throughout this article it is assumed that the microstructure of the composite is fine compared with the size of the test piece or component under consideration. This means that the composite can be treated as homogeneous, i.e., *effective* properties can be considered. Of course this requires that the second phase be distributed in a quasi-uniform manner throughout the composite (either in a regular array or more usually randomly distributed). For the majority of composite systems this is approximately true.

The approaches for modeling thermal conductivity, electrical conductivity, magnetic and electrostatic vector fields, as well as stress tensor fields are all very similar because the governing equations all have a common form (Taya 1990). Each can be written in terms of a flux vector/tensor (Y) and a field vector/tensor (Z) related by a tensor (β) that is material dependent (see also Table 1):

$$Y_i = \beta_{ij} Z_j \quad \text{or} \quad Y_{ij} = \beta_{ijkl} Z_{kl} \tag{1}$$

According to field theory the flux vector (Y) and field vector (Z) of the four vector quantities conform to:

$$\nabla \cdot Y = 0 \quad \text{and} \quad \nabla \times Z = 0 \tag{2}$$

where ∇ is the grad operator (d/dx_1, d/dx_2, d/dx_3) and $\cdot$ and $\times$ denote the inner (dot) and vector (cross) products. These are satisfied for a homogeneous body if Z is written in terms of a scalar potential ϕ ($z = -\nabla\phi$) where ϕ obeys Laplace's equation:

$$\nabla^2 \phi = 0 \tag{3}$$

The stress and strain tensors are related by a fourth-rank tensor of materials coefficients (Table 1). In this case $Z_{ij} = \varepsilon_{ij} = sym(\nabla u) = \frac{1}{2}(du_i/dx_j + du_j/dx_i)$ where u is the displacement vector. In this case the displacement can be written as $u_i = \nabla_i(\phi_o + r_i\phi_i) - 4(1-v)\phi_i$ where v is Poisson's ratio, r_i is the position vector and ϕ_o and ϕ_i are scalar and vector potentials that satisfy Laplace's equations (Taya 1990). For inhomogeneous materials, such as composites, $\nabla^2\phi$ becomes nonzero at the interface. The variation of the field variables can be found by using Gauss' theorem to convert from a surface integral at the interface to a volume integral and then solving the

appropriate Green's function subject to certain boundary conditions. Eshelby's analytical solution is applicable to composites containing ellipsoidal inclusions. There is a particularly powerful, elegant, and simple way to evaluate this, which is described in Sect. 4. In most circumstances numerical solutions can be obtained or, alternatively, if detailed information about the composite microstructure is not available then bounds within which composite properties must lie are the best one can obtain.

A framework for describing and understanding many different physical properties is presented here. Rather than take each property in turn, this article is categorized by the different modeling strategies in order to emphasize the areas of commonality between the different properties. The article starts with simple approaches, which can be completed with pencil and paper, moving on to complex ones requiring considerable computing resources. Most assume a perfect coupling between the two or more phases, but in others more complex couplings can be included. In general each section focuses initially on a description of elastic behavior before going on to discuss other physical properties. For each property, the performance of composite systems is examined in the light of the available models and the extent to which they reach their potential is discussed. In the final section a means of identifying promising new composite combinations is presented.

1. Symmetry of Physical Properties

Throughout this article it is assumed that the individual phases are elastically isotropic although in some cases the treatment can be modified to take account of anisotropic matrix or fiber properties (Hashin 1979, Withers 1989). Of course even when the constituents are isotropic, the geometry of the reinforcement and its orientation may confer upon the composite anisotropic properties. Fiber-reinforced composites can exhibit a very wide range of symmetry elements because of the opportunity for different fiber alignments (uniaxial, planar random, laminates, etc. (Table 2)).

Table 2

Composite type	Symmetry
Particulate	m4m
Aligned long- or short-fiber composite	4mm
Unidirectional laminate	mmm
Cross-ply laminate or planar random mat or layered material	42m
Angle-ply laminate	222

Source: Newnham (1994).

2. Summation Rules for Composite Properties

The simplest rule for combining the properties of two or more materials in a composite is to assume that the composite obeys some form of summation law of the form:

$$P = f_1 P_1^n + f_2 P_2^n + f_3 P_3^n + \cdots \qquad (4)$$

where $f_1, f_2 \ldots$ are the phase volume fractions, P_1 the value of the property for phase one, and the power n describes the nature of the coupling. The most straightforward relation of all is the so-called rule of mixtures (also called the rule of averages) assumption which assumes that the properties of the constituents combine in direct proportion to their volume fraction:

$$P = \sum_i f_i P_i = f_1 P_1 + f_2 P_2 + f_3 P_3 + \cdots \qquad (5)$$

2.1 Density

Density (ρ) is one property that almost always obeys the rule of mixtures (ROM) relation:

$$\rho = \sum_i f_i \rho_i = f_1 \rho_1 + f_2 \rho_2 + f_3 \rho_3 + \cdots \qquad (6)$$

In many composites the density should be thought of as combining three components, the matrix, the

reinforcement, and any porosity. In fact the accurate measurement of density often provides a good means of assessing whether there is any residual porosity after consolidation or porosity introduced by damage or degradation while in service. Although generally true, the ROM relation is not obeyed in cases where a reaction product is formed. Reaction products might be formed deliberately as in reaction-formed ceramic composites; for example, Refil in which silicon is reacted with carbon powder to consolidate around SiC particles. Alternatively, reaction products might be formed accidentally as in the case of metal matrix/ceramic reinforcement reactions (e.g., Ti/SiC composites).

2.2 Stiffness

As with many other physical properties, the ROM relation is successful at predicting the axial stiffness response of long-fiber composites. This is because the axial strains (ε_1, ε_2, …) are the same in each phase (the so-called Voigt bound) so that the phase stresses are proportional to their stiffnesses (E_i), and the force (F_i) borne by each phase is $f_i A E_i \varepsilon$ giving:

$$E_{\text{comp}} = (F_1 + F_2 + \cdots)/A\varepsilon = f_1 E_1 + f_2 E_2 + f_3 E_3 + \cdots \tag{7}$$

However, for most phase geometries the strains are not equal and the ROM tends to overestimate the stiffness (Fig. 1). This is because the strains in the more compliant phases tend to be larger than those in the stiffer phases. At the other extreme, the series mixing or Reuss relation (i.e., $n = -1$ in Eqn. (1)) is valid for the normal stiffness of layered systems and is an acceptable approximation for the transverse stiffness of uniaxial fiber composites:

$$E_{\text{trans}}^{-1} = f_1 E_1^{-1} + f_2 E_2^{-1} + f_3 E_3^{-1} + \cdots \tag{8}$$

In the majority of cases, however, the reinforcement shape/arrangement gives rise to more complex couplings, which are neither solely in parallel nor in series. As a result the Voigt and Reuss relations act as extreme bounds (Fig. 1).

2.3 Thermal Conductivity

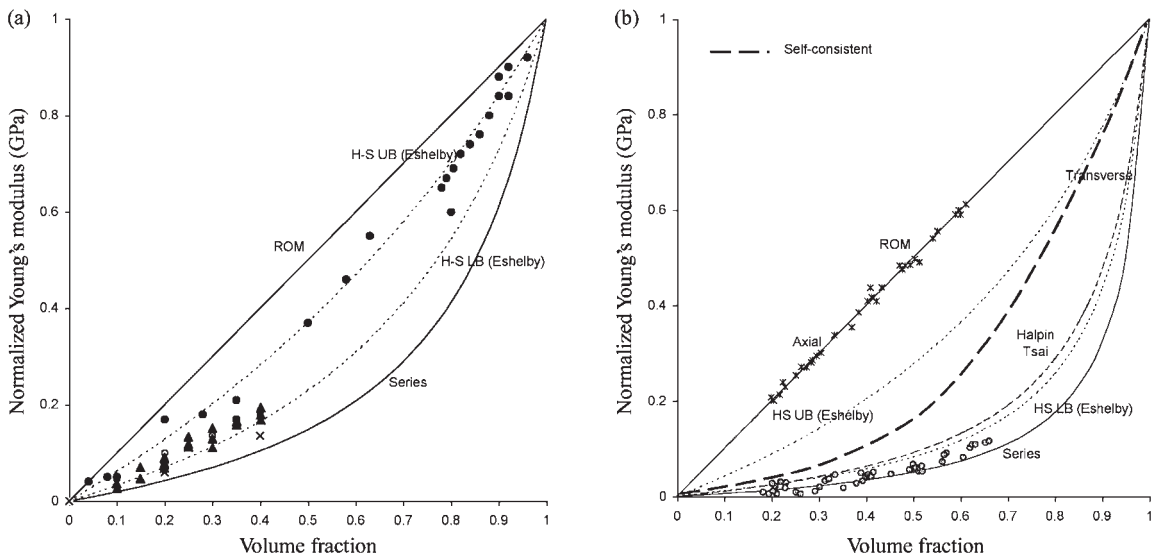
There are many applications for which the high thermal stability and low thermal conductivity coupled with the reasonable thermal shock resistance of ceramic matrix composites makes them attractive. As mentioned in the introduction, the basic physical equations governing thermal conductivity (Q) are rather similar to those for elasticity (Table 1) and for this reason it is possible to apply many of the models


Figure 1
Normalized stiffness (($E - E_R$)/($E_R - E_M$)) plots including the ROM, series, Halpin–Tsai, Eshelby, self-consistent predictions, and HS bounds (dashed lines) for stiffness ratios characteristic of (a) metal and ceramic particle composites ($E_R/E_M \sim 6$) and (b) polyester/glass-fiber composites ($E_R/E_M \sim 15$). In (a) data is for WC/Co cermet (circles) (Shaw and Uhlmann (1987), alumina/spinel (squares) (Hunter and Bronwell 1967), glass/alumina (crosses) (Davidge and Green 1968), and Al/SiC particles (triangles) (Clyne and Withers 1993). In (b) data is for polyester/glass fiber (Bintrup 1975).

derived for predicting elastic behavior to thermal conductivity.

The conductivity of a composite is usually intermediate between the properties of the two phases. However, only in special cases does the ROM summation rule correctly describe the variation. This is because the heat tends to flow predominantly through the microstructural path of highest conductivity rather than sample each phase equally. Parallel (ROM) and series summation ($n = 1$ and -1 in Eqn. (4) respectively) do apply, however, for layered composites parallel and perpendicular to the layers:

$$Q_{\mathrm{parallel}} = f_1 Q_1 + f_2 Q_2 + \cdots$$
$$1/Q_{\mathrm{perpendicular}} = f_1/Q_1 + f_2/Q_2 + \cdots \quad (9)$$

The ROM also predicts the axial conductivity of fiber composites with good reliability.

3. Semiempirical Methods

A number of semiempirical methods have been developed. These combine ease of computation with basic elements of micromechanics, but lack a rigorous fundamental basis.

3.1 Shear Lag Model for Axial Stiffness

The shear lag model is perhaps the simplest model for axial stiffness, which takes into account the geometry of the phases as well as their volume fraction (Cox 1952). It assumes that the load is transferred from the matrix to the fibers by the generation of shear stresses at the fiber/matrix interface. The model predicts an axial composite stiffness given by:

$$E_{\mathrm{axial}} = f_R E_M \left(1 - \frac{\tanh(ns)}{ns} \right) + (1 - f_R) E_M \quad (10)$$

where

$$n = \sqrt{\left(\frac{2 E_M}{E_R (1 - f_R) \ln(1/f_R)} \right)}$$

Because the model neglects the transfer of stress normal to the fiber ends, the model tends to underestimate the stiffness of very short fiber- and particle-containing composites (Fig. 2), for which the transfer of normal stresses is as important as shear.

3.2 Halpin–Tsai Equation for Transverse Stiffness

The Halpin–Tsai equation provides a means of estimating the elastic modulus, E_{22}, of a long-fiber composite transverse to the fiber alignment direction:

$$E_{22} = \frac{E_M (1 + \xi \eta f_R)}{(1 - \eta f_R)} \quad (11)$$
Figure 2
The variation in the predicted axial and transverse stiffness as a function of particle aspect ratio for a 20% alumina (400 GPa)-containing glass (75 GPa) matrix composite. This illustrates how the Eshelby and shear lag models predict an increase in axial stiffness with increasing aspect ratio. Note that both the shear lag and the Eshelby models tend to the ROM estimate at high ratios and that the series (Reuss) bound provides an underestimate of transverse stiffness at all aspect ratios.

where

$$\eta = \frac{E_R - E_M}{E_R + \xi E_M}$$

and ξ is an adjustable parameter, dependent on the fiber arrangement, of order unity. Although it is not founded on rigorous elasticity theory, it does express the increased load bearing of the reinforcing phase relative to the equal stress relation. It is correct at the extremes of reinforcement content and is usually found to be a good estimate over the whole range of reinforcement (Hull and Clyne 1996).

3.3 Stiffness Relations for Porous Materials

While general purpose models for composite stiffness can be applied to porous materials simply by setting the stiffness of the reinforcing phase to zero, a number of models have been developed specifically to describe porous materials, such as the empirical form:

$$E = E_M (1 - a f_p + b f_p^2) \quad (12)$$

where f_p is the pore fraction and a and b are constants (1.9 and 0.9 respectively for spherical pores (MacKenzie 1950)). Note that at low volume fractions the effect of the pores is essentially twice that predicted by the ROM estimate (i.e., $a = 1$, $b = 0$) and is in good agreement with the more complex Eshelby relation (Fig. 3). Another model proposed to describe the elastic behavior of concrete is simply $E = E_M (1 - f_p)^3$ (Weidmann *et al.* 1990), for which the pores are three
Figure 3
Stiffness of porous ceramics (diamonds, Kingery *et al.*
(1976); circles, Larsen (1979)) as compared with the
Eshelby, ROM, MacKenzie, and $(11 - f_p^3)$ models.

times as important as that predicted by ROM at low
pore fractions.

3.4 Thermal Microstresses

In two-phase materials the propensity for large ther-
mal microstresses is considerable and it is important
to be able to estimate their likely magnitude. For
spherical inclusions, the pressure P (or average rein-
forcement stress $<\sigma>_R$) generated within the inclu-
sions by a matrix/inclusion misfit $\Delta\alpha\Delta T$ is given y:

$$P = \frac{4G_M \dfrac{K_R(1 + v_M)}{3K_M(1 - v_M)}}{1 + \dfrac{(K_R - K_M)(1 + v_M)}{3K_M(1 - v_M)}}\Delta\alpha\Delta T = -<\sigma>_R \quad (13)$$

Simpler alternative approaches include $P = \Delta\alpha\Delta T/$
$((1 + v_M)/2E_M + (1 + v_p)/2E_p)$ (Selsing 1961) de-
signed for isolated crystals in glass matrices, and
$\sigma_i = K(\alpha - \alpha_i)\Delta T$ where K and α are the composite
bulk modulus and thermal expansion coefficients
and α_i the expansion coefficient of the phase under
consideration.

4. The Eshelby Model

Perhaps the most important rigorous analytical
model for the distribution of stress (and many other
properties) in a composite is the Eshelby model.
Strictly, it applies only to the placement of a single
ellipsoidal inclusion in an infinite matrix. The reali-
zation that the method could be extended to com-
posites containing practically useful reinforcement
volume fractions was made by Brown and Stobbs
(1971) and Mori and Tanaka (1973). Using their
mean field approach in which an inclusion experi-
ences the average effect of the neighboring inclusions

means that it is not a strict geometrical model. But
since the distribution of the phases is usually chaotic
and impractical to determine anyway, a model which
does not require accurate reinforcement coordinates
has distinct advantages. The model can make accu-
rate predictions for oblate and prolate spheroids at
volume fractions below 30% beyond which self-con-
sistent approaches are required (Sect. 6).

4.1 Stiffness

The stiffness tensor, $\mathbf{C}$, for the composite is given by:

$$\mathbf{C} = \Big(\mathbf{C}_M^{-1} - f_R\{(\mathbf{C}_R - \mathbf{C}_M)[\mathbf{S} - f_R(\mathbf{S} - \mathbf{I})] + \mathbf{C}_M\}^{-1}$$
$$\times (\mathbf{C}_R - \mathbf{C}_M)\mathbf{C}_M^{-1} \Big)^{-1}. \quad (14)$$

where $\mathbf{I}$ is the identity matrix, $\mathbf{C}_M$ and $\mathbf{C}_R$ the stiffness
tensors for matrix and reinforcement, and $\mathbf{S}$ is the
Eshelby tensor which is given in Clyne and Withers
(1993) along with computer programs for stiffness
and internal stress calculation. Its predictive capabil-
ity is better than shear lag models and the errors as-
sociated with applying it to nonellipsoidal geometries
(cylinders, plates, etc.) are small.

For axial loading of a spherical-particle-containing
system, Eqn. (14) leads to (Clyne and Withers 1993):

$$E = \frac{E_M}{1 + f_R[(K_M - K_R)/3K_R 8G_M + (G_M - G_R)/3G_R G_M]} \quad (15)$$

where G and K are the shear and bulk modulus, re-
spectively. Eshelby's approach can also be used to
model the stiffness of systems in which the interface
has no strength, the particles crack, or the particles
crumble. In this context, the model has been used to
assess the development of damage in composite sys-
tems as a function of loading by the progressive fall-
off in the measured stiffness (Brechet *et al.* 1991).

4.2 Thermal Conductivity

The composite conductivity tensor is given by:

$$\mathbf{Q} = \Big(\mathbf{Q}_M^{-1} - f_R\{(\mathbf{Q}_R - \mathbf{Q}_M)[\mathbf{S} - f_R(\mathbf{S} - \mathbf{I})] + \mathbf{Q}_M\}^{-1}$$
$$\times (\mathbf{Q}_R - \mathbf{Q}_M)\mathbf{Q}_M^{-1} \Big) \quad (16)$$

which is directly analogous to Eqn. (14), but with the
$\mathbf{S}$ tensor now appropriate for conductivity (Clyne and
Withers 1993) and $\mathbf{Q}_R$ and $\mathbf{Q}_M$ the reinforcement and
matrix conductivity tensors. The variation with rein-
forcement loading is shown in Fig. 4.
Figure 4
Thermal conductivities of periclase (MgO)/fosterite (Mg$_2$SiO$_4$) ceramic composites of different fosterite volume fractions at 100 °C, 400 °C, and 800 °C compared with various model predictions (Kingery *et al.* (1976). In each case the ROM and series predictions are shown with solid lines, the HS bound (Eshelby) predictions with dashed lines.

4.3   Thermal Expansion and Thermal Microstresses

Stress balance requires that the volume-averaged mean field thermal stresses $<\sigma_i>$ in the two phases conform to (Fig. 5):

$$(1 - f_R)<\sigma>_M + f_R<\sigma>_R = 0 \qquad (17)$$

The stress-free misfit ($\Delta\varepsilon = \Delta\alpha\Delta T$) between the phases upon changing the temperature T is equivalent to Eshelby's stress-free transformation (Clyne and Withers 1993). The matrix stress is then given by:

$$<\sigma>_R = f_R\mathbf{C}_M(\mathbf{S} - \mathbf{I})\{(\mathbf{C}_M - \mathbf{C}_R)[\mathbf{S} - f_R(\mathbf{S} - \mathbf{I})]$$
$$- \mathbf{C}_M\}^{-1} \times \mathbf{C}_R\Delta\alpha\Delta T \qquad (18)$$

Of course this approach assumes that the thermal expansion misfit is accommodated wholly elastically. In many composites there exist many mechanisms by which the thermal stresses can partially relax (creep, plasticity, cracking, etc.). In such cases the equivalent stress-free temperature T_{esf} (Arsenault and Taya 1987) is often useful. This is the temperature that would generate the stresses actually observed were the misfit accommodated completely elastically. A large difference between the actual temperature change and T_{esf} is indicative of active relaxation micromechanisms.

The Eshelby model also provides a good prediction of thermal expansivity:

$$\alpha_{(comp} = \alpha_M - f_R\{(\mathbf{C}_M - \mathbf{C}_R)[\mathbf{S} - f_R(\mathbf{S} - \mathbf{I})]$$
$$- \mathbf{C}_M\}^{-1}\mathbf{C}_R(\alpha_R - \alpha_M) \qquad (19)$$
Figure 5
The variation in hydrostatic stresses in Al$_2$O$_3$/ZrO$_2$ composites as a function of the ZrO$_2$ volume fraction (Wang *et al.* 1984). Triangles delineate the net macrostress and indicate that the thermal stresses are self-equilibrating in agreement with Eqn. (17).

5.   Bounds

If one is to predict accurately a property of a composite then one needs to know the arrangement/distribution of the phases as well as their volume fractions. Without this one can only place bounds in the range within which that property must lie.

5.1   Stiffness

The simplest bounds are the Reuss and Voigt bounds (Sect. 2). These bounds are unnecessarily wide apart for most composite systems and more useful bounds have been developed by Hashin and Shtrikman (1963) among others. Their lower bound is equivalent to the Eshelby model and the upper bound is essentially equivalent to the Eshelby model with the phases reversed, i.e., the contiguous phase having the properties of the reinforcement and the isolated phase those of the matrix.

The upper E_{Uaxial} and lower E_{Laxial} bounds for the axial elastic modulus of a long-fiber composite containing a reinforcement fraction f_R are given by (Hill 1964):

$$E_{Uaxial} = f_R E_R + (1 - f_R)E_M$$
$$+ \frac{4f_R(1 - f_R)(v_R - v_M)^2}{f_R/K_M + (1 - f_R)/K_R + 1/G_R} \qquad (20)$$

$$E_{Laxial} = f_R E_R + (1 - f_R)E_M$$
$$+ \frac{4f_R(1 - f_R)(v_R - v_M)^2}{f_R/K_M + (1 - f_R)/K_R + 1/G_M}$$

where v_R and v_M are Poisson ratios, K_R and K_M are bulk modulus, and G_R and G_M are shear modulus of

reinforcement and matrix respectively. Note how these bounds collapse to give the ROM result when the Poisson's ratios of the two materials are equal.

Hashin and Shtrikman (HS) (1963) have derived best possible bounds for all the elastic constants (K, G, E, and v) for an isotropic composite material. The lower bounds for K and G are given by:

$$K_L = K_M + \frac{f_R}{1/(K_R - K_M) + 3(1 - f_R)}(3K_M + 4G_M)$$

$$G_L = G_M + \frac{f_R}{1/(G_R - G_M) + 6(K_M + 2G_M)(1 - f_R)} \quad (21)$$
$$[5G_M(3K_M + 4G_M)]$$

The corresponding upper bounds can be obtained by reversing the properties of the matrix and reinforcement in the above. Since only two elastic constants are independent, E_L, E_U, v_L, and v_U can be determined from Eqn. (21). Such bounds are shown in Fig. 1.

5.2 Thermal Conductivity

For long-fiber composites, the axial conductivity is well described by the ROM (Eqn. (9)). The transverse conductivity lies between the upper Q_{Utrans} and lower Q_{Ltrans} bounds:

$$Q_{Utrans} = Q_R + \frac{(1 + f_R)Q_R(Q_M - Q_R)}{Q_R + f_R(Q_M - Q_R)/2} \quad \text{and}$$
$$Q_{Ltrans} = Q_M + \frac{f_R Q_M(Q_R - Q_M)}{Q_M + (1 - f_R)(Q_R - Q_M)/2} \quad (22)$$

These are analogous to the HS bounds for elasticity and, as before, the lower bound is identical to the Eshelby prediction and the upper bound can be obtained by swapping the properties of the dispersed and contiguous phases. Note that in the limit of $Q_R = 0$ the transverse thermal conductivity is given by $Q_{trans} = Q_M(1 - f_R)/(1 + f_R)$. By comparison the composite cylinder assembly model for aligned long fibers makes the prediction:

$$Q_{trans} = Q_M \left(\frac{Q_M(1 - f_R) + Q_R(1 + f_R)}{Q_M(1 + f_R) + Q_R(1 - f_R)} \right) \quad (23)$$

A relation has been proposed to describe the conductivity of particulate systems (Kingery *et al.* 1976), which is equal to the HS bound:

$$Q = Q_M \left(\frac{1 + 2f_R(Q_R - Q_M)/(2Q_M + Q_R)}{1 - f_R(Q_R - Q_M)/(2Q_M + Q_R)} \right) \quad (24)$$

5.3 Thermal Expansivity

The relation of Levin (1967):

$$\alpha = \alpha_{ROM} + \frac{\alpha_M - \alpha_R}{(1/K_M) - (1/K_R)}(1/K - 1/K_{ROM}) \quad (25)$$

where the subscript ROM denotes rules of mixtures volume averages, can be combined with HS bounds for bulk modulus to obtain the best possible bounds for the expansion coefficient for isotropic composites (e.g., particulate or random fibers):

$$\alpha_U = \alpha_R - \frac{(\alpha_R - \alpha_M)K_M(1 - f_R)(3K_R + 4G_R)}{K_R(3K_M + 4G_R) + 4(K_M - K_R)G_R(1 - f_R)} \quad (26)$$

This is identical to the value obtained by the composite sphere assemblage model. Once again the lower bound is obtained by swapping the properties of the phases over.

Turner (1946) derived the following expression:

$$\alpha = \frac{\sum \alpha_i K_i f_i}{\sum K_i f_i} \quad (27)$$

which assumes that the thermal stresses are not significant. Although not a formal bound, this formulation has been shown to be a reasonable approximation for mullite/coordierite (see Fig. 6). In brittle matrix or reinforcements systems the thermal stresses may cause microcracking to occur. This can give rise to nonlinearities in the thermal expansion curve as well as a hysteresis between the expansion coefficient observed on heating and cooling (Fig. 7).
Figure 6
Expansivity as a fraction of silica/glass (circles) (Tummala and Firedber 1970) and ($Al_6Si_2O_{13}$)/cordierite ($Mg_2Al_4Si_5O_{18}$) composite (squares) (Mussler and Shafer 1984). The relatively small difference in elastic properties means that the ROM and Turner models are relatively close together, but note how both lie outside the Levin/HS/Eshelby bounds (dashed lines) (Eqn. (25)).
Figure 7
Thermally induced intergranular stresses can cause microcracks leading to hysteresis in the thermal expansion curve, as shown here for TiO_2 (Kingery *et al.* 1976).

For transversely isotropic composites (e.g., aligned fiber composites), Levin (1967) derived the following for the axial and transverse expansion coefficients:

$$\alpha_{axial} = \alpha_R + (\alpha_M - \alpha_R)[(1 + v_M)(E_{axial} - f_R E_R)$$
$$- (1 + v_R)(1 - f_R)E_M]/[E_{axial}(v_M - v_R)] \quad (28)$$

$$\alpha_{trans} = (\alpha_M - \alpha_R)[(1 + v_M)(f_R v_{axial} E_R - v_R E_{axial})$$
$$+ (1 - f_R)v_{axial} E_M (1 + v_R)]/[E_{axial}(v_M - v_R)]$$

These can be used to obtain bounds simply by using the appropriate upper or lower bounds on the composite modulus. Schapery (1968) and Rosen and Hashin (1970) have derived upper and lower bounds for thermal expansivity along similar lines. An equivalent representation is given by:

$$\alpha_{axial} = \alpha_{ROM} + \frac{\alpha_R - \alpha_M}{1/K_R - 1/K_M}$$
$$\times \left(\frac{3(1 - 2v_{axial})}{E_{axial}} - 1/K_{series}\right) \quad (29)$$

$$\alpha_{trans} = \alpha + \frac{\alpha_R - \alpha_M}{1/K_R - 1/K_M}$$
$$\times \left(3/2K_{trans} - \frac{3v_{axial}(1 - 2v_{axial})}{E_{axial}} - 1/K_{series}\right)$$

where $\alpha_{ROM} = f\alpha_R + (1-f)\alpha_M$ and $1/K_{series} = f/K_R + (1-f)/K_M$. The lower bound is equivalent to the Eshelby model (Pedersen 1983, Clyne and Withers 1993), while the upper bound is equivalent to the Eshelby model with the phases reversed.

6. Self-consistent Models

In Sect. 5 we saw that the Eshelby treatment represented the lower bound for stiffness. However,

problems arise at high volume fractions ($>30\%$) because the lower bound is structurally biased. It assumes a connected matrix phase and isolated reinforcements. This picture becomes increasingly unrealistic at high reinforcement loadings when the percolation threshold is breached (between $f = 0.15$ and 0.4) and the reinforcements begin to touch. In simple terms, rather than consider a reinforcing inclusion in a matrix, self-consistent methods use iterative procedures to place the phases in a matrix having the properties of the composite. At low volume fractions self-consistent methods approach the lower (Eshelby) bound, while at high reinforcement fractions they approach the upper bound (Fig. 1). Much the same behavior is observed in Fig. 4 where the actual thermal conductivity of the periclase/fosterite composite at a given temperature transfers from the upper curve (fosterite is the dispersed phase) to the lower (periclase is the dispersed phase) as the volume fraction of periclase is decreased. Such a transition is analogous to that predicted by self-consistent models (e.g., Pedersen and Withers 1992). Furthermore, this is to be expected given the probable contiguity of both phases in the intermediate volume fractions.

7. Finite Element Modeling

Finite element modeling is becoming increasingly popular. This is due in part to the increased freedom one has in terms of reinforcement geometry and distribution, interface, and mechanical properties, and in part due to advances in computational power and user-friendly codes. With modern computers elastic models containing many thousands of elements can be constructed and solved quickly. The basic tenet underlying this approach is that one can describe the behavior of the composite through the performance of a representative unit cell. This is necessary because, except for a few idealized cases, the distribution of the phases is ill defined and chaotic. It is not normally possible to determine the complete arrangement of the phases in three dimensions over a volume comparable with mechanical test dimensions, and even if it were, it would not be computationally feasible to build a model with such a level of detail. As a result it is both computationally and experimentally desirable to exploit a unit cell. This may comprise many fibers in a matrix, but it is more usual to use a cell that may only comprise a part of one reinforcement and to rely upon symmetry operations to build up the complete composite structure. Of course the results are dependent on the precise reinforcement shape and distribution selected. On the whole, because thermoelastic properties are volume-averaged linear elastic properties, they are very well determined. In fact thermoelastic properties are relatively insensitive to local details (peak stresses and locations) and for this

reason the increased computational complexity involved in using finite element models is not usually warranted from the viewpoint of predicting thermoelastic properties. Of course this is not the case for nonlinear properties such as fatigue and failure.

8. Dielectric Constant and Electrical Conductivity

By convention the symbols for composite dielectric constant (ε) and electrical conductivity (σ) are the same as those for strain and stress respectively (Table 1) and so the two are treated separately from the mechanically coupled properties here simply to avoid confusion. Because many of the mathematical expressions for conductivity can be obtained simply by exchanging σ for ε in the corresponding equations for dielectric constants, this section is focused primarily on dielectric properties without loss of generality. All of the modeling strategies introduced in the preceding sections can be applied to the prediction of dielectric constants.

At the simplest level the summation rules described by Eqn. (4) act as extreme bounds representing the two phases as layers in series ($n = -1$) or parallel ($n = 1$):

$$\varepsilon_{\text{comp}}^{n} = f_1 \varepsilon_1^{n} + f_2 \varepsilon_2^{n} + f_3 \varepsilon_3^{n} + \cdots \qquad (30)$$

As an extension of this, Lichtencker proposed the empirical logarithmic mixing rule:

$$\log \varepsilon = \sum f_i \log \varepsilon_i \qquad (31)$$

The Rayleigh relation applies to a dilute dispersion of spheres:

$$\varepsilon = \varepsilon_{\text{M}} \frac{2\varepsilon_{\text{R}} + \varepsilon_{\text{M}} + 2f_{\text{R}}(\varepsilon_{\text{R}} - \varepsilon_{\text{M}})}{2\varepsilon_{\text{R}} + \varepsilon_{\text{M}} - f_{\text{R}}(\varepsilon_{\text{R}} - \varepsilon_{\text{M}})} \qquad (32)$$

and is equivalent to the Eshelby model and the HS lower bound (if $\varepsilon_{\text{R}} - \varepsilon_{\text{M}}$) or the upper bound (if $\varepsilon_{\text{R}} - \varepsilon_{\text{M}}$) for isotropic composites. Once again the opposite bound is found simply by interchanging the matrix and reinforcement properties. Maxwell's equation for resistivity is equivalent to Rayleigh's formulation with the dielectric constant replaced by resistivity. Self-consistent models have also been developed (Sect. 6) for which each phase is surrounded by the composite (ε) rather than phase one (ε_1). For example, for spheres (Hale 1976):

$$\varepsilon = \varepsilon_2 + \frac{3f_1 \varepsilon(\varepsilon_1 - \varepsilon_2)}{2\varepsilon + \varepsilon_1}$$

or equivalently

$$\varepsilon = f_1 \frac{\varepsilon_1 - \varepsilon}{\varepsilon_1 + 2\varepsilon} + f_2 \frac{\varepsilon_2 - \varepsilon}{\varepsilon_2 + 2\varepsilon} \qquad (33)$$
Figure 8
Plot of dielectric constant for TiO_2-fired clay composites (Kingery *et al.* 1976) alongside ROM, HS upper and lower bound, logarithmic, and series models. The Rayleigh relation and the Eshelby model are coincident with the lower bound predictions.

which is clearly symmetric with respect to both phases. All of these equations have direct analogues for electrical conductivity. Plots of dielectric constant for clay composites for the various models are shown in Fig. 8.

9. Composite Design

In attempting to identify attractive matrix/reinforcement combinations for a given application, it is often illuminating to derive "merit indices" for the performance characteristics required. These merit indices combine appropriate properties such that a single index can be maximized or minimized to optimize performance (Ashby 1993).

When considering new composite combinations, models have an important role to play. Generally, one would like to add a second phase that lies essentially perpendicular to the merit guide lines (shown as dashed lines) relative to the position of the matrix because this leads to the biggest improvements. Of course one needs to be careful to ensure that the properties of the composite do indeed lie between the extremes of the constituent phases. With regard to stiffness, for example, the composite will only have a stiffness intermediate between matrix and reinforcement if the two phases are well bonded to one another.

Predictive models give more precise information regarding the best properties that are likely to be achieved. For example, one could determine the optimal reinforcement loading/reinforcement geometry needed to obtain the target properties. Even in cases where it is not possible to make precise predictions, it is often possible to produce bounds on the best and worst properties that could arise. The framework for exploiting predictive composite models in composite
Figure 9
An elastic modulus/density selection map including bounds for the elastic modulus for polyester/glass-fiber composites. Of course on a log–log plot the ROM relation does not appear as a straight line. The dashed lines are $\sqrt{E/\rho}$ merit guidelines for designing light, but flexurally stiff, beams. Data measured parallel (filled circles) and perpendicular (open circles) to the fiber direction at various fiber fractions are also shown (Bintrup 1975) (after Ashby 1993).

design has been laid out by Ashby (1993). An example is given in Fig. 9. The stiffness/density data for glass fiber/polyester composites is well described by the upper (ROM) and lower (series) models for the axial and transverse properties respectively. Note that while better estimates than the ROM and series bounds could be employed, any difference would be relatively small on a log–log plot. In this example the axial composite performance is comparable to that of glass alone (merit index of $3\frac{1}{2}$) even at relatively low glass fractions ($<50\%$), but with the significant toughness and processing advantages characteristic of polymer composites.

Composites: Interfaces

The interface between matrix and reinforcement is important in all types of composite material. The nature of the interface can influence various aspects of the performance of the composite. For example, it may be essential to ensure that load is transferred efficiently between the two constituents, so as to capitalize on the high load-bearing capacity of the reinforcement. This can be particularly important if the aspect ratio of the reinforcement is relatively low. In other cases, it may be desirable for the mechanical characteristics of the interface to be such that debonding can occur, so as to deflect propagating cracks within the material and thus to promote energy absorption and raise the toughness. A further requirement concerning the interfacial region may be that it should be highly resistant to chemical attack or

to penetration of species from the environment. It is thus rather difficult to offer reliable generalizations concerning the optimal structure of interfaces in composites. Nevertheless, it is possible to identify certain principles, which can be applied when designing specific types of composite material. As a prelude to this, this article incorporates a brief outline of the technical procedures commonly used to study the mechanical characteristics of interfaces in different types of composite.

1. Mechanical Characterization of Interfaces

1.1 Interfacial Mechanics

There are two main approaches to the identification of parameters characterizing the "strength" of an interface in a composite. The simpler one is to assume that there is some critical stress level that will cause the interface to debond. This could be a normal stress acting transverse to the interface (crack opening, or mode I, loading) or a shear stress acting parallel to the interface (shear, or mode II, loading). In practice, both types of stress may be acting simultaneously (mixed-mode loading). It should be recognized that, whereas a crack in a monolithic material will always tend to follow a mode I path, an interface often represents a plane of weakness along which a crack will propagate even if the stress state at the crack tip is heavily mixed mode or pure shear.

One problem with critical stress level tests is that they tend to be initiation dominated. The measured stress level is usually that at which a crack is observed to propagate in an unstable manner. Such tests are therefore sensitive to the presence of flaws in the interface, at which local stress concentrations become sufficient to trigger crack growth. This initiation dependence tends to be rather marked for many composites, in which the interfaces are often relatively brittle regions. The flaws at which crack initiation occurs may be statistically representative of the structure of the interface, but they can also be created during specimen preparation. Furthermore, there is a danger with some types of test that local stress concentrations can be generated by small misalignments in the loading arrangements. It is certainly common to observe a wide scatter in measured critical stress levels for interfacial debonding. In general, a more reliable measure of interfacial "strength" can be obtained by adopting a fracture mechanics approach. This is based on examining the energetics of crack propagation. A crack will propagate under steady-state conditions when the driving force (expressed as an energy release rate per unit area of crack face) equals the fracture energy of the interface, which is a measure of its toughness (or strength). The initiation problem can be eliminated by ensuring that a pre-crack of suitable size is present before testing starts.

It is often a little complex to apply fracture mechanics-based tests to interfaces in composites—at least in conventional fiber composites. This is mainly because the geometry associated with a cylindrical surface means that calculation of the driving force for debonding (difference in stored elastic strain energy before and after crack advance) is not simple. Nevertheless, the disadvantages of critical stress measurements should be recognized and it may be noted that fracture mechanics analyses of several interfacial tests applicable to fiber composites have been developed. It should also be appreciated that both types of test are susceptible to effects arising from the presence of residual stresses. If the residual stress state is known, then it should be possible to introduce a correction for its effect on the apparent critical stress level or interfacial fracture energy, but in practice this effect is often overlooked or treated in a simplified manner.

Finally, a distinction should be drawn between initial debonding (crack propagation) and subsequent relative displacement of the crack flanks, i.e., frictional sliding. The latter can be of considerable importance in composites, particularly in terms of the energy absorbed during fiber pull-out—which is usually much greater than that associated with the initial debonding event. Moreover, frictional sliding usually takes place under quasisteady-state conditions, so that measured critical shear stresses for this process are expected to be more reliable than estimated critical stresses for debonding.

1.2 Test Procedures

Many test methods have been developed to interrogate the mechanical response of interfaces within composite materials. The main methods are listed in Table 1, together with an indication of some of their characteristics and identification of some references giving detailed information about them. Each test focuses on the behavior of single fibers or on the collective response of a group of fibers. In some cases, the test can be carried out on a conventional composite material, while in others it is necessary to manufacture a special specimen, commonly one containing a single isolated fiber. The table refers exclusively to fiber composites, in which the interfacial geometry is necessarily cylindrical. As a consequence of this, the interfacial stress state during testing is often predominantly mode II (shear parallel to the fiber axis).

In some of the tests, tensile stress normal to the interface is also imposed, so that mixed-mode loading is generated. (The residual stress state is often such that there is a substantial normal stress across the interface, but, since the thermal expansivities of most matrices are greater than those of most fibers, this is usually compressive and hence must be offset before a

Table 1
Classification of the tests developed for measurement of interfacial strength in fiber-reinforced composites.

Name	Entity tested	Type of specimen	Parameter measured	Loading mode	References
Fiber pull-out	Single fiber	Single embedded fiber	Critical stress or fracture energy	II	DiFrancia *et al.* (1996), Quek (1998), Zhang *et al.* (1999), Liu and Kagawa (2000)

Full fragmentation	Single fiber	Single embedded fiber	Critical fiber aspect ratio	II	Tripathi and Jones (1998), Shia *et al.* (2000), Park *et al.* (2000)
Protrusion (slice compression)	Group of fibers	Composite	Critical stress	II	Hsueh *et al.* (1996), Kagawa and Hsueh (1999)
Microbond	Single fiber	Single embedded fiber	Critical stress	II	Day and Young (1993), Schuller *et al.* (1998), Kessler *et al.* (1999)
Fiber bundle pull-out	Group of fibers	Composite	Critical stress or fracture energy	II	Domnanovich *et al.* (1996), Sakai *et al.* (2000)
Tensioned push-out	Single fiber	Composite	Critical stress	I/II	Watson and Clyne (1993), Kalton *et al.* (1994)
Cruciform transverse tension	Single fiber	Single embedded fiber	Critical stress	I/II	Majumdar *et al.* (1998)

mode I component to the loading can be generated.) It is thus difficult to generate pure mode I loading at a fiber–matrix interface (and, even if this were to be done, reliable detection of debonding events would be problematic in the absence of a shear stress). However, for certain types of composite, such as layered systems or coatings, the interface may be planar. Various tests have been developed for such interfaces, several of which allow mixed-mode or pure mode I loading.

2. Interfacial Microstructures and their Effects on Mechanical Properties

2.1 Polymer Matrix Composites

In most long-fiber polymer matrix composites (PMCs), random fiber fractures accumulate as the applied stress level is raised during axial loading. The extent of interfacial debonding, or local yielding in the interphase, determines the degree to which stress concentrations around fractured fibers become redistributed, and hence whether a catastrophic crack is likely to propagate from such fracture sites. It is therefore desirable for some kind of plastic strain accommodation to occur readily at the interface and in its immediate vicinity. However, in general interfaces in PMCs are required to be relatively strong and also to be chemically stable. For example, it is known that interfacial strength often dictates the transverse strength of a unidirectional laminate and first ply cracking of an angle-ply laminate. Furthermore, the interface must be resistant to the penetration of water and other solvents.

However, the way in which desirable properties are achieved varies somewhat, depending on the type of

fiber concerned. Early development of carbon fibers relied on optimization of surface oxidation (i.e., degree of adhesion) for a good balance of properties, whereas the properties of glass fiber composites have been optimized by choice of size composition. The use of sizing resins on carbon and aramid fibers is a better way of creating an interphase, which can control the stress concentration experienced by an adjacent fiber. It should be noted that very strong interfacial bonding (relative to the strength of the fiber) is often undesirable, since, not only will it tend to make the region around fractured fibers more prone to crack propagation, but it will also tend to eliminate fiber pull-out, which is an important source of toughening in PMCs. This rather complex set of requirements for the interface in PMCs has led to the evolution of manufacturing procedures that are specific to individual composite systems. As an example of the significance of these surface treatments, it can be seen from the data in Fig. 1 that the sizing can have a substantial effect on the strain to failure under transverse loading. This property is often of critical importance in determining the resistance of the composite to crack formation during applied loading and thermal cycling. Some details of the treatments commonly applied to different fibers are given below.

(*a*) *Carbon fibers*. Newly carbonized fibers do not adhere adequately to polymeric matrices. An essential stage of fiber manufacture is a surface treatment to optimize fiber–matrix adhesion. While inferior interfacial adhesion can lead to poor shear properties, over-treatment can render the composite brittle.

Carbon fibers, from acrylic or PAN precursors, are defined by the heat treatment temperature used for carbonization. High-modulus (HM) fibers tend to have a skin–core structure with a highly organized graphitic sheaf-like surface. The electrolytic oxidation employed commercially (with NH_4HCO_3 or $(NH_4)_2SO_4$ aqueous electrolytes) etches away the ends of the basal planes (which are parallel to the fiber axis) at the crystallite boundaries and functionalizes them, leading to a microporous structure exhibiting carboxylic acid, hydroxyl, amine groups, and active sites. However, with high-strength (HS) fibers, the less organized graphitic structure means that the functionalized edge sites will meet the surface at an angle.

After surface oxidation, the fibers are coated with a polymeric size, usually an epoxy resin. Whether this resin coating can be subsequently dissolved efficiently into the matrix is unclear. This aspect of the fiber–matrix interaction in carbon fiber composites is under-researched, but the possibility of a matrix–size interface also needs to be considered.

(*b*) *Glass and polymeric fibers*. For glass fiber-reinforced plastics (GRPs), the surface treatment for the
Figure 1
Stress–strain plots (Benzarti *et al.* 2001) for aligned, long fiber glass-reinforced epoxy composites, during loading in transverse tension, illustrating the effect of various fiber sizings. The sizings are: A, a commercial sizing containing bifunctional DGEBA prepolymers; B, methyl-phenyl-silicone (an elastomer, miscible but nonreacting with epoxy resins); C, a trifunctional epoxy; D, penta-glycidyl ether of cyclosilicone (reactive with the matrix and with a flexible backbone).

fibers is more complex. Interfacial debonding is generally not observed and "matrix" yielding is the most probable interfacial event. (For high-performance polymer fibers, "interfacial" failure is likely to occur within the fiber, because of their poor transverse properties.) Surface treatments have therefore been developed that generate cross-linked polymeric coatings. It is perhaps more appropriate to describe the interfacial region as an "interphase," which may include material that has penetrated the fiber surface and has different properties from those of the matrix.

The surfaces of commercially available glass fibers (principally E-glass) have in many cases been developed specifically to facilitate composite manufacturing, with ease of handling often being at least as important as optimization of interfacial properties. The finish is applied to glass fibers immediately after water cooling at the bushing during fiber production. Typically, an aqueous emulsion consisting of the following is deposited at a rubber roller:
(i) adhesion promoter or coupling agent;
(ii) protective polymeric size or film former; and
(iii) lubricant.
Items (ii) and (iii) impart good ease of handling, and controlled wet-out kinetics with matrix resins, and are therefore chosen for compatibility during the fabrication process. For chopped fibers (chopped strand mat), an additional polymeric binder (emulsion or powder) is often deposited. For specialist requirements, such as high environmental resistance, the chemical nature of the size and binder are crucial. Item (i) is generally an organosilane, trifunctional in

alkoxy groups and monofunctional in a matrix-reactive or matrix-compatible group. A common one is γ-amino propyl triethoxysilane (γ-APS). It acts to displace adsorbed water, to create a surface that can be fully wetted by the resin, and to develop strong interfacial bonds. On hydrolysis, the silane will be deposited as a complex mixture of oligomer and polymer, of which part is chemically bonded to the surface. Thus, after composite manufacture, a bonded semi-interpenetrating network of silane and matrix containing the polymeric size will form. With the diffusion of the oligomeric silane component into the matrix, a complex interphase will be created.

2.2 Metal Matrix Composites

In metal matrix composites (MMCs), the objective of introducing the reinforcement may be enhancement of stiffness, creep resistance, wear resistance, etc. It is often a prime requirement that these enhancements should be achieved without unacceptable degradation to the toughness. The scope for generating energy absorption in MMCs by processes such as fiber pull-out is usually small compared with that which is potentially available via matrix plasticity, provided the reinforcement disposition and interfacial characteristics are not such that it becomes severely inhibited or constrained. Poor bonding commonly leads to premature failure, for example by interfacial cracking or cavitation, whereas a high bond strength allows at least relatively high levels of matrix plasticity to be induced.

Another factor of significance for many types of MMC concerns interfacial chemical reaction. Processing to produce MMC materials and components commonly involves high temperatures. During such processing, the high reactivity of the metal often leads to the production of thick interfacial layers (e.g., of intermetallic compounds), which tend to be defective and brittle. These usually embrittle and weaken the composite as a whole. An example of this effect is shown in Fig. 2, which demonstrates how the tensile strength of monofilament-reinforced titanium MMCs is degraded as the interfacial reaction layer thickness increases. It is often possible to control such layer formation by the use of protective coatings on the fibers, although this is more difficult for particulate MMCs.

2.3 Ceramic Matrix Composites

The objective of making a composite material based on a ceramic matrix is usually to raise the toughness. This is commonly achieved by ensuring that there are weak interfaces present, at which cracks are deflected. Fabrication of such composites has always presented something of a challenge, although it is certainly easier with layered structures than with fiber reinforcement.
Figure 2
Experimental and predicted variation of composite strength with interfacial reaction layer thickness for axial tensile loading of two long-fiber composites—CP Ti and Ti–6Al–4V matrices reinforced with the SCS-6 monofilament (Onzawa *et al.* 1991). The predictions are obtained using a simple fracture mechanics-based model.
Figure 3
Effect on mechanical properties of carbon coatings on Nicalon fibers in a SiC matrix. The plot is of measured interfacial shear strength (from push-down testing) and material toughness (from the area under the stress–strain curve during loading along the fiber axis) as a function of coating thickness (Lowden 1993).

In both cases, there is usually a requirement for extended periods at elevated temperature and this tends to cause interfaces to sinter and strengthen. It is, however, sometimes possible to introduce an interfacial coating of some sort which inhibits this. For example, graphite layers are often introduced for this purpose. Data are shown in Fig. 3 that illustrate the

228

effects involved. The plot shows interfacial and macroscopic mechanical properties for composites made up of graphite-coated Nicalon fibers in a SiC matrix. Raising the thickness of the graphite layers leads to a decreased interfacial shear strength, but an increase in the toughness of the composite.

3. Summary

The nature of the matrix–reinforcement interface within a composite often has a profound effect on its overall properties. In general, interfaces in PMCs must be relatively strong, to promote good load transfer and to ensure that transverse properties are adequate, but not so strong as to create stress concentrations and eliminate fiber pull-out during fracture. In addition, they are often required to be chemically stable, to confer good environmental stability. It is in some cases beneficial to generate an extended interfacial region having a structure and properties different from those of the matrix—the so-called "interphase." Various chemical fiber surface treatments have been developed to achieve desirable interfacial structures in PMCs. For MMCs, the main objective is normally to ensure a strong bond, especially for particulate and short-fiber composites. Optimization of composite toughness comes from retention of as much matrix plasticity as possible. Avoidance of the formation of brittle interfacial reaction zones during processing is often a priority. Finally, in ceramic matrix composites it is usually desirable to retain weak interfaces, thus maximizing crack deflection and the associated energy absorption during mechanical loading. It is often necessary to take special measures to ensure that the interfaces remain poorly bonded during composite production.

Concrete as a Building Material

Concrete is the most widely used engineering material in the world, with an annual consumption of around 5 billion tonnes. Concrete structures, including buildings, bridges, power plants, dams and other hydraulic structures, constitute a large part of the modern civil infrastructure. The major constituents of concrete are Portland cement, aggregates, and water. When mixed together, the cement reacts with water to form a binder that holds the aggregates together. The resulting composite material is strong in compression but relatively weak in tension. Therefore, steel reinforcements are often incorporated to carry the tensile stresses. Since reinforced concrete is covered elsewhere in this encyclopedia, the present article will focus on plain concrete alone (see *Reinforced Concrete**).

The typical properties of concrete are listed in Table 1, together with those for steel, its major competitor for the construction of large structures. It is obvious that steel is far superior in terms of strength and modulus. However, the low cost of concrete makes it the material of choice in many cases. Moreover, the energy content of concrete (i.e., the energy consumed in producing a unit volume of the material) is much lower. Its use over steel is therefore favorable from an energy and environmental conservation viewpoint. As a construction material, concrete possesses a number of other advantages. Since concrete stays plastic for some time after the constituents are mixed, members of complex shapes can be easily constructed by casting. The shape flexibility makes possible the minimization of joints, and can enhance the aesthetics of structures. With high resistance to both water and fire, concrete is widely used in dams and hydraulic structures as well as in buildings. In building applications, concrete also offers good thermal insulation that serves to reduce the energy cost for heating/cooling.

1. Constituents of Concrete

Cement is the binding phase in concrete and it usually constitutes about 15 to 25% of the concrete weight. Details on cement production, composition, hydration, and microstructures are provided in a separate article in this encyclopedia (see *Portland Cement**). Here, it suffices to mention that the cement content in the concrete, and the water/cement ratio, are important parameters governing the properties of concrete at the fresh and hardened states, as well as durability in the long term. Aggregates in concrete are classified into coarse and fine aggregates, with the boundary set arbitrarily at about 4.75 mm (3/16 in), which is the size of a No. 4 sieve. For fine aggregates, the smallest size is often around 0.075 mm. For reinforced concrete structures, the maximum aggregate size seldom goes beyond 25 to 40 mm, as the aggregates need to be smaller than the reinforcement spacing by a certain margin. For mass concrete, aggregates up to 150 mm in size are commonly used.

In most concrete constructions, aggregates are obtained from local sources. Indeed, any natural or crushed aggregate can be used in concrete provided the following requirements are satisfied. The aggregate should be strong, dense, and difficult to cleave. Also, it should not react with alkalis (e.g. NaOH or KOH) in cement. Aggregates contaminated with deleterious materials, such as organic impurities or salt, need to be washed until they are clean. The soundness of aggregates is important as well. In other words, the aggregate should be dimensionally stable under

Table 1
Comparison between concrete and steel as construction materials.

Material	Concrete	Steel
Density ($kg\,m^{-3}$)	2400	7800
Strength (MPa)	3–6 (tension)	250 to >1000
	30–100 (compression)	
Failure strain (%)	~ 0.01 (tension)	10 to 35
	0.1–0.2 (compression)	
Young's modulus (GPa)	30–50	210
Energy requirement ($GJ\,m^{-3}$)	3	300
Energy content ($kWh\,m^{-3}$)	400–800	~ 20000
Cost ($\$\,tonne^{-1}$)	20–50	250 to >1000

environmental changes such as freezing/thawing and wetting/drying.

Most natural aggregates have a density between $1520\,kg\,m^{-3}$ and $1680\,kg\,m^{-3}$, and are referred to as normal weight aggregates. The density of concrete produced with these aggregates is around $2400\,kg\,m^{-3}$. The strength of normal weight aggregates ranges from 70 to 350 MPa. This is sufficient for common applications. However, when high-strength concrete (with strength up to or above 100 MPa) is to be produced, the engineer needs to ensure that strong aggregates are employed. In some cases, to reduce the loading on the foundation or supporting structures, it is desirable to reduce the dead weight of the superstructure. Lightweight aggregates, with a density of below $1120\,kg\,m^{-3}$, are used to produce concrete with a density below $1850\,kg\,m^{-3}$. Lightweight aggregates can be obtained from natural sources (e.g., volcanic tuff or pumice) or produced artificially through thermal treatments of clays, slag, fly ash, etc. Heavyweight aggregates are defined as those with a density above $2080\,kg\,m^{-3}$. Examples include barium ore, iron ore, or steel shots. With the capability to attenuate gamma rays, x-rays, and neutrons effectively, heavyweight aggregates are used in radiation shields for hospitals and nuclear power plants.

Water for making concrete should ideally be suitable for drinking. Impurities in water may affect the setting of cement, reduce the strength of concrete, cause staining of the concrete surface, or lead to corrosion of the steel reinforcement. In reality, the use of undrinkable water is not necessarily harmful. When in doubt, setting time and strength tests can be carried out on samples made with both clean water and the water of unknown quality. Note that some impurities such as salt do not affect concrete properties but can significantly accelerate steel corrosion. Seawater should therefore never be used.

Besides water, cement, and aggregates, other materials may be added to concrete for various purposes. These materials are collectively called admixtures, and may be broadly categorized into surfactants, set-controlling admixtures, and mineral admixtures. Surfactants are long-chain organic molecules adsorbed to the surface of cement particles. Some surfactants are air-entraining agents as their presence will lower the surface tension, leading to formation of small bubbles around solid particles. With a uniformly distributed system of small bubbles, the freeze/thaw resistance of concrete can be greatly improved. Other surfactants, called water-reducing admixtures, introduce charges on the surface of cement particles, causing repulsion and dispersion. As a result, water trapped inside flocculated cement particles is released, thus improving the flow properties of concrete. A surfactant that is particularly effective in water reduction (several times more effective than normal water-reducing agents) is called a superplasticizer, and it is a key component in the production of high-strength and high-workability concrete.

Set-controlling admixtures are added to retard or accelerate the hydration reaction between water and cement. When concreting is carried out in hot weather, the chemical reaction is so fast that setting may occur very rapidly, allowing little time for proper placing and finishing. Also, the rapid generation of hydration heat may lead to degradation in long-term strength. The addition of a set-retarder can alleviate the situation. Conversely, during cold-weather concreting, to attain sufficient strength within a reasonable period of time, an accelerator is required.

Surfactants and set-controlling admixtures are often added to the cement in small amounts ($<1\,wt.\%$), and their addition has no effect on the final hydration products. Mineral admixtures, on the other hand, are applied in much larger quantities (over $10\,wt.\%$). Mineral admixtures are available in nature, with the volcanic glasses used in Roman concrete being classical examples. However, most mineral admixtures employed today, such as fly ash, blast furnace slag, and silica fume, are byproducts of industrial processes. The use of such admixtures in concrete therefore also provides the solution to a waste disposal problem. Many common mineral admixtures are

pozzolans. By definition, these are materials that possess no cementitious properties on their own, but can react with calcium hydroxide (a reaction product of cement hydration) to form cementitious materials. Examples include low-calcium fly ash and silica fume. Others, such as blast-furnace slag, can react directly with water to form a cementitious material. High-calcium fly ash is both pozzolanic and cementitious. Due to their cementitious or pozzolanic properties, mineral admixtures are often used to replace part of the cement in the concrete. By reducing the cement content, heat of hydration is reduced, thus lowering the chance of thermal cracking in thick structures. When fly ash or blast furnace slag is used to replace cement, the early strength is usually reduced, but the ultimate strength is higher than that of concrete without cement replacement. For silica fume, its small size allows the pozzolanic reaction to occur very rapidly, resulting in higher early strength as well. With the use of mineral admixtures, the final microstructure of the concrete becomes denser and less permeable. Both the strength and durability of concrete are thus improved.

2. Concrete at Fresh State

After the constituents are mixed, concrete initially behaves as a fluid and can be cast to form the required shape. As the cement hydration reaction progresses, concrete will eventually change from a fluid to a rigid state. This stiffening process is referred to as setting. Stiffening is indeed a gradual process, but two reference points in the process, referred to as initial set and final set, have been defined. These points are obtained through a standard penetration resistance test. Physically, the initial set represents the approximate time when the concrete can no longer be properly mixed and compacted. The final set is the approximate time when concrete strength starts to develop at a high rate. In engineering applications of concrete, knowledge of initial and final set values can allow the proper scheduling of various operations, such as mixing, placing, and formwork removal.

To make concrete components of good quality, the fresh concrete must exhibit good workability. Workability can be defined as the property governing the required effort to place, compact, and finish a concrete mix with minimum loss of homogeneity. It can be described in terms of two separate components, consistency (the ease of flow) and cohesiveness (the tendency for segregation). Workability, as formally defined, is very difficult to measure. For practical applications a number of simple tests, including the slump test, Vebe test, compacting factor test, flow table test, and the ball penetration test, have been developed. The ASTM and BS publications contain details of the tests (see, for example, Klieger and Lamond 1994). It should be noted that the above tests attempt to measure consistency only. Cohesiveness is often assured through empirical knowledge regarding the proportioning of concrete mix, as well as proper procedures during concrete transportation and placing to prevent segregation.

The workability of concrete is affected by many factors. By increasing the water content, consistency is improved. For example, by keeping the same water/cement ratio but increasing the cement/aggregate ratio, the mix exhibits higher workability. For the same water/cement/aggregate ratio, consistency can be improved by using coarser sand, and by replacing rough aggregates with round/smooth ones. When the consistency of the mix becomes too high (e.g., through the excessive use of water), the components tend to separate, and the cohesiveness is adversely affected. Care should therefore be taken to achieve an optimum. In some cases, cohesiveness and consistency can be improved at the same time. Examples include the partial replacement of fine aggregates with small fly ash particles, and the addition of silica fume to very low water/cement ratio mixes. Besides material parameters, the type of construction also affects workability. For example, a mix may have sufficient workability for a lightly reinforced concrete slab, but is not workable for the heavily reinforced wall of a power plant. Workability also varies with time. At a longer time after mixing the consistency becomes lower due to the loss of water through absorption, evaporation, and chemical reaction. This reduction in consistency is commonly referred to as slump loss. It occurs most commonly in hot weather, and can be prevented by using ice to replace part of the mixing water.

In most concrete constructions the concrete is batched and mixed in a central plant, and transported to the site. During transportation, agitation is applied to prevent segregation. After arrival at the site, concrete is placed as near as possible to its final position. Compaction is achieved through the use of internal immersion-type vibrators or external form-type vibrators. During vibration, it is common for water to separate from the other components, and travel upwards. This phenomenon is known as bleeding. Most bleed water gets to the concrete surface, but some will be trapped under large aggregate particles or the reinforcing bars to form weak zones with an increased water/cement ratio. Some methods to reduce bleeding include the use of finer cement particles, addition of fine pozzolans or air entraining agents, and the reduction of water content (provided sufficient workability can be maintained).

After casting and compacting, concrete needs to be properly cured for strength development. The objective of curing is to keep concrete wet until the hydration reactions have progressed to a certain level. It is usually achieved by water spraying, ponding, or by covering concrete with wet sand, hessian, or burlap. Curing membranes, which are plastic sheets applied

on the concrete surface, can also be used. In most cases, curing needs to be carried out for seven days. At lower temperatures, longer time is required. If curing is not properly carried out, the ultimate strength of concrete can be significantly affected. Moreover, if there is excessive surface water evaporation when concrete is still in the plastic state, plastic shrinkage will occur. In many cases, plastic shrinkage is accompanied by surface cracking. Besides being unsightly, the cracks often run on top of steel reinforcements, and act as convenient paths for water to reach the steel. The durability of the concrete structure will then be affected.

Besides site casting, concrete members can also be precast in the factory and transported to the site for assembly. This approach is advantageous when the same type of component is repeatedly used in different parts of a structure, or in a large number of identical structures. In precasting, concrete is often placed and compacted in the same way as in site casting. Research has demonstrated the possibility of fabricating concrete components through a continuous extrusion process. The extrusion approach is particularly suitable for nonstructural components such as tiles, pipes, roofing, and partition walls. To improve the properties of extruded products, small fibers are often added. In precasting work, the turnover rate is an important consideration, and it is desirable to accelerate the development of strength so that the final product can be delivered to the site at the earliest possible time. Steam curing is the common approach to obtain high strength at an early age. Various researchers have investigated the use of microwave energy to accelerate concrete curing, and the results appear to be promising.

3. Hardened Concrete Under Loading

The mechanical behavior of concrete depends on properties of the hardened cement paste, the aggregates, and the interphase between the aggregate and the paste. The paste–aggregate interphase is a thin layer of cementitious material (about 10–20 μm in thickness) around the aggregate that possesses a higher porosity than the bulk paste. Its formation is attributed to ineffective particle packing at the aggregate surface (compared with the bulk), as well as the trapping of bleed water at the bottom of the aggregates. For normal weight concrete, the interphase is weaker than both the aggregate and the bulk paste. Also, when loading is applied, stress concentrations exist around aggregates due to the mismatch in paste and aggregate modulus. Low strength of the interphase, together with the presence of stress concentration, makes it the weakest link at which damage will start.

The stress–strain curves for two different types of concrete are shown in Fig. 1. Compressive behavior is
Figure 1
Stress–strain curves for normal and high-strength concrete (positive sign is used for compressive stress and strain).

shown on the positive quadrant. The lower curve represents normal-strength concrete, while the upper one is an example of high-strength concrete. For both types of concrete, the compressive behavior is approximately linear up to about 30–40% of the ultimate strength (for normal- and high-strength concrete, respectively). Nonlinear behavior then commences due to the formation of microcracks within the interphase. When compressive loading is gradually increased beyond the linear range, the microcracks initially propagate in a stable manner, first along the aggregate surfaces, and then into the cement paste. On further loading, some of the microcracks coalesce into localized macrocracks. Unstable propagation of the macrocracks leads to the "crushing" of concrete (or disintegration into multiple fragments) when the compressive strength is reached.

Many features about the failure of concrete can be explained in terms of the cracking process. Since repeated loading can accelerate the propagation of cracks, concrete strength under cyclic loading is lower than the static strength. Under a given loading, cracks can grow to larger sizes if sufficient time is allowed for the propagation to occur. Therefore, if concrete is stressed to a high level (above 75% of the ultimate load) and the loading is maintained, failure will eventually occur. Since crack formation and propagation is accompanied by an increase in volume, the presence of confining stress can delay and stabilize crack growth. As a result, both the compressive strength and ductility of concrete increase with lateral confinement.

When concrete is under tension, the growth and coalescence of microcracks occur much more easily.

Crack localization and tensile failure therefore occur at a stress significantly lower than the compressive strength. An empirical formula relating the tensile strength (f_t) and compressive strength (f_c) is given by:

$$f_t = 0.615(f_c)^{0.5} \quad \text{(for 21 MPa} < f_c < \text{83 MPa)}$$

Substituting numerical values for f_c, f_t is found to be around 7–13% of the compressive strength, with a lower f_t/f_c ratio for higher concrete strength. In the above formula, f_c is obtained from the direct compression of cylinders while f_t is measured by the splitting tensile test. In some countries, compressive strength is obtained from the cube specimen instead. Due to the effect of lateral constraint from the top and bottom platens, the cube strength can be higher than the cylinder strength by 5–25%. Normally, the two measurements become closer as concrete strength is increased. To measure the tensile behavior of concrete, the flexural test is also commonly performed on a standard beam specimen. Depending on the concrete mix, the flexural strength is 50–100% higher than the splitting strength.

The water/cement ratio (w/c), or water/binder ratio when mineral admixtures are employed, is the most important factor governing concrete strength. The variation of f_c with w/c is shown in Fig. 2, where the two curves represent the upper and lower bounds. As cement hydration progresses, the space originally occupied by water is filled with hydration products. For a lower w/c, a relatively large amount of hydration products is available to fill a smaller space. The hardened cement paste (both in the bulk and within the interphase) becomes denser. Hence it is
Figure 2
Variation of concrete strength with water/cement ratio (lines represent upper and lower bounds).

more difficult for crack initiation and growth to occur. While it is possible to make high-strength concrete by reducing w/c alone, it is often more effective to increase concrete strength with the addition of pozzolanic admixture as well. The pozzolanic reaction converts calcium hydroxide, the weak phase in the hardened paste, into C–S–H gel, the major cementing material. Also, when very fine particles such as silica fume is added, microvoids are filled and the compactness of the material is improved. It should be noted that concrete workability is significantly reduced when w/c becomes very low. The addition of superplasticizer is then essential to maintain the proper rheological properties.

Other factors affect concrete strength besides w/c. If the aggregate is weaker than the hardened cement paste, concrete strength will be limited by aggregate failure. Rough and angular aggregates make stronger concrete than round and smooth ones, as it is more difficult for cracks to go around them. With larger aggregates, the size of the weak interfacial zone is also increased, resulting in reduced strength. For the production of high-strength concrete the maximum aggregate size is therefore limited to 19 mm. The curing process also has an important effect on strength. High temperature at the initial curing stage leads to more rapid strength gain, but the long-term strength is reduced. For concrete with admixtures, the amount of admixture added as well as its type (silica fume, fly ash, slag, etc) strongly affects the final strength. The effects of these other variables are reflected in the width of the "band" in Fig. 2, which shows the variation of f_c for a given w/c.

The elastic modulus of concrete is usually determined from test data up to about 50% of the ultimate strength (i.e., within or slightly beyond the linear range). From Fig. 1, it can be observed that high-strength concrete also has a higher modulus. In high-strength concrete, the w/c is lower, and hence both the hardened paste and the interphase are denser and stiffer. Also, to make high-strength concrete, good quality aggregates with lower porosity are often employed. With all the components being stiffer, the composite modulus of concrete is increased.

In the design of most reinforced concrete structures, the low tensile strength of concrete is neglected and steel reinforcement is relied upon to carry the tensile load. However, in a number of situations, such as the failure of anchoring elements in concrete, bond failure of steel reinforcements, cracking in concrete dams, failure of unreinforced concrete pipes as well as shear and torsional failure of concrete members, the structural capacity is strongly dependent on the tensile properties of the concrete. In these cases, the governing material parameters include not only the tensile strength, but also the postpeak tension-softening curve (Fig. 3). Physically, the softening behavior results from the bridging of cracks by aggregates, and it therefore reflects the ability of the
Figure 3
Derivation of the tension-softening curve from the complete tensile behavior.

material to resist crack propagation. The study of tension softening and its proper implementation in computational analysis have been two major foci in the investigation of the fracture mechanics of concrete.

Currently, computational tools are available to simulate structural behavior when failure is dominated by the tensile behavior of concrete (e.g., as in the situations mentioned above). Moreover, with improved understanding of tensile failure in concrete, it is now possible to explain and quantify the well known "size effect" in concrete structures. The capability to quantify this phenomenon of decreasing load carrying capacity with increasing member size is of great engineering significance.

The area under the tension-softening curve represents the total energy required to create a unit area of crack surface, and is called the fracture energy (G_F). A characteristic length, l_{ch}, defined as EG_F/f_t^2, where E is Young's modulus, is an useful parameter reflecting the brittleness of concrete. With a lower value of l_{ch}, failure will occur in a more brittle manner. As concrete strength is increased, f_t increases at a faster rate than E and G_f. As a result, failure of high-strength concrete occurs in a more catastrophic manner than normal strength concrete.

The incorporation of fibers is an effective way to improve the crack resistance of concrete and reduce its brittleness. Fibers made of steel, glass, polypropylene, carbon, PVC, and other polymers are commercially available. With fiber addition, besides the increase in fracture energy, the flexural strength, shear strength, fatigue resistance, and impact resistance of concrete can all be increased. More importantly, the "ductility" of concrete, indicated by the deformation capacity before final failure, is greatly improved. Indeed, when the fiber volume fraction goes beyond a critical value, concrete will show a pseudo-strain-hardening behavior under tension: after first cracking,

stress will continue to increase with strain. Physically, this is due to the high bridging stress provided by the fibers that makes possible the formation of multiple fine cracks in the member as loading is increased beyond first cracking. Pseudo-strain-hardening concrete has very high shear strength and energy absorption as well as excellent crack control. Fibers are therefore very useful in improving the durability and seismic resistance of concrete structures.

When concrete is kept under sustained loading, creeping occurs and the deformation increases with time. Many theories (e.g., moisture diffusion, gel sliding, microcracking, etc.) have been proposed to explain the mechanism of concrete creep. However, no universal theory that can explain all the experimental observations is yet available. Since creeping occurs in the cement paste only, it can be reduced with the use of stiffer aggregates, or a higher aggregate fraction. Being a thermally activated process, creep increases with temperature. When air humidity is low, or when the concrete member has a large surface/volume ratio, there will be increasing moisture movement from the concrete to the surrounding environment, resulting in more creep. The creep of concrete is also affected by the density (or gel/space ratio) of the hydrated cement. With lower w/c and higher age (or higher maturity) when loading is applied, creep is reduced.

Time-dependent dimensional change of concrete can also occur under zero applied loading. When moisture moves out of concrete drying shrinkage occurs. Since both drying shrinkage and creep are dependent on moisture movement and are governed by the behavior of the cement paste, many parameters affect both in a similar manner. Shrinkage also occurs as carbon dioxide reacts with calcium hydroxide in the paste to from calcium carbonate. Since carbonation proceeds slowly from the surface of the concrete, carbonation shrinkage only occurs in the

surface layer. Its effect, however, is implicit in many experimental data for concrete shrinkage. Under many common situations, concrete shrinkage is restrained and tensile stresses are induced. To prevent excessive shrinkage cracking, reinforcements in the form of rods or fibers are incorporated for crack control.

In practice, design charts are available for the prediction of creep and shrinkage. Note that shrinkage occurs simultaneously with creep when the concrete member is under loading. The effect of shrinkage is therefore implicit in the charts for creep.

4. Other Important Properties of Concrete

The thermal properties of concrete are of interest in that nonuniform or restrained thermal expansion and contraction induce stresses. The thermal conductivity and heat capacity of concrete govern the insulation and energy efficiency of buildings with concrete walls. In concrete buildings, fire resistance is an important concern. The expansion coefficient (α) of concrete depends on the aggregate type, the mix proportion, the age of the concrete, and moisture content. For both normal and lightweight concrete, α ranges from 7.5 to $13 \times 10^{-6} \, \mathrm{K}^{-1}$. The thermal conductivity of concrete increases with material density (or, decreases with porosity). The value ranges from 1.5–$3.5 \, \mathrm{Wm}^{-1}\mathrm{K}^{-1}$ for normal-weight concrete to 0.5–$1.1 \, \mathrm{Wm}^{-1}\mathrm{K}^{-1}$ for lightweight concrete, which is more porous. The heat capacity of concrete is insensitive to the aggregate type, but is dependent on the porosity (or w/c) and moisture content of the cement paste. Its value normally ranges from 800 to $1200 \, \mathrm{J\,kg}^{-1}\mathrm{K}^{-1}$. In the case of fire, the high heat capacity delays the heating-up of concrete members. Also, the low thermal conductivity delays the penetration of heat into the members. As temperature increases, the strength of concrete is reduced. However, up to $500\,°\mathrm{C}$ concrete can still retain up to 75% of its room temperature strength. The fire resistance of concrete is better than steel and timber, the other two major construction materials. Indeed, concrete is often employed in buildings for the fire protection of steel members.

The electrical properties of concrete are useful parameters for the nondestructive evaluation of concrete structures. The resistivity of the concrete cover is an indicator of the probability of steel corrosion, as low resistivity limits the flow of ions around the steel and hence slows down electrochemical reactions. When radar is employed to measure the thickness of concrete members, or to identify delaminations, the wave velocity depends on the dielectric constant of concrete, while the depth of penetration is a function of both the dielectric constant and conductivity. Values of these parameters are therefore required for the choice of radar wavelength and proper interpretation of results.

5. Durability of Concrete

To design durable concrete structures, a good understanding of the deterioration mechanisms of concrete is essential. Concrete may degrade under physical action, chemical action, or a combination of the two. An example of physical action is the freezing of water in saturated capillary pores. The volume increase due to ice formation induces high local stresses and microcracking. With repeated freezing and thawing, damage becomes more severe. To protect concrete from freeze-thaw damage, air-entraining agents are used to introduce small bubbles (0.05 to 1 mm in size) at close spacing (about 0.2 mm). When ice starts to form in the capillary pore, the unfrozen water, which is under pressure, moves to the bubbles and is temporarily stored. With part of the water moving out of the capillary pore, freezing no longer introduces high stresses. Air entrainment increases the overall porosity of concrete but this reduces the strength for a given w/c. However, the incorporation of air bubbles improves the consistency of concrete. Keeping the same workability, the strength reduction can be partly compensated for by using a lower w/c.

Concrete degrades in the presence of sulfates (e.g., from groundwater). Calcium sulfate reacts with monosulfate hydrate (a hydration product of calcium aluminate in the cement) to form an expansive reaction product. The physical effect of expansion results in disruption of the concrete. Sodium sulfate can also react with the calcium hydroxide; with magnesium sulfate the C–S–H gel is attacked as well. The chemical conversion of calcium hydroxide and C–S–H into calcium sulfate reduces the strength and stiffness of the paste. The severity of sulfate attack therefore depends on the cation and increases in the order calcium—sodium—magnesium. To control sulfate attack, cement with a low percentage of calcium aluminate can be used. As the chemical reactions involve water, a low w/c can be specified to achieve lower concrete permeability. The replacement of cement with pozzolans is also effective as a means to remove the hydroxide, "dilute" the aluminate, and decrease the concrete permeability.

When the aggregates of concrete contain certain minerals (such as glassy silicates or dolomite), and the cement contains a relatively high alkali content ($>0.6\%$ sodium equivalent), alkali–aggregate reaction will occur. The absorption of water, by either the reaction product or minerals exposed by the reaction, leads to expansion and internal stresses. To prevent alkali–aggregate reaction, cement with low alkali content or nonreactive aggregates should be employed. In cases where this is not practical, the concrete surface can be coated to prevent water penetration.

The corrosion of steel reinforcements in concrete structures is a major durability problem. When the pH inside concrete is high, a stable iron oxide layer is formed on top of the steel, and corrosion is not a

In the continual quest for improving concrete performance, it was soon realized that the size of aggregates is an important factor. By using very fine aggregates, superplasticizers, and a high dose of silica fume (about 20–30% of the cement content) concrete strength beyond 200 MPa can now be achieved by conventional techniques. One example is DSP—densified system with fine particles. Using strong aggregates of small size (e.g., calcined bauxite with maximum size of 4 mm), DSP with compressive strength over 250 MPa can be produced. Reaction powder concrete (RPC) is another example. With the maximum particle size limited to 0.4 mm, the compressive strength reaches 170 MPa by 28 days under room temperature curing. Curing at 80–90 °C will further increase the strength to 230 MPa. If pressure is applied before and during setting, and curing is carried out at 400 °C, strength as high as 680 MPa can be attained. With very high strength, both DSP and RPC are extremely brittle. Fiber reinforcement is therefore essential to prevent catastrophic failure at ultimate load.

Concrete: Failure Mechanics

Concrete is a heterogeneous engineering material made from hydraulic cement (most common is Portland cement), aggregates, and water. Modern concretes contain many different additives to improve the density, compressive strength, and workability of the material. It is used extensively in the building and civil engineering construction industry. For the design of sound economic and durable structures knowledge of fracture mechanics of concrete is essential. For structural design, fracture mechanics helps to assess the limit state of the structure under consideration and the safety against collapse can be assessed. For development of new concrete composites, fracture mechanics may help in the design of materials with the best deformation, strength, and fracture toughness characteristics. This article deals with the failure mechanisms of this composite material at the micro-, meso-, and macroscale.

1. Size and Scale Levels

In principle the size range can be extended, but for practical purposes these three levels suffice. At the microlevel the structure of cement is widely accepted. The characteristic size is 10^{-6} m. The buildup of the cement from calcium silicate hydrates (CSH), calcium hydroxide, and water films between the different microstructural elements determines the strength and fracture toughness. Furthermore, the porosity either in the cement structure itself (gel pores) or between the CSH crystals as open space left over after excess water has evaporated from the cement is important for strength and toughness. The structure of hydrated cement is shown schematically in the lower left of Fig. 1. Observing the cement with larger or smaller magnification reveals more or less fine detail. In fact the fluctuations in microstructure diminish when the scale increases. This is shown schematically in the upper part of Fig. 1.

With increasing size scale, the cement can be regarded as a continuum: the microstructure is small with regard to the size of the structural element. For concrete, the mesolevel is now reached. The characteristic size is 10^{-3} m, and individual aggregate particles, larger entrained air bubbles, patches of
Figure 1

Multiple cracking leading to branching and bridging (after van Mier 1991).

hardened cement, and a distinct open interfacial transition zone between aggregates and cement matrix are observed. Again, the mesostructural fluctuations are large at a small scale, and diminish with decreasing resolution. The mesolevel with varying mesostructural fluctuations is shown schematically in the lower center of Fig. 1. One of the most important features at the mesolevel is the aggregate skeleton of the concrete.

Finally, the macrolevel is reached on further decreasing resolution. At this level the structural fluctuations from the cement microstructure and aggregate mesostructure cannot be observed any more, and the material is considered as a continuum (lower right of Fig. 1). Applications of concrete in structures are commonly in combination with steel reinforcement as the concrete itself has little bearing capacity in tension. At the macrolevel, the reinforcement forms its own structure, and again (macro-) structural fluctuations will appear when analyzing the behavior of reinforced concrete structures.

Modern concretes contain additions such as condensed silica fume to improve the uniaxial compressive strength, even above 200 MPa, the ductility, or fracture toughness with the addition of smaller or larger quantities of fibers. Attempts have also been made to improve the workability or the ease to place the material, which is achieved by additions such as superplasticizers and by choosing a well-balanced aggregate grading (Okamura *et al.* 1993). This latter type of material is called self-compacting concrete and is positioned without adding vibrational energy.

When subjected to loading, the material structure is prone to cracking. The applied loading can be mechanical, physical (temperature and moisture gradients), or chemical in nature, or combinations thereof; it can be uniaxial or multidirectional. Under low confinement, fracture of the material is generally quasibrittle. The cracks are almost immediately
stress-free, although different types of mechanisms at different scales may enhance the relative ductility. The heterogeneity of the material acts at different size/scale levels both as an arrest mechanism and an accelerator mechanism.

2. Crack Propagation

At the micro- and mesolevel, small cracks may be arrested when they coalesce with a small pore. The mechanism can be regarded as crack tip blunting and is shown schematically in Fig. 2(a). Depending on the type of inclusion, cracks can be deflected (Fig. 2(b), high E-contrast and high strength of the inclusion) or propagate through the inclusion (Fig. 2(c), at low E-contrast and low strength).

Figure 3 shows most levels of crack growth in concrete subjected to uniaxial tension. Distributed cracking may occur in the tip zone of larger macroscopic

cracks. Moreover intact regions in macroscopic cracks, often referred to as "crack face bridging," have been observed at many different size/scale levels (Fig. 4). One of the leading factors in the bridging mechanisms is the relative size of stiff aggregate particles, see Schlangen and van Mier (1992). The larger the maximum size of the stiff aggregates, the larger the bridging stress. The bridging of a crack is a three-dimensional phenomenon, and appears in many different materials at different size scales (van Mier 1997).

Next to aggregate bridging, load transfer may also occur through fibers bridging the crack. Again, this type of bridging mechanism appears to be governed by the fiber length (aspect ratio), the bond of the fiber to the cement matrix, and the fiber properties such as elasticity and strength.

3. Models

Heterogeneity of the material at different scales has an important influence on the specific fracture mechanisms. Once the mechanisms have been identified, modeling the fracture process becomes possible. Different approaches may be selected, namely a continuum approach where the different toughening mechanisms are implicit in the (mostly) nonlinear fracture law that is used, or it is possible to develop a material model in which the structure of the material is modeled explicitly. Depending on the level of operation, these models are referred to as "micromechanical" or "mesomechanical" models. An example of a nonlinear macroscopic model for concrete fracture is the "fictitious crack model," which was developed by Hillerborg and co-workers as an extension of the Dugdale–Barenblatt plastic crack tip model (Hillerborg *et al*. 1976). The main problem of the fictitious crack model is the parameter identification. Hillerborg proposed the use of a uniaxial tension test on a small double-notched concrete prism to measure
the fracture energy and the shape of the softening curve in tension, as shown in Fig. 5. The fracture energy, tensile strength, and shape of the softening curve strongly depend on the size of the specimen and the adopted boundary conditions in the experiments. This implies that a unique determination of the parameters is almost impossible. Approximate use of the macroscopic models is possible only.

The micromechanical and mesomechanical models have the advantage that failure mechanisms are included directly. These models are often incorporated in a numerical model, such as those developed by Roelfstra *et al*. (1985) and Schlangen and van Mier (1992). The latter approach is based on developments in theoretical physics and starts from a regular or random triangular lattice of beam elements. A realistic structure of the material is projected on top of the lattice, and after the elastic properties are matched to those of a representative volume element of the real material, fracture studies can be performed. Removing the (in each computation step only one) beam element with the highest stress over strength ratio simulates fracture. In this way local elastic–purely brittle behavior is modeled. An example of an analysis with the model showing the effect of aggregate content on the fracture patterns under uniaxial tension is shown in Fig. 6.

When a high aggregate fraction is included, the bond zones around the aggregates touch and the percolation threshold for the bond zone is reached. In other words, continuous paths of connected bond beams can be found from one side of the structure to the other side. This implies that under uniaxial tension fracture is dominated by the behavior of the bond elements. Consequently relatively low structure strength is measured in this case (see Figs. 6(c) and (f)). The other extreme is when very sparse aggregates are included, as in Figs. 6(a) and (d). Now continuous paths of matrix beams connect the two specimen sides and the behavior is dominated by the matrix strength. Figure 6(d) shows that before the peak is attained a relatively long nonlinear portion is observed. The

Figure 7
Simulated crack growth in a concrete disk subjected to a vertical splitting load (after Lilliu *et al*. 1999).

breaking of the weak bond elements around the aggregates causes this nonlinearity. In the examples shown in Fig. 6, the ratio of bond to matrix to aggregate strength is the most important parameter. The ratios are set at 1:4:8. Many of the toughening mechanisms mentioned at the beginning of this article can be recognized from the crack patterns of Figs. 6(a)–(c).

Another example is the simulation of a Brazilian splitting test (Lilliu *et al.* 1999), see Fig. 7. In this case strong boundary condition effects are measured. If the test is carried out in deformation control, i.e., by controlling the increase of the width of the vertical splitting crack, a secondary mechanism develops including radial bending cracks that grow from the edges of the cylinder to the main splitting crack.

Construction: Cellular Materials

Many materials have a cellular structure made up of an interconnected network of struts or plates. Such cellular materials occur in nature as wood, cancellous bone, and cork. There are also many man-made cellular materials, both in the form of honeycomb-like materials and foams. Although initially honeycombs and foams could only be made from a limited range of materials, both can now be made from a wide range of polymers, metals, ceramics, and glasses. Micrographs of several natural and man-made cellular materials are shown in Fig. 1.

Cellular materials currently are used extensively in a wide variety of applications. Wood artifacts have been found in Egypt dating back 5000 years. Approximately 1×10^9 t of wood are produced annually (Gibson and Ashby 1997). They are used extensively in lightweight sandwich panels. Separating two strong, stiff faces with a lightweight core creates a structure resistant to bending or buckling. They are a fine choice for insulation because of the low volume percentage of solids and their generally small cell size. Due to their low weight and ability to undergo large deformations at low loads, they are used by the packaging industry to protect materials from impacts.

This article summarizes the structure and mechanical behavior of cellular materials, production methods, and their uses in construction.

1. Structure and Mechanical Behavior

The properties of cellular materials are determined by a number of geometric and structural properties. The most important property is the relative density, determined by the density of the material divided by the density of the solid material from which it is made.

Cells generally extend in one of three forms: a 2D honeycomb, 3D open foam, or a 3D closed foam. The foam is determined to be open or closed based on whether or not the cell faces are covered by the solid material or empty. These structures are all shown in Fig. 1.

The cells are often anisotropic and often display anisotropic mechanical properties. Anisotropy is evident when the cells are elongated or have varying mean intercept lengths. This is often the case in rising
Figure 2
A typical stress–strain curve for a cellular material in uniaxial compression.

Figure 3
Alignment of the cell edges during tensile loading. The limiting strain is about 0.3 (reproduced by permission of Cambridge University Press from 'Cellular Solids: Structure and Properties', 1997).

foams where cells elongate in one direction. Another common case is in wood, which accounts for some of the difference in behavior when loads are placed along or across the grain. Figure 1 shows this property.

A typical stress–strain curve for a cellular material is shown in Fig. 2. There are three distinct regimes of behavior. At relatively low loads, the material is linear elastic. At some critical level of load, the cells begin to collapse by elastic buckling, plastic yielding, or brittle fracture, depending on the nature of the cell wall properties. Cell collapse then progresses at a roughly constant load, producing a roughly horizontal stress plateau, until, at relatively large strains (typically about 0.8), the opposing cell walls begin to meet and touch. The stress then rises steeply as the material densifies (Maiti *et al.* 1984).

Each of these regimes of behavior is related to the mechanism by which the cells deform within that regime. Observation of model honeycomb materials and of foams in a scanning electron microscope reveals that the initial linear elasticity is produced by bending in the cell walls. Cell collapse is caused by elastic buckling in elastomeric honeycombs and foams, by plastic yielding in materials which yield, and by brittle crushing in materials which fracture (Gibson and Ashby 1982, Maiti *et al.* 1984). The strain at which the honeycomb or foam begins to densify depends on its relative density.

The behavior of foams in tension is similar, but there are some notable differences. The linear elastic period is determined by the same modulus of the material in compression. At slightly larger strains buckling as in compression is not possible. Instead cell edges rotate toward the tensile axis. After a strain of approximately 0.3 increasing strain requires the stretching of the cell walls. These stages are demonstrated in Fig. 3.
Failure in tension is by the propagation of a single crack.

This stress–strain behavior can be characterized by several mechanical properties. The linear elastic regime is described by a set of elastic moduli such as the Young's modulus E, the Poisson ratio v, and the shear modulus G. The plateau stresses corresponding to elastic buckling, plastic yielding, and brittle crushing are σ_{el}, σ_{pl}, and σ_{cr}, the limiting strain for densification is ε_D, and the tensile fracture toughness is K_{Ic}. By modeling the structure of cellular materials and the mechanisms by which they deform, relationships between the properties of the cellular material and its relative density, its solid cell wall properties, and its geometry can be found. Table 1 summarizes these relationships for both honeycombs and foams. A more detailed analysis can be found in Maiti *et al.* (1984).

2. Production Methods

A wide variety of materials can be used to create cellular solids. Production methods depend upon the structure and material of the cellular solid being formed.

Honeycomb structures are commonly made in four ways. They can be pressed into half hexagonal shapes and then glued together. Alternatively, glue can be applied in strips to flat sheets, stacked, and then expanded to create the honeycomb shape. Honeycombs can also be created by casting into a mold or by extrusion.

Foams are made in a variety of ways depending upon the material being used. Polymers are generally foamed by introducing gas bubbles into a hot polymer using either mechanical stirring or by mixing a blowing agent into the polymer. Glass foams are made using similar methods to polymers. Metallic foams are made using either liquid or solid state processing (Shapovalov 1994, Davies and Zhen 1983).

Table 1
Property-density relationships for cellular materials.

| Property | Open celled foams | Honeycombs | |
		In-plane	Axial
E	$C(\rho/\rho_s)^2 E_s$	$C(\rho/\rho_s)^3 E_s$	$C(\rho/\rho_s)E_s$
v	C	C	C
G	$C(\rho/\rho_s)^2 E_s$	$C(\rho/\rho_s)^3 E_s$	$C(\rho/\rho_s)E_s$
σ_{el}	$C(\rho/\rho_s)^2 E_s$	$C(\rho/\rho_s)^3 E_s$	$C(\rho/\rho_s)^3 E_s$
σ_{pl}	$C(\rho/\rho_s)^{3/2}\sigma_{ys}$	$C(\rho/\rho_s)^2 \sigma_{ys}$	$C(\rho/\rho_s)^2 \sigma_{ys}$
σ_{cr}	$C(\rho/\rho_s)^{3/2}\sigma_{fs}$	$C(\rho/\rho_s)^2 \sigma_{fs}$	$C(\rho/\rho_s)\sigma_{fs}$
K_{Ic}	$C(\rho/\rho_s)^{3/2}\sigma_{fs}\sqrt{\pi l}$	$C(\rho/\rho_s)^2 \sigma_{fs}\sqrt{\pi l}>$	$C(\rho/\rho_s)\sigma_{fs}\sqrt{\pi l}$

The constants of proportionality are different for each property and each case (foams, honeycomb-in-plane, and honeycomb-axial). E_s, σ_{ys}, and σ_{fs} are the Young's modulus, yield strength and modulus of rupture, respectively, of the solid cell-wall material. The characteristic length of the cell size is l.

3. Applications of Cellular Materials in Construction

3.1 Sandwich Panels

Structural panels made up of two stiff, strong faces separated by a lightweight core are known as *sandwich panels*. The core acts to separate the faces, increasing the moment of inertia of the panel, with little increase in weight, producing an efficient structure for resisting bending and buckling loads. Usually the core is made up of a honeycomb, end-grain balsa wood, or cellular foams made from metals, polymers, or glass. The high stiffness and strength to weight ratios make sandwich panel construction successful in their use in space craft, aircraft structures, marine vessels, train and truck structures, containers, tanks, car body parts, and building structures (Burman and Zenkert 1997).

The technology for producing sandwich panels was first developed in the aerospace industry, beginning with the balsa core-plywood face sandwiches of the World War II Mosquito aircraft (Allen 1969). Modern aerospace sandwich components are now made almost exclusively with honeycomb cores and fiber-composite faces bonded together with advanced adhesives. Sandwich panels are now made routinely and are reliable for components such as the rotor blades of helicopters, wing tip sections, tail sections, and flooring panels. This technology is now well developed and is being transferred to the construction industry.

The main use of sandwich panels in the construction industry is in building panels. Sandwich construction is used in wall, roof, and door paneling. Different combinations of face and core materials are used; typically the faces are made of steel, aluminum, or waferboard and the cores are made of foamed polyurethane, foamed polystyrene beadboard, or foamed glass.

Sandwich panels provide a strong, yet economic, material for construction. Their rigid faces provide strength and stiffness to a structure while their lightweight centers often provide insulative as well as important construction properties.

The lightweight, yet rigid, property of sandwich panels allows for other current applications. Sandwich design is used in the development of downhill skis, domed covers of water reservoirs, and even the folding bridges employed by the US Army.

3.2 Wood

Wood is still one of the most widely used structural materials throughout the world.

The cellular structure of wood is shown in Fig. 1. Softwoods used in construction have two main types of cells: tracheids and parenchyma. The tracheids are the long, narrow cells (aspect ratio 100:1) which make up the bulk of the tree. They conduct fluids and nutrients within the tree and give it its structural support. The parenchyma cells, found in the rays, store sugars.

At a finer level, the walls of cells have a fiber-composite structure with partially crystallized cellulose molecules forming stiff, strong, fiber-like chains helically wound in a matrix of amorphous lignin and semicrystalline hemicellulose. Each cell wall is made up of four layers, each with a different orientation of cellulose fibers.

The mechanical behavior of wood can be modeled by analyzing the mechanisms by which it deforms (Easterling *et al.* 1982). When loaded across the grain, the cell walls bend in the same way that a honeycomb does when loaded in the plane of the honeycomb. Because of this, the Young's moduli and compressive strength of woods loaded across the grain depend on the cube and the square of the relative density of the wood. Figures 4 and 5 show this. When loaded along the grain, the cell walls compress uniaxially, as the honeycomb does if loaded normal to the plane of the hexagonal cells. Because of this the

Soc. A*, 1982, **383**, 31–41).

Young's modulus along the grain depends linearly on
the relative density of wood. Finally, the axial com-
pressive strength of wood is related to yielding in the
cell walls, again giving a linear dependence on relative
density. These results are plotted in Figs. 6 and 7,
along with data for wood. The modeling begins to
explain the dependence of the properties of wood on
the loading direction and the relative density of the
wood. The tensile fracture toughness of wood has
been explained in a similar way; see for example,
Ashby *et al.* (1985).

The mechanical properties of wood tend to be var-
iable, due to the presence of defects in the wood, such
as nonparallel grain and knots. Recently, glue-lam-
inated wood members (glulam) have been developed
to minimize the effect of such defects. Gluing to-
gether thin strips of wood, from which the defects

Glass foam ($\rho^*/\rho_s = 0.05$)	0.050	

or scattering), and sound absorbency capabilities
(providing great acoustical insulating properties)
(Gibson and Ashby 1997).

have been cut out, makes glue-laminated members.
The properties of such members are more uniform
than those of dimensioned lumber. Glulam sections
also have the advantage that they can be curved and
built up to any size. The efficiency of wood members
can also be improved by using them in sandwich
constructions. Typically, plywood faces are used in
conjunction with honeycomb, foam, or balsa cores.

3.3 Foams and Polymers

Cellular forms of thermal, electrical, and acoustic in-
sulation exist as foams and polymers made of metals,
glass, or plastics (polyethylene, polystyrene, poly-
urethane, etc.). Foam and polymer insulation have
many properties allowing them to perform well.
Foams have low thermal conductivity (perfect for
thermal insulation) (see Table 2), low dielectric loss
(allowing microwave transmission without attenuation

Construction Materials: Lightweight Aggregates

Many materials serve as lightweight aggregates in concrete, plaster blocks, and formed products. Many are mineral raw materials, others are waste or synthetic products, and some are organic materials (Table 1).

The distinction between normal weight and lightweight aggregates is at about $75\,lb\,ft^{-3}$ ($1200\,kg\,m^{-3}$) for loose graded aggregate. Most lightweight aggregates used for structural purposes are in the range 35–$60\,lb\,ft^{-3}$ (560–$960\,kg\,m^{-3}$), those used for nonload-bearing purposes (ultralightweight aggregates) are in the range 5–$20\,lb\,ft^{-3}$ (80–$320\,kg\,m^{-3}$).

Expanded clays, shales, and slates make up about 51% by weight of the lightweight aggregates used annually in the USA, with the remainder divided among scoria (see below), expanded slag, fly ash, vermiculite, and perlite. Vermiculite and perlite are the most used ultralightweight materials, but less than 25% is used as construction aggregate. They are used in about equal amounts. Pumice–pumicite and diatomite, in about a 10:1 ratio, constitute the remaining third of that market.

About 7.8 million short tons ($7.1 \times 10^6\,t$) of rock were used in 1997 for structural lightweight aggregates, and perhaps as much as 1.5 million short tons ($1.36 \times 10^6\,t$) were used for ultralightweight aggregates for nonload-bearing concretes, blocks, plaster insulation board, fillers, filters, agricultural aids, and loose fill insulation.

Excellent detailed review articles include Mason (1994) for structural lightweight aggregates, Geitgey (1994) for pumice and scoria, Breese and Barker (1994) for perlite, and Hindman (1994) for vermiculite.

1. Structural Lightweight Aggregates

Aggregates suitable for structural uses have several common ideal characteristics, high porosity, poor permeability, and relatively thick pore walls (compared to void diameter), that give the aggregates high compressive strengths. The porosity of all these aggregates results from heat treatment. A porous but relatively impermeable texture makes lightweight aggregates both thermal and acoustic insulators, desirable for bulk use in floor and roof fill and with an added advantage in saving weight in concrete.

Higher strength and increased weight go together. Compressive strength ranges, for example, from about 1200 psi ($8.3 \times 10^6\,Pa$) for $60\,lb\,ft^{-3}$ ($960\,kg\,m^{-3}$) scoria aggregate concrete to more than 6000 psi ($42 \times 10^6\,Pa$) for $120\,lb\,ft^{-3}$ ($1920\,kg\,m^{-3}$) expanded (sintered) shale concrete. In this broad range, lightweight aggregate concretes can be used for fill, bridge decks, shell walls, concrete floors, concrete frames using precast, prestressed, or post-tensioned girders, precast tilt-up units, poured barge and ship hulls, and lightweight masonry blocks. In bulk form, the aggregates are used as railroad ballast, as highway and embankment fill, and in the surface course of bituminous paving mixtures.

Structural lightweight aggregates allow higher buildings, more fire-resistant steel frameworks, and better insulated floors and ceilings. They save money, materials, and time because concrete can be pumped higher and further; plates, girders, and shell walls can be mass produced offsite; and additional thermal and acoustic insulation can be reduced. Additionally, lightweight aggregates and concretes allow innovative, experimental construction and design.

The USA has abundant domestic supplies; there are virtually no import or export markets. The materials have low unit value but high place value (transportation costs largely govern whether the materials can be used). Production data for pumice reveal some imports are used for lightweight block, but in 1997 about 0.29 million short tons ($2.63 \times 10^5\,t$) were imported for *all* purposes, as compared with nearly 1.5 millionshort tons ($1.36 \times 10^6\,t$) of domestic lightweight aggregates used in lightweight block. Almost all pumice imports (less than 2% of the market) are used along the eastern seaboard, where marine freight rates allow competition from domestic western resources.

1.1 Clays, Shales, and Slates

Many clays, shales, and slates expand somewhat on heating to about 2000 °F (1100 °C). The rocks differ in their physical characteristics, but are chemically,

Table 1
Classification and properties of lightweight aggregate materials.

Material	Composition (wt.%)	Texture (unexpanded)	Expansion needed	Texture (expanded)	Weight (lb ft^{-3}/kg m^{-3})	Remarks
Products of explosive volcanism						
Pumice	Silicic	Frothy, very vesicular	None	Unchanged	30–60/480–960	Blocks and fragments of coherent glass
Pumicite	Silicic	Porous	None	Unchanged	60–70/960–1120	Shards of glass; very fine grained; very low strength; expansible
Scoria	Basic	Clinker-like, very vesicular	None	Unchanged	35–75/560–1200	Tephra as bombs and lapilli; vesiculated zones in lava flows
Perlite	Silicic (H_2O:2–5)	Fractured, onionskin, partings	To × 6, ∼1400 °F	Cellular, frothy spheres	6–16/100–250	Low strength; high permeability-to-surface area ratio; ultralight
Obsidian	Silicic (H_2O: <2)	Dense, glass, conchoidal fracture	To about × 5, 1400–1500 °F	Cellular, frothy spheres	25–30/400–480	Low strength; high permeability-to-surface area ratio; ultralight
Deposits of sedimentary origin						
Clays, shales, slates	Wide range; silty, calcareous, carbonaceous, ferruginous	Dense, may be fissile	To × 2–3, ∼1800– 2200 °F	Cellular, fairly uniform	30–60/480–960	Kiln or sinter product; good strength; red ores least likely to expand
Diatomite	SiO_2: ∼100; may be "clayey", petroliferous	Porous, may be friable	None	Cellular	30–50/480–800	Coproduct of calcining for filter-aid products
Alteration of mafic silicate minerals						
Vermiculite (hydrobiotite)	Hydrated Mg–Fe–Al silicates; varies considerably	Micaceous	To × 8–15, ∼2000 °F	Accordian- like	6–15/100–240	Supergene alteration of biotite, phlogopite, hornblende, diopside, augite, olivine, chlorite, serpentine; low strength; ultralight

By-products of manufacturing processes

Blast furnace	Best slag is SiO_2: 35–88; $CaO + Al_2O_3$: 44–47; low MgO, FeO, S	Liquid slag	About $\times 8$, ambient temperature	Cellular, fairly	35–60/560–960	Zinc and phosphate smelter slags have also been used successfully
Fly ash, bottom ash, coke breeze	Wide ranges; $SiO_2 + Al_2O_3 + Fe_2O_3$: >70; MgO: <5; SO_2: <3; alkalis: $<1\cdot5$	Extremely fine grained	None	Cellular	35–55/560–880	Ash from burning pulverized coal; sintered to cause agglomeration
Cinders	Wide ranges; $SiO_2 + Al_2O_3 + Fe_2O_3$: >70; MgO: <5; SO_2: <3; alkalis: $<1\cdot5$	Cellular, nonuniform	None	Unchanged	40–60/640–960	From burning pea-sized or larger coal, coke

Synthetic and miscellaneous materials

Plastic beads and foams	Polyurethane, polystyrene, polyvinyl chloride	Does not apply	Various temperatures, reactions	Cellular, uniform spheres	$<15/<240$	Many patented techniques and applications
Foaming compounds	Al powder, vinyl resins, H_2O_2	Does not apply	Various temperatures, reactions	Does not apply	Various	Does not substitute for aggregate; lowers density by adding voids
Rice hulls, wheat hulls, sawdust, wood fibers	Organic	Fibrous, cellular	None	Unchanged	No data	Generally low strength; very minor usage

Source: Bush (1973).

and to some extent mineralogically, similar. Their chemical composition makes them amenable to thermal expansion. Representative chemical analyses for argillaceous rocks suitable for use as lightweight aggregate are given in Bush (1973), p. 338). The range in composition is wide and overlaps for all three materials. Unfortunately, the analyses of rocks that expand suitably, inadequately, or not at all, also fall in these ranges.

The basic requirement for expansion is a sufficient source of gas within the raw material to cause a full bloat, in the pyroplastic temperature range, so that the gas can be trapped; there must be enough vitrification, at a high enough viscosity, so that the gas can be held in small, evenly distributed pores; and the temperature range between softening and liquefaction must be large enough (about $100\,°F$ ($40\,°C$)) that the bloating can be controlled in large-scale commercial production. Almost all production is in horizontal kilns at temperatures between 1800 and $2200\,°F$ ($980–1200\,°C$), although temperatures may be as low as $1600\,°F$ ($870\,°C$) or as high as $2400\,°F$ ($1300\,°C$).

There is little agreement on the relative importance of the sources for the gas evolved within the raw material. Details of numerous laboratory studies can be found in the summary article by Bush (1973). Conventional wisdom in the early days of the industry held that the argillaceous rocks required a significant organic content, but laboratory investigation of the evolved gases showed that many materials with very little total carbon expanded better than those with an appreciable amount, and that CO_2, SO_2, and H_2O all played a part in the bloating.

Additional studies suggested sources of CO_2, SO_2, and H_2O from thermal destruction of hydrous iron oxides (goethite, limonite, hydrated hematite), pyrite, calcite, dolomite, ankerite, and from sulfides and sulfates, from dehydroxylation of amphiboles and micas, and gas from chemical interactions between organic matter, iron oxides, and water. Perhaps some reactions may operate simultaneously.

A range of compositions (52–80% SiO_2, 11–25% Al_2O_3) and combined fluxes (10–25% Fe_2O_3, FeO, CaO, MgO, and $(K,Na)_2O$) that included most of the bloatable materials and excluded the nonbloatables was defined by Riley (1951) on the basis of 85 chemical analyses of clays and shales. Additional investigations since 1951 redefined this bloating range as White (1960) (with an additional 93 samples) showed that the range had to be extended to higher Al_2O_3 and lower flux content, whereas Sweeney and Hamlin (1965) extended the range to a higher flux content. Laboratory methods for evaluating raw materials are cited in Bush (1973). The ultimate evaluation is how several tons of material expands in a commercial operation.

Distinguishing favorable from unfavorable argillaceous rocks in the field is difficult because so many types are suitable. Illitic and montmorillonitic rocks and sediments seem to be more consistently favorable

than kaolinitic ones. Dark-colored clays, shales, and slates are more suitable than light-colored (particularly red) ones, especially if they contain dispersed organic carbon. In general, unweathered materials are more suitable than weathered ones.

Common or brick clay is more suitable both physically and economically than flint or ball clay. Thinly fissile shales and slates tend to expand unidimensionally, which is undesirable. Most of these features tend to vary more in short vertical intervals across the rock units than laterally along them, but lateral variation is enough that units unsuitable at one point may be suitable a few hundreds yards to a few miles away.

Marine, littoral, lacustrine, and fluviatile clays, and shales and slates derived from them, are all possible raw materials. Geologic mapping in the USA, at scales adequate to identify the presence of argillaceous rocks, is sufficiently complete to virtually rule out the possibility of finding significant additional units.

In addition to the expandable materials, argillaceous rocks can be ground, mixed with combustible materials, such as ground coal, and sintered to produce lightweight aggregates. The mass becomes pyroplastic and voids form as the combustibles are burned out. Inasmuch as units that may not bloat of themselves can thus be used for lightweight aggregate, classification of materials as unfit is unwise unless testing has shown unsuitability for both processes.

Reserves of expandable clays, shales, and slates are so large that they will satisfy the USA's needs for many years.

1.2 Volcanic Rocks

Various volcanic rocks worldwide are suitable for use as lightweight aggregates; all are extrusive ejecta that range in composition from mafic to silicic. Scoria and volcanic cinder (both mafic), and pumice and pumicite (silicic) make moderate- to low-strength structural aggregates; expanded perlite and expanded pumicite are ultralightweight materials. Water content in basalt is little different from that in scoria and cinder, but the difference between water in rhyolite and that in silicic glassy rocks is significant. An excess of water allows the perlites and pumicites to be thermally expanded. In a general way, viscosity of extruded rock melt varies directly with the SiO_2, Na_2O, and K_2O content and inversely with the Fe_2O_3, FeO, CaO, and MgO content; the mafic rocks are more fluid and the silicic rocks are more likely to retain gases.

1.3 Scoria and Volcanic Cinder

Scoria (larger than 1 in (2.5 cm) in size) and volcanic cinder (smaller) are cellular, frothy products of

explosive mafic volcanism—erupted as bombs, blocks, lapilli, volcanic gravel, or lava flows. Much of the material is lava forcefully ejected from the vent, vesiculating as volcanic gases expand and are entrapped by rapid cooling, either while airborne as ejecta or at the surface of flows; broken blocks and irregular fragments result from continued movement. There is a wide range in vesicle size (particularly in the ejecta) and in the thickness of the cell walls, resulting in a considerable variation in the density of the rocks. Scoria and cinder form cones and blankets near the vent; lava flows are fluid, extending laterally to tens of miles, and to tens of feet in thickness. Scoriaceous zones in flows are highly variable and are confined to the upper few feet.

Most of the deposits of scoria and volcanic cinder are geologically youthful, surface or near-surface deposits, some only a few thousand years old. Although ejecta enter readily into the sedimentary cycle, they lack sufficient resistance to abrasion to survive reworking for very long.

In the USA deposits of scoria and cinder are restricted to states west of the 104th meridian; production was recorded from all but Alaska. Arizona, Oregon, California, Hawaii, and New Mexico are the largest producers, generally in that order; however, in 1997 New Mexico was first. In the states west of the 104th meridian nearly all large cities (at least 50 000 people) and most cities of at least 25 000 are within about 100 miles (160 km) of economic deposits of scoria or cinder.

Available USA resources are estimated to be about 3 cubic miles (12 km^3) of scoria (based in part on Higgs (1949), about 9000 million short tons $(8.2 \times 10^9 \text{ t})$. At a projected level of 3 million short tons $(2.7 \times 10^6 \text{ t})$ annually, scoria production for more than 1000 years can be adequately accommodated within this total resource.

1.4 Pumice and Pumicite

Pumice and pumicite are used both as structural lightweight aggregates and as ultralightweight aggregates. They are lighter colored, of lower density, and more highly cellular than are scoria and cinder. Composition ranges from high-silica (rhyolitic) to low-silica (basaltic), but most pumices are in the rhyolite range. High-silica rock melts generally lead to violent extrusion; gas and steam during explosive extrusion commonly shatter the pumice froth, and the shards and finer fragments form pumicite (volcanic ash). Low-density pumice and pumicite are thrown much further from the vents than scoria and cinder; many pumicite deposits are several hundred miles from their sources. In pumice, cell walls are commonly very thin, and the rock is light enough to float.

Deposits of pumice and pumicite commonly occur as an air-fall blanket, semiconcentric to a crater source vent or broadly fan-shaped lateral to fissure vents, sometimes with cones. Very large volumes occur in ash-flow tuffs and in the upper parts of rhyolite and "obsidian" domes. They are subject to rapid erosion, reworking, and redeposition as stream or lake sediments. Thicknesses range up to tens of feet, and areal extents range up to tens of square miles; amounts may be as large as many hundreds of thousands of tons.

Ash falls are air-sorted. Reworked and redeposited materials commonly are interbedded. Some ash falls also retain enough heat to weld and to form glassy zones. Most ash flows are unsorted or crudely sorted heterogeneous mixtures of pumice, ash, and rock fragments. The pumice as fragments and blocks may be as much as 10 ft (3 m) in maximum dimension. Block sizes decrease outward from the source.

Pumice occurs in all the western USA from the Rocky Mountains to the Pacific Ocean, and pumicite deposits are found in California, Texas, Oklahoma, Kansas, North and South Dakota, and Nebraska (nearly to the Missouri River). In 1997 at least 15 US mines operated, with Oregon being the leading pumice producer, followed by New Mexico, California, Idaho, and Arizona. Pumicite was produced in Kansas. Although the range in deposit size is large, a conservative estimate suggests that many occurrences have dimensions of 500 ft by 1000 ft by 10 ft (150 m by 300 m by 3 m). Bulk densities range from 850 lbyd^{-3} (500 kg m^{-3}) for pumice to 1750 lbyd^{-3} (1040 kg m^{-3}) for pumicite; amounts for the sample deposits lie between 80 000 and 160 000 short tons $(7.3 \times 10^4$–$14.5 \times 10^4 \text{ t})$.

The total US pumice resource, based on the estimate of Higgs (1949), can only be approximated to between 150 and 300 million short tons $(1.35 \times 10^8$–$2.7 \times 10^8 \text{ t})$. Great Plains pumicite deposits are numerous and vary greatly in size; Ham (1949) reported one in Oklahoma of about 1×10^7 yd^3 $(7.6 \times 10^6 \text{ m}^3)$, and estimated about 2×10^7 yd^3 $(15 \times 10^6 \text{ m}^3)$ in the known Oklahoma deposits. Carey *et al.* (1952) estimated about 20 million short tons $(18 \times 10^6 \text{ t})$ for Kansas. Data are lacking for Nebraska, but about the same tonnage as Kansas and Oklahoma is reasonable. A conservative estimate for all the Great Plains states is a total resource of about 100–150 million short tons $(9 \times 10^7$–$14 \times 10^7 \text{ t})$.

1.5 Diatomite

Diatomite is composed of the siliceous skeletons of unicellular aquatic algae, both marine and freshwater, typically in the range 80–95% SiO_2. Although diatomite is used as a lightweight aggregate, the usage seldom exceeds a few tens of thousands of tons per year and is not a significant factor as a construction aggregate. Its value for other uses, such as filter aids, is far too great to justify its use as a low-cost aggregate. For information on origin, composition, etc.,

see Antonides (1999), Breese (1994), and Durham (1973).

1.6 Expanded Blast Furnace Slag

Expanded blast furnace slag is a small part of the supply of structural lightweight aggregates. Annual production since 1985 has been about 1 million short tons (9×10^5 t); in 1997 that was about 12% of the total lightweight aggregate construction-related usage. The amount used was only 0.6% of all blast furnace slag produced, and the supply seems ample for many years to come. The slag typically contains 32–42% SiO_2, 7–16% Al_2O_3, 32–45% CaO, 0.1–1.5% Fe_2O, 0.2–1.0% MnO, 0.5% MgO, and 1–2% S (R. S. Kalyoncu, personal communication, June 1999).

1.7 Fly and Bottom Ash

Fly ash and bottom ash, by-products of power plant coal combustion, are produced in large quantities (77.5 million short tons (7×10^7 t) in 1997) but only 22% is used for construction. From 1992 to 1997 total ash production increased steadily from about 60 to 77.5 million short tons (5.5×10^7–7×10^7 t) and the construction component followed. Average composition of fly and bottom ash is 40–55% SiO_2, 20–30% Al_2O_3, 6–10% Fe_2O_3, 8–20% CaO, $\sim$2% MgO, 0–1% TiO_2, $\sim$0.5% P_2O_5, 1–5% SO_2, and $\sim$0.5% CO_2 (R. S. Kalyoncu, personal communication, June 1999). There probably is sufficient material for many years to come.

1.8 Exploitation

Pumice was used as construction material by the Romans about 2000 years ago. Cinders from coal-fired furnaces and boilers were used in cinder block from the late 1800s to World War II; conversion to gas and oil and the use of pulverized coal has virtually ended the cinder block industry. Fly ash and bottom ash, residues of pulverized-coal combustion, are used as pozzolans, aggregates, and starting materials for synthetic zeolites. In the USA expanded clay and shale aggregates were used as early as World War I in concrete ships, and a small market (partly owing to patent restrictions) persisted to the end of World War II. A rapid increase in US plants and production of expanded clay and shales began in about 1947 (patents on the rotary kiln (Hayde) process expired); production reached a high of more than 10.2 million short tons (9.3×10^6 t) in 1973 and remained steady at 4–5 million short tons (3.5×10^6–4.5×10^6 t) annually to 1997. Production and consumption of pumice and expanded blast furnace slag also increased very rapidly in the post-war construction boom of 1945–50. Since 1956 overall production of the structural lightweight aggregates has reflected construction trends fairly

closely, although a long-term decline in the market share of expanded slag has occurred.

From 1964 to 1982 US scoria production was about 3 million short tons (2.7×10^6 t), then to 1997 about 2.5 million short tons (2.3×10^6 t). Pumice tonnage used as structural aggregate decreased from a 1965 high of 3 million short tons (2.7×10^6 t) to less than 55000 short tons (5×10^4 t) by 1997. Concurrently, usage in concrete block rose from about 30000 short tons (2.7×10^4 t) in 1977 to about 375000 short tons (3.4×10^5 t) in 1997.

Expanded slag production peaked near 3 million short tons (2.7×10^6 t) between 1955 and 1958, and has declined since then, hovering near 2 million short tons (1.8×10^6 t) annually since 1991. The decreases reflect a loss of markets to competitive products, particularly the expanded and sintered clays, shales, and slates. Sources of slag are chiefly iron blast furnaces in only a few areas of the USA. Suitable sources of clay, shale, and slate are widespread and new facilities compete with slag in market areas close to the furnaces, as well as in the areas where slag use is a marginal operation. Usage of fly and bottom ash has also contributed to the decline.

The lightweight aggregate industry is faced with the environmental problems of open-cast mining, the control of fine materials formed in the manufacturing process, the destructive consumption of water, and the degradation of water quality in other processes. These problems cause extra expense in production in a highly competitive market that has commonly slender profit margins. As low-unit-value, high-place-value commodities, raw material sources and production sites have to be close together and centrally located to the market area. Consumption of structural aggregates is mostly in urban areas except for highway construction; environmental impacts and conflicts are increased because they take place close to where many people live. One further complication is that in some areas the raw material must be extracted before the area is irretrievably lost to residential or industrial and office construction.

2. Ultralightweight Aggregates

The natural ultralightweight aggregates are perlite (product of silicic volcanism), vermiculite (a low-temperature alteration product of ultramafic igneous and metamorphic rocks), and, to a small degree, pumice and pumicite (described above). All require high-temperature heating to cause expansion and vesiculity (pumice is the exception). All develop high porosity, low permeability, and very thin cell walls. They make excellent thermal and acoustic insulators, but have low compressive strength in concrete and plaster (100 psi (7×10^5 Pa) to about 2200 psi (1.5×10^7 Pa)); more cement results in greater strength and higher weight. Ultralightweight aggregates are used in

fireproof plasters, concrete curtain walls, floor fills, and roof decks, in refractory and insulating walls in bake ovens, and in decorative, nonload-bearing blocks and facings. In loose fill or bulk form they are used for insulation, but much is used for inert carriers and extenders in horticultural products and in manufacturing processes.

2.1 Volcanic Rocks

(*a*) *Perlite*. Perlite, obsidian, and pitchstone are volcanic glasses that differ in water content: obsidian, less than 2% H_2O; perlite, 2–5%; and pitchstone, more than 5%. The general range of composition (Bush 1973, p. 341) is 70–75% SiO_2, and about 10–15% Al_2O_3. The water content is critical to expansion, but obsidians with as little as 0.2% H_2O are reported to have expanded satisfactorily. Originally, perlite meant a glassy rock characterized by concentric cracks, but commercial usage includes any glassy rock (except pumicite) that can be expanded by heating to about 2000 °F (1100 °C).

Many of the traditional applications of perlite are in the construction field, but US usage decreased in 1997 to less than 5%. Most 1997 production went into formed products such as acoustic ceiling tiles, pipe insulation, roof insulation board, etc. (67%), filter aids (9%), and horticulture (10%). Diatomite is the principal material used in filtration, but perlite has made significant inroads into that market. In the construction field, the principal competition comes from exfoliated vermiculite: in 1997 some 30 000–40 000 short tons (2.7×10^4–3.6×10^4 t) perlite vs. 31 000 short tons (2.8×10^4 t) vermiculite. Breese and Barker (1994) give a comprehensive discussion of perlite processing, marketing, uses, and substitutes.

Perlite is found in three major associations: in glassy zones in welded ash-flow tuffs (Smith 1960), in silicic lava flows from volcanic domes, and in the wall zones of felsitic intrusive plugs and dikes. In a simple ash flow, the central zone of dense welding is a glass with virtually no porosity (composed of completely collapsed pumice and ash), bordered both above and below by zones of partial welding and no welding. Recurrent ash flows, above still hot flows, can form composite cooling units in which zones of dense welding may coalesce; intermediate partially welded and nonwelded zones are obliterated and a zone of glass borders and envelops a zone of tuff. If cooling is sufficiently rapid to prevent crystallization, the glass may be preserved for some millions of years. Preservation of glasses is increasingly rare from the Pliocene (1.6 million years ago) back to the Paleocene (about 60 million years ago) and is very rare in rocks older than that.

Glass in lava flows and volcanic domes represents the surface of rapidly cooled liquid lava which may be rolled under as the flow advances, in the process

being brecciated, remelted, and annealed. As the flow stops, glass can be at both its top and its base, and if rapidly cooled, the zones may coalesce to make a virtually all glass flow.

Perlite very commonly surrounds microscopic to 1 in (2.5 cm) size cores of obsidian whose original water content is a few tenths of 1%. Around the cores is meteoric water at 2–5% due to hydration by groundwater, rain, and snow (Ross and Smith 1955; Hindman 1994 and references therein). Increasing hydration outward and increasing devitrification inward are of importance to the assessment of perlite resources.

Perlite occurs worldwide. It is widely distributed throughout the western conterminous USA. In 1997 by far the most crude ore came from New Mexico; the remainder came from Arizona, California, Nevada, and Oregon. In earlier years crude ore came from Colorado, Idaho, and Texas, and deposits are known in Montana, Wyoming, and Washington.

Resources of perlite in the USA are ample and based on the very large volumes of available extrusive rocks, no shortage is foreseeable. There are very large deposits in New Mexico, and numerous sizable deposits in California, Arizona, Nevada, and smaller ones in Idaho, Utah, and Colorado. The total resource may be about 650 million short tons (6×10^8 t). However, hydration by meteoric water raises the problem of how far the glasses are hydrated inward from their margins. In the absence of data on the extent of hydration, the resource estimate must be considered a maximum.

(*b*) *Pumicite*. Laboratory investigations by the Oklahoma Geological Survey in 1944 revealed that pumicite was capable of considerable expansion upon heating in excess of 1100 °C. Additional investigations by the Kansas Geological Survey provided more data on temperatures and strengths and suggested industrial uses (filter aids and ultralightweight construction materials) (see also Sect. 1.4) Commercial usage of expanded pumicite was minor to 1999, but two operations are known from deposits in Kansas.

2.2 Vermiculite

Vermiculite is a mica, a hydrated, magnesium–iron–aluminum trioctahedral sheet silicate of varied composition. Its basic unit is two tetrahedral silicate sheets interlayered by an octahedral sheet that contains aluminum and iron (Grim 1962). Each tripartite layer, on its upper and lower surfaces, has regularly arranged ''holes'' that oppose corresponding sites on other layers. In biotite, potassium atoms occupy these sites; in vermiculite, only some sites are occupied, and these only by magnesium, but a double layer of water molecules also is present in these interlayer regions.

Vermiculite ore is invariably an alteration product of a variety of mafic minerals: biotite, phlogopite, rarely muscovite, diopside, tremolite, augite, hornblende, olivine, chlorite, and serpentine. All known deposits have formed in the zone of circulating groundwater above the water table. The alteration may include an intermediate biotite or chlorite stage, for some x-ray diffraction studies showed interlayering with biotite or chlorite, although no biotite or chlorite may remain in the host rock. Biotite is the common parent mineral; the similarity of crystal structures permits intimate interlayering on a molecular scale, in a series that ideally extends either regularly or irregularly from pure biotite through 1:1 biotite–vermiculite to pure vermiculite. The 10–50% vermiculite varieties are called hydrobiotite and are least likely to be useful commercially.

Virtually all vermiculite ores require beneficiation, by either dry comminution and air classification or by wet froth flotation methods, before exfoliation, almost always in vertical furnaces at temperatures commonly of 1700 °F (900 °C) or hotter for some ores. Gangue material is removed by air classification after exfoliation. Commercially, ''vermiculite'' includes any micaceous mineral that is capable of expansion. Pure vermiculite can be exfoliated up to 30 times its original thickness when heated to about 1600–2000 °F (870–1100 °C); impure varieties expand less. The exfoliation results from the flash conversion of interlayer water molecules into steam. High porosity develops as the layers are forced apart into an accordion-like structure. The resulting material is easily compressed along the line of expansion but has moderate strength in other directions.

Unexpanded vermiculite has very few uses, but exfoliated has many: in the construction industry (concrete as aggregate, in plaster and premix, and in blocks), in insulation (loose fill, acoustical tiles), in horticulture (aggregate, soil amendment, fertilizer carrier), and miscellaneous other uses. In 1990, the last year for which detailed US data are available, about 45% went to construction, 40% to agriculture, and 15% to insulation and other uses.

Vermiculite deposits occur worldwide and the largest are at large ultramafic intrusives, such as pyroxenite plutons, sometimes zoned, cut by syenite or alkalic granite and by carbonatitic rock and pegmatite (examples are deposits at Libby, Montana, and Phalaborwa, South Africa). Moderate size deposits are at small to large ultramafic intrusives, such as dunite and unzoned pyroxenite and peridotite cut by pegmatite and syenitic or granitic intrusive rock (examples are deposits in the Blue Ridge region of the southeastern USA). The smallest deposits are associated with ultramafic metamorphic rocks, commonly layered amphibolite schists that may have originally been igneous rocks, in places cut by or in contact with pyroxenite or peridotite, and cut by pegmatite (examples are deposits in the Enoree district, South

Carolina, and most of the deposits in Colorado, Wyoming, and Texas). With the major exception of the Cretaceous deposit at Libby, almost all the vermiculite deposits in the USA appear to be in rocks of Precambrian age.

The geologic relations of all deposits suggest that pyroxenes, amphiboles, and olivine in the ultramafic rocks were altered by solutions and volatiles from intrusive syenite, carbonatite, and pegmatite (supplying mostly OH), and biotite, phlogopite, serpentine, and chlorite were formed. Supergene alteration by circulating groundwater later removed the alkalis, redistributed magnesium, and added H_2O as interlayer water molecules to form vermiculite.

The vermiculite deposits of Montana produced about three-quarters of the US crude ore to 1990 (cumulatively about 9 million short tons (8×10^6 t)). Since then the production is estimated to have come about equally from Virginia and South Carolina, although detailed data are unavailable. Production from all other states is very minor. The almost invariable association of vermiculite with Precambrian rocks allows Hawaii and virtually all the central part of the country from the Rocky Mountains east to the Blue Ridge to be dismissed from consideration, except possibly the Wichita Mountains and the Ozark Mountains.

Deposits of the Libby size, which would contain the largest resource, have geologic relations that are suggestive for additional discoveries. The association of ultramafic plutons with syenite, alkalic rock, and carbonatite is too common to be coincidence. The association of these rocks is known from several deposits in the USA (Rocky Boy, Montana; Gem Park-McClure Mountain and Powderhorn, Colorado), in Russia, in Brazil, and, in particular, in many parts of Africa. Several generalized clues to places where these rocks may be found together are (i) the rocks are usually in Precambrian terranes, (ii) they may be related to Precambrian structural trends, (iii) they may exhibit significant magnetic anomalies, and (iv) they may be characterized by ring-dike structures.

2.3 Exploitation

In the USA production trends of perlite and vermiculite were broadly similar before 1977, and very similar from about 1955 to 1992. To 1997 perlite usage increased whereas vermiculite was virtually unchanged. Perlite production began after World War II; output rose rapidly to 1951 and continued at a generally steady rate to more than 0.9 million short tons (0.8×10^6 t) in 1978. It has ranged from about 0.6 to 0.9 million short tons (0.5×10^6–0.8×10^6 t) since then, with about 0.72 million short tons (0.65×10^6 t) in 1997. The first sustained vermiculite production was in 1925, reached a high of 0.31 million short tons (0.28×10^6 t) in 1973, was about 0.3 million short

tons (0.27×10^6 t) until 1988, and since has dropped to less than 0.2 million short tons (0.18×10^6 t). Since 1989 South Africa has been the world's largest source of crude vermiculite, in 1995 (the most recent year with detailed data) producing about 0.25 million short tons (0.22×10^6 t); the USA is second with about 0.2 million short tons (0.17×10^6 t) (US Geological Survey Minerals Yearbooks). Consumption of expanded perlite has varied more than that of exfoliated vermiculite, in part reflecting the closing of the major vermiculite deposit at Libby, Montana, and in part the movement of perlite into the filler, formed products, and filter-aids fields while vermiculite use decreased in concrete and plaster.

The USA produces all the perlite and pumicite that it consumes and has ample material to export, but, with its low unit value, only a few thousand tons of crude perlite is exported annually—all of it to Canada. No pumicite is exported. Almost all vermiculite used in the USA is produced domestically, but along the eastern seaboard, oceanic freight rates allow some vermiculite to be imported economically from South Africa.

Perlite, pumicite, and vermiculite share the common problems of open-cast mining. Large amounts of fines are produced in mining and processing, in the grinding circuits, and in the explosive expansion ("popping") of perlite and pumicite. These materials are glasses and the fines are pointed, sharp slivers and shards. Disposal and dust control are major problems, both in preventing and alleviating pollution and in protecting plant workers from respiratory injuries and diseases. Similar problems exist for vermiculite, which yields thin flakes to the fines rather than shards, but which may have asbestiform minerals in the gangue. Where wet classification methods are used, the disposal of vermiculite slimes presents other difficulties.

Continuous Parallel Fiber Composites: Deformation and Strength

This article is concerned with the deformation and failure processes that occur in continuous unidirectional (UD) composites in tension, compression, and shear. Methods for calculating thermoelastic constants and strengths in both the longitudinal and transverse fiber directions are presented. The models for predicting longitudinal tensile strength allow for both weak and strong interface bonding between fibers and the matrix. The higher level of coverage given to thermoelastic properties and longitudinal tensile strength reflects the level of understanding and confidence in the predictive analysis for these properties.

The main failure modes associated with longitudinal tensile loading are fiber fracture and matrix

cracking normal to the fiber direction. Fiber fracture is often accompanied by debonding of the fiber–matrix interface in the neighborhood of the fiber fractures. Three types of behavior need to be considered when modeling UD composites. At relatively low applied loads, there is no microstructural damage or matrix yielding/plasticity. The composite deforms as a linear material (i.e., stresses and strains are linearly related). All interfaces between fibers and matrix are perfectly bonded. Many models predicting the thermoelastic properties of UD composites have been developed for this type of behavior (see *Composites, Physical Properties of**). For larger applied loads, the composite experiences the second type of behavior where stable nonlinear deformation occurs, arising from matrix yield and/or from microstructural damage formation. Following the progressive stable growth of plasticity and/or microstructural damage, the third type of behavior ensues, where instability and catastrophic failure of the composite occur.

The results to be presented can be applied to any fiber-reinforced composite whose constituents can be regarded as deforming in a linear manner, such as thermosetting polymer matrix composites (PMCs) and fiber-reinforced ceramic matrix composites. For monotonically loaded, fiber-reinforced thermoplastic and metal composites, for which the matrix may undergo plastic deformation or creep, extensions of these analyses also exist; however, for clarity in presentation, we will place emphasis on the case of an elastic matrix. In general, it is assumed for UD composites that the fiber and matrix are made of different materials (possibly anisotropic, having directional properties), and that in the undamaged state they are perfectly bonded everywhere along the length of the fiber–matrix interfaces. The cross-section of the fibers is assumed to be uniform and circular. The fibers are assumed to be uniformly distributed, having a hexagonal packing structure leading to transverse isotropic composite properties.

1. Prediction of Thermoelastic Constants for Undamaged Composites

This section presents suitable methods for calculating the thermoelastic constants of undamaged UD composites, some of which are almost impossible to measure. Concentric cylinder models of fiber and matrix in conjunction with variational techniques have been used extensively to predict the properties of undamaged UD composites (Hashin 1983). UD composites are realistically modeled as transverse isotropic solids (i.e., axial properties differ from properties in directions normal to the fiber direction). UD composites are characterized by seven independent thermoelastic constants: (i) axial Young's modulus (E_A); (ii) axial shear modulus (μ_A); (iii) transverse Young's modulus

(E_T); (iv) axial Poisson's ratio (v_A); (v) transverse Poisson's ratio (v_T); (vi) axial thermal expansion coefficient (α_A); and (vii) transverse thermal expansion coefficient (α_T). These parameters appear in stress–strain relations of the form:

$$\varepsilon_{rr} = \frac{1}{E_T}\sigma_{rr} - \frac{v_T}{E_T}\sigma_{\theta\theta} - \frac{v_A}{E_A}\sigma_{zz} + \alpha_T \Delta T \qquad (1)$$

$$\varepsilon_{\theta\theta} = -\frac{v_T}{E_T}\sigma_{rr} + \frac{1}{E_T}\sigma_{\theta\theta} - \frac{v_A}{E_A}\sigma_{zz} + \alpha_T \Delta T \qquad (2)$$

$$\varepsilon_{zz} = -\frac{v_A}{E_A}\sigma_{rr} - \frac{v_A}{E_A}\sigma_{\theta\theta} + \frac{1}{E_A}\sigma_{zz} + \alpha_A \Delta T \qquad (3)$$

$$\varepsilon_{rz} = \frac{\sigma_{rz}}{2\mu_A}, \varepsilon_{\theta z} = \frac{\sigma_{\theta z}}{2\mu_A}, \varepsilon_{r\theta} = \frac{\sigma_{r\theta}}{2\mu_T} \qquad (4)$$

The stress σ and strain ε components refer to cylindrical polar coordinates (r, θ, z), with the z-axis oriented parallel to the fibers.

1.1 Method for Estimating Properties

For an undamaged UD composite having fiber and matrix volume fractions V_f and V_m ($=1-V_f$), respectively, the axial Young's modulus, axial Poisson's ratio, and transverse bulk modulus are given by:

$$E_A = V_f E_A^f + V_m E_A^m + 2\lambda(v_A^m - v_A^f)^2 V_f V_m \qquad (5)$$

$$v_A = V_f v_A^f + V_m v_A^m - \frac{\lambda}{2}(v_A^f - v_A^m)\left(\frac{1}{k_T^f} - \frac{1}{k_T^m}\right)V_f V_m \qquad (6)$$

$$\frac{1}{k_T} \equiv \frac{2(1-v_T)}{E_T} - \frac{4v_A^2}{E_A} = \frac{V_f}{k_T^f} + \frac{V_m}{k_T^m}$$
$$- \frac{\lambda}{2}\left(\frac{1}{k_T^f} - \frac{1}{k_T^m}\right)^2 V_f V_m \qquad (7)$$

where

$$\frac{1}{\lambda} = \frac{1}{2}\left[\frac{1}{\mu_T^m} + \frac{V_f}{k_T^m} + \frac{V_m}{k_T^f}\right] \qquad (8)$$

E, v, k, μ, and α denote Young's modulus, Poisson's ratio, bulk modulus, shear modulus, and thermal coefficient of expansion, respectively. Suffixes f and m denote fiber and matrix, respectively. As the values of E_A and v_A are known, the value of $(1-v_T)/E_T$ can be calculated using Eqn. (7). Assuming that the composite is transversely isotropic, then the following relationship holds:

$$E_T = 2\mu_T(1+v_T), \quad \text{but} \quad E_A \neq 2\mu_A(1+v_A)$$

Clearly both E_T and v_T can be calculated once the value of μ_T has been determined. Christensen and Lo

(1979) developed a concentric cylinders model (including a surrounding effective composite region) that can be used to estimate transverse shear modulus, which lies between the bounds given by Hashin (1983), and is likely therefore to predict more accurate values. The model can be used to calculate the transverse shear modulus μ_T, thus enabling values of E_T and v_T to be determined. The following expression given by Hashin (beware a misprint in his paper), leads to either an upper or lower bound value for μ_T, depending upon the values of μ_f, μ_m, k_f, and k_m:

$$\mu_T = V_f \mu_T^f + V_m \mu_T^m - \lambda_1 (\mu_T^f - \mu_T^m)^2 V_f V_m$$

where

$$\frac{1}{\lambda_1} = V_m \mu_T^f + V_f \mu_T^m + \frac{k_T^m \mu_T^m}{k_T^m + 2\mu_T^m} \tag{9}$$

Hashin's (1983) expression for the axial shear modulus μ_A may be written as:

$$\mu_A = V_f \mu_A^f + V_m \mu_A^m - \lambda_2 (\mu_A^m - \mu_A^f)^2 V_f V_m$$

where

$$\frac{1}{\lambda_2} = \mu_A^m (1 + V_f) + \mu_A^f V_m \tag{10}$$

The axial and transverse thermal expansion coefficients predicted by the model may be written as:

$$E_A \alpha_A = V_f E_A^f \alpha_A^f + V_m E_A^m \alpha_A^m + 2\lambda (v_A^m - v_A^f) V_f V_m$$
$$\times [\alpha_T^m + v_A^m \alpha_A^m - \alpha_T^f - v_A^f \alpha_A^f] \tag{11}$$

$$\alpha_T = -v_A \alpha_A + (\alpha_T^f + v_A^f \alpha_A^f) V_f + (\alpha_T^m + v_A^m \alpha_A^m) V_m$$
$$+ \frac{\lambda}{2} \left(\frac{1}{k_T^f} - \frac{1}{k_T^m} \right) V_f V_m$$
$$\times [(\alpha_T^m + v_A^m \alpha_A^m) - (\alpha_T^f + v_A^f \alpha_A^f)] \tag{12}$$

The relations in Eqns. (10) to (12) are equivalent to those given by Hashin (1983) and Rosen and Hashin (1970). For composites where fiber coatings or reaction products (e.g., fiber-reinforced titanium) are encountered, thermoelastic constants can be predicted using a multiple concentric cylinder model (McCartney 1992a). This model can deal with any number of transverse isotropic concentric layers.

2. Deformation of Undamaged Composites in the Presence of Matrix Yield

Thermoplastic and metal matrices deform by (permanent) plastic deformation once a certain stress is exceeded: when unloaded, composites with such matrices can show a permanent deformation even in the absence of damage. Hill (1964) has explored extensions of elastic modulus bound predictions for the deformation of elastoplastic fiber composites, and has in particular shown that for uniaxial composite deformation parallel to the fibers, the slope of the stress–strain curve is close to the equistrain rule of mixtures (as is the case for elastic deformation, Eqn. (5) above). For this case, then, prediction of the composite deformation laws is relatively straightforward, and can be extended to include other matrix rheologies (such as creep), and also to take into account the influence of residual stresses caused by differential matrix–fiber cooling during cool-down from composite processing temperatures.

For all other modes of composite straining in the presence of matrix plasticity, prediction of the composite flow stress becomes complicated. This is in large part because the matrix strain distribution is highly inhomogeneous in such materials and can essentially only be predicted using numerical analysis methods. Finite-element micromechanical models for the deformation of fiber-reinforced elastoplastic matrices are described by Dvorak (1991), Suresh and Brockenbrough (1993), and Clyne and Withers (1993), together with approximate analyses based on extensions of elasticity models. Overall, numerical models show good agreement with experiment and account relatively well for phenomena such as the strong Bauschinger effect that is observed with such composites, or the influence of residual thermal stresses. The main outstanding difficulty in modeling the deformation of elastoplastic fiber composites is that, contrary to elasticity, the intrinsic rheology of the matrix may be affected by the fibers: in metal matrix composites, fibers a few micrometers in diameter are on the same length scale as those microstructural elements that govern plastic deformation in metals. Hence, it is quite possible that the matrix flow stress will be affected by the fibers, and will differ from its value in the unreinforced state. This is indeed observed: the flow stress of fiber-reinforced metals has been found to depend on the reinforcement diameter (Pedersen 1990), something that is not predicted by (scale-independent) elastoplastic mechanical models.

3. Failure Processes during Axial Tensile Loading

The behavior of UD composites when loaded in the fiber direction can be dominated by the properties of the fibers, especially for relatively high volume fractions of high-modulus fibers in a comparatively low-modulus matrix. This is particularly the case for carbon fiber-reinforced epoxy composites, where the high modulus of the fibers and low modulus of the matrix results in the fibers supporting most of the applied load. For metal and ceramic matrix composites where the matrix has much higher moduli than for polymers, the fibers do not carry as much load;

however, the difference in stress between fiber and matrix often remains high (and ncreases if the matrix yields by plastic deformation). The strengths of UD composites, as with their moduli, are very anisotropic. The strength transverse to the fiber direction is strongly affected by both matrix and fiber–matrix interface properties, and also by potential stress concentration sites at free surfaces perpendicular to the fibers. Its reliable prediction is therefore very difficult.

3.1 Statistics of Fiber Strength

The majority of the literature regards materials strength as a random variable, without inquiring too deeply into the causes of material failure, and most statistical treatments of failure adhere strictly to the weakest link failure hypothesis. A chain breaks in tension when one or more of the links fail. The failure event is thus controlled by the weakest link (or links) in the chain. The failure of a fiber is perhaps the simplest application for weakest link statistics (see *Fiber Strength**). The fiber length is considered to consist of N elements of equal length that are small enough for just one defect to be present. The strength of such elements is a random variable. The assembly of elements (i.e., the whole fiber) breaks when the load carried by the fiber is large enough for the weakest element (containing the largest defect) to fail. Just one element needs to fail to cause the failure of the fiber. Suppose that $F(\sigma)$ is the cumulative strength distribution for one element of the system, i.e., $F(\sigma)$ is the probability that the strength of the element is less than σ, so that $1-F(\sigma)$ is the probability that the strength is greater than σ.

For an assembly of N elements arranged as a chain (as would be the case for a fiber), each with statistically independent strength characteristics and each subjected to a uniform stress σ, the probability that the assembly survives is $[1-F(\sigma)]^N$, since each element must have strength greater than σ. The probability that the application of the stress σ causes the failure of at least one element is then given by:

$$P_f(\sigma) = 1 - [1 - F(\sigma)]^N \qquad (13)$$

which is a mathematical statement of the weakest link failure hypothesis. When the number of fiber elements N becomes very large, as their length decreases, it is possible to apply the asymptotic results of extreme value theory (Gumbel 1954). In the asymptotic limit $N \to \infty$ there are just three statistical distributions that arise from Eqn. (13). Two of these involve a statistical distribution for strength σ defined over the interval $-\infty < \sigma < \infty$, which is not suitable for applying to strength measurements because the strength of fibers can be sensibly defined only for positive values. The third possible asymptotic distribution, the Weibull distribution (1951), is the only asymptotic distribution that is defined on the interval $0 < \sigma < \infty$. Thus, there are sound statistical reasons, based on extreme value theory, for using the Weibull distribution when correlating experimentally measured values of fiber strength. The cumulative form of the Weibull distribution is:

$$P_F(\sigma) = 1 - \exp[-\delta(\sigma/\sigma_o)^m] \qquad (14)$$

where $P_F(\sigma)$ is the probability of failure in the stress range $0 \to \sigma$ and where δ is the length of each fiber element. The parameter m is the Weibull modulus and σ_o is a scaling parameter.

3.2 Strength of Fiber Bundles and UD Composites with Weakly Bonded Interfaces

For PMCs where interface bonding is poor, to the extent that it can be neglected, the UD composite, when loaded in the fiber direction, behaves in a similar way to a loose bundle of fibers where *equal load sharing* (or global load sharing) can be assumed following fiber fractures. For such composites, a fiber failure means that the failed fiber is unable to support load at any point along its length and the load it carried is shared equally amongst all surviving fibers. The classical work of Daniels (1945) showed that, as the number of fibers increased, the statistical distribution for bundle strengths is asymptotic to a normal distribution. The analysis provides an accurate value for the mean strength of the bundle and it indicates that the standard deviation tends to zero as the number of fibers in the bundle tends to infinity.

The important result is that if the number of fibers in a bundle is large enough, then the strength of the bundle has a determinate value that is easily derived from the strength distribution for individual fibers, namely $\sigma_o m^{-1/m}$. Coleman (1958) applied the general theory of Daniels to the case when the fiber strengths are governed by the Weibull distribution. The early analyses were not able to indicate just how large a bundle must be before its strength distribution can be represented by the normal distribution. McCartney and Smith (1983) carried out extensive, computer-based calculations showing that the strength distribution could be accurately approximated by a normal distribution whenever the number of fibers in a bundle exceeded 200. The strength properties of the fibers have an effect on this number. It is worth noting that for some ceramic composites in the last stages of damage development before final catastrophic failure, the interfaces are all debonded and the cracked matrix is behaving as though it is detached from the fibers. The composite strength derives solely from the fibers, with the result that catastrophic failure of such composites can be modeled using loose-bundle theory.

3.3 Strength of UD Composites with Strong Interface Bonding

Most PMCs have reasonably strong interfacial bond strength between fibers and matrix, leading to the situation that a failure in one fiber does *not* mean that the failed fiber cannot support load in regions along its length which are remote from the point of fiber fracture. Strong interfacial bonding also leads to the action of shear tractions at the interface in the stress transfer zone that is located in the neighborhood of the fiber break. Fiber fracture then results in local transfer of load from the failed fiber to the surrounding matrix and nearby intact fibers. This is known as *local load sharing* and occurs only within the *stress transfer length* (usually a few fiber diameters) associated with a fiber fracture or matrix crack.

Statistical models have been developed that allow load carried by a broken fiber to be shared equally amongst only the neighboring fibers. These models are applied only to very small lengths of composite material, of the order of several fiber diameters, representing the region where fiber–matrix stress transfer occurs. As macroscopic lengths of composite need to be considered, the models have been modified so that the composite is represented by series of bundles of fibers, where each bundle has the length of the stress transfer zone and is subject to local load sharing. These models are often referred to as series/parallel models that can be analyzed for both equal and load sharing when fibers break (Smith and Phoenix 1981, Smith 1982, Phoenix and Smith 1983, Smith *et al.* 1983).

When the interface is strong, a fiber fracture occurs with very little fiber–matrix debonding. Stress transfer from the broken fiber to the neighboring matrix and surrounding fibers is localized and involves significant stress concentrations in the matrix and some stress concentration in neighboring unbroken fibers. This type of interface behavior leads to the growth of a dominant crack from the first fiber to fail. Fracture surfaces of the composite are almost smooth in nature and, contrary to what is observed with weak interfaces, there is little fiber pullout. For strongly bonded composites, stress transfer at broken fibers or matrix cracks can be modeled, assuming that the interface is perfectly bonded for all stress states.

For this case, *shear lag* modeling (a rather approximate technique for predicting stress transfer between fiber and matrix due to the action of shear tractions on the interface) was first proposed by Cox (1952), and further developed by Aveston and Cooper (1973) and Nayfeh (1977). A variational method (based on minimizing an energy function for an assumed approximate representation of the stress field) predicting the stress field was provided by Nairn (1992) and complete solution methods, giving both stress and displacement fields, have been developed by McCartney (1989), 1999a, Extensions of global and local load sharing analyses to the case of an elastoplastic

or creeping matrix can be found in Beyerlein and Phoenix (1996), Foster *et al.* (1998), and Iyengar and Curtin (1997).

3.4 Characterising Interfacial Debonding

The measurement of fiber–matrix interface properties is usually carried out using special tests. Examples include the micro-drop test (suitable for polymer composites), fiber fragmentation test (suitable for matrices with high failure strain), fiber pull-out test (suitable for polymer composites), and fiber push-through test (suitable for metal and ceramic composites reinforced with large-diameter fibers). Each of these tests is designed to lead to fiber–matrix debonding, and the interpretation of the results of such experiments requires the use of a suitable model that enables interface properties to be related to the applied load and corresponding displacement. Interface "strength" is a very difficult concept to define unambiguously.

If one imagines that a fiber–matrix interface is subject to a uniform tensile radial stress, then one can accept that at a critical value of this radial stress the interface will fail, although failure may initiate from an interfacial defect. This type of interface failure does not usually occur in practice except from the effects of thermal residual stresses, where thermal expansion mismatch between fiber and matrix can in some cases lead to a sufficiently large uniform tensile stress at the interface. For the interface tests mentioned above, the loading of the interface is much more complex, involving combined shear and normal tractions and the influence of friction for regions of debonded interfaces.

Two distinct approaches have been made to modeling the complex stress states occurring during interface failure. The first approach assumes that the interface fails at a critical value of the interfacial shear stress τ, and that in the debonded region the interfacial shear stress has the uniform value τ (refer to the shear lag model of Aveston *et al.* 1971). The second approach assumes that stress transfer from fiber to matrix in the debonded region is governed by the Coulomb friction law, where the coefficient of friction is the interface parameter rather than τ (see McCartney 1989, Hutchinson and Jensen 1990). For this case the shear stress is nonuniform in the debonded region.

The constant shear stress model and the Coulomb friction law do not involve the interfacial energy associated with the progressive growth of an interfacial debond during loading. This energy can be included in the model only if the singularity at the debond tip is modeled correctly. This is very difficult to achieve using analytical modeling methods (see Tandon and Pagano 1996, 1998, Pochiraju *et al.* 1999). Analytical modeling is possible, however, if one ignores frictional effects resulting from debonding and

considers only the energetics of propagation for a debond that is long enough for there to be negligible interaction between the debond tip and the crack in the fiber or matrix. For a frictionally bonded composite, where there is mechanical contact and negligible bonding between fiber and matrix, the use of the Coulomb friction model of interfacial behavior is justified.

3.5 Matrix Cracking and Bridged Cracks

Aveston *et al.* (1971) applied a shear lag model of fiber–matrix stress transfer to the prediction of matrix cracking in brittle matrix composites using an energy balance approach. The fiber and matrix strengths are such that all fibers remain intact when the matrix is traversed entirely by a crack. The well-known classical result for the matrix cracking stress ε_{mc} is:

$$\varepsilon_{mc} = \left(\frac{12\gamma_m\tau}{R} \frac{V_f^2 E_f}{V_m E_m^2 E_A} \right)^{1/3} \qquad (15)$$

where $2\gamma_m$ is the fracture energy of the matrix, R is the fiber radius, and where E_A is the axial modulus of the composite in an undamaged state. Marshall *et al.* (1985), Budiansky *et al.* (1986), and McCartney (1987) have adopted a fracture mechanics approach to such predictions by considering the loading conditions that will cause a pre-existing defect in the matrix (bridged by fibers) to propagate unstably.

Key aspects are: (i) modeling the crack bridging relationship between the effective traction applied to the crack faces by intact fibers and the crack opening displacement; and (ii) the development of the energy release rate for bridged cracks in terms of the crack bridging relationship. Analyses of bridged cracks have shown that as the crack length increases the energy release rate becomes independent of the crack length, provided that fibers remain intact during loading. McCartney (1987), 1992b, 1992c, showed that Eqn. (15) was consistent with the fracture mechanics approach to the prediction of matrix cracking, provided that bridged matrix cracks are sufficiently long. Marshall and Cox (1987), Cox and Marshall (1991), and Cox (1991) have analyzed in detail the behavior of bridged cracks for the case when fiber fracture occurs during propagation. McMeeking and Evans (1990) and McCartney (1996) have modeled the growth of matrix cracks during fatigue loading. Cox and Rose (1994) have considered the modeling of crack bridging for the case of time and cyclic loading.

3.6 Monte Carlo Models of Tensile Strength

The modeling of the strength of a well-bonded composite using statistical principles has required simplifications that enable the analysis to be tractable. Statistical approaches to static strength prediction using equal or local load-sharing concepts with series/parallel structures are very rudimentary when dealing with stress transfer from fiber to matrix caused by fiber fracture. Imposing more realistic load-sharing methods leads to intractable statistical analysis. To overcome this problem and also to test statistical models that have been developed, Monte Carlo concepts have been used for static strength prediction. The Monte Carlo approach does not attempt to formulate and solve the problem of failure prediction using probability distribution functions and analytical techniques. The approach is to set up a numerical simulation of the failure of a UD composite, where the composite is regarded as an assembly of thin layers of equal thickness δ, having the same order as the stress transfer length.

Each layer is regarded as an array of representative volume elements of the composite, where each element comprises just one fiber element together with the matrix with which the fiber element is associated. This representative volume element can be thought of as a fiber–matrix cell. The failure strain of any fiber element in a cell is randomly generated from some statistical distribution function that characterizes their strength. Having attributed a failure strain to each fiber element, the model of the composite can be used to determine the failure strain of the composite by identifying the locations of fiber–matrix cells in the system where fibers fail and redistributing the load carried by a failing cell to surrounding fiber–matrix cells. For a given set of failure strains for the fiber elements in the system, the model predicts a single failure strain for the composite. The mean strength and statistical variability of composite strength can be determined only by carrying out many repeated simulations of composite failure.

Curtis (1986) developed a model that was designed to simulate the behavior of the composite by representing the composite as a set of stacked layers of rectangular arrays of fibers. For the Curtis model, the effects of the matrix are neglected and failure is assumed to occur when all of the fiber elements have failed in just one of the layers. A consequence of this assumption is that the fracture surface will be very flat and normal to the direction of the applied load. This would only be appropriate for composites where the interface strength is high. Curtis assumes that the failure strains of fiber elements can be modeled by the normal distribution. More recently, Curtin and Takeda (1998a) have developed a Monte Carlo model for the prediction of the tensile strength of UD fiber-reinforced composites in which stress transfer associated with fiber breaks is accounted for by a shear-lag model that imposes a uniform shear stress in the debonded region. Curtin and Takeda (1998b) have applied their model to investigate the strength behavior of polymer composites. Curtin *et al.* (1998)

developed the model further to allow for the effects of matrix cracking in brittle matrix composites.

The effective stress–strain behavior of the failed cell is an important input to any Monte Carlo simulation technique. This can be modeled through the use of a micromechanical model (McCartney 1999a) that accounts for localized load transfer between fiber and matrix associated with fiber failure. The model also takes account of the effects of debonding at the fiber matrix interface. Debonding will have a significant effect on the local stress transfer between fiber and matrix, leading to a significant effect on the effective axial stiffness of the fiber–matrix cell. The change in cell stiffness arising from a fiber fracture and associated fiber–matrix debonding leads to stress transfer between neighboring cells where the stress carried by the failed cell is reduced and that carried by the neighboring cells is increased, according to a specified load-sharing rule.

3.7 Longitudinal Compressive Strength

Failure of continuous, aligned, fiber-reinforced laminae under uniaxial compressive load may occur as a result of three competing mechanisms: (i) fiber microbuckling (or fiber kinking); (ii) Euler macrobuckling; and (iii) interlaminar shear failure. Both Euler macrobuckling and interlaminar shear failure can be avoided by careful consideration of the specimen dimensions (Soutis 1991). It is thought that microbuckling in composite laminates initiates as a result of the elastic bending of fibers, loaded by the matrix in shear (Weaver and Williams 1975). At a critical strain, the fibers fail in compression on their concave side at points of maximum fiber curvature. The microbuckle then spreads across the specimen width by a process of successive buckling and fracture along the fibers and by the transfer of load to adjacent fibers which have already buckled under the axial strain (see Fig. 1).
Figure 1
Fiber microbuckling under compressive loading (β = boundary orientation angle, ϕ = inclination angle (5–10°), and w = kink band width (10–15 fiber diameters)).

The process can be described in three stages: (i) elastic kinking; (ii) plastic kinking; and (iii) final collapse as a result of the fiber failure at the kink boundaries. The elastic kinking is initiated at the free edges of the laminate or at a defect, such as a void, fiber curvature or interfacial debond. The plastic kinking stage consists of plastic shear deformation of the matrix material under compression load. There is no definitive theoretical model for predicting longitudinal compressive strength, $S_{11}(C)$, of continuous aligned fiber-reinforced laminates. However, combining the modeling of Weaver and Williams (1975) and Budiansky (1983) it is possible to obtain a reasonable estimate of the longitudinal compressive strength. The critical composite stress can be calculated using the Euler buckling equation (Soutis 1991):

$$S_{11}(C) = \left(\frac{\pi d_{\mathrm{f}}}{4w}\right)^2 E_{11} \qquad (16)$$

where d_{f} is the fiber diameter, w is the kink band width (typically 10–15 fiber diameters), and E_{11} is the longitudinal elastic modulus of the composite (see Fig. 1). The fiber diameter and kink band width are related as follows (Soutis 1991):

$$\frac{w}{d_{\mathrm{f}}} = \frac{\pi}{4}\left(\frac{2\tau_{\mathrm{m}}^{\mathrm{u}}}{E_{11}}\right)^{-1/3} \qquad (17)$$

Combining Eqns. (16 and 17) gives:

$$S_{11}(C) = (2\tau_{\mathrm{m}}^{\mathrm{u}})^{2/3}(E_{11})^{1/3} \qquad (18)$$

Recent modeling attempts to include fiber waviness, which is experimentally determined (Berbinau *et al.* 1999). These models are still under development.

3.8 Transverse Compressive Strength

An aligned, continuous, fiber-reinforced laminate under transverse compressive load usually fails by shear failure of the matrix (Fig. 2). This mode of failure may be accompanied by fiber–matrix debonding and crushing. Transverse compressive strength $S_{22}(C)$ for these materials is generally higher than the stress at which the unreinforced matrix material yields under compressive loading. This is due to the difficulty of fibers sliding across each other along the shear surfaces. Based on Mohr's strength theory, Skudra (1985) suggests that $S_{22}(C)$ can be determined from the following relation:

$$S_{22} = \frac{2S_{22}(T)\sin 2\phi}{(1 + v_{23})(1 - \cos 2\phi)} \qquad (19)$$

where $S_{22}(T)$ is the transverse tensile strength of the lamina, ϕ is inclination angle of the fracture path (experimentally determined) with respect to the direction of loading (see Fig. 2). The value of ϕ is typically
Figure 2
Transverse compressive fracture.

30° for a wide range of fiber-reinforced plastics (e.g., glass and carbon fiber-reinforced epoxy).

3.9 In-plane Longitudinal Shear Strength

Micromechanics modeling of in-plane shear strength S_{12} has not developed to the stage where a reliable prediction based on constituent material properties is possible. The simplest method of estimating shear strength is to assume that a "rule of mixtures" applies:

$$S_{12} = \tau_i^u A_i + \tau_m^u (1 - A_i) \qquad (20)$$

where A_i is the fraction of the fracture area occupied by the interface, and τ_i^u and τ_m^u are the interfacial and matrix shear strengths, respectively. This approach assumes that the fracture path is planar and bisects a regular square array. Fracture usually propagates preferentially through the matrix in a nonplanar manner without disturbing the fibers, not conveniently along the fiber–matrix interface as assumed in Eqn. (20). Shu and Rosen (1967) performed a more rigorous analysis of the unidirectional laminae and obtained "lower" and "upper" bounds to S_{12}.

It was assumed that the fibers were elastic-brittle and rigid and the matrix was elastic-perfectly plastic, obeying the von Mises yield criterion. An upper shear strength limit of $4\tau_m^u/\pi$ was predicted for $V_f \rightarrow 1$, which is a 27% increase on the lower bound value τ_m^u. Hancox (1982) showed that for a well-bonded, carbon fiber-reinforced epoxy material, the predicted and experimental values are in tolerable agreement for $V_f \leqslant 0.6$.

In the case where the fiber–matrix interface is the weakest link, it has been suggested (Purslow 1976) that:

$$S_{12} = \frac{\tau_m^u}{(1 + V_f)^2}. \qquad (21)$$

This approach ignores the presence of stress concentrations within the lamina, which increase in magnitude as $V_f \rightarrow 1$. It is possible to obtain reasonable agreement between the experimental data and the following empirical relationship (Chamis 1987, 1989):

$$S_{12} = [1 - (\sqrt{V_f} - V_f)(1 - G_m/G_{12f})]\tau_m^u \qquad (22)$$

For laminae with a brittle matrix, the stress concentration effect will cause the strength of the composite to be lower than that of the unreinforced matrix material. If the matrix is able to relieve these stress concentrations through local deformation processes, then $S_{12} \approx \tau_m^u$.

4. Conclusion

The current state of the art for modeling the thermoelastic properties of undamaged, unidirectional composites from fiber and matrix properties is well developed and used in design, and it is unlikely to be improved significantly in the future. For regular, hexagonal arrays of fibers the transverse isotropic properties are well modeled by analytical formulae (McCartney 1992a), as has recently been demonstrated for glass- and fiber-reinforced plastics, and for silicon carbide-reinforced aluminium alloy composites, by comparing predictions with FEA solutions and other analytical techniques (unpublished work by Li and McCartney 2000). Issues of future interest are the effects of nonuniform fiber distributions on the properties of both undamaged and damaged composites.

The failure of most unidirectional fiber-reinforced composites, tested in the longitudinal direction, is dominated by the behavior of the fibers whose strength is statistically distributed. While such composites are rarely used in practice, they are however used in fiber-reinforced laminates, whose failure is often dominated by the behavior of the fibers in the 0° plies of a laminate. The failure mechanisms and statistical behavior of UD composites are thus highly relevant to laminate behavior, but proper account must be taken of the triaxial stress states arising in the

individual plies of a laminate and of the effects of thermal residual stresses arising from thermal expansion mismatch between the plies.

In current design methodologies, the failure of individual fibers is rarely considered. The conventional approach is to apply one or more of a wide variety of laminate-failure criteria to local stress states in laminated structures. Usually no account is taken of the modes of failure that may arise, or of any damage formation that can lead to localized strain softening and to significant reductions in stress concentrations. This is a very important future development area for the design of composite structures and the failure behavior of individual fibers in such structures will be a key factor in the development of physically based models of damage development and failure of composite structures. The major technical requirement is the need for reliable scale bridging of composite performance from the fiber–matrix level to the ply level, and then to the laminate level, taking full account of complex loading modes and damage formation and the various modes of failure that can arise.

Continuous Parallel Fiber Composites: Fracture

The purpose of this article is to provide a brief overview of the micromechanics associated with fracture of unidirectional composites with particular emphasis on toughening mechanisms. Overload fracture is a common failure mode for high-strength, high-stiffness materials. Crack-like flaws are inevitably generated in a material either during fabrication or during service life. If the severity of the flaw is large or the load is high enough, then the flaw becomes the initiation site for catastrophic unstable fracture. A major advantage of composites, however, is that their microstructure promotes the accumulation of small flaws (damage), rather than the growth of a dominant crack. This mechanism of damage accumulation imparts significant energy dissipation capability or fracture toughness to the material, and is most exploited in brittle matrix composite systems.

Composites are most often classified in terms of their matrix, and are designated as polymer matrix composites (PMCs), metal matrix composites (MMCs), or ceramic matrix composites (CMCs). Although these systems possess widely different mechanical properties, they experience similar damage accumulation processes. More significantly, although damage introduces a high level of complexity in determining the stress field ahead of a crack tip or a notch, energy-based fracture mechanics concepts allow an elegant means of characterizing the condition for failure, which spans across all the three matrix systems. These issues on the mechanics and mechanisms of fracture of unidirectional composites are discussed in this article.

As an introduction to the fracture of a material from a dominant flaw, it is useful to consider an elliptic hole embedded in an isotropic or an orthotropic material under plane strain deformation (Fig. 1). The major and minor axis are represented by a and b, respectively, so that the radius of curvature at the end of the major axis (ρ) is b^2/a. For a far-field applied stress, σ_a, perpendicular to the major axis, the maximum stress σ_{yy} in the loading direction occurs at the crack tip (A), and is given by:

$$\sigma_{yy} = \sigma_a \left(1 + 2\sqrt{\frac{a}{\rho}}\right) \tag{1}$$
Figure 1
Sketch illustrating an infinite specimen with a notch.

for an isotropic material (Timoshenko and Goodier 1951, Inglis 1913), and by:

$$\sigma_{yy} = \sigma_{\mathrm{a}}\left\{1 + \sqrt{\frac{a}{\rho}}\left[2\left(\sqrt{\frac{E_{yy}}{E_{xx}}} - v_{yx}\right) + \frac{E_{yy}}{G_{xy}}\right]^{1/2}\right\} \quad (2)$$

for an orthotropic material (Bishop 1972, Green and Taylor 1945), when loaded in one of the material's principal directions. Here E_{xx} and E_{yy} are the elastic moduli in the principal x and y directions, respectively, and G_{xy} is the in-plane shear modulus of the composite. Also, v_{yx} is the principal Poisson's ratio, equal to the normal contraction in the x direction divided by the tensile elongation in the y direction, when a uniaxial stress is applied in the y direction.

There are two important implications of these results:

(i) In the limit for a sharp crack, when b and ρ approach zero, the stress σ_{yy} at A becomes singular (tends towards infinity). Under this condition, the simple stress-based design concept of a stress concentration factor (SCF) to specify the condition for failure at the crack tip can no longer be used.

(ii) At any value of ρ, the σ_{yy} stress at the notch tip is significantly higher (typically up to 3.5 fold) in a longitudinally loaded unidirectional lamina of comparatively high E_{yy} than in an isotropic material.

Item (i) requires the concepts of fracture mechanics and is treated in greater detail later. However, a few

comments regarding item (ii) are worth mentioning here. The higher σ_{yy} stress for a longitudinally loaded unidirectional lamina may imply that it is more susceptible to transverse fracture (fracture plane perpendicular to the fiber axis) than an isotropic material, for the same geometry and far-field applied stress. However, the anisotropic properties of a unidirectional lamina, primarily the weak strengths in the transverse direction and in shear, introduce crack blunting and stress–relaxation pathways that reduce the level of σ_{yy} ahead of the notch tip. These stress-reduction or crack-shielding mechanisms often make the composite more fracture resistant than the monolithic constituents. Interface mechanics and mechanisms play a critical role in determining the damage tolerance of a composite structure, and are discussed in *Composites: Interfaces** (Cook and Gordon 1964, Kendall 1975, Warrier *et al.* 1997, Gupta *et al.* 1992, He and Hutchinson 1989, Majumdar 1998).

In the case of fracture of a unidirectional lamina with a crack perpendicular to the fiber axis, the unit energy dissipation processes include crack blunting by fiber-matrix delamination, crack bridging by the intact fibers, fiber fracture, matrix plasticity, and crack pinning or trapping. The first tier composite properties, such as the elastic modulus and tensile strength in the principal material directions, dictate how the composite might respond to the presence of a sharp crack. In one case (see Fig. 2(a)) damage may accrue ahead of the notch and lead to crack growth along the original notch/crack plane. Alternatively, if the transverse strength is very low compared to the longitudinal strength, large-scale blunting by splitting along the fiber axis may occur (Fig. 2(b)). The principal stress in the loading direction (σ_{yy}) is thereby relaxed ahead of the crack tip, making the material highly resistant to the propagation of a dominant crack. A low shear strength can also produce a similar blunting effect and contribute to the material's resistance to crack growth. Indeed, some systematic experiments performed by Cooper and Kelly (1967) indicated that if the lamina shear strength was less than 8% of the longitudinal strength, then large-scale shear band growth parallel to the fibers occurred in preference to crack propagation along the original plane of the notch. A more general fracture mode is a combination of damage ahead of the notch in both the x and y directions (Fig. 2(c)), followed by tortuous crack growth in an overall direction perpendicular to the loading axis.

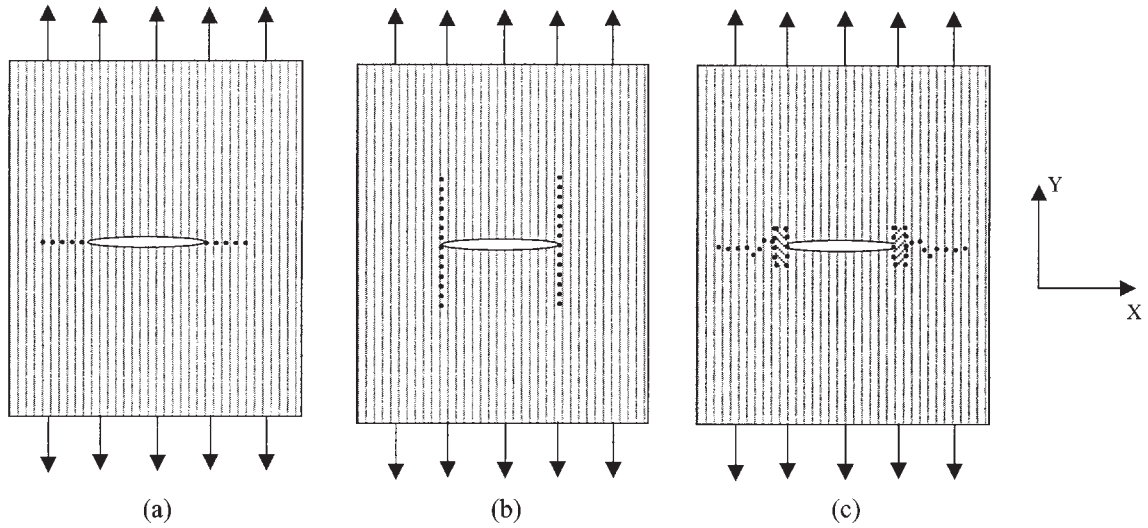
In monolithic materials, the crack path morphology follows that of Fig. 2(a). Ahead of the crack tip, the different stress components then bear a constant ratio to one another as the crack grows, although their overall magnitude increase with crack length; note from Eqn. (1) that the stress σ_{yy} ahead of the crack tip at constant σ_{a} is proportional to $\sqrt{a}$. This type of crack growth is termed as *self-similar* growth. Alternatively, the crack growth profile in


Figure 2
Failure modes in a longitudinally loaded notched/cracked lamina, with the dots indicating the crack extension paths. (a) Crack extension along the original crack plane; (b) damage and crack growth parallel to the loading direction; and (c) damage along the loading direction, followed by tortuous crack growth in an overall direction perpendicular to the loading axis.

most composites follows Figs. 2(b) and 2(c), where the stress components no longer bear the same ratio with growth of the crack. This loss of self-similarity makes the application of established rules of fracture mechanics rather questionable. However, experimental data indicate that for a given mode of fracture (Fig. 2), the energy required for a significant advance of the initial crack is often characteristic of the material, being only slightly dependent of the specimen geometry. These observations have provided impetus in extending the energy concepts of fracture mechanics, developed primarily for isotropic materials, to composites, thereby allowing a means to assess damage tolerance of a structure in the presence of a notch or a crack-like flaw.

1. Fracture Mechanics Concepts

Fracture of materials can be classified under three major modes of loading, Mode I (or opening mode), Mode II (or in-plane shear mode), and Mode III (or out-of-plane shear mode). Confining attention initially on an isotropic elastic material, the stresses ahead of the crack tip for any combined mode of loading can be expressed as:

$$\sigma_{ij} = \frac{K_{\mathrm{I}}}{\sqrt{2\pi r}} f_{ij}^{\mathrm{I}}(\theta) + \frac{K_{\mathrm{II}}}{\sqrt{2\pi r}} f_{ij}^{\mathrm{II}}(\theta) + \frac{K_{\mathrm{III}}}{\sqrt{2\pi r}} f_{ij}^{\mathrm{III}}(\theta) \quad (3)$$

where r is the radial distance from the crack tip, the $f_{ij}(\theta)$ functions provide an angular dependence, and

K_{I}, K_{II}, and K_{III} are the stress intensity factors that characterize the magnitude of the stress singularity for Modes I, II, and III type of loading, respectively (Paris and Sih 1964, Tada *et al.* 1973). In the context of Fig. 1 and Eqn. (1), K_{I} can immediately be identified as $\sigma_{\mathrm{a}} (\pi a)^{1/2}$. The stress intensity factors are related to the elastic energy released per unit advance of the crack tip (designated by the symbol, G) through equations of the form:

$$G_{\mathrm{I}} = \frac{(1 - v^2)K_{\mathrm{I}}^2}{E} \quad (4)$$

where Eqn. (4) is for a plane strain case and for a pure Mode I type of loading.

Note that K or G characterize the driving force due to an applied load, and can be calculated for any given crack length and load using analytical or computational procedures. Fracture under Mode I loading is postulated to occur when K_{I} or G_{I} reaches a critical value, designated as K_{Ic} and G_{Ic}, respectively, known as the *fracture toughness* of the material. The applicability of this concept in monolithic materials has been validated experimentally using specimens with widely different geometry and crack length. Similar arguments hold good for combined modes of loading, and the effective G is given by:

$$G_{\mathrm{total}} = G_{\mathrm{I}} + G_{\mathrm{II}} + G_{\mathrm{III}} \quad (5)$$

Although K_{Ic} or G_{Ic} can be interchangeably used to characterize the criticality of fracture, they have

traditionally involved two modes of thinking. In the case of K, failure is viewed as occurring when a critical stress field is realized ahead of the crack tip. Alternatively, G is most often viewed in terms of the overall energetics of failure, making it more amenable to experimental determination. Thus, it can be shown that G can simply be expressed as:

$$G = \frac{P^2}{2B} \frac{\mathrm{d}C}{\mathrm{d}a} \qquad (6)$$

where P is the applied load, C is the specimen compliance, which is a function of crack length a, and B is the specimen thickness.

The lack of self similarity of crack growth in composites makes it difficult to ascribe the onset of crack advance in terms of a defined level of stress field. Alternatively, G_{Ic} retains its significance, in that it still characterizes the level of elastic energy released per unit of crack advance. That is why the energy release rate parameter is most often used in the composites literature, although the K_{Ic} level is also specified through equations of the form shown in Eqn. (5).

There are two additional parameters that become important when inelastic processes dominate. One is the J integral, which is a path-independent integral for any path around the crack tip, and represents the energy associated with a unit advance of the crack tip under situations where stress increases monotonically. Thus, J is quantitatively equal to and synonymous with G for initiation of crack propagation; however, the J integral more rigorously accounts for inelastic processes near the crack tip, and in monolithic materials it characterizes the crack-tip stress and strain fields, similar to K in linear elastic solids.

A final parameter that often enters into fracture mechanics formulations is the crack tip opening displacement (δ), which is the total displacement at the crack tip due to elastic and inelastic deformation processes. In the case of ductile metal alloys, the largest contribution to δ comes from plasticity, and at the onset of fracture it is of the order of distance between precipitates/second phase particles where ductile void nucleation occurs. When plasticity is the dominant inelastic mechanism, δ is related to J through equations of the form:

$$\delta = \frac{kJ}{\sigma_o} \qquad (7)$$

where k is of the order of unity, and σ_o is the yield strength of the material in uniaxial tension. At the onset of fracture, δ attains a critical value δ_c associated with a critical value of J_{Ic} (or equivalently G_{Ic} or K_{Ic})

2. Fracture Mechanisms

Physically δ_c represents the blunting of the crack tip due to inelastic deformation. In monolithic materials

it ranges from submicron to about 10–20 μm. Alternatively, the crack opening displacements in composites are much larger due to damage ahead of the crack tip, making the use of conventional fracture mechanics difficult. Unlike highly plastic solids, where the entire structure may behave nonlinearly due to spread of the yield zone, in composites the material behaves elastically in most of the structure, and large nonlinear processes dominate only in the near crack tip region. Therefore, it is convenient to describe the toughness of the composite in terms of a local crack separation law, which now includes all nonlinear effects.

Figure 3 illustrates such a traction law, and the fracture resistance of different composites (PMCs, MMCs, and CMCs) can be traced to variations in this traction law due to different inelastic mechanisms. The area under the curve represents the work of fracture contributed by such a local traction law, and is best designated by its contribution to the energy spent in propagation the crack in the form of parameter ΔG:

$$\Delta G = \int_0^{\delta_c} \sigma(\delta)\mathrm{d}\delta \qquad (8)$$

In Fig. 3, the rising portion of the curve is due to increasing stresses that take the material point at the crack tip from an initial state to a state of maximum tension. The declining portion is due to different separation mechanisms, such as debonding, pull-out, etc. Most of the analytical formulations in the fracture mechanics of composites deal with the rising portion of the traction separation law, implicitly assuming that there is a vertical drop off to zero load from the point of maximum stress. However, the declining portion can contribute substantially to the work of fracture.

In this section, attention will be concentrated on cracked unidirectional composites loaded in the fiber
Figure 3
Stress-displacement traction law.

direction (Figs. 2(a)–2(c)), since the best properties of the composite are obtained in this configuration. Also, at this point it is important to distinguish between different types of systems: (i) brittle matrix system, and (ii) ductile matrix system. The former includes CMCs and PMCs based on brittle polymers like polyimides, while the latter includes MMCs and PMCs that are made with ductile polymers like thermoplastics and toughened resins. This distinction is needed because failure of composites with brittle matrices is preceded by transverse matrix cracks that propagate from the crack/notch tip, leaving intact fibers in their wake. Alternatively, in ductile-matrix systems, it is the fibers that crack first which are then followed by bridging by the ductile matrix. In CMCs, damage tolerance is achieved through a weak fiber-matrix interface. Otherwise, matrix cracks can propagate right through the fiber, making the brittle matrix composite of little engineering value. Energy dissipation in these systems is largely through: (i) crack bridging by the intact fibers, which produce a stress intensity factor (K_B) that opposes the K_{appl} due to the applied load (this is also called crack tip shielding), and (ii) pull-out of cracked fibers, where the fiber cracks are located at some nonzero distance from the crack-plane. In ductile matrix systems, energy dissipation is completely dominated by plastic deformation of the ductile matrix between the cracked fibers. One consequence of this difference is that a higher fiber volume fraction often enhances toughness in brittle matrix systems, whereas it can reduce toughness in ductile matrix systems.

2.1 Brittle Matrix Systems

In terms of the mechanisms of fracture, it is useful to consider the two configurations depicted in Figs. 4(a) and 4(b). These are designated as Case I and Case II, respectively.

In Fig. 4(a), a steady-state condition is considered wherein a single matrix crack emanates from the notch tip at a sufficiently low load. As this matrix crack grows, leaving behind intact fibers, a situation is reached where the fiber at the notch tip just begins to fail. Thereafter, failure of the composite can occur in a steady state manner, and the fracture toughness corresponds to the applied stress intensity factor at which lead fiber fails. The toughening associated with Case I has been worked out by Budiansky and Amazigo (1989). In Case II, we consider fracture of fibers that have a statistical strength distribution so they fail at different distances from the crack plane. Final failure requires that these fibers pull-out of the matrix. Because of frictional resistance, substantial energy is dissipated in the decreasing segment of the stress-displacement traction law (Fig. 3), contributing to significant increase in the toughness of the composite. The work of pull-out has been worked out by a number of investigators (Kelly 1970, Phillips 1972),
Figure 4
Crack propagation in brittle matrix composites. (a) Steady-state bridging of matrix cracks by intact fibers, with the lead fiber failing at the original crack plane. (b) Matrix crack bridging, but in this case the fibers fail statistically at different distances from the crack plane. The traction law is sketched for the two cases.

and we present here the results of Thouless and Evans (1988).

(*a*) *Case I.* As shown in Budiansky and Amazigo (1989), a simple *J* integral calculation provides the following relationship:

$$\frac{J_{\text{applied}}}{A} = (1 - c)J_{\text{matrix}} + \int_0^{\delta_c} \sigma(\delta)\mathrm{d}\delta \qquad (9)$$

where *c* is the volume fraction of fibers, *A* is a factor that accounts for the orthotropy of the sheet in Fig. 4(a) (= 1.0 for identical elastic constants of the fiber and the matrix), $J_{\text{appl}} = (1 - v^2)K^2_{\text{applied}}/E_c$, and $J_{\text{matrix}} = (1 - v^2)K^2_m/E_m$, where K_m is the critical stress intensity factor for the monolithic matrix. Also, E_m is the modulus of the matrix, and E_c is the composite longitudinal modulus ($= cE_f + (1 - c)E_m$, where E_f is fiber modulus). Values of *A* as a function of *c* and E_f/E_m are plotted in Budiansky and Amazigo (1989). Note that *J* is synonymous with *G*, but is more appropriate here because of inelastic processes. Also, if there are parallel matrix cracks emanating from the notch tip, then the first term in Eqn. (9) is multiplied by the number of those matrix cracks.

Assuming relative sliding/slipping between the cracked matrix and the intact fibers in the wake of the matrix crack, it follows that:

$$\frac{J_{\text{applied}}}{J_{\text{matrix}}} = A(1 - c)\left[1 + \frac{2c\sigma_f^{\text{avg}}}{\sigma_{\text{ss}}}\right] \qquad (10)$$

where σ_f^{avg} is the average bundle strength of the fiber, and σ_{ss} is the steady-state matrix cracking stress (sometimes referred to as the pseudo yield stress) for the composite. As shown in the ACK theory (Aveston, Cooper, and Kelly 1971), and also analyzed in the BHE theory (Budiansky, Hutchinson, and Evans 1986) σ_{ss} can be represented as:

$$\sigma_{\text{ss}} = E_c\left[\frac{6c^2 E_f \tau}{(1 - c)E_c E_m}\right]^{1/3}\left[\frac{J_{\text{matrix}}}{rE_m}\right]^{1/3} \qquad (11)$$

where τ is the axial frictional sliding stress between the fiber and the matrix, and *r* is the radius of the fiber. Note that $c\sigma_f^{\text{avg}}$ is approximately the breaking strength of an unnotched longitudinal composite, since only the fibers carry the entire load after matrix cracks run through the entire length of the composite at a stress of σ_{ss}. A typical value of $c\sigma_f^{\text{avg}}/\sigma_{\text{ss}}$ is five, so that Eqn. (10) indicates that a 10-fold toughness increase is obtainable based on this mechanism of toughening.

It is useful to note that the toughness ratio varies inversely as σ_{ss} (Eqn. (10)). Thus, while a higher frictional resistance (τ) and a smaller fiber radius (*r*) would increase the "yield strength" of the brittle matrix composite, it is detrimental to the fracture toughness.

Consequently, material design will need to be optimized, depending upon the desired application in components.

(*b*) *Case II.* In this case, we consider the statistical failure of brittle fibers, whose strength can be expressed by the two-parameter Weibull distribution. In this methodology, the cumulative probability of failure (P_f) of a fiber at a stress σ is given by:

$$P_f = 1 - \exp^{-(L/L_0)(\sigma/\sigma_0)^m} \qquad (12)$$

Here σ_o is the characteristic fiber strength at length L_o, and is usually designated as the Weibull strength, and m is the Weibull modulus.

The problem of Fig. 4(b) was analyzed by Thouless and Evans (1988). Figure 5 from Evans (1990) shows the traction law, in nondimensional co-ordinates, that result for different values of Weibull modulus, *m*. Here a value of infinity corresponds to a deterministic strength (similar to Case I), and may occur in epoxy based composites toughened with polymeric fibers, or even with SiC fibers ($m \sim 15$ in the virgin condition). Alternatively, a value of $m = 5$ more closely resembles situations that may be encountered in CMCs. Note that as *m* decreases, the declining portion of the traction law contributes more and more to the toughness of the composite. In terms of the design parameters, the toughness increase is approximately proportional to $\{r^{m-3}/\tau^{m-1}\}^{1/(m+1)}$. Thus, the toughness increases with increasing fiber radius when $m > 5$, but decreases when $m < 3$. Conversely, it increases with increasing τ when $m < 1$, and decreases when $m > 2$. This type of behavior arises because of the competing importance of the contribution to toughness from intact bridging
Figure 5

Nondimensional traction law (σ versus *u*) for the pull-out fiber case, for different values of Weibull modulus, *m* (after Evans 1990).

fibers and the failed fibers that experience pull out. Thus, knowledge of m and τ are important for optimization of composite toughness under fiber pull-out conditions.

(*c*) *Case of ductile fiber toughening in brittle matrix composites.* This type of toughening mechanism, although developed for particle toughened composites, is also applicable for ductile fiber toughened CMCs and PMCs. Under the condition that the ductile fiber is perfectly plastic and fully yielded ($\sigma = \sigma_Y$), Eqn. (8) shows that the toughening contribution per ductile fiber is simply $k\sigma_Y\delta_c$, where k accounts for a higher strength of the constrained ductile fiber. Assuming no debonding between the cracked matrix and the ductile fiber (for example, a metallic fiber), the value of δ_c is of the order of the fiber diameter, $2r$. The value of k is more difficult to estimate, but should not exceed that ahead of a crack tip, namely 3–$4\sigma_Y$. These parameters then allow a fair assessment of toughening associated with ductile fibers in a brittle matrix. A more rigorous treatment (Budiansky *et al.* 1988) leads to the result:

$$\frac{K_{\text{applied}}/K_{\text{m}}}{\sqrt{\bar{\omega}(1-c)}} = \left[1 + \frac{2c}{1-c}\frac{E_{\text{m}}S\delta_{\text{c}}}{K_{\text{m}}^2(1-v_{\text{m}}^2)}\right]^{1/2} \quad (13)$$

where S is the effective strength of the ductile fiber and c is fiber volume fraction. Also,

$$\bar{\omega} = \frac{E_{\text{c}}(1-v_{\text{m}}^2)}{E_{\text{m}}(1-v_{\text{c}}^2)} \quad (14)$$

It is useful to note that substantial increase in δ_c is possible if there is relative sliding between the fiber and the matrix, since bridging can be sustained over much larger matrix crack length. Essentially, δ_c becomes the gage length over which the debonding occurs, times the strain to failure in uniaxial tension. However, S is close to σ_Y in this case, so that there is substantial loss of stiffness of the system in the presence of matrix cracks. Since component functionality is also often based on maximum possible displacement, there will always be a need to optimize the interface for component specific performance.

2.2 Ductile Matrix Systems

In ductile matrix systems, a number of different behaviors have been observed depending on the strength of the matrix, the fiber-matrix bond strength, and the volume fraction of fibers.

When the matrix strength is low, matrix dominated shear deformation occurs prior to any fiber fracture. Indeed, in boron fiber reinforced aluminum composites, a deformation mode similar to Fig. 6 is observed (Dvorak *et al.* 1989, Awerbuch and Hahn 1979, Reedy 1980), where an intense slip zone develops over
Figure 6
Sketch illustrating H-type plastic zone development at the notch tip, followed by composite fracture along original notch plane.

a plastic zone of length (R) perpendicular to the crack plane. At a critical load, when R is on the order of 3–17-fold the crack length, the damage zone stops propagating and is replaced by failure of fibers at the crack tip. This, in turn leads to catastrophic fracture of the composite along the original notch plane. Most notable is the fact that the H-shaped shear zone is created prior to crack extension, and is absent during propagation of the crack, i.e., crack extension is non self-similar. A similar type of damage zone and crack extension has also been observed in glass fiber reinforced epoxy composites (Tirosh 1973).

In the above type of deformation mode, the effective toughening is extremely high, because the blunted crack tip attenuates the stress ahead of the crack tip over a distance of the order of the crack tip opening displacement. For crack lengths of a few millimeters or longer, toughness values of $100\,\text{MPa}\,\text{m}^{1/2}$ have been realized for the B/Al system. The effect reduces at smaller crack length, and approaches approximately $30\,\text{MPa}\,\text{m}^{1/2}$ at crack length $<0.5\,\text{mm}$. Thus,

fracture toughness may not be the appropriate parameter for predicting failure in these systems which do not obey self-similar crack growth. Dvorak *et al.* (1989) attempted to estimate the onset of fracture based on attainment of a critical strain in the fiber direction over two fiber diameter distance ahead of the crack tip. It was found that the local strain in the representative volume element for specimens with different notch lengths all fall in the error band for the failure strain of unnotched composites. The following set of equations may be used to estimate the failure load (P_{ult}) for a center-cracked panel of width W and crack length $2a$ (Zarzour and Paul 1992), and possessing an unnotched strength, $\sigma_{unnotched}$:

$$\frac{P_{ult}}{\left(1 - \frac{2a}{W}\right)} + 2\frac{\tau^*}{\pi(a_2 - a_1)}\left[-a_1^2 \ln\left(\frac{1 + \sqrt{1 + a_1^2\beta^2}}{a_1\beta}\right)\right.$$
$$\left. + a_2^2 \ln\left(\frac{1 + \sqrt{1 + a_2^2\beta^2}}{a_2\beta}\right)\right] = \sigma_{unnotched} \quad (15)$$

where

$$a_{1,2}^2 = \left(\frac{E_1}{2G_{12}} - v_{12}\right) \pm \sqrt{\left(\frac{E_1}{2G_{12}} - v_{12}\right)^2 - \frac{E_1}{E_2}} \quad (16)$$

and

$$b \approx d\left(\frac{2\pi}{3\sqrt{3}c}\right)^{1/2} \quad \beta = \frac{aP_{ult}}{b\tau^*}$$

Here, d is the fiber diameter, c is the volume fraction of fibers, τ^* is the in-plane shear strength of the unidirectional composite in the fiber direction, E_1 is the modulus in the fiber direction, E_2 in the transverse direction, G_{12} is the shear modulus, v_{12} is the Poisson's ratio, and b is of the order of distance between two adjacent fibers.

When the matrix strength is high, or the fiber volume fraction is high, the dominant damage mode is fiber fragmentation in the zone of intense matrix plastic deformation near the crack tip, and ultimately composite fracture. This is illustrated in Fig. 7(a). In order to predict the fracture toughness, some estimate of the flow stress and the critical displacement is needed, for plugging into Eqn. (8). Friler *et al.* (1993) and Argon (2000) modeled the failure process by considering that the periphery of fractured fiber tips act as the nucleation center from which intense matrix plasticity develops (see Fig. 7(b)). This is a form of macroscopic void growth, at a length scale that is significantly larger than the distance between intermetallic particles, which act as the void nucleation site for fracture of monolithic metallic alloys. Using Eqn. (8), Friler *et al.* (1993) estimate the fracture

toughness as:

$$J_{Ic} \approx \frac{1}{\sqrt{3}}(1 - c)\sigma_Y L_D \quad (17)$$

where

$$L_D \approx \beta_n d \frac{1 - \sqrt{c}}{\sqrt{c}} \quad (18)$$

and β_n is approximately 2. Here d is the diameter of the fiber, c is the volume fraction of fibers, and σ_Y is the yield stress of the matrix.

Very few experiments have been conducted on the fracture toughness of titanium matrix composites. Connell *et al.* (1994) reported a toughness of approximately $71\,kJ\,m^{-2}$ for a SiC/Ti-alloy, which may be compared with a typical toughness of $40\,kJ\,m^{-2}$ (based on $K_{Ic} = 70\,MPa\,m^{1/2}$) for monolithic Ti–6Al–4V alloy. Using Eqn. (17) with $\sigma_Y = 1040\,MPa$, $c = 0.32$, and $d = 100\,\mu m$, a toughness value of $62\,kJ\,m^{-2}$ is estimated, which compares reasonably well with the experimental data.

It is useful to note that J_{Ic} predicted by Eqns. (17) and (18) is quite strongly dependent on the volume fraction of fibers. Thus, $(1-c)(1-\sqrt{c}/\sqrt{c})$ decreases from approximately 0.59 to 0.12 on increasing the volume fraction from 0.3 to 0.6. High volume-fraction alumina/aluminum composites are currently being developed for a variety of applications, such as high-tension electrical cables and piston rods. Because of the lower strength of the alloy, and the high volume fraction of alumina fibers, toughness values significantly less than titanium matrix composites are anticipated.

A final note is in order regarding the role of the fiber-matrix interface. Equation (17) shows that the toughness is an increasing function of L_D. Weak interfaces would permit greater fiber-matrix sliding, thereby increasing the fracture toughness. This effect was elegantly utilized by Argon *et al.* (1998) to toughen aluminum-based composites, while maintaining acceptable transverse strengths. In SiC reinforced titanium matrix composites, pull-out lengths are typically less than one fiber diameter, even for weak carbon based interfaces. This is largely because of the high radial compressive stress that is generated at the fiber-matrix interface at the tip of a cracked fiber. For strong interfaces, such as those formed without a carbon layer on the SiC monofilaments, the pull-out length will be even shorter. However, the effect of a smaller L_D may be balanced by a higher flow stress associated with constrained yielding of the matrix in the fragmentation zone. Tensile tests on unnotched SiC/Ti-matrix composites with different interfaces indicate correlated fiber fractures, independent of the type of interface. Slip band observations and ultrasonic images of fiber breaks confirm that correlated fractures are a result of slip band
Figure 7
(a) Overall damage pattern in ductile matrix composites. There is a zone of plasticity where fibers are fragmented, followed by propagation of the matrix crack through that damaged region. (b) The Friler model for determining the toughness, assuming chiseling of the matrix from the broken fiber ends (Friler *et al.* 1993).

interactions, whereby a slip band impinging on a fiber localizes sufficient strain to fracture that fiber (Majumdar *et al.* 1998). Similar experiments have to be conducted with notched composites to provide an assessment of the role of interface strength on the toughness of composites with high matrix strength.

2.3 Intermediate Ductility Matrix Systems

An important characteristic of polymer matrix composites is that their behavior can range from brittle to ductile matrix systems depending on the particular polymer used. Moreover, changing the temperature or loading rate (loading history) will alter the ductility for any polymer. Higher temperatures and/or lower loading rates generally increase ductility. Both the amount of ductility and the dependence on temperature and loading history are determined by the microstructure of the polymer. This includes molecular level structure as well as morphology since many polymer matrices are two phase systems where the base polymer contains particles of a polymeric additive to improve toughness and other desirable properties. In a sense, the polymer itself is a composite.

The relationship between microstructure and ductility of polymers has been studied extensively, but is beyond the scope of this article. The reader is referred to some of the many references in this area (Bucknall 1977, Bitner *et al.* 1981, Pearson and Yee 1989, Wu *et al.* 1990, Huang *et al.* 1993, Kinloch *et al.* 1983). What

should be noted here, however, is that the effect of polymer ductility on matrix toughness can often be described in terms of a toughening mechanism involving crack tip blunting, see Eqn. (7). Thus, increasing the ductility allows more blunting of the crack tip. This, in turn, reduces the local stress concentration, thereby postponing damage initiation and retarding damage growth. The ultimate result is increased fracture toughness of the polymer. Kinloch *et al.* (1983) have investigated this mechanism, by plotting the toughness of the polymer as a function of crack tip radius, where the radius was obtained either by blunting of an initially sharp crack or by incorporating artificially drilled holes of fine enough radius at the end of a sharp notch. Specimens with sharp cracks were tested at different temperatures and cross-head speeds to vary the amount of blunting, while specimens with the artificial crack tip radii were loaded at high cross-head speeds to minimize further blunting of the crack tip. A clear relationship between the measured toughness and the root radius was found, but more importantly the behavior was independent of how the tip radius was incorporated into the specimen.

In addition to crack blunting, three other toughening mechanisms are also important in polymer composites: crack pinning, crack diversion or bifurcation, and crack bridging. The interaction of these mechanisms can be illustrated by considering the two most common forms of composites fracture in PMCs, i.e., interlaminar and transverse.

(*a*) *Interlaminar fracture.*
Crack Blunting: In interlaminar fracture, the crack propagates in the resin and/or at the resin-fiber interface parallel to the fibers. As a result, the matrix toughness would be expected to play a major role in the interlaminar fracture energy. One example of this is shown in Fig. 8 where the Mode I interlaminar fracture energy is plotted versus the Mode-I fracture toughness of the "neat" resin (i.e., the unreinforced matrix) (Hunston *et al.* 1987). The results show that tougher resins produce tougher composites, but the relationship is not a simple one; see the trend lines in Fig. 8. In the brittle range, the composite is significantly tougher than the resin so the transfer of toughness is good. Beyond a certain point, however, the transfer is less complete. To increase the fracture energy of the composite by $1 \, J \, m^{-2}$, the fracture energy of the resin must be increased by approximately $2 \, J \, m^{-2}$. The proposed explanation is that all crack blunting mechanisms involve inelastic deformation of the matrix material in the crack-tip region, with the toughness increasing with the size of the plastic/viscoplastic zone, consistent with elastic-plastic fracture mechanics principles. For brittle materials, this inelastic zone is smaller than the inter-fiber spacing, so that the resin toughness is completely transferred to the composite. For tougher materials, however, the size of the inelastic zone in the bulk resin is larger than the inter-fiber spacing. Consequently, in the interlaminar fracture experiment, the fibers limit the extent of toughness increase per unit increase in resin toughness. In support of this argument, the estimated size of the deformation zone at the transition point in behavior (intersection of the trend lines in Fig. 8) compare very well with the interfiber spacing between plies.
Figure 8
Composite interlaminar fracture energy as a function of the fracture energy for the corresponding resin. Lines indicate the general trends only. The relative standard uncertainty in the determination of G_{Ic} is 15% (after Hunston *et al.* 1987).

Crack Pinning or Trapping: Because interlaminar fracture is an important failure mode in polymeric systems, methods have been developed to improve the fracture toughness. One approach is to add rubber particles between the fiber layers during fabrication. The particles are thereby trapped between the fiber layers and form a barrier to crack propagation. When an interlaminar crack propagates it runs into these barriers and is held back because the particles have a higher fracture toughness than the matrix. In effect, the matrix crack is pinned or trapped by these barriers. Higher loads are then required to force the crack through or around the particles. This toughening mechanism has been shown to be effective even for impact loading indicating that the pinning mechanism is relatively independent of loading rate. This is in contrast to the case of the crack blunting mechanism, where the toughness is significantly rate sensitive. Bower and Ortiz (1990) have modeled the crack trapping behavior and have shown good correlation with experimental results.

Crack Diversion or Bifurcation: It was proposed in some early studies of interlaminar fracture that under the proper conditions, poor fiber-matrix bonding could increase the fracture energy (McKenna *et al.* 1974). For this to occur, the weak interface bonding needed to be localized, randomly distributed along the fibers, and interspersed with areas of good bonding. Under these conditions, a growing crack would be diverted back and forth between the many weakly bonded areas so that the trajectory became very tortuous. Moreover, the crack may be split into several branches that grow for a short distance and then end. When poor interface bonding becomes too extensive, however, the result is a decrease in fracture toughness because the weak interface provides an easy path for crack growth. This is illustrated in Fig. 8 where the thermoplastic resins generally show lower interlaminar fracture toughness than thermoset resins with the same resin fracture energies. Examination of the fracture surface shows that the fiber-matrix interface bonding in the thermoplastics was much poorer than it was in the corresponding thermoset.

Crack Bridging: Another interesting feature in Fig. 8 is that the interlaminar fracture energy for composites with the more brittle resins is almost always higher than the fracture energy for the resin itself. This has been attributed to the fact that the composite has an additional toughening mechanism: fiber bridging (Hunston *et al.* 1987), discussed earlier in this article.

(*b*) *Longitudinal fracture.* These same four types of toughening mechanisms are present when a crack propagates perpendicular to the fibers. As discussed previously, toughening involves a combination of work associated with interface debonding, the work

of stretching and breaking fibers, and the work required for fiber pull-out.

With polymers, experiments generally show that the highest resistance to crack growth occurs at intermediate bond strength. Moreover, with very strong interface bonding, a post failure examination shows relatively few fiber ends protruding from the fracture surface. As the interface bond strength decreases, there is an increase in the number of protruding fiber ends and their length. The authors (Kelly 1970, Harris *et al.* 1975) explain these results by noting that when the interface bond is strong, there is resistance to crack diversion and fiber-matrix debonding, and the matrix crack can propagate into the fiber. Consequently, fewer fibers protrude on the fracture surface. As the interface strength is decreased, the amount of crack diversion and interface debonding increases, so that fiber fractures can now occur statistically at locations away from the crack plane. Consequently, there is an increase in energy dissipation due to both debonding and pull-out, consistent with Figs. 3 and 5. However, when the interface strength becomes very low, the work of debonding may actually decrease even with a greater length of debonding, because of lower frictional resistance per unit area of the fiber-matrix interface. For polymer matrix systems, the frictional resistance is quite low, indicating that below a certain bond strength the pull-out energy could also decrease with a decrease in interface strength. Consequently, the highest fracture energy is obtained at an intermediate value of interface strength.

3. Concluding Remarks

Although the variety of composite materials is very large, fracture mechanics provides a common approach to analyze failure. Examining the similarities and differences among the various types of composites shows that the toughening mechanisms often extend across a wide range of composites. Consequently, much can be learned from such studies. In order to design composites intelligently, it is important to develop predictive equations based on the observed micromechanisms of fracture. Such models have to be validated experimentally, and this article illustrates a number of examples where good correlations between experiments and model predictions have been obtained. Conventional and Super Abrasive Materials

Abrasives are used extensively for high material removal rate applications as well as for the production of the desired shape, size, finish, and accuracy for a wide range of workmaterials including metals (soft versus hard, ferrous alloys versus nonferrous alloys), ceramics, glasses, wood, concrete, stone, and composites. They differ from conventional cutting tools in that the geometry of the abrasives is random to begin with and changes continuously and in an unpredictable manner as the process continues. In contrast, conventional cutting tools, be it single or multiple point, possess geometrically defined edges whose geometry is more or less maintained the same throughout the process.

1. General

The term *abrasive* is derived from the word *abrasion* meaning one that abrades or scratches another softer material. Scratch hardness is, in fact, one of the oldest forms of hardness measurement. It depends on the ability of one material (in this case a mineral) to scratch another material or mineral. Moh in 1922 introduced an arbitrary, not a linear, semi-quantitative scale for scratch hardness, known popularly as the Mohs scale of hardness. Moh selected 10 minerals as standards, beginning with talc, an extremely soft material (with an arbitrary scratch hardness of one) and ending up with diamond, an extremely hard (the hardest material known) with an arbitrary scratch hardness of 10 (see Table 1).

This way, a mineralogist can thus handily carry the 10 standard minerals to the field to determine the relative hardness of any unknown mineral in the field without the need for elaborate instrumentation. Accordingly, a mineral with a higher Mohs number, for example, quartz (Mohs hardness of seven) can scratch all the minerals directly below it in the hardness scale but not the ones above it. Unfortunately, most hard materials of importance for use as abrasives and cutting tools are in the range of 9–10. Consequently, it is extremely difficult to distinguish them in the Mohs scale. Hence, alternate hardness scales, known as Knoop or Vickers hardness scale, were developed for this purpose based on the principle of indentation.

Grinding operations can be broadly classified into two categories, namely, *form and finish grinding*

Table 1: Mohs hardness scale.

Material mineral	Mohs hardness or scratch hardness scale
Talc	1
Gypsum	2
Calcite	3
Fluorite	4
Apatite Feldspar	5
Orthoclase	6
Quartz	7
Topaz	8
Corundum	9
Diamond	10

(FFG) and *stock removal grinding* (SRG). In FFG operations, such as surface grinding, internal grinding, cylindrical grinding, and centerless grinding, a medium-to-fine abrasive is used while in SRG operations, such as snagging or conditioning of castings in the foundry and abrasive cut-off operations, a coarse abrasive grain is used. The emphasis in FFG is the generation of the required form, finish, accuracy, and surface integrity with less emphasis on the material removal rate, while in SRG, it is just the opposite, namely, the emphasis is on the stock removal rate. Thus, the abrasives used in FFG are medium-to-fine in grain size and very friable while the abrasives used in SRG are generally coarse-to-medium and very strong. Also, abrasives used in the FFG operations are dressed periodically while that in the SRG operations are rarely dressed. Dressing involves the removal of metal chips occupying in the void spaces between the grains in the grinding wheel, removal of the worn flats on the abrasive grains by microfracture and the generation of sharp cleavage fracture facets on the abrasives. This can be accomplished by using a single point diamond dresser, or a multipoint grinding wheel, or an abrasive stick that removes the loading of the wheel and worn flats on the abrasives leaving the wheel with sharp fracture facets and adequate space for the temporary storage of the chips during grinding so that the grinding process can proceed efficiently. The self sharpening action of an abrasive during grinding as well as the generation of sharp fracture facets during dressing depend significantly on the friability of an abrasive. The more friable the abrasive is, the easier it is to generate the self-sharpening action during grinding as well as during dressing. This is the reason why single crystal, refractory ceramics are used as abrasives instead of ceramics or carbides held together with a metal binder, such as cemented tungsten carbide or cermets used in the cutting tools. Abrasives used in FFG are dressed periodically while those in SRG are never dressed. Consequently, the abrasives used in FFG are medium to fine grain and very friable while in SRG, they are generally coarse grain and very strong. FFG is characterized by high wheel speeds (1000–2000 $\mathrm{m\,min^{-1}}$ in conventional grinding and up to 8000 sfpm in high-speed grinding), fine chip thickness values (1–150 μm), and table speeds in the range of 15–18 $\mathrm{m\,min^{-1}}$.

Chemistry and microstructure of an abrasive (including the defect structure) play an important role in its performance. Various properties of interest of abrasives include the hardness, melting temperature, strength and toughness (or its inverse, namely, friability), and thermal conductivity. The efficiency of a material removal process using an abrasive, be it grinding, polishing, honing, etc., depends on the sharp fracture facets on the abrasives that act as cutting points in the removal of material. The ability of these grains to self-sharpen as a result of cleavage or

microfracture during the process is the key to the success of an abrasive. Thus defect structure in the abrasive, be it impurities, or voids formed due to the gases evolved during the synthesis of the material, plays an important role in the performance and efficiency of the process. At the same time, this minimizes the cost of production of the abrasives as it is not required to produce pure or defect-free material in contrast to the cutting tool materials where the requirements demand that they be produced with minimal defects and impurities thereby increasing their strength, toughness, hardness, and wear resistance.

The character of an abrasive depends on the method of comminution or the size reduction process used. In the case of conventional abrasives, generally, huge lumps of material produced by fusion are reduced to different sizes using different types of jaw crushers, impact crushers, and ball mills. They are subsequently sieved to separate them according to the grain size required. While crushing to the required grain size is the only practical method presently used to reduce grain size of most abrasives, it frequently introduces micro- and even macrocracks which can be quite objectionable particularly for large and medium sized grains. When the grain size under consideration is very small, defects due to microcracks disappear and such grains are found to be very strong and yet exhibit sharp cleavage facets which are ideal for material removal operations by abrasives. In some cases, flaws introduced in crushing are removed by a crack-healing thermal treatment. There are, however, other methods by which abrasives can be produced to the desired size without the need for crushing or subjecting it to minimal size reduction processes.

Grain size of an abrasive plays an important role in the material removal and surface generation process. The grain size, G, is related to the mean diameter of the abrasive grain, d (Fig. 1). It is given by an approximate relationship of the form, $G\,d = 0.6$, where d is in inches. Thus, a grain size of 100 would have a mean diameter of ~ 0.15 mm. Sieves with different size openings are used for sorting out abrasives by the grain size. Thus an abrasive of 100 grain size would pass through a sieve with 100 openings per 6.25 cm^2. In the specification of grinding wheels, a grain size in the range of 8–24 is considered coarse, 30–60 coarse, 70–180 medium, and 220–600 fine to very fine. A similar classification exists for the use of abrasives in loose form as in polishing and lapping as well as in coated form. The abrasive grains used in coated abrasives generally have a long aspect ratio or needle-like shape to enable stronger bonding of the abrasive to the backing material and to obtain longer life. These abrasives are oriented along their length disection.

Abrasives are used in both conventional machining processes, such as grinding, polishing, lapping, honing as well as nonconventional processes, such
Figure 1
Relationship between the grain size and mean grain diameter of abrasives.

as ultrasonic machining, abrasive jet machining, magnetic field assisted polishing. Abrasives are used in three different forms (i) bonded abrasive form, such as in grinding wheels, honing sticks; (ii) coated abrasive form, such as in coated abrasive paper or cloth (popularly known as *sand paper* although other abrasives, such as alumina, granet, and SiC are often used); and (iii) loose abrasive form, such as in polishing, and lapping. The focus of this article is on abrasives both conventional and superabrasives.

The performance of a grinding wheel in grinding a given workmaterial depends on the type of abrasive used, its grain size, the wheel hardness (soft to hard, depending on the amount of the binder used and represented by an alphabet A to Z), wheel structure (dense to open, represented by a numerical value 1–15), and the type of bond. Figure 2(a) and (b) are ANSI specifications of grinding wheels used with conventional abrasives and superabrasives, respectively. In the case of conventional abrasive, the specification gives the type of abrasive used (Al_2O_3 or SiC), the grain size, the grade (which measures the relative hardness or the strength with which the abrasive grains are held by the bond), the structure (the openness or the spacing between the grains), and the type of bond used. Both the hardness and the structure depend on the amount of binder content used.

A typical vitrified bonded conventional abrasive grinding wheel would consists of $\sim 50\%$ abrasive, $\sim 10\%$ bond, and $\sim 40\%$ porosity. Voids (or porosity in the wheel) are intentionally created for the temporary storage of chips by incorporating a volatile filler material in the initial powder mix. For example, sawdust or a material which sublimes on firing, such as hexachlorethane ($C_2H_2Cl_6$) is

introduced in the mix before pressing the wheel. A typical vitrified bond material may consist of $\sim 63\%$ SiO_2, 12% Al_2O_3, 1.2% CaO, 6.3% Na_2O, 7.5% K_2O, and 10% B_2O_3 (by weight). The abrasive, bond material, and saw dust are mixed with temporary binders to hold it in the green state and the grinding wheels are pressed to shape in steel molds. They are then removed from the molds and fired at ~ 900–$1300\,^\circ C$, held at this temperature for ~ 8 hours, and cooled down to room temperature. When these materials volatize, they leave behind voids in the grinding wheel. The final product is inspected by such tests as measurement of the ratio of mass to volume, modulus of elasticity, resistance to penetration by rotating a chisel point or by a blast of known volume of sand or other abrasive under a known pressure.

Phenol formaldehyde bonded alumina-based or alumina–zirconia-based wheels make up for the largest part of the organic bonded or resinoid bonded grinding wheels for SRG. For high-speed (~ 5000–$8000\,\text{m}\,\text{min}^{-1}$) applications, they are usually reinforced with fiberglass. Resin bonded wheels can be phenol formaldehyde, epoxy, polyurethane, polyester, or shellac. The bond usually includes suitable filler materials, such as cryolite, iron sulfide, CaF_2, ZnF_2, and ammonium chloride. In the case of resinoid bonded superabrasive (diamond or cBN) wheels, a rim of resin bonded abrasive is used on top of a nonferrous disk. Hence, in the specification, its thickness is given. Also, the concentration of the diamond (or cBN) in the resin is also given. This can vary from 25% to 50% depending on the application and cost. A 100% concentration corresponds to 72 carats of diamond (or cBN) in one cubic inch of the active wheel medium (i.e., rim of the resin bonded abrasive). Also, five carats of the superabrasive is equivalent to one gram.

Of the various types of binders used in the manufacture of grinding wheels, glass or vitrified bond (V), resin bond (B), and metal bond (M) are the most common. Vitrified bond is used with conventional abrasives (alumina and SiC) in FFG and resin bond in SRG. With superabrasives (diamond and cBN) a resin bond is used extensively for grinding wheels while a metal bond is used for saw blades. Electroplated wheels contain a monolayer of the superabrasive mounted on the periphery of a metal disk. As the disks have already been machined concentric, there is no need for dressing or truing the wheel which is rather critical in the performance of superabrasive wheels. In addition, the cost of the wheel is only a fraction of a resin bonded or a metal bonded wheel. Vitrified bond is used for selective applications of both diamond and cBN wheels. Soft grinding wheels with open structure (i.e., containing less amount of the binder) are used for machining hard workmaterials while hard wheels with dense structure (containing more amount of the binder) are used for machining soft workmaterials.

1.1 Coated Abrasives

Coated abrasives are available in a variety of forms including sheet, disk, roll, and belt and can be used for a range of applications from very light to heavy duty. A coated abrasive consists of an abrasive held in a backing material by an appropriate bonding medium (Fig. 3). The backing material serves as the base upon which a coating of an adhesive known as the *make* coat is uniformly applied to anchor a single layer of an abrasive. A typical make coat comprises of a solution containing ∼48% phenol formaldehyde resin and ∼52% calcium carbonate filler. Usually, abrasive grains with a long aspect ratio are specially prepared and used for this application (Fig. 4). Individual abrasive particles are applied uniformly to the "make" coat and oriented by an electrostatic field to maximize the probability that an abrasive will be positioned with its major or long axis perpendicular
Figure 3

to the backing material. After the make coat hardens (generally precured for ∼30 minutes at 107 °C), a second coating of adhesive known as the "size" coat (of a similar composition as the make coat) is applied for anchoring the abrasives strongly to the backing material and cured for ∼10 hours at 107 °C. A wide range of abrasives both natural and synthetic is used for coated abrasive applications. They include conventional abrasives such as the various alloys of alumina, sintered sol-gel alumina, SiC, emery, garnet, flint as well as superabrasives, diamond, and cBN. They are available in all grit sizes (36–600) for a wide range of applications. The coated abrasive can be either open-coat abrasive (∼50–70% of its backing surface is covered with the abrasive) for free cutting action or closed-coat (>70%) for obtaining high removal rates.

1.2 Honing

Honing is a finishing process used for the generation of functional characteristics specified for a surface, including geometric and dimensional accuracy as well as surface requirements, such as roughness, lay pattern, and surface integrity. It is a low speed abrading operation using bonded abrasive sticks inserted into a tool holder. The sticks are spring loaded to expand away from the tool to grind irregularities in the surface of the part. The process involves both rotational and reciprocating action and generates a crosshatched pattern. Honing can correct out-of-roundness, taper, bell shaped, and barrel shaped bores. Honing sticks are available in all grits sizes (36–600) of SiC, alumina, and superabrasives (diamond and cBN) and in all types of bonds including vitrified, resin, and metallic depending on the application.

1.3 Lapping

Lapping is a finishing operation used for the production of flat surfaces. The abrasive is applied on to a cast iron lap of a lapping machine in the form of an abrasive slurry in a water-soluble glycol solution. Alternately, a coated abrasive product can be used on a backing plate. A continuous feed system ensures fresh supply of the abrasive. To provide uniform lapping, the workpiece is loaded to provide uniform pressure and is rotated during the lapping operation.

Although abrasives, in general, are hard, brittle materials they can be softer than the workmaterial in which case the material removal or finish generated does not involve mechanical abrasive action but chemical- or chemo-mechanical action. Abrasives can be either natural minerals or synthetic materials.

Both are extensively used depending on the type of application although synthetic materials are rapidly replacing, in many cases, because of their ready availability, reliability, consistency, controlled properties, and cost benefits. The most common natural

minerals include quartz, or silica sand, zircon sand, corundum, emery, garnet, flint, and diamond. Corundum and emery are natural forms of aluminum oxide containing varying amounts and nature of impurities. Many of the natural abrasives, because of varying amounts of impurities, tend to perform nonuniformly and, hence, are used only for those applications where this is not a serious limitation but the low cost and easy availability of the abrasive are beneficial factors. Synthetic materials include various types of aluminum oxide and its alloys, silicon carbide, boron carbide, zirconium oxide as well as alumina–zirconia, cubic boron nitride (cBN), and diamond. Chemo-mechanical abrasives include, cerium oxide (CeO_2), magnesium oxide (MgO), silica (SiO_2), chromium oxide (Cr_2O_3), alumina (Al_2O_3), titania (TiO_2), zirconia (ZrO_2), iron oxide or rouge (Fe_3O_4), and yttrium oxide (Y_2O_3). Their performance depends on the interactions between the abrasive–workmaterial–environment as well as on the conditions of polishing, such as the temperature and the pressure at the contacting zone.

In the following, various types of natural and synthetic abrasives as well as conventional abrasives and superabrasives will be briefly described along with some of their applications in different manufacturing operations.

2. Natural Abrasives

Natural abrasives possess varying amounts of impurities and defect structure. Hence, their performance generally is somewhat nonuniform and unpredictable. But, because of their limited volume usage or intrinsic value, their synthesis is not justified for they perform satisfactorily and economically in certain operations.

Quartz sand (SiO_2) or flint is used both in the loose form and in coated abrasive form. The former was used for the grinding of plate glass (prior to the development of float glass manufacturing technology) and is still used for sand blasting mostly in foundries for cleaning the castings and in the preparation of metal surfaces prior to painting. Flint is used as a coated abrasive paper for the sanding of wood. Quartz is hexagonal in structure and has a distinct rhombohedral cleavage and a conchoidal fracture characteristics. Its Knoop hardness is $\sim 820\,\mathrm{kg\,mm^{-2}}$.

Garnet is an orthosilicate of iron (or magnesium) aluminum silicate. Two common minerals of garnet are (i) almandite with a chemical formula of $Fe_3Al_2(SiO_4)_3$ and (ii) pyrope garnet with a chemical formula of $Mg_3Al_2(SiO_4)_3$. Hardness of garnet is ~ 7.5–8.5 on the Mohs scale or $1360\,\mathrm{kg\,mm^{-2}}$ on the Knoop scale with a decomposition temperature of $\sim 1100\,^\circ C$. The color of garnet ranges from dark red to brownish red. Though superior to quartz in performance, it is higher in cost and used for similar

applications. In the coated abrasive form it is used extensively especially in fine grinding of softwood. It is also used in the finishing of glass, stone, leather, and varnished and painted surfaces. In loose form, it is used in abrasive jet processes, such as sand blasting. The intrinsic value of garnet is determined more by its friability (which is its ability to cleave easily along certain weak crystallographic planes and directions to provide sharp fracture facets) than its hardness.

Feldspars are a class of aluminum silicate minerals containing K, Na, or Ca or a combination. They are a major component of igneous and metamorphic rocks. The rocks are mined, crushed, screened and ground to size. The hardness of the feldspar is ~ 6 on the Mohs scale. They break with a semi-conchoidal fracture that make them useful as a mild abrasive. A major use of fledspar is in scouring powders. They are not as hard as quartz, so they are safer to use on glass and enamel surfaces.

Pumice is a light colored volcanic glass produced by explosive volcanic eruptions. It is used as an abrasive in the form of fine powder for polishing metals and in finishing painted surfaces.

Corundum is a natural form of α-Al_2O_3 available in various states of purity and crystallinity formed by contact metamorphism. Its hardness is ~ 9 on the Mohs scale and its color varies considerably from blue, green, gray, brown, and black to colorless. Transparent blue sapphire and the red ruby are valuable gemstones of natural corundum. The natural forms of alumina are distinguished as corundum, emery, and spinel (γ-alumina with a spinel structure). Natural corundum crystallizes in the rhombohedral form and has a basal cleavage not found in the synthetic counterpart, fused alumina. As an abrasive, corundum is used primarily in the grinding and polishing of glass lenses. However, much of it use has been replaced by its counterpart, synthetic alumina.

Emery is an impure form of corundum, a natural aluminum oxide in which the impurity is mostly magnetite or spinel depending on the location of the available deposits. The hardness ranges from 7.5–8.5 on the Mohs scale. Processing involves washing, crushing, and sizing, followed by heat treatment. Coarse emery is extensively used in nonskid concrete floors and pavements and to produce millstones for rice milling. The medium-to-finer grades are used to make emery paper and cloth, and the very fine goes in the production of polishing pastes.

Natural diamond is a class by itself amongst all abrasives. Its unique properties include the highest hardness, excellent wear resistance, good thermal conductivity, easy cleavage along certain crystallographic planes and directions, and extremely low friction. Its applications extend from the finishing of diamond itself to the cutting, grinding, and finishing of a range of hard materials, such as stone, concrete, glass, hardened alloy steels, cemented carbides, and ceramics. It is an indispensable and strategically

important material whose role cannot be replaced except by itself in the synthetic or man-made form. Until the successful synthesis of diamond at high pressure–high temperature (HP-HT) in the mid1950s and subsequent synthesis of cubic form of boron nitride (cBN) (which incidentally does not exist in nature) natural diamond occupied a strategic role in the manufacturing field. Similar to all other natural mineral abrasives, the performance of natural diamond depends on the impurity content as well as the defect structure in the material. Synthetic diamond (as well as cBN) with more control on the impurity content as well as crystal morphology (similar to the other conventional abrasives), is leading its natural counterpart in its application and use in manufacturing. It is amazing that the synthetic materials (diamond and cBN) are not only more controlled in terms of chemistry, crystallinity, and defect structure but are also available in unlimited quantities economically.

Silicon carbide has the distinction of being the first commercial synthetic abrasive while cBN has the unique distinction of a synthetic ultrahard material (or superabrasive) that does not even have a natural counterpart and whose synthesis is based on the similarities in the crystal structures between the hexagonal forms of carbon (graphite) and boron nitride prior to the synthesis and their cubic counterparts (diamond and cBN) after the synthesis.

Various types of synthetic abrasives are used in the manufacturing industry. They can be classified as alumina-based (white alumina, monocrystalline alumina, regular alumina, sintered bauxite, sol-gel alumina, Al$_2$O$_3$–ZrO$_2$), SiC, B$_4$C, cBN, and diamond. Alumina based abrasives are used for the finishing of steels and SiC abrasive is used for the finishing of nonferrous alloys as well as cast iron. Diamond is used for all hard materials, such as stone, concrete, cemented carbide, ceramics, glass, or silicon but is not recommended for low carbon steels for it reacts chemically with Fe. cBN is used for the finishing of hardened steels (R$_c$ 45–65) and nickel-base superalloys.

3. Synthetic Abrasives—Alumina-based

Aluminum oxide (Al$_2$O$_3$) has a hexagonal crystal structure ($a = 4.758$ Å, $c = 12.99$ Å and $c/a = 2.73$), a melting temperature in the range of 2015–2050 °C and a hardness $\sim$2100 kg mm^{-2} depending on the purity. Various types of aluminum oxide abrasive are used in industry including white aluminum oxide, monocrystalline aluminum oxide, regular aluminum oxide, modified (chromium oxide or vanadium oxide) aluminum oxide, sintered bauxite or sintered alumina, alumina–zirconia, and sintered sol gel alumina. Table 2 gives the hardness and chemical composition of various types of alumina-based abrasives.

White aluminum oxide is manufactured either by the fusion of alumina or using the Bayer processed

(dissolving the bauxite in caustic soda and then re-precipitating it to remove all impurities) alumina. The first method uses a furnace of the Higgins-type made of a water cooled, truncated cone shaped steel vessel with carbon electrodes (Fig. 5). Graphite or coke is used at the beginning to serve as a conducting path. Initially ∼20–25% of charge containing a mixture of 80% bauxite, 15% iron filings, and 5% coke is added to the furnace. The purpose of the coke is to reduce the silica to silicon and the iron oxides to iron. Iron then combines with silicon to form ferrosilicon which settles at the bottom due to higher density and can be easily separated by magnetic means. Once fusion starts, the initial charge acts as the conducting path and the rest of the charge is added over a period of 15–30 hours. depending on the size of the furnace.

In the second method, bauxite is treated with sodium hydroxide (Na_2O) at a temperature of 120–140 °C to form sodium aluminate, which is filtered from insoluble impurities. The precipitate is then washed to remove soda and then calcined at 1100 °C and fused in Higgins type of furnace. A typical Higgins furnace is ∼1.8 m in diameter and 1.8 m in height. It operates on a 3-phase, 60 Hz current at an applied voltage of ∼100–150 V and a power of ∼750 kW. The furnace is under power for ∼18 hours. The resulting ingot weighs ∼5442 kg. When fusion is complete, the electrodes are removed and the molten material is allowed to cool for 3–4 hours in the furnace and about a week outside the furnace.

Figure 5
Photograph of a Higgins-type furnace used for the fusion of Al_2O_3 from bauxite.

The slow cooling produces coarse crystallites. If finer crystallites are desired, it is poured into a thin, water cooled, steel container for rapid cooling. The ingots are crushed and sieved to size to obtain the abrasive of various grain sizes.

As can be seen from Table 2 (Komanduri and Shaw 1974b), this material is very pure except for the small amounts of residual sodium hydroxide (Na_2O) (0.25–0.5%) that volatilizes during melting giving rise to a porous structure. Figure 6(a) is an SEM micrograph of a coarse grain (12 grain size) white aluminum oxide showing considerable number of gas holes due to the formation of Na_2O. However, when the abrasive it reduced by comminution to a finer grain size, the crystal breaks through these imperfections resulting in sharp fracture facets that are characteristic of alumina abrasive (Fig. 6(b)).

Monocrystalline aluminum oxide abrasive is produced by the fusion of a mixture of bauxite, coke, iron sulfide, iron filings, and alkaline metal oxides. The resulting ingot consists of hydrolyzable alumina in a decomposable sulfide matrix. In this process, the fused ingot is cooled slowly to crystallize as numerous single crystals. A light crushing operation followed by water treatment that disintegrates the glassy matrix and leaves the abrasive in loose, single crystal form. The material is free from Na_2O and hence is free from gas holes.

As shown in Table 2, this abrasive contains small amounts of (up to 0.1%) Fe_2O_3, SiO_2, and ZrO_2 and up to 0.6% TiO_2. These oxides alloy with the base alumina and improve the properties of this material. This abrasive is characteristically very light pink in color. Figure 7(a) and (b) show SEM micrographs of an 80 grain size monocrystalline aluminum oxide abrasive at two magnifications showing a series of sharp stepwise cleavage facets formed during the manufacture. Such a structure can be seen throughout the size range.

Regular aluminum oxide, also known as high titania fused alumina, comprises a coarse crystalline product having typically ∼2.65% residual TiO_2 as shown in Table 2. It is manufactured in a batch process by the fusion and partial reduction of calcined bauxite (with its associated impurities comprising of titania, silica, and iron oxide) with coke and iron filings in a Higgins furnace. Conditions in the arc furnace during fusion are distinctly reducing. The silica in the bauxite is reduced to silicon and the iron group oxides to metal. Iron then combines with silicon to form ferrosilicon which settles at the bottom due to higher density and is separated by magnetic means. Since, Ti_2O_3 is appreciably soluble in alumina, titanium acts as a modifying element and improves its properties. Although this material has lower hardness and friability than white aluminum oxide, it has higher strength. Hence, it finds applications in abrasive machining ranging from semifinish to rough grinding.
282

Figure 7
SEM micrograph of a 80 grain size monocrystalline Al$_2$O$_3$ abrasive showing a series of sharp stepwise facets formed during growth (Komanduri and Shaw 1974a).

Figure 8 shows an SEM micrograph of a regular aluminum oxide abrasive showing a somewhat rougher surface that can facilitate in the formation of a strong bond in a grinding wheel. The abrasive after fusion and cooling is crushed and sent pan mills for rounding of the edges. The topographical features of this material suggest that it is composed of more than one phase and that one of the phases is more resistant to abrasion than the other. That is, during the pan milling operation, it appears that the softer phase is preferentially removed, thereby generating rougher surface as shown in Fig. 8.

Modified aluminum oxide abrasives are developed because the properties of α-alumina can be modified by significant additions of other alloying oxides in the fusion of calcined Bayer processed alumina. Two such alloying oxides are Cr$_2$O$_3$ and V$_2$O$_5$. Chromium oxide alloyed with alumina has a pink to ruby color depending on the percentage of the alloy while the vanadium oxide alloyed alumina has a light to dark green color. They are, therefore, identified as ruby and emerald abrasives, respectively. The purpose of tinting is partly aesthetic and partly due to the fact that chromium ions in solid solution in the α-alumina lattice tend to lock slip planes producing a hardening effect. The improved hardness of vanadium oxide alloyed alumina is also attributed to a similar origin.

Figure 6
(a) SEM micrograph of a 12 grain size white Al$_2$O$_3$ abrasive showing no sharp cleavage facets and considerable porosity due to escape of volatile gases during fusion and (b) SEM micrograph of a 36 grain size white Al$_2$O$_3$ abrasive showing sharp cleavage fracture facets (after Komanduri and Shaw 1974a).

283

Figure 8
SEM micrograph of a 12 grain size regular Al$_2$O$_3$ abrasive showing no sharp cleavage facets (Komanduri and Shaw 1974a).

Figure 9
SEM micrograph of a 12 grain size chromia modified Al$_2$O$_3$ abrasive showing no sharp cleavage facets but pyramid shaped projections on the surface which can act as cutting points (Komanduri and Shaw 1974a).

Grinding wheels made of this abrasive are slightly more expensive than conventional white or mono-crystalline alumina wheels but used in grinding of hardened tools steels and stainless steels with slightly improved performance.

Both Cr$_2$O$_3$ and V$_2$O$_5$ modified alumina are found to exhibit entirely different topographical features. Figure 9 is an SEM micrograph of a 12 grain size chromia modified alumina. The surface appears to have been formed by intercrystalline fracture and consist of several pyramid shaped sharp edges which can act as cutting edges. Several white spots can also be seen. It appears that as a result of static charge, these grains collect numerous minute specks of the abrasive during comminution. Figure 10(a) is an SEM micrograph of a 12 grain vanadium oxide modified alumina. The grain appears to be a solid mass containing several cavities possibly resulting from entrapped gases formed during the fusion of this alloy. The cavities have the appearance of mini-volcanoes unlike the continuous holes observed in white alumina or SiC. Figure 10(b) is an SEM micrograph at higher magnification showing details of the crater-like appearance of one of the gas pockets. Around the hole, the material has the appearance of an interwoven network although the walls inside the hole show no such texture.

Sintered bauxite or sintered alumina is manufactured by pressing or extruding a finely milled (1–5 µm) paste of calcined bauxite to shape in the form of rods or platelets. They are then chopped to size in the green state and sintered in a rotary kiln at a temperature of ~1450–1500 °C. No sintering aid is necessary for impurities in the calcined bauxite provide this function. Consolidation, diffusion bonding, and grain growth takes place at the sintering temperature. Sintered bauxite has relatively low hardness as a result of high impurity content and microporosity (Table 2). Also, the density of this material is significantly less than theoretical. Nevertheless, it has low friability and high strength. It also does not show cleavage facets; instead the grains are rounded. Hence, sintered bauxite is suitable for conditioning and other heavy duty applications where coarse grain size of this material is used.

Figure 11(a) is an SEM micrograph of a sintered bauxite grain. It contains neither sharp edges nor microvoids as found in the very friable alumina abrasives (e.g., white or monocrystalline alumina). Figures 11(b) and (c) show, at higher magnifications, details of the knobby structure generated by inter-granular separation either in the green state or during sintering. The knobby structure closely resembles the

284
Figure 10
SEM micrographs of (a) a 12 grain size vanadium oxide modified Al_2O_3 abrasive showing several cavities formed due to escape of volatile gases formed during fusion. (b) Details of the inter-like appearance of one of the gas pockets. Around the hole, the material has the appearance of an inter-over network although the walls inside show no texture (Komanduri and Shaw 1974a).

morphology of the finely milled calcined bauxite. The size of the individual crystallites in the sintered product is $\sim 4\,\mu m$. Considerable void space can also be seen, indicative of density less than theoretical. As there is no further comminution, the morphology of sintered bauxite remains the same regardless of the grain size.

Sol-gel microcrystalline alumina abrasive (both unseeded and seeded) is one of the newest developments in the conventional abrasive field for both coated and bonded abrasive applications developed by Norton as well as 3 M company in the USA. It may be noted that the state in which fine particles (nano or submicrometer sized) are dispersed in a liquid is called a *colloid*. When the colloid is sufficiently fluid and stable for a long period of time, it is termed the *sol*. Rigid solids formed by the evaporation of the solvent from a sol is called the *gel*. By manipulating the sol-gel transformation appropriately, it is possible to form a variety of extremely fine-grained shapes rapidly. The essence of this method lies in its ability to produce extremely fine microcrystalline (submicron) abrasive of interest. Such an abrasive provides very high toughness and enables high removal rates in grinding or coated abrasive applications. Various oxide ceramics can be made by the sol-gel method but the current commercial applications are focused on α-alumina and alumina–zirconia abrasives.

Sol-gel microcrystalline alumina abrasive can be produced with or without seeding with fine (submicron) α-alumina particles. The seeds (up to $\sim 5\%$ by weight) provide the nucleation sites for the conversion of the precursor to the α-alumina phase. In general, the seed material should be isostructural with α-alumina with lattice parameters within 15% and be present in the dried gel at the temperature at which the conversion to α-alumina takes place. In the synthesis of seeded sol-gel alumina, submicron sized particles of α-alumina are uniformly dispersed in an aqueous sol or a gel, of an α-alumina precursor, such as boehmite ($Al_2O_3 \cdot H_2O$). To this mixture a peptizing agent, such as HNO_3 in water is added. In order to insure complete peptization of the alumina and homogenization of the gel, the mixture is forced through a kneader/mixer and subsequently extruded. Gelation greatly restricts chemical diffusion and segregation. The mixture is then dried and crushed either before or after sintering to form a roughly graded particulate material. This was then calcined at $>400\,^{\circ}C$ for ~ 16 hours and then fired for ~ 30 minutes in a rotary kiln to a temperature above the conversion temperature at which α-alumina is formed and sintered essentially to very high density ($>95\%$ theoretical). The sintering temperature is generally in the range of $1300–1400\,^{\circ}C$ in the case of seeded sol-gel material and about $100\,^{\circ}C$ more in the case of nonseeded sol-gel. Excessive temperatures or long sintering times can lead to grain growth which should be prevented in order to obtain high toughness of this
Figure 11

(b and c) SEM micrographs of sintered bauxite (or sintered alumina) at higher magnifications showing details of the knobby structure generated by intergranular separation in the green state or during subsequent sintering. Individual particles are seen to be diffusion bonded together into clusters and separated by microvoids (Komanduri and Shaw 1974a).

material. Magnesium nitrate hydrate, which converts to an MgO spinel during firing can be added to the sol-gel mix to inhibit grain growth. The fired material is cooled and separated to various grit sizes by sieving. Figure 12(a) is an SEM micrograph of a tough sol-gel abrasive and Fig. 12(b) is an SEM micrograph at higher magnification showing the microcrystalline nature of this abrasive responsible for high toughness at the same time sharp cutting action generating good finish.

Sol-gel abrasive described above involves the production of desired grit size by comminution of larger particles and grading the product to various grit sizes by sieving. This approach can be somewhat wasteful since all grit sizes may not be useful and as such material may have to be discarded, recycled, or used for low value applications. To overcome this problem, an interesting development in the synthesis of sol-gel abrasive took place which involves the formation of sol-gel alumina filaments, with an aspect ratio in the range of 2:1 to 8:1 which requires no or minimal comminution. The green abrasive filaments are formed from the gel by a variety of techniques including extrusion and spinning. Extrusion is the
Figure 12

oxide abrasive.

preferred mode for green filaments between 0.25–
1.5 mm in diameter, which after drying and firing, are
roughly in the range of 100–24 grit size. Spinning is
preferred for fired filaments $<100\,\mu m$. Fired fila-
ments as fine as $0.1\,\mu m$ can be produced by this
method. For the filaments formed by extrusion, the
seeded gel is extruded through a smooth walled die
with multiple holes to produce continuous gel
filaments. They were then dried for 24–72 hours
at a temperature of 75–80 °C and a relative humidity
of $>85\%$. The filaments are converted to fibrous
bodies with an average length of 2–8 mm. They were
then converted to α-alumina by heating at a rate
of $<2\,°C\,min^{-1}$ to 800 °C, at a rate of $\sim 5\,°C\,min^{-1}$ to
1370 °C, held at this temperature for ~ 5 minutes and
then allowed to cool. For a gel filament of $\sim 1.19\,mm$
diameter, the filaments after firing are $\sim 0.58\,mm$ di-
ameter corresponding to ~ 30 grit size. For filaments

formed by spinning, ~ 1–5% of a nonglass forming
spinning aid, such as polyethylene oxide is added to
the gel to impart the desirable viscoplastic properties
for the filament formation. Figure 13 is an SEM mi-
crograph of a sol-gel alumina filamentary material
produced by a special extrusion process.

Alumina–zirconia is a simple eutectic system with a
very limited solid solution at higher temperature
(Fig. 14). When zirconia is added to alumina, the
structure becomes more equiaxial. Addition of $\sim 40\%$
zirconia to alumina results in the eutectic composi-
tion. Three compositions commercially considered
for this alloy are 10% zirconia, 25% zirconia, and
40% zirconia. It is preferable to use the zirconia in
the tetragonal form. By rapidly quenching on thin
plates, the high temperature stable tetragonal form is
retained instead of reversion to the weaker mono-
clinic form. As the zirconia content increases, the
amount of eutectic structure increases resulting in an
increase in the toughness at the expense of hardness.
Thus, a 10% zirconia–alumina alloy is harder than
25% or 40% alloy with the toughness inversely
proportional. This abrasive is manufactured by the
fusion of a mixture of calcined bauxite, zircon sand,
petroleum coke, iron filings, and rare earth modifiers
in an electric arc furnace at ~ 1900 °C. The modifiers
serve to stabilize the zirconia component of the abra-
sive grain.

The molten material is then poured in thin layers
on a water cooled steel container or carbon clad re-
ceptacles containing calcium chloride at a tempera-
ture of 800 °C. This ensures rapid cooling of the
molten material to a temperature in the range of
1350–1550 °C. This is the temperature range within
which the crystal growth stops in alumina–zirconia
alloy. Further cooling of this rapidly cooled material

287
Figure 14
Al$_2$O$_3$–ZrO$_2$ phase equilibrium diagram (after Coes 1971).

to a temperature in the range of 500–800 °C proceeds slowly at a rate of 20 °C min^{-1}. This slow cooling helps in producing tensile stress-free and crack free crystals. The rapidly solidified and fine grain structure of alumina–zirconia alloy provides high impact strength and toughness which are desirable characteristics for an abrasive to be useful for heavy grinding applications, such as snagging, conditioning, and cut-off operations. The eutectic structure is composed of zirconia dendrites in an α-alumina matrix. Figure 15(a) shows an SEM micrograph of a 46 grit tough alumina-40% zirconia abrasive and Figure 15(b) is an SEM micrograph higher magnification showing the eutectic microstructure.

4. Synthetic Abrasives—Silicon Carbide

The crystal structure of α-silicon carbide (SiC) is hexagonal ($a = 3.073$ Å and $c = 15.07$ Å and $c/a = 4.899$). The structure of SiC is based on the stacking of hexagonal Si–C layers such that each Si atom is tetrahedrally surrounded by four C atoms and each C atom is also tetrahedrally surrounded by four Si atoms. The decomposition temperature of SiC is in the range of 2000 °C to 2400 °C and the Knoop hardness of SiC is ~2550 kg mm^{-2}.

In the synthesis of SiC, a mixture of silica sand, coke, and salt (to convert impurities to volatile chlorides) is charged into a furnace. The furnace comprises of a trough-like base with removable sides made of steel frame to which are fastened refractory

bricks. At the ends are concrete or brick "heads" through which carbon or graphite electrodes pass (Fig. 16). The electrodes are connected to an electrical supply. The charge in the furnace surrounds the graphite core. Typical processing conditions include an applied voltage ~200–500 V, 60 Hz current with a power input of ~1800 kW, and operating at a total power of 54 MWH. The time under power is ~30 hours. Such a furnace is typically ~15 m long and produces an ingot of SiC ~8100 kg.

As the electrodes are powered, an electric current flows through the core causing it to become very hot (~2600 °C). The mixture adjacent to the core begins to convert into SiC according to the sequential reactions: $SiO_2 + 2C \rightarrow Si + 2$ CO; $Si + C \rightarrow SiC$; and $SiO_2 + 3C \rightarrow SiC + 2CO$. The temperature range for good SiC formation is ~1800–2200 °C. The carbon monoxide is permeated through the reactive mix and burns to CO_2 at the surface of the mix in the furnace as a soft, rippling blanket of blue flame. SiC by itself is an electrical conductor.

As the mixture around the core is converted to SiC, it begins to consume some of the electric current, necessitating a downward adjustment in the applied voltage to limit the power input. After the run, the furnace is cooled, the sides removed, and the excess partially reacted mix is stored separately for reuse. The ingot is broken apart and sorted out manually. Since, considerable thermal gradient exits outwardly of the core, the ingot is not uniform in structure but consists of concentric zone of varying quality.

Various crushing and shaping stages are employed to crust the SiC ingots, and the product may be chemically treated with alkali to remove free silicon, and with acid to remove iron. Washing it with water containing surface active agents help in removing any free graphite present in the material. The grain is customarily roasted in a rotary kiln to condition the surface and remove any traces of organic matter. Grading to standard grit sizes is done in stages using screens.

Two types of SiC abrasive are marketed commercially, namely, the green SiC and the black SiC. The green variety is more pure than the black. The difference in color stems from the raw materials used and the conditions used in the furnace during firing. Green SiC is produced using a new mix each time while unreacted material from the previous mix is recirculated in the synthesis of black SiC. The abrasive performance of the two types is similar and the small improvement in hardness and performance is offset by higher cost of green SiC. Bulk of the SiC used as abrasive is black SiC. Figure 17 is an SEM micrograph of a 12 grit green SiC abrasive showing porosity due to volatile CO gases formed during manufacture of the abrasive. The surface features are similar to that of a fracture glass indicating very brittle nature of this abrasive. The high friability and low strength of SiC is attributed to these voids and

the relatively weak bonding between carbide particles joined to form a grain.

Boron carbide (B_4C) is a very hard abrasive (Knoop hardness $\sim 3400\,kg\,mm^{-2}$), next only to

diamond (till the synthesis of cBN) in hardness. It is used extensively in loose or powered form for polishing and as an abrasive in ultrasonic machining. It is, however, not used in grinding as an abrasive due to rapid wheel wear associated with the oxidation of B_4C to B_2O_3. Boron carbide is commercially manufactured by initially heating boric acid in an electric furnace to remove water of crystallization and to form anhydrous boric oxide, B_2O_3. To this is added high purity petroleum coke and the charge is heated in an electrical resistance furnace to about 2400 °C. Sawdust is added to provide pores for the escape of large quantities of reducing gas generated. Boron is condensed from the vapor phase and combines with carbon to form crystalline boron carbide.

5. Synthetic Abrasives—Superabrasives

In the materials world, the successful synthesis of diamond and CBN in the mid-1950s can be hailed as one of the most important technological and scientific achievements of the twentieth century. Diamond (Knoop hardness $\sim 8000 \, \mathrm{kg \, mm^{-2}}$) and cubic boron nitride (cBN) (Knoop hardness $\sim 4700 \, \mathrm{kg \, mm^{-2}}$), the two hardest materials known, come under this category and are termed the superabrasives. The synthesis of diamond has not only enabled the economic manufacture of diamond for industrial use but also facilitated tailoring of grain size, grain morphology, strength, and friability by controlling the pressure, temperature, time, and other processing conditions during the synthesis. It may be noted that grains of different strength and friability are required for different applications. It has also addressed the strategic aspect of this material. The direct production of diamond of a given size eliminates the need for crushing which weakens the product leaving behind cracks of uncontrolled size.

Long before the successful synthesis of diamond, the thermodynamic pressure–temperature equilibrium line between diamond (the cubic form of carbon) and graphite (the hexagonal form of carbon) was postulated by Rossini and Jessup of the National Bureau of Standards (now NIST) in 1938. Much of the initial high pressure work related to diamond synthesis was performed by Professor Bridgman of Harvard University before World War II. He was able to maintain a temperature of $\sim 3000 \, \mathrm{K}$ at a pressure of $\sim 29 \, \mathrm{kbar}$ but only for a short interval of time, conditions not sufficient for the direct conversion of graphite into diamond. It remained for a team of innovative researchers at General Electric (GE) to discover that certain catalyst–solvents made it possible to increase the rate of conversion to a practical level at relatively low temperatures ($\sim 1500 \, ^\circ\mathrm{C}$) and pressures ($\sim 50 \, \mathrm{kbar}$).

Hall (then of GE) built a HP-HT press, known as the "belt," and accomplished the successful synthesis

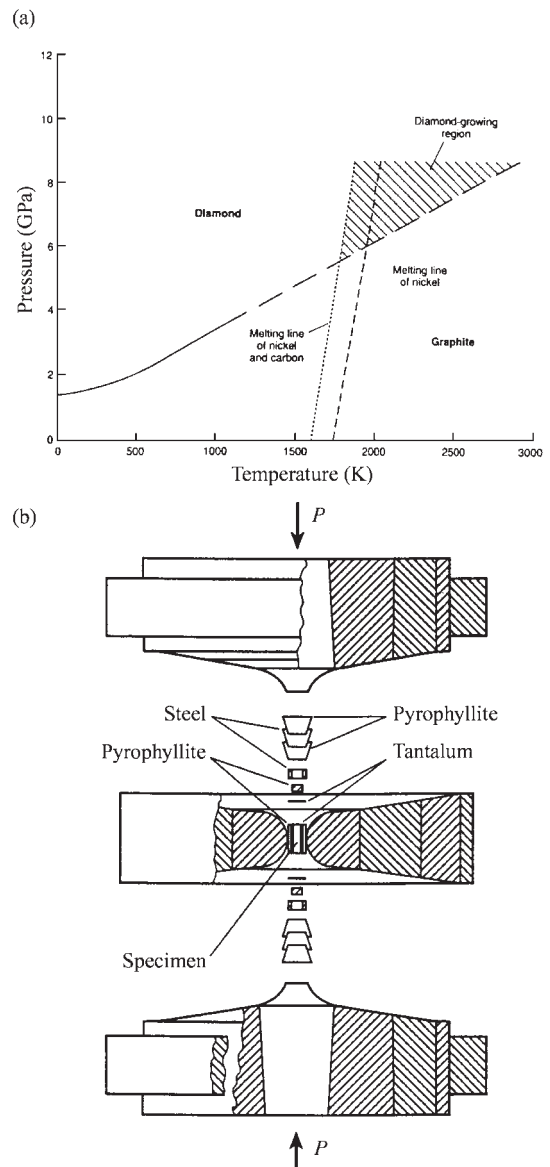
of diamond along with his co-researchers. Figure 18(a) is a temperature–pressure equilibrium diagram showing diamond growth region in the presence of nickel as a catalyst–solvent and Fig. 18(b) is a schematic of the "belt" HP-HT press.


Figure 18
(a) Pressure–temperature equilibrium phase diagram showing the stability regions of diamond and graphite and the region of diamond growth in the presence of nickel as a catalyst–solvent (Clark and De Vries) and (b) HP-HT press, know as the "belt," used in the synthesis of diamond and cBN (after Hall 1960).

The elements that are effective as a catalyst–solvent include the transition elements Cr, Mn, and Ta, plus all the elements of group III of the periodic table. Carbides and compounds of these elements that decompose at or below the diamond synthesis conditions can also be used. These elements and their compounds are believed to play a duel role, namely, that of a catalyst, and as a good solvent for graphite. It appears that graphite first dissolves into the catalyst and it then converts into diamond at the appropriate conditions of pressure and temperature within the diamond stable region. Diamond being relatively insoluble in the molten catalyst, precipitates thus allowing more nondiamond form carbon to go into solution. Since, the catalyst–solvent must be in the molten state, this establishes a lower temperature limit for a given catalyst.

The rate of diamond nucleation is sensitive to pressure, the higher the pressure above the equilibrium line at a given temperature, the greater the rate of nucleation and growth. Diamond formed at pressures substantially above the equilibrium line develop from many nuclei and have a skeletal structure. Such a diamond is very friable and is designated as RVG, since they are used in resin or vitrified bonded grinding wheels for grinding cemented tungsten carbide. Conversely, by subjecting the reaction mixture to pressures and temperatures close to the equilibrium line for a longer time, fewer nucleation sites develop and larger and more perfect single crystals of diamond are formed. Temperature has a major influence on the crystal habit of the diamond produced. At the lowest temperatures, the cubic form is predominant. Mixed cubes, cubo-octahedra, and dodecahedra are preferred at intermediate temperatures while octahedra from at the highest temperatures. The color of the diamond produced also vary with the temperature from black at low temperatures, through dark green, light green, and yellow at intermediate temperatures, to white at the highest temperatures. The color pretty much depends on the nitrogen content and graphite inclusions. Since the lowest possible temperatures at which conversion into diamond takes place are controlled by the melting temperature of the catalyst metal–carbon eutectic system, it appears advantageous to use performed alloys that can reduce the minimum temperatures. This has the additional advantage of simultaneously lowering the pressure requirements. Lower temperatures and pressures can increase the life of the dies used and hence the economics of the process.

The most common metal alloys used with graphite, are Fe–Co–Ni (Mn) although other catalysts can be used. The effectiveness of nickel could be due to the fact that the unit cell of nickel is very close to that of diamond. In one process, alternate layers of metal alloy and graphite are loaded in the high-pressure press. First, the pressure is raised to the diamond stable region. Following this, the temperature is raised to the diamond stable region. They are held at these conditions for the required amount of time to complete the synthesis. Following it, the cell is cooled maintaining the high pressure and then the pressure is released. The rate of nucleation of diamond under HP-HT conditions is estimated to be $\sim 10000\,\mu m\,min^{-1}$.

In the lower temperature region but at pressures exceeding that of diamond–graphite equilibrium by a few kilobars, the rate of nucleation and growth of diamond is very high. The growing crystals interfere and produce a skeletal structure with numerous defects. The resulting grain is relatively weak and friable and is designated as RVG by one of the producers of diamond abrasive. Such a material is ideal for making resin-bonded grinding wheels to grind cemented tungsten carbide without causing thermal damage to the surface. Figures 19(a) and (b) are SEM micrographs of RVG diamonds (50–60 grain size) of single grain polycrystalline diamond at higher magnification showing the skeletal structure. Diamonds of this type are self-sharpening and provide sharp cutting edges without forming wear flats and rubbing. Although microchipping wear may be considerable, it frequently is justified in terms of improved surface integrity.

The life of the polycrystalline diamond abrasives of the skeletal structure can be improved significantly by encapsulating them in a metal sheath, chiefly Ni or Cu. This is important because fine grains of diamond or cBN can get dislodged before they can be worn and resharpened because of weak interfacial bonding between the abrasive and the resin bond. The metal coating add texture to the surface of diamond or cBN and retain the abrasive in the resin bond by improved mechanical anchoring. Typically, electroless plating is used for this purpose. Originally a thickness corresponding to $\sim 55\%$ of the weight of diamond (which corresponds to an increase in mean diameter of $\sim 15\%$) was used. In addition to providing more surface area of the grains for improved bonding, the metal sheath acts as a shield and strengthens the polycrystalline diamond. The metal also improve the heat transfer from the diamond abrasive to the surroundings. Nickel encapsulation on the diamond abrasive is used for resin bonded diamond grinding wheel for wet grinding while copper is used for dry grinding. Figures 20(a) and (b) are SEM micrographs of Ni and Cu plated polycrystalline diamond showing details of the surface morphology of the metal coating. Unlike the copper coating that conforms to the topography of polycrystalline diamond, the nickel coating completely encompasses the grain and the topographical features of the base crystal are not discernible. Sometimes, to increase the bonding of the nickel coated crystals to the resin bond of the grinding wheel, the material is subjected to further heat treatment that provides a spiky surface (Fig. 20(c)). The thickness of metal encapsulation was varied from 30–70% depending on the applications. For example,
Figure 19
SEM micrographs of polycrystalline diamond crystals showing (a) and (b) skeletal structure (Komanduri and Shaw 1974a).

for obtaining longer wheel life in resin bonded grinding wheels, thicker coatings ($\sim 70\%$) are used to minimize premature dislodgement of the abrasives from the wheel while for applications requiring lower power requirements, thinner coatings ($\sim 30\%$) are used. Also, for metal bonded grinding wheels, the abrasives are coated initially with a thin layer of either Ti or Cr to enhance the bonding between the superabrasive and the metal bond.

Polycrystalline diamond of the RVG-type can also be grown using the low pressure–high temperature (LP-HT) CVD diamond synthesis, although the rates of growth are much lower ($\sim 150\,\mu m$) than the HP-HT technology. Figure 21 is an SEM micrograph of polycrystalline diamond grown using combustion synthesis by LP-HT synthesis. Polycrystalline diamond or cBN cutting tools made by the HP-HT synthesis can also be reused as polycrystalline diamond or cBN by breaking up the diamond layer. However, its use as a commercial product would depend on the economics of making such an abrasive by this route. While the strength of the polycrystalline diamond (or cBN) by this method is significantly higher, the cost can also be high, if prepared exclusively for this purpose. However, this may be one way to reclaim used polycrystalline diamond (or cBN) cutting tools for further use. Of course, if this method is used, then the polycrystalline diamond (or cBN) layer has to be produced without the underlying cemented carbide substrate, unlike the current practice of producing

diamond (or cBN) cutting tool with a cemented carbide substrate.

Single crystal diamond of the MBG and MBS are stronger than the polycrystalline diamond (RVG-type). They are used generally in the metal bonded grinding wheels or saw blades for cutting, such hard materials as stone, concrete, and ceramics. The principal crystal habit of growth of these crystals is cubo-octahedral, although some faces may not be well formed. There are several varieties of MBG, namely, MBG II, MBG-P, and MBG-T. Due to a wide range of imperfections in the structure these crystals have medium friability and strength and fall between the weak RVG and the fully developed blocky MBS-type. Figure 22 is an SEM micrograph of a fully developed, cubo-octahedral, single crystal diamond formed under favorable growth conditions. MBG-T crystals, though fairly well developed, differ from other crystals in that their surfaces are etched and are uniformly rougher on a microscale. This will provide better bonding between the diamond crystals and the metal in the metal bonded diamond grinding wheels. Also, a thin coating of Cr or Ti is deposited on MBS crystals to enhance adhesion between the crystals and the metal binder used in the grinding wheels or saw blades.

Cubic boron nitride (cBN), next only to diamond in hardness (Knoop hardness 46.1 GPa, $\sim 4700\,kgf\,mm^{-2}$), was developed in the late 1960s by Robert Wentorf Jr, of the GE. It is a remarkable material in
Figure 20
SEM micrograph of a nickel coated polycrystalline diamond crystal showing complete encapsulation of the crystal by the coating used for wet grinding of hardened steels. (b) SEM micrographs of a copper coated polycrystalline diamond crystal used for dry grinding of hardened steels. Note that the metal conforms to the grain topography and the character of the base polycrystalline diamond is maintained. (c) SEM micrograph of a spiked nickel coating on a polycrystalline diamond crystal to increase the bonding of the crystal in the resin bond and to improve the grinding ratio significantly in wet grinding of hardened steels (Komanduri and Shaw 1974b).

that it does not exist in nature and is produced by the high temperature–high pressure (HP-HT) synthesis in a process similar to that used to produce diamond from graphite. Hexagonal boron nitride (hBN) is used as the starting material. Alkali and alkaline-earth metal and their compounds (instead of Ni in the case of diamond) are found to be suitable catalyst–solvents for the production of cBN by the HP-HT process.
Figure 21
SEM micrograph of a polycrystalline diamond crystal grown by the LP-HT CVD diamond technique.
Figure 22
SEM micrographs of well formed cubo-octahedral single crystal diamond crystals used in saw blades (see Komanduri and Shaw (1974b).

In 1981, a tough, microcrystalline cBN abrasive was developed based on the direct conversion of cBN from pyrolitic hexagonal BN (hBN) without the use of a catalyst–solvent. This process involves pretreatment of

hBN in a vacuum furnace to remove the boric oxide from the surface and form a layer of free boron followed by HP-HT synthesis. Initially hBN powder is loaded in a vacuum furnace and the furnace is evacuated to pressures of $\sim 1 \times 10^{-5}$ to 1×10^{-6} torr. It is subsequently heated to a temperature of 1400–1900 °C for a period of 60–90 minutes. The pressure increases to $> 1 \times 10^{-3}$ torr during heating due to the evolution of nitrogen gas as a result of surface decomposition of the hBN power. This is followed by cooling of the material under vacuum, removing the hBN powder from the vacuum furnace and loading it on to the HP-HT press. Synthesis of cBN is carried out for about 3–10 minutes at a pressure of ~ 55–80 kbar and a temperature of ~ 1600 °C in the absence of any catalyst–solvents as well as impurities (which would interfere with the conversion or sintering of cBN). Such a material (with or without a metal coating) being very tough (amongst various types of cBN) can be used for heavy material removal operations and at the same time can be used for obtaining good surface finish due to the microcrystalline nature of the abrasive.

Cubic boron nitride, though not as hard as diamond, is less reactive with ferrous materials, such as hardened alloy steels, hard chill-cast iron, and nickel-base and cobalt-base superalloys. Hence, it can be used to grind these materials. cBN crystallites are stronger than polycrystalline diamond of the RVG-type but weaker than fully formed, single crystal (MBS-type) diamond. The principal growth habits of cBN crystals are octahedra and tetrahedra. Figure 23(a) is an SEM micrograph of a cBN crystal showing a well developed crystal with sharp edges. The surfaces of these crystals are somewhat smooth and featureless. At high growth rates twinning is predominant. Figure 23(b) is an SEM micrograph of a twinned cBN crystal. Figure 23(c) is an SEM micrograph of a microcrystalline cBN crystal grown without a catalyst–solvent. Similar to the coatings on RVG diamond, nickel is also used for coating cBN crystals (Fig. 24).

6. Synthetic Abrasives—Chemo-mechanical Abrasives

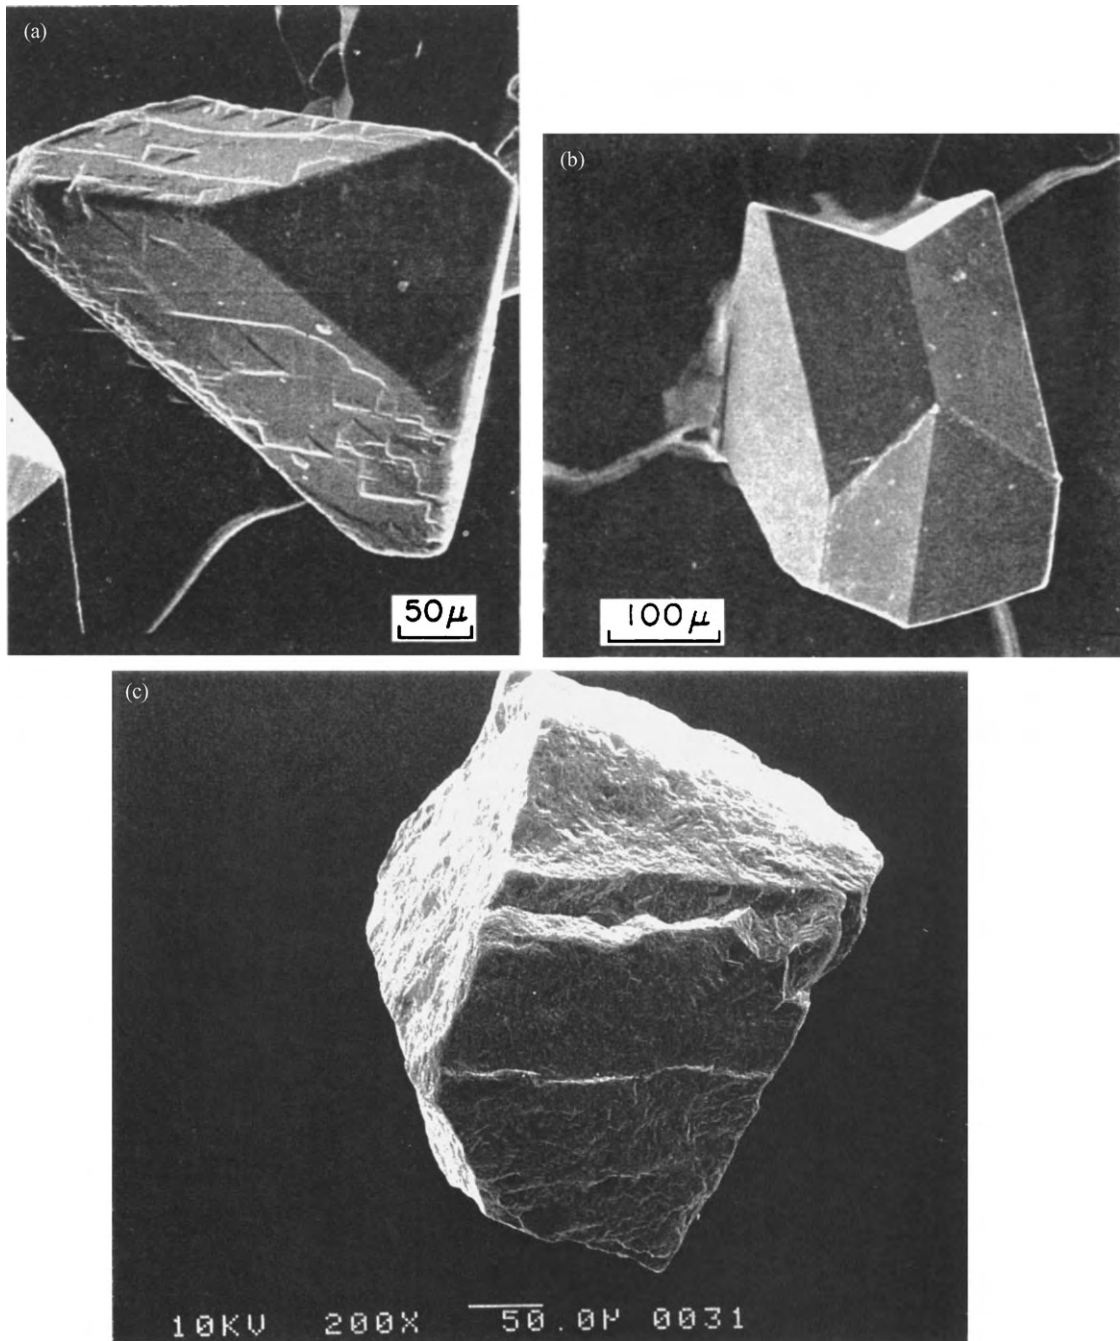
In mechanical finishing, where an abrasive harder than the workmaterial is used, the surface damage due to abrasion can be minimized but not eliminated altogether even when a very fine, hard abrasive is used. To improve the final surface finish and to meet the application requirements for reliable performance in service, further finishing needs to be carried out preferably involving, what is known as chemo-mechanical polishing (CMP). With the advent of microelectronics circuits, CMP has assumed a much broader role in that it not only encompasses polishing but also extends it to produce plane surfaces or planarization. So, the 'P' in the 'CMP' is extended to include planarization.


Figure 23

edges. (b) SEM micrographs of a single crystal twinned cubic boron nitride (cBN) crystal. Note the relatively smooth
and featureless surface. (c) SEM micrograph of a tough, microcrystalline cubic boron nitride (cBN), obtained using
higher pressures and temperatures and in the absence of any catalyst–solvent normally used (Komanduri and Shaw
1974b).
Figure 24
SEM micrographs of a nickel coated cubic boron nitride (cBN) crystal showing complete encapsulation of the crystal by the coating used for wet grinding of hardened steels (Komanduri and Shaw 1974b).

Figure 25
Schematic showing chemo-mechanical action between the abrasive, the workmaterial, and the environment (after Yasunaga *et al.* 1979).

CMP depends on the availability for a short duration of a certain threshold pressure and temperature at the contact zone of the polishing process provided a chemical reaction layer can be formed by the interaction of the workmaterial, the abrasive, and the environment (Fig. 25). The material removal by CMP is believed to be at the molecular level thereby yielding a smooth surface. The formation of the reaction layer and its removal controls the process. Similarly, the dissolution of the reaction products in the carrier fluid also plays an important role.

Many abrasives softer than the workmaterial can be used for finishing some of the difficult-to-finish workmaterials, such as advanced ceramics, glasses, and silicon. Here, material removal occurs due to chemical interaction between specific combinations of the abrasive–workmaterial–environment under the conditions of operation, such as the local pressure and temperature at the interface. Abrasives that come under this category include cerium oxide (CeO_2), magnesium oxide (MgO), silica (SiO_2), chromium oxide (Cr_2O_3), alumina (Al_2O_3), titania (TiO_2), zirconia (ZrO_2), iron oxide, or rouge (Fe_3O_4). For example, it has been found that damage-free surfaces can be produced using silica (SiO_2) for polishing sapphire;

$BaCO_3$, CeO_2, and $CaCO_3$ for polishing silicon single crystals; iron oxide or rouge (Fe_3O_4) and magnesia (MgO) for polishing quartz; Cr_2O_3, CeO_2, and ZrO_2 for finishing Si_3N_4. In the microelectronics industry, nanoparticle-sized SiO_2 is used for oxide polishing, while alumina and silica are used for metal polishing. CeO_2, MgO, TiO_2, ZrO_2, iron oxide or rouge (Fe_3O_4), and hafnia (HfO_2) are also used for polishing.

Ceria or cerium dioxide (CeO_2) has a cubic crystal structure with a fluorite-type structure while the cerous oxide (Ce_2O_3) has a hexagonal structure. They are rare earth compounds. The melting point of ceria is $\sim 2750\,^{\circ}C$. Although cerium occurs in nature in its trivalent form, cerium dioxide (CeO_2) is more stable than cerous oxide (Ce_2O_3), particularly in the presence of free oxygen. There are two valence forms of cerium, namely, the trivalent (cerous) as in Ce_2O_3, and the tetravalent (ceric) as in CeO_2. Cerium oxide is produced using cerium salt solutions. Cerium carbonates or hydroxides are precipitated and then calcined in rotary kilns or muffle furnaces to cerium oxide at temperatures of $\sim 1000\,^{\circ}C$. The impurities (CaO, SrO, nonrare-earth elements) must not exceed certain level in the raw material; otherwise, cerium oxide will agglomerate during calcination and lose polishing capability. The calcined concentrates are milled and cleaned by sieving.

Cerium dioxide, or ceria (CeO_2) is produced by electrolytic oxidation of cerium (III) to cerium (IV) ions, or chlorination with pure chlorine gas. Ceria salts are easily hydrolyzable and precipitate in the form of insoluble basic salts, leaving cerous salts in solution. The calcination of basic salts results in the formation of ceria as a fine white power. Ceria is extensively used for the polishing of optical glass and has been found to be a superior polishing agent than iron oxide rouge. It is also found to be an excellent polishing agent for CMP of silicon nitride for reasons similar to that of glass polishing. Its use can also be extended for the finishing of silicon as well. CeO_2 has been reported to be particularly effective in water and in alcohols only when hydroxyl groups are present. Thus CeO_2 slurry in water is required for polishing.

The oxide contains polyvalent cerium atoms, Ce(IV) and Ce(III), which can provide chemical action with the workmaterial and the environment.

Magnesium oxide or magnesia (MgO) is a very soft material with Mohs hardness of ~ 5.5 which is in between apatite(s) and orthoclase(s). The melting point of magnesia is $\sim 2800\,°C$. The principal commercial source of magnesia is magnesite ($MgCO_3$) and dolomite ($MgCO_3 \cdot CaCO_3$). Magnesia is produced by calcining dolomite and treating the resulting mixture of magnesia and calcia with a strong solution of ammonium chloride, or with a solution of magnesium and calcium chlorides. The insoluble magnesia is then separated from the calcium chloride solution. Magnesia is used as an abrasive in CMP.

Chromium oxide (Cr_2O_3) has a hexagonal rhombohedral structure of the corundum-type. Cr_2O_3 is green in color when in a finely dispersed form. It melts at $2435\,°C$ and has hardness slightly higher than alumina. Hence, it can be used singly as an abrasive like alumina or alloyed with alumina. The production of Cr_2O_3 involves the reduction of sodium dichromate, generally with sulfur. The mixture is fed into a brick-lined furnace, brought to a dark-red heat when the reaction proceeds exothermically. After cooling, the sodium sulfate produced is leached out with water. The remaining solid is separated, rinsed, dried, and ground.

Cr_2O_3 is a well-known catalyst. It is this role of Cr_2O_3 that is widely believed to take in the polishing. However, recent studies have shown that the role of Cr_2O_3 is more than that of a catalyst, at least in the polishing of Si_3N_4. It is found that Cr_2O_3 does participate in the CMP of Si_3N_4 to form chromium nitrate (CrN) and chromium silicate (Cr_2SiO_4), in addition to the formation of a silica layer on Si_3N_4. Cr_2O_3 is widely used as a chemo-mechanical abrasive. However, some of the reaction products are not environmentally friendly and hence its use will in future be somewhat limited till this problem has been solved.

Titania (TiO_2) is found in nature in the form of rutile. It is manufactured mainly from ilmenite ($FeTiO_3$), a widely available mineral. It is leached with sulfuric acid and the hydroxide subsequently precipitated from the solution is then calcined to TiO_2.

Zirconia (ZrO_2) is produced from zircon sand ($ZrO_2 \cdot SiO_2$). At room temperature its structure is monoclinic, which changes to tetragonal at higher temperatures, and to cubic at still higher temperatures. It is used in the natural form for abrasive jet cutting and as a coated abrasive. Pure zirconia is used as a polishing medium or alloyed with alumina to form alumina–zirconia for stock removal grinding (SRG) applications where toughness of the eutectic mixture plays an important role.

Silica or silicon dioxide (SiO_2) is available in crystalline, nano to microcrystalline, and noncrystalline forms. Silica constitutes $\sim 60\%$ of the earth's crust either alone or combined with other oxides or silicates. Silica represents a limiting case in which an infinite 3 D network is formed by the sharing of all the oxygen atoms of a given tetrahedron with neighboring groupings. For microelectronics applications, silica sols and colloidal silica are used. Colloidal silica is a stable aqueous dispersion or sol of discrete amorphous silica particles having a grain size of 1–100 nm. The pH value should be ~ 7 to maintain sufficient negative charge on the silica particle surface to prevent aggregation. To produce sols that are stable at relatively high silica concentrations, particles must be grown to a certain size in a weakly alkaline aqueous dispersion.

Iron oxide or rouge (Fe_3O_4) has been used for a long time for the polishing of glass, and precious metals like silver and gold. In some cases it has been replaced by zirconia or ceria because they are cleaner materials to use and have less tendency to strain.

Creep and Creep-fatigue of Metal-Matrix Composites

A metal-matrix composite (MMC) comprises a metallic matrix reinforced by a ceramic phase, which can be added as continuous fibers, discontinuous fibers, or particulates. Some MMCs possess good mechanical properties at high temperatures and these MMCs are considered as potential candidate materials for advanced high-temperature components. High-temperature components operate in the creep range where they have to withstand static (creep) and cyclic loads (fatigue). The term creep-fatigue interaction is used to describe the complex service conditions that are encountered in high-temperature systems, which are characterized by stationary as well as periodically, or irregularly, changing loads.

1. Creep of Metal-matrix Composites

Creep is the time-dependent plastic deformation of materials, which is important at temperatures above half of the melting point of a metallic material in kelvin (Riedel 1987). Creep strongly depends on microstructure, stress, and temperature. During tensile creep, strains accumulate until rupture occurs. Figure 1 illustrates how reinforcing an aluminum alloy with 15vol.% of Al_2O_3 fibers improves the creep rupture strength (Dlouhy *et al.* 1993). MMCs generally exhibit lower rupture ductilities than the matrix materials without reinforcements. Creep deformation of metals and alloys is generally characterized by a homogeneous type of deformation, which occurs in

the whole volume of the specimen. Creep damage is generally an internal damage like creep cavitation, e.g., in copper or in ferritic steels (Riedel 1987). Creep data for complex engineering alloys like MMCs are commonly represented by equations, which originally were developed to describe the behavior of materials that had much simpler microstructures. For example, it is often assumed that a regime of steady state creep can be identified where the constant steady state creep rate $\dot{\varepsilon}_S$ depends on stress σ and temperature T as

$$\dot{\varepsilon}_S = C\sigma^n \exp\left(-\frac{Q_{eff}}{kT}\right) \qquad (1)$$

where C is a constant, n is the stress exponent, and Q_{eff} is the apparent activation energy of creep, and k is the Boltzmann constant. MMCs differ in creep behavior from pure metals and simple alloys in two important respects: (i) there is no steady-state creep regime, but an inflection from primary to tertiary creep resulting in a minimum creep rate; and (ii) the use of Eqn. (1) to represent minimum creep rate data leads to values of n and Q_{eff} that are much larger than those associated with creep of simple metals and alloys. For short fiber-reinforced aluminum alloys the shape of individual creep curves as well as the stress and the temperature dependence of the minimum creep rate could be rationalized on the basis of an interaction of three elementary microstructural processes, which are schematically illustrated in Fig. 2. Fibers are loaded by dislocations, which form a work hardened zone around them. This results in a stress transfer from the matrix to the fibers. Recovery processes in the course of which dislocations from the work hardened zone move to the fiber ends (recovery path) where they shrink and annihilate counteract
Figure 2
Elementary microstructural processes which govern creep of short fiber-reinforced aluminum alloys (after Dlouhy *et al.* 1995).

this strain hardening process. Once fibers reach a critical stress they break and this reduces the length of the recovery path. The example given here (Dlouhy *et al.* 1995) describes the creep behavior of one specific type of short fiber-reinforced MMC. However, the results are of general validity in showing that it is possible to rationalize high values of Q_{eff} and n (Eqn. (1)) on the basis of the interaction of elementary deformation processes, which can be detected in the MMC microstructure.

2. High-temperature Fatigue of MMCs and Creep-fatigue Interaction

Fatigue is characterized by the failure of a material subjected to cyclic loading (in stress or strain control) which occurs after a given number of load cycles. One of the load cycles alone would not result in failure. In fatigue, damage accumulates with increasing cycle number, as creep damage does with increasing time. Plastic deformation under fatigue conditions is often associated with localized plastic deformation. Fatigue life is generally associated with the initiation and growth of surface cracks and strongly depends on the environment. In high-temperature fatigue experiments, the response of a material to cyclic loading is investigated at creep temperatures. This has important consequences for the mechanisms of fatigue deformation and damage accumulation. High-frequency fatigue experiments are often found to yield results, which are quite similar to what is observed in low-temperature fatigue tests. In low-frequency experiments there is more time for recovery and this results in a decrease of the saturation stress observed in the hysteresis of a total strain controlled low cycle fatigue (LCF) test. There is also more time for an interaction between the environment and surface

cracks. The first effect is often considered as representing the influence of creep, the second effect represents the influence of high-temperature corrosion on fatigue life. With respect to a microstructural understanding of high-temperature fatigue and creep-fatigue three questions need to be answered: (i) what effect has creep-fatigue loading on the stress strain hysteresis; (ii) how do microscopic cracks develop in the surface of the MMC (nucleation of engineering cracks); and (iii) how does a macroscopic fatigue crack propagate in the microstructure of an MMC?

In total strain controlled isothermal testing, creep-fatigue interaction can be addressed in various ways, such as: (i) determining the influence of the imposed total deformation rate; (ii) studying the effect of different wave shapes; (iii) investigating the effects of hold times in tension or compression on fatigue life; (iv) low cycle fatigue testing using pre-crept specimens; or (v) performing creep and fatigue tests sequentially. It is well known that high-temperature fatigue loading can be anisothermal such that temperatures and stresses change simultaneously, "in-and out-of-phase." Such types of loadings are referred to as thermal mechanical fatigue (TMF). There are different experimental and theoretical approaches to high-temperature fatigue and to creep-fatigue interaction of MMCs ranging from TMF tests to modeling creep-fatigue interaction on the basis of constrained cavity growth models. In the case of tungsten fiber-reinforced copper it was shown that TMF loading resulted in lower fatigue lives than isothermal LCF. In the case of *in situ* composite solders it was not possible to fully account for creep-fatigue interaction merely on the basis of a constrained cavity growth model. From a microstructural point of view it has been qualitatively discussed how the superposition of static and cyclic high-temperature loading in a MMC affects dislocation dynamics near the fiber-matrix interface (Eggeler and Earthman 1997). There is little information on which factors affect high-temperature fatigue crack initiation in MMCs.

3. The Role of the Reinforcement-matrix Interface, Mechanical Anisotropy, and Multiaxial Loading

Given the wide range of different types of MMCs and the multitude of possible creep-fatigue loading conditions the present text cannot provide one simple set of clear microstructural conclusions on creep and high-temperature fatigue behavior of MMCs. However, in both, creep and fatigue of MMCs the role of the interfaces between reinforcement and matrix is crucial. Strengthening of MMCs relies on load transfer from the matrix to the fiber across the interface. In the case of fiber-reinforced composites, fracture toughness is influenced by fiber pullout events and

crack propagation is affected by the interaction of the propagating crack with the fiber-matrix interface. Ductility is affected by relaxation of stresses near the fiber-matrix interface. Mechanical anisotropies also are important. Thus a short fiber-reinforced MMC with aligned fibers can be strong at high temperatures in the fiber direction where fibers can constrain the material during creep and toughen the material during fatigue crack growth (where fiber pullout can dissipate energy). On the other hand, when loaded perpendicular to the fibers, debonding of the reinforcement-matrix interface under creep conditions will result in poor creep properties. Fast fatigue crack propagation along a reinforcement-matrix interface—which would also be expected under low-temperature fatigue conditions (Suresh 1991)—will result in poor fatigue performance. High-temperature components generally have to withstand multiaxial loading and this adds a further degree of complexity (Leckie 1996).

4. Conclusions

It is more difficult to design high-temperature components using MMCs. Their properties are dependent on the mix of matrix and reinforcement materials, on the spatial distribution of the constituent phases, on the properties of fibers and reinforcements, and on the build up of the fiber-matrix interface. The high-temperature properties of MMCs moreover depend on the interaction and coupling of elementary microstructural deformation and damage processes. A better understanding of all aspects of high-temperature loading of MMCs is required to enable safe design of high-temperature MMC components.

Creep of Bituminous Aggregates

Bitumen is a complex hydrocarbon produced for industrial use by oil refining. For its various applications it is almost always mixed with mineral aggregate, the particular blend depending on the end use. The largest field of application is for roads and other paved areas but it is also used for waterproofing of roofs, bridge decks, and underground construction.

The oil industry is able to produce a wide range of bitumens, including many with properties modified through the use of a variety of polymers or other additives.

The principal characteristics of bitumen, which are attractive for its various applications, are its adhesive and waterproofing properties (see also *Bituminous Materials*[#]).

1. Basic Physical Properties of Bitumen

Bitumen is a viscous fluid at medium to high temperatures and a brittle solid at low temperatures. Its consistency is quantified as viscosity and as stiffness, which is defined as applied stress divided by corresponding strain, for these temperature regions, respectively. The relationship between consistency and temperature is a very important one, since the use of bitumen requires it to be in a fluid state for mixing with mineral aggregate and a somewhat stiffer state for compaction by roller to form a road layer and to act as a solid for its in-service role at ambient temperatures.

Bitumen is a viscoelastic material, the properties of which are influenced not only by temperature but also by rate of loading. Figure 1 shows the three phases of behavior including elastic, viscoelastic, and viscous as the temperature rises. It is the viscous property of bitumen that causes it to exhibit creep characteristics. These are apparent both when it is subjected to static loading and under the repeated loading which arises from moving traffic on highways or runways. Figure 2 shows the effect of deformation in the wheel tracks of a major highway causing a dangerous level of rutting.

Many grades of bitumen may be regarded as "rheologically simple" meaning that a given rise in temperature has the same effect on stiffness as a
Figure 1

Figure 3
Master curves relating stiffness to loading time for a normal and an elastomer-modified bitumen.
Figure 4
Relationships between strain and loading time for tests under static and repeated loading on a typical bituminous material.

corresponding decrease in rate of loading. It follows that the stiffness or viscosity of bitumen may be determined for a very wide range of temperature or loading rate by conducting experiments over a limited range and "shifting" the data to extrapolate over a large range to produce a "master curve" of response. The result of such a procedure is shown in Fig. 3 for both a normal bitumen and a polymer-modified material.

2. Creep Characteristics of Bitumen–Aggregate Mixtures

Bituminous material used for road construction has three phases, typical volumetric properties being 12% bitumen, 83% mineral aggregate, and 5% air voids. The creep characteristics of this mixture are influenced by the properties of the two solid components.

However, the presence of air is important, since an aggregate matrix saturated with bitumen would exhibit high creep deformation, which would be unacceptable in practice and cause serious rutting of the type shown in Fig. 2.

When a bituminous mixture is subjected to applied stress, there are, in general, three components of strain which result: elastic, plastic, and viscous. The plastic component is independent of time and temperature, being generated by the interaction between aggregate particles. Both the other components are time and temperature dependent. Elastic strains are influenced by the bitumen and the aggregate, while viscous strain derives only from the bitumen.

Under a static creep load, Fig. 4 shows how the total strain develops with time. When the load is removed, a small elastic (recoverable) strain is apparent. Under repeated loading of the same magnitude, the accumulated strains are larger. This is partly because of the plastic strains contributed by the relative movement between aggregate particles.

The addition of a polymer changes the consistency/temperature relationship for a bitumen as shown in Fig. 3 for an elastomer-modified material. When mixed with aggregate, this produces a material that will be less susceptible to temperature changes and more resistant to creep strains than one made with a conventional bitumen.
Figure 5
Relationships between strain rate and stress at 20 °C.

The effect of increasing the volume of aggregate in a bituminous mixture is shown in Fig. 5 for a typical case. These data show how the steady strain rate (slope of the linear parts of relationships in Fig. 4) varies with applied uniaxial stress and illustrates the substantial reduction in strain rate when aggregate is blended with bitumen. The relationship between these two parameters is only linear up to a particular stress level; in this case about 50 kPa. In the linear range the response is known as Newtonian with strain rate proportional to stress, while in the non-linear range the material is described as non-Newtonian. Since viscosity is the quotient of stress and strain rate, it follows that a Newtonian bitumen has a unique value of viscosity at a particular temperature regardless of the stress or strain level. In reality, under working conditions, most bitumens are often in the non-Newtonian range.

Creep of Concrete

Under sustained load, concrete continues to deform. This phenomenon is called creep. Creep, along with instantaneous (or elastic) strain, is defined as the strain difference between loaded and load-free specimens. When exposed to drying, the load-free specimens exhibit drying shrinkage (typically reaching 0.0002 to 0.0004, and in poor concrete even 0.0008). After many years, the creep strain typically attains values 2 to 6 times larger than the initial elastic strain. After unloading, a partial creep recovery takes place. The creep at drying greatly exceeds the sum of shrinkage and the creep of a sealed specimen. The difference, called the drying creep (or Pickett effect), is a manifestation of a coupling between deformation and water content changes. Imbibition of water causes swelling (normally much less than the drying shrinkage) or, if concrete has dried, a partial reversal of shrinkage.

Drying shrinkage (Fig. 1 left and middle) is caused by compressive stresses in the microstructure balancing changes in the capillary tension and surface tension on pore walls, as well as the disjoining pressure in hindered adsorbed water layers. The chemical processes of Portland cement hydration cause autogeneous shrinkage, which is observed in sealed specimens and amounts to only about 5% of drying shrinkage (but much more in high-strength concretes). Creep is caused by bond ruptures (with restorations at adjacent sites) in the hardened Portland cement paste, which is strongly hydrophilic, having a disordered colloidal microstructure, porosity about 0.4 to 0.55, and an enormous internal surface area—about $500\,\mathrm{m^2\,cm^{-3}}$. Its main component is the tricalcium silicate hydrate gel ($3\,CaO \cdot 2\,SiO_3 \cdot 3\,H_2O$, in short $C_3S_2H_3$); it forms crystalline sheets and needles of colloidal dimensions, weakly bound by van der Waals forces.

1. Constitutive Law

At service stresses in structures, which are less than about one-half of the strength, and in the absence of cracking, the creep strain depends on stress linearly. It may be fully characterized by the compliance function $J(t,t')$ (Fig. 1 right), defined as the strain ε at time (or age) t caused by a unit uniaxial stress $\sigma = 1$ applied at age t'. As t' increases, the creep diminishes. This phenomenon, called aging, causes J to depend not only on the time lag $t-t'$. At variable stress $\sigma(t)$, each stress increment $d\sigma(t')$ applied at time t' produces strain history $d\varepsilon(t) = J(t,t')d\sigma(t')$. By the superposition principle (introduced by Boltzmann and Volterra), one gets the linear creep law of aging viscoelasticity:

$$\varepsilon(t) = \int_{t_1}^{t} J(t,t')d\sigma(t') + \varepsilon^0(t) \tag{1}$$

where ε^0 denotes the sum of shrinkage strain ε_{sh} and thermal strain (and also smeared cracking strain, if any). The integral is the Stieltjes integral, which admits histories $\sigma(t)$ with jumps; for time intervals with no jump, one may set $d\sigma(t') = [d\sigma(t')/dt']dt'$. When history $\varepsilon(t)$ is prescribed, then Eqn. (1) represents a Volterra integral equation for $\sigma(t)$, which is not integrable analytically for realistic forms of $J(t,t')$, although numerical integration is easy. The solution $\sigma(t)$ for strain $\varepsilon = 1$ imposed at age $\hat{t}$ (and for $\varepsilon^0 = 0$) is called the relaxation function, $R(t,\hat{t})$ (Fig. 1 right) [$R(t,\hat{t}) \approx 0.992/J(t,\hat{t}) - 0.115\psi/J(t,t-1\,\mathrm{day})$, $\psi = J(\bar{t},\hat{t})/J(t,\bar{t})-1$, $\bar{t} = (\hat{t}+t)/2$]. Generalizing Eqn. (1) according to the principle of superposition, and taking isotropy into account, yields a triaxial stress–strain relation, in which the shear and bulk compliance
Figure 1
Typical time evolution of shrinkage, and of basic creep and drying creep compliances, for various slab thicknesses D, environmental humidities h_e, and ages at loading t'.

functions are $J_G(t,') = 2(1 + 2v)J(t,t')$ and $J_K(t,t') = 3(1-2v)J(t,t')$ ($v \approx 0.18 = $ Poisson ratio). At high stress, the creep law appears to be nonlinear (Fig. 2) but Eqn. (1) remains valid if the strain due to time-dependent growth of cracks is included in $\varepsilon^0(t)$.

The value $J(t',t') = q_1$, corresponding to extrapolation of creep curves to zero load duration, may be considered as an age-independent constant. The conventional Young's elastic modulus, implied as $E(t') = 1/J(t' + \delta, t')$ where usually $\delta \in (0.0001 \text{ s}, 10 \text{ min.})$, increases with age t'. A realistic form of the compliance function (Bažant *et al.* 1997; bold curves in Fig. 1 right) may be conveniently expressed by its rate:

$$\dot{J}(t, t') = v^{-1}(t)\dot{C}_g(t - t') + 1/\eta_f \qquad (2)$$

$$v^{-1}(t) = q_2(\lambda_0/t)^m + q_3 \qquad (3)$$

$$\dot{C}_g(t, t') = \frac{n(t - t')^{n-1}}{\lambda_0^n + (t - t')^n} \qquad (4)$$

For creep of sealed specimens, called the basic creep:

$$1/\eta_f = q_4/t \text{ (at constant } w) \qquad (5)$$

and then the flow part of $J(t,t')$ is simply $q_4\ln(t/t')$.

The superior dots denote partial derivatives with respect to t; $\theta = $ load duration; $\lambda_0 = 1$ day, $m = 0.5$, $n = 0.1$; q_2, q_3, $q_4 = $ empirical constants; $C_g(t-t') = $ (age-independent) compliance function for delayed elasticity of the cement gel (hardened cement paste without its pores); $v(t) = $ volume of gel per unit volume of concrete, growing due to hydration; and $\eta_f = $ effective viscosity for the flow of concrete. By integration, $C_g(t-t') = \ln \{1 + [(t-t')/\lambda_0]^n\}$. As for $J(t,t')$, it can be obtained only by numerical integration (however, for computer structural analysis in time steps, the rate $\dot{J}(t,t')$ suffices and in fact allows a simpler algorithm).
Figure 2
Creep isochrones.

2. Variable Environment

At variable w (mass of water per unit volume of concrete), a physically realistic constitutive relation may be based on the idea of microprestress S, considered to be a dimensionless measure of the stress peaks at the creep sites in the microstructure. The microprestress is produced by chemical volume changes and by changes in the disjoining pressures in the hindered adsorbed water layers (up to ten water molecules, or 2.7 nm, in thickness) confined between sheets of calcium silicate hydrates. The disjoining pressures must vary with the relative humidity h in the capillary pores, so as to maintain thermodynamic equilibrium (equality of chemical potentials). The rate of bond breakages may be assumed to be a quadratic function of the level of microprestress, which leads to the expression:

$$1/\eta_f = q_4 S \qquad (6)$$

303

The microprestress is not appreciably affected by the applied load. It relaxes in time, and its evolution at each point of a concrete structure may be solved from the differential equation:

$$\dot{S} + c_0 S^2 = -c_1 \dot{h}/h \qquad (7)$$

where c_0, c_1 = dimensionless constants. The fact that changes of w or h produce new microstress peaks, and thus activate new creep sites, explains the drying creep effect (however, a part of this effect is caused by the fact that microcracking in a companion load-free specimen makes its overall shrinkage less than the shrinkage that occurs in a specimen creeping under compression, thus increasing the difference between the two).

The concept of microprestress is also needed to explain the stiffening due to aging. One physical cause of aging is that the hydration products gradually fill the pores of hardened cement paste, as reflected in function $v(t)$ in Eqn. (3). But hydration ceases after about one year, whereas the effect of age at loading t' is strong even after many years. The explanation is that the peak microstresses relax with age, which reduces the number of creep sites and the rate of bond breakages causing creep.

The evolution of distributions $h(\mathbf{x},t)$ ($\mathbf{x}$ = coordinate vector) may be considered uncoupled from the stress and deformation problem, and may be solved numerically from the diffusion equation $\dot{h} = \text{div}[C(h)$ grad $h] + \dot{h}_s(t_e)$ where $h_s(t_e)$ = self-desiccation (caused by hydration) (which is mild in normal concrete but strong in high-strength concretes) and $C(h)$ = diffusivity, which decreases about 20 times as h drops from 100% to 60%. The field of free (unrestrained) shrinkage strain rates

$$\dot{\varepsilon}_{sh} = k_{sh} \dot{h} \qquad (8)$$

where k_{sh} = shrinkage coefficient. Since $\dot{\varepsilon}_{sh}$ values at various points are incompatible, shrinkage stresses are induced, and the calculation of the overall shrinkage of structures as well as test specimens is a stress analysis problem, in which creep and cracking must be taken into account.

For finite element structural analysis in time steps, it is advantageous to convert the constitutive law to a rate-type form. This may be achieved by approximating $C_g(t,t')$ with a Kelvin chain model (or the associated relaxation function with a Maxwell chain model). The history integrals such as Eqn. (1) then disappear from the constitutive law, the history being characterized by the current values of internal state variables (the partial strains or stresses of the Maxwell or Kelvin chain).

Conversion to a rate-type form is also convenient to introduce the effect of variable temperature, which affects the Kelvin chain viscosities (according to Arrhenius law) and also the rate of hydration. The latter is captured by introducing into the laws for creep and shrinkage an equivalent hydration period, t_e, based again on the Arrhenius law for the hydration reaction. For a three-dimensional tensorial generalization of (2)–(8), see Bažant *et al.* (1997).

3. Approximate Cross-section Response at Drying

Although multidimensional finite element calculations of creep and moisture diffusion are nowadays feasible, simplified one-dimensional analysis of concrete beams or girders still reigns in practice. In that approach, one needs as input the average cross-sectional compliance function $\bar{J}(t,t',t_0)$ (Fig. 1 right, light lines) and average shrinkage function $\bar{\varepsilon}_{sh}(t,t_0)$ of the cross-section (Fig. 1 left and middle) (t_0 = age at start of drying). The algebraic expressions for such average characteristics are considerably more complicated and inaccurate than the constitutive law for a material point, because of ignoring the differences due to cross section geometry, reinforcement, and loading (compressive or tensile axial force, bending moment, shear, torque, etc.). The following approximations (Bažant and Baweja 2000), partly based (under strong simplifications) on the foregoing constitutive relations, have been derived and their coefficients optimized by fitting a large test data bank; for environmental humidities h_e below 98%:

$$\bar{\varepsilon}_{sh}(t,t_0) = -\varepsilon_{sh\infty} k_h S(t), \quad k_h = 1 - h_e^3 \qquad (9)$$

$$S(t) = \tanh\sqrt{\frac{t - t_0}{\tau_{sh}}}, \quad \tau_{sh} = k_t(k_s D)^2 \qquad (10)$$

where $D = 2v/s$ = effective thickness, v/s = volume-to-surface ratio, $k_t = 1$ for normal (type I) cement; k_s = shape factor (e.g., 1.0 for a slab, 1.15 for a cylinder); and $\varepsilon_{sh\infty} = \varepsilon_{s\infty} E(607)/(E(t_0 + \tau_{sh}))$, $\varepsilon_{s\infty}$ = constant; $E(t) = E(28)\sqrt{4 + 0.85t}$ = age dependence of Young's modulus (all times are in days). Eqns. (2), (3) and (4) apply, except that $1/\eta_f$ must be replaced by:

$$\frac{1}{\bar{\eta}_f} = \frac{q_4}{t} + q_5 \frac{\partial}{\partial t}\sqrt{F(t) - F(t_0')} \qquad (11)$$

where q_4, q_5 are constants, $F(t) = \exp\{-8[1-(1-h_e)S(t)]\}$, and $t_0' = \max(t',t_0)$. The form of the expression for shrinkage halftime τ_{sh} is based on the diffusion theory. Function tanh in Eqn. (9) is the simplest function satisfying two asymptotic conditions ensuing from the diffusion theory: (i) for short times $\bar{\varepsilon}_{sh} \propto \sqrt{t - t_0}$, and (ii) the final shrinkage must be approached exponentially. Generalizations taking into account the effect of temperature have also been formulated.

Empirical formulae have been developed for predicting the parameter values in the foregoing

equations on the basis of concrete strength and some parameters of the concrete mix. However, they are very crude, leading to prediction errors with coefficients of variation 23% for creep and 34% for drying. These high uncertainties can be drastically reduced by updating certain coefficients of the formulae according to short-time creep and shrinkage tests of the given concrete. However, the evolution of weight loss of the drying test specimens must be measured simultaneously (or else the updating problem is ill-conditioned). A fully rational prediction of concrete creep and shrinkage properties from its composition is a formidable problem, not yet resolved satisfactorily.

4. Engineering Applications

Nonuniform creep and restrained shrinkage may cause deleterious cracking in bridges, buildings and other structures, which may trigger or promote other processes endangering durability. Creep nonuniformity is caused by differences in the histories of pore humidity and temperature, age, and concrete type. In slender structures, creep may cause collapse due to long-time instability. Transfer of compressive stresses from creeping and shrinking concrete to steel bars or other non-creeping parts (e.g., stone cladding or masonry liner) may induce their buckling or compression failure. The creep effects are particularly important for prestressed concrete structures (because of their slenderness and high flexibility), and are paramount in the safety analysis of nuclear reactor containments and vessels. The stress relaxation caused by creep is useful in mitigating the effects of shrinkage, cooling, differential creep, and differential settlements, but is undesirable in the case of a stress loss in prestressing tendons. At high-temperature exposure, as in fire or postulated nuclear reactor accidents, creep is very large and plays a major role.

Creep of Particle Reinforced Materials

Two types of particle-strengthened materials are used in high-temperature applications:

• Precipitation and dispersion-strengthened materials with typical particle dimensions below about 100 nm. As interparticle spacing is small, strengthening occurs by direct interaction with dislocations. Particles causing this type of strengthening are referred to as small throughout this paper.

• Composite materials containing discontinuous reinforcements with typical dimensions above about 1 μm. Since the back stress exerted on moving dislocations is insignificant as a result of the large interparticle spacing, strengthening does not occur by direct interaction with dislocations. Instead, load transfer from the softer matrix onto the harder particles is the underlying mechanism. This particle class will be referred to as large in the following.

In addition to direct strengthening, both particle types may also have an indirect effect as they modify the microstructure (e.g., grain size and dislocation substructure) relative to the unreinforced matrix. The goal of this article is to discuss and compare the underlying strengthening mechanisms, concentrating on direct strengthening by small and large particles in Sects. 1 and 3 while discussing indirect effects in Sect. 2. Finally, interaction of small and large particles in so-called dual scale particle-strengthened materials is addressed in Sect. 4.

1. Creep Strengthening by Small Particles

1.1 The Climb Process

The most obvious cause for particle strengthening at high temperatures is the need for dislocations to circumvent particles by climb. It is therefore not

surprising that early theories concentrated on this mechanism. Historically, there have been two schools of thought regarding climb geometries: in the so-called local climb model developed by Brown and Ham (1971), it is assumed that the climbing dislocation segment profiles the dispersoid while the dislocation between the dispersoids remains in its glide plane (Fig. 1(a)). In contrast, general climb models (Lagneborg and Bergmann 1976, McLean 1985, Rösler and Arzt 1988) assume that the dislocation is allowed to unravel, i.e., to reduce, under the action of its line tension, the high curvature at the point where it meets the dispersoid (Fig. 1(b)). A particular attraction of the local climb concept was that it offers a simple explanation for the extreme stress sensitivity of the creep rate found in dispersion-strengthened materials: as a significant length of new dislocation

(a)

(b)

Figure 1
Schematic profile of a dislocation climbing over a cube shaped particle according to the local climb assumption (a) with a sharp bend at point C and the general climb assumption (b) where the high curvature at C is relaxed by climb of the dislocation segment adjacent to the particle. Geometrical details of a climbing dislocation identifying particle height h, particle diameter d, ramp angle β, and the dislocation shape parameters x_0, z_0 are also shown.

line has to be created in the course of dislocation climb, a relatively large threshold stress σ_{th} is predicted which depends on particle geometry and is roughly given by $\sigma_{th} \approx 0.4 \ldots 0.7\sigma_0$. Nevertheless it is known today that this coincidence is fortuitous and that the special creep behavior of dispersion-strengthened materials has to be related to the detachment barrier caused by an attractive particle-dislocation interaction (see below). Furthermore, it is apparent that the sharp bend in the dislocation line (see point C, Fig. 1(a)), instrumental in producing a significant threshold stress, is extremely unstable and can be rapidly relaxed by diffusion, leading to more general climb as schematically depicted in Fig. 1(b).

Accepting the general climb concept as relevant, estimates of creep retardation by dislocation climb can be made. Noting that the length l of the climbing dislocation segment BD (Fig. 1(b)) is increasing in the course of climb, a back stress τ_{back} results that can be calculated provided the shape of the climbing dislocation segment is known as a function of applied stress, climb position z_0, and particle geometry:

$$\tau_{back} = \frac{Gb}{2\lambda}\left(\frac{dl}{dy}\right) \qquad (1)$$

(dl/dy: increase in dislocation line length dl per advance dy of dislocation segment BD in glide direction y). Modeling the particles as noninteracting (no repulsive force due to misfit stresses or elastic constant misfit), Lagneborg finds that the maximum back stress τ_{back}^{max}, which is attained when the dislocation has climbed to the top of the particle, is proportional to the applied stress

$$\tau_{back}^{max} \approx 0.7\tau \qquad (2)$$

but practically independent of particle size and interparticle spacing. Analyzing the climb geometry by requiring equilibrium conditions, i.e., constant chemical potential for vacancies along the climbing segment ABD (Fig. 2), Rösler and Arzt (1988) derived an implicit expression for equilibrium shape $x_0(z_0)$

$$\frac{x_0}{d} = \left[\sqrt{1-(\tau/\tau_0)^2}\left(\frac{x_0}{z_0}+\frac{z_0}{x_0}\right)\right.$$
$$\left. \times \left(\frac{\tau}{\tau_0}\frac{1}{\tan\beta}-1+\left(1-\frac{z_0}{x_0}\right)9/4\right)\right]-1 \qquad (3)$$

from which the line length differential dl/dy can be easily calculated. Here, d and β are diameter and ramp angle of a cuboidal particle. The results, showing the normalized back stress τ_{back}/τ as a function of normalized dislocation position z_0/d, are given in Fig. 2. Although a significantly lower back stress ($\tau_{back}^{max} \approx 1/3\tau$) is predicted, the qualitative findings are in good agreement with Lagneborg's earlier work (1976)

● the maximum back stress τ_{back}^{max} is attained at the particle top; and

Figure 2
Calculated normalized back stress τ_{back}/τ as a function of normalized climb position z_0/d for different normalized applied stress levels τ/τ_0 (ramp angle $\beta = 45°$).

- τ_{back}/τ is independent of particle diameter d and weakly dependent on Orowan stress, i.e., interparticle spacing 2λ.

The latter point may be best understood by the following example: imagine a situation where the particle volume fraction is doubled at constant particle size. As τ/τ_0 is reduced accordingly at given applied stress τ, the unraveling distance x_0 increases so that less extra line length is needed for climb. In consequence, force in forward direction $\vec{F} = \tau \lambda b$ and retarding force, associated with the need to create additional dislocation line length, decrease at the same time so that the overall effect of interparticle spacing on τ_{back}/τ is small. In the context of the back stress concept, this means that creep retardation by particles is largely independent of particle parameters. However, it is important to note that a number of limitations apply. First, it is apparent that τ_{back} cannot exceed the particle cutting or Orowan stress so that the onset of measurable creep retardation is dependent on particle parameters, while the magnitude of strengthening by climb at sufficiently low stresses is not.

Furthermore, it is important to note that general climb models are based on the assumption of equilibrium dislocation shape, i.e., minimum dislocation energy, which requires that vacancies are provided rapidly enough. This prerequisite breaks down when particles are too large and/or deformation rates too

fast so that back stress levels calculated under the above assumptions are no longer meaningful. In such a situation it may be more appropriate to consider climb past particles as rate controlling and derive the creep kinetics via

$$\dot{\gamma} = \frac{\rho b 2\lambda}{t_c} \tag{4}$$

where t_c is the time required to surmount a particle by climb and 2λ is the mean free dislocation path, which is equivalent to the interparticle spacing. Following the analysis by Rösler and Arzt (1988) leads to

$$\frac{1}{t_c} = \frac{Gb^4}{d^3} C_i A \left(\frac{\tau - \tau_{\text{back}}}{\tau_o} \right)^n \tag{5}$$

where stress exponent n and preexponential factor A are weakly dependent on particle height h and ramp angle β as

$$n = 3.5 \beta^{0.3} (h/d)^{0.2} \tag{6}$$

and

$$A = 60 \times 10^{-1.9\beta} (d/h)^{1.6} \tag{7}$$

Note that a stress exponent $n \approx 3$ results for typical particle parameters. If a stress exponent of two, accounting for a quadratic stress dependence of dislocation density, is added, then n lies in a range typical of the stress dependence of the creep rate in precipitation-strengthened alloys at low stresses. As noted by Lagneborg, the frequently observed break in the strain rate curves of precipitation-strengthened materials to larger n-values at high stresses can be associated with the transition from climb to particle cutting or Orowan bowing irrespective of the applied climb model.

C_i in Eqn. (5) is a kinetic constant given by $C_v = 2\pi D_v d/kTb$ and $C_p = a_p D_p/kT\lambda b$ for volume and pipe diffusion control. In the original analysis, τ_{back} is associated with a threshold stress occurring because a dislocation threads over and under neighboring particles, limiting the unraveling distance x_0. This effect, however, is insignificant and can be neglected in most situations. Hence, it may be of more practical significance to associate τ_{back} to other matrix strengthening mechanisms, such as solid solution hardening.

Inserting for C_i and τ_0 and taking $n = 3$, we find that the dislocation velocity $v = 2\lambda/t_c$ is proportional to $(d/f)^2$ and $(1/f)^{3/2}$ for volume and pipe diffusion, respectively (where f is particle volume fraction). This demonstrates the strong influence of particle parameters on creep rate once climb past particles is rate controlling. In conclusion, it is noted that there are two limiting cases. For small particle dimensions and volume fraction, particle strengthening may be best described by a back stress of the order $\tau_{\text{back}} \approx 0.3 \dots 0.7$ independent of particle parameters.

Once vacancy supply for dislocation climb past particles becomes rate limiting, particle parameters have a pronounced effect and the creep rate may be best modeled using Eqn. (4) with (5).

1.2 The Detachment Process

The elastic constant of thermally stable ceramic particles such as carbides and oxides is usually larger than that of the metallic matrix. For this reason, one would expect a repulsive interaction between dislocations and particles. However, it was shown by Srolovitz *et al.* (1983) using computer simulation that an attractive interaction results at high temperature provided the particle/matrix interface is incoherent, so that part of the dislocation stress field can be relaxed at the particle by short-range diffusion, whereby the incoherent interface serves as source and sink for vacancies. The theoretical prediction is confirmed by TEM studies (Nardone and Tien 1983, Schröder and Arzt 1985), which show that dislocations are captured at the detachment side of dispersoid particles after climb has been completed. Hence, one has to distinguish between noninteracting particles where creep retardation results merely from climb and particles exerting an attractive interaction on dislocations so that detachment also has to be considered. Since stress relaxation at interfaces requires absorption and emission of vacancies, the interaction strength between particles and dislocations depends on the degree of incoherency whereby coherent particles stand for the one extreme of noninteracting particles. The other extreme is represented by stable voids allowing for maximum stress relaxation.

The interaction strength can be described by the so-called relaxation factor κ defined as

$$\kappa = \frac{T_{\mathrm{p}}}{T_{\mathrm{m}}} \qquad (8)$$

where T_{p} and T_{m} are dislocation line tension at the particle and in the matrix, respectively. For $\kappa = 1$, no attraction between particle and dislocation exists because line energy is not relaxed. For $\kappa < 1$, an attractive interaction results which becomes stronger with diminishing κ. Analyzing the energetics of dislocation detachment, a simple relation between maximum back stress τ_{d} and κ was found by Arzt and Wilkinson (1986)

$$\tau_{\mathrm{d}} = \tau_0 \sqrt{1 - \kappa^2} \qquad (9)$$

whereby τ_{d} is always obtained at the point of dislocation detachment from the particle.

It is important to note that τ_{d} is not a true threshold stress for creep. As a result of the stress-distance profile exhibiting a sharp stress peak at the point of detachment, the extra activation energy needed for detachment to occur well below τ_{d} is small. Thus,

dislocation detachment has to be treated as a thermally activated process. Taking this into account, Rösler and Arzt (1990) have derived a constitutive creep law

$$\dot{\varepsilon}_{\mathrm{d}} = \dot{\varepsilon}_0 \exp\left(-\frac{Gb^2 r[(1 - \kappa)(1 - \sigma/\sigma_{\mathrm{d}})]^{3/2}}{kT}\right) \qquad (10)$$

whereby $\dot{\varepsilon}_{\mathrm{d}}$ is the creep rate for detachment-controlled creep and the numerator of the exponential term represents the activation energy E_{a} for dislocation detachment. The reference strain rate is given by $\dot{\varepsilon}_0 = 6D_{\mathrm{v}}\lambda\rho/b$ ($\rho =$ dislocation density, $r =$ dispersoid radius). As any equation treating a creep deformation process, it can apply strictly only if (i) contributions of other strengthening mechanisms can be neglected and (ii) other deformation mechanisms such as diffusional creep are not operating. It is important to bear this in mind and carefully examine the underlying creep mechanisms when attempting quantitatively to fit experimental creep data of dispersion-strengthened materials to the above equation. However, in any case a number of important conclusions pertaining to alloy development can be made from Eqn. (10):

- since the activation energy E_{a} for dislocation detachment passes through a maximum as a function of particle radius r (note that σ_{d} is dependent on r), an optimum particle size exists which contrasts predictions of classical threshold stress concepts. Physically, this results because (i) the glide distance between the equilibrium position of the dislocation and their point of detachment is proportional to the particle dimensions and, thus, E_{a} is proportional to r at given normalized stress $\sigma/\sigma_{\mathrm{d}}$ and (ii) larger particles are associated with a lower Orowan stress, i.e., athermal detachment stress σ_{d}, at given volume fraction. Analytically, the optimum particle size is given by $(r/b)_{\mathrm{opt}} = (5/3(1 - \kappa))^{3/2}(\ln(\dot{\varepsilon}_0/\dot{\varepsilon})kT/Gb^3)$. Depending on loading conditions and κ-value, $(r/b)_{\mathrm{opt}} = 10 \dots 100$ is typically found.

- Low values of k are essential for superior high-temperature performance, because the influence of the κ-factor in Eqn. (10) is twofold (note that σ_{d} is dependent on κ).

- As the normalized stress exponent n/r of the creep curve is a good measure for κ, optimum dispersoid/matrix combinations can be identified from creep curve analysis: the steeper the creep curve at fixed particle size and test temperature, the stronger the attractive force between particles and dislocations.

Furthermore, it is important to note that experimental observations of temperature dependent threshold stresses and activation energies exceeding values for self diffusion (Kucharova *et al.* 1988, Rösler *et al.* 1992) are readily explained by taking thermal activation into account.

Dispersion strengthening is usually dominant at low strain rates and very high temperatures due to the

very high stress sensitivity of the creep rate. However, at faster deformation rates other hardening mechanisms have to be considered as well. One possibility is to assume a sequence of glide steps whereby a dislocation by-passes a dispersoid in step one at creep rate $\dot{\varepsilon}_1$, defined by Eqn. (10), and glides a distance 2λ between particles in a second step at creep rate $\dot{\varepsilon}_2$, given by the power law equation of the matrix. The overall behavior is then described as $1/\dot{\varepsilon} = 1/\dot{\varepsilon}_1 + 1/\dot{\varepsilon}_2$. Another approach is to associate a back stress $\sigma_{\text{back}i}$ with each individual strengthening mechanism, so that the effective stress to be inserted into the power law equation of the unreinforced matrix is given by

$$\sigma_{\text{eff}} = \sigma - \sum_i \sigma_{\text{back,i}} \qquad (11)$$

Following a suggestion by Reppich *et al.* (1999), we can rewrite Eqn. (10) resulting in an expression for the back stress caused by thermally activated dislocation detachment from dispersoids

$$\frac{\sigma_{\text{back}}(\dot{\varepsilon},\ T)}{\sigma_{\text{d}}} = 1 - \frac{1}{1-\kappa}\left[\frac{kT}{Gb^2 r}\ln\left(\frac{\dot{\varepsilon}_0}{\dot{\varepsilon}}\right)\right]^{2/3} \qquad (12)$$

Note that σ_{back} decreases the higher the temperature and the lower the strain rate which, once again, demonstrates the absence of a threshold below which creep deformation vanishes.

In Fig. 3, both procedures are compared for material data given in the figure caption. As expected, the back stress concept leads to somewhat higher strength estimates because it assumes a long range back stress associated with dispersoids, while the first approach assumes free dislocation glide between obstacles. It also predicts a more gradual transition from matrix like creep (low stress exponent) to detachment-controlled deformation (high stress exponent) as often observed experimentally. Because arguments can be found for both concepts, it appears to be a matter of taste which one to use. Reppich *et al.* (1999) have demonstrated that dispersion-strengthened materials can be successfully described using the back stress concept and considering thermally activated dislocation detachment.

2. Effect on Microstructure

In addition to direct strengthening, small and large particles can also indirectly influence creep performance because they affect matrix microstructure, in particular dislocation density and (sub-)grain size (Gonzalez-Doncel and Sherby 1993, Heilmaier *et al.* 1996, Lin and Sherby 1981, Reppich *et al.* 1999). A popular approach to correct for substructure stabilization by particles is to apply Sherby's constant structure steady-state creep equation (Sherby *et al.* 1977), which was developed for cases where subgrain
Figure 3
Calculated strain rate $\dot{\varepsilon}$ as a function of applied stress for dispersion-strengthened aluminum containing 5% dispersoids with radius $r = 15$ nm and relaxation factor $\kappa = 0.9$ (all material parameters according to (Frost and Ashby 1982), dislocation density ρ: $1 \times 10^{13}\,\text{m}^{-2}$). The curve labeled back stress model results when an effective stress according to Eqns. (11) and (12) is inserted in the power law creep equation of the matrix. For the curve labeled sequence of glide steps it is assumed that the dislocation bypasses a dispersoid at creep rate given by Eqn. (10) and glides between particles at creep rate given by the power law for matrix creep.

size does not vary with stress. However, detailed measurements often show a clear stress dependence (Reppich *et al.* 1999). Hence, it appears to be more accurate (but also more tedious) to use stress dependent laws for substructure evolution, which have to be calibrated to experimental data and, by that, quantify the back stress exerted on moving dislocations.

Microstructural stabilization is not necessarily beneficial, especially in the case of dispersion-strengthened materials operating at extreme temperatures. Often grain sizes in the range of a few micrometers are stabilized (Kucharova *et al.* 1988) which promote diffusional creep. This effect is clearly seen by comparing fine- and coarse-grained dispersion-strengthened materials (Gregory *et al.* 1985, Lin and Sherby 1981, Rösler *et al.* 1992). However, a striking observation is that (i) deformation rates are grossly overestimated using Coble– and Nabarro–Herring creep

equations and (ii) stress exponents $n \gg 1$, but smaller than in the coarse grained material, are observed. Some authors have suggested a coupling between grain boundary sliding and dislocation creep as a possible cause. However, it has been demonstrated by finite element calculations that, except in a narrow transition region, the stress exponent is still determined by dislocation creep when such a coupling takes place. A second model capable of explaining anomalously high stress exponents is that of interface reaction-controlled diffusional creep (Arzt *et al.* 1983). It assumes that vacancy generation and annihilation require the motion of grain boundary dislocations, which have to bypass dispersoids in the grain boundary. Assuming that this bypass process is, as in the bulk material, controlled by thermally activated dislocation detachment, a rate equation can be derived (Rösler *et al.* 1992)

$$\dot{\varepsilon}_{\text{diff}} = \frac{4\lambda \rho_{gb}^e D_v}{d_g b_{gb}} \cdot \exp\left(-\frac{G b_{gb}^2 r[(1-\kappa)(1-\sigma/\sigma_d)]^{3/2}}{kT}\right) \tag{13}$$

where ρ_{gb}^e is the density of grain boundary edge dislocations and $b_{gb} \approx 0.3 \ldots 0.5b$ is a typical estimate of the Burgers vector of a grain boundary dislocation. As the stress exponent n scales with the square of the Burgers vector for both detachment-controlled diffusional creep and detachment-controlled dislocation creep (Eqns. (10) and (13)), the stress exponent should be reduced by $(b_{gb}/b)^2 \approx 0.1 \ldots 0.25$ when the rate controlling mechanism changes accordingly. This prediction matches well with experimental observations made for dispersion-strengthened aluminum and superalloys, although direct evidence for interface reaction-controlled diffusion creep is still missing.

3. Creep Strengthening by Large Particles

In Sect. 1, retardation of dislocation motion by small particles was discussed. In all cases, the Orowan stress has to be a significant fraction of the applied stress for noticeable strengthening to occur. This condition is not normally met for large reinforcements in the micrometer to millimeter size range because interparticle spacing is too large to exert an appreciable back stress on moving dislocations. Nevertheless, direct strengthening is observed, in addition to indirect strengthening as discussed above, due to load transfer from the soft matrix onto the hard reinforcements (Christman *et al.* 1998, Kelly and Street 1972, Dragone and Nix 1990). Moreover, hydrostatic stresses develop in the matrix as a consequence of constrained plastic flow, which increase the load carrying capacity of the composite as the deviatoric stresses in the matrix are reduced. Consequently, for matrix materials exhibiting power law creep, reinforcement strengthening by large particles can be accounted for using a modified power law for steady-state creep

$$\dot{\varepsilon} = A \frac{D_v G b}{kT} \left(\frac{\sigma}{\Lambda G}\right)^n \tag{14}$$

whereby $\Lambda > 1$ is the strengthening coefficient dependent on reinforcement volume fraction and aspect ratio, as well as stress exponent n. Λ can be readily interpreted as the factor by which the effective flow stress is reduced due to load transfer and build-up of hydrostatic stresses in the matrix. Trends in Λ have been calculated by Bao *et al.* (1991) using finite element analysis for aligned, axisymmetric reinforcements and approximated by analytical equations for stress exponent $n \to \infty$ (Rösler *et al.* 1991), giving

$$\Lambda \approx 1 + 2(2 + l/R) f_r^{3/2} \tag{15}$$

for fibers with length $2l$, diameter $2R$ and reinforcement volume fraction f_r. It should be noted that particle distribution plays an important role and thus, calculations assuming idealized arrangements capture trends, but not the precise situation in a particular material. Nevertheless, Eqn. (15) demonstrates that high aspect ratios and volume fractions are key in attaining significant strengthening. Considering SiC-whisker-strengthened aluminum with $l/R = 5$ and $f_r = 13\%$ for example, $\Lambda = 1.56$ results from Eqn. (15) which is in good agreement with experimental observations. Since Λ is independent of applied stress, theory predicts identical stress exponents as in the unreinforced matrix material. Of course, the real situation may be more complicated due to indirect strengthening effects and damage accumulation, which may be initiated in a very early state of the total lifetime.

Interestingly, absolute particle dimensions do not come into play in the above analysis, although it is generally accepted that they must be large compared with the microstructural scale for continuum mechanics to apply. Hence, the question arises to which extent particles can be reduced in size and still contribute to strengthening by load transfer. This is of particular practical significance because many materials, such as particulate-reinforced aluminum alloys, contain fairly small reinforcements in the micrometer range (Gonzalez-Doncel and Sherby 1993). It has been argued that, at high temperatures, a lower limit for acceptable particle size results from the onset of diffusional creep of the volume element associated with the reinforcement. Regardless of particle strength, the volume element can be deformed by vacancy flux, much as a single grain included in an otherwise single crystalline material. As it is sufficient to move matrix atoms around the particle, the mechanism does not require shape change of the particle

by diffusion of reinforcement atoms. Only when the creep rate by diffusion is negligible compared to the matrix creep rate, can the full strengthening contribution due to load transfer be expected. In contrast, if diffusional creep is infinitely fast, the volume element acts like a void and weakening occurs. By equating both deformation rates, a critical dimensionless particle parameter χ can be identified below which reinforcement strengthening is eliminated at high temperatures (Rösler *et al.* 1991)

$$\chi = \frac{Rl^2}{\Omega} = \frac{4(\delta D_b + D_v l/\pi)}{kT} \frac{\sigma}{\dot{\varepsilon}} \qquad (16)$$

(using an effective diffusion coefficient).

Here, $\dot{\varepsilon}$ is the creep rate of the unreinforced matrix material at stress σ. The predictions of the analytical Eqn. (16) have been precisely reproduced by finite element calculations for a number of particle aspect ratios and volume fractions (Nimmagadda and Sofronis 1996).

Taking a PM 6092 aluminum alloy operating at $350\,°C$ and $\dot{\varepsilon} = 10^{-8}\,s^{-1}$ as an example, a strength of about $10\,MPa$ results. Using diffusion data from Frost and Ashby (1982) and assuming that interface and grain boundary diffusion coefficients are roughly identical, $r \approx 40\,\mu m$ is obtained from Eqn. (16) as a critical dimension for equiaxed particles. In the light of this result it seems surprising that aluminum composites containing SiC, TiC, or Al_2O_3 particles with dimensions typically in the range of a few micrometer exhibit superior strength at temperatures as high as $500\,°C$. However, one has to remember that hardening may also stem from indirect effects and, in fact, there is no common opinion in the literature whether direct or indirect strengthening is responsible for the observed behavior. Since it is hard to imagine a mechanism preventing diffusional creep at the location of the particles, it is reasonable to conclude that strengthening by load transfer cannot account for strengthening at extreme temperatures, unless significantly larger particles are used. In particular, the high stress sensitivity of the creep rate observed for composites processed by powder metallurgy should not be seen as argument for direct strengthening because it is very likely that this effect is caused by dispersoids introduced during processing (Park *et al.* 1990).

Focusing on direct strengthening for the moment, it is interesting to compare small and large particles. Small particles causing attractive interaction with dislocations are best for applications at very low normalized strain rates $\dot{\varepsilon}/D_v$ because of the very high stress exponent associated with dislocation detachment. No other strengthening mechanism produces similar effects. In the absence of an attractive interaction, the situation is less obvious. According to Lagneborg's results (Lagneborg and Bergmann 1976) and the above analysis, the effect of small particles on

creep may be approximated assuming a back stress of about 0.5σ for the limiting case of low volume fractions and stresses below the particle cutting or Orowan stress (hereby, the effect of climb kinetics is neglected, see Sect. 1.1). Identical strengthening by large reinforcements would require $\Lambda = 2$ (see Eqn. (14)). It is easily seen from Eqn. (15) that this requires high aspect ratio reinforcements because unrealistically high volume fractions of more than 30% would be needed using equiaxed particles. Although strengthening by large equiaxed particles appears to be comparably unattractive from this point of view, there are also clear advantages: (i) strengthening is effective over the entire stress range, whereas the back stress exerted by small particles is insignificant for $\sigma \gg \sigma_o$; (ii) thermal stability of ceramic reinforcements far exceeds the stability of coherent precipitates; and (iii) large reinforcement volume fractions improve elastic stiffness and wear resistance in addition to high-temperature performance. Hence, it is primarily a matter of application temperature and overall performance requirements whether to rely on precipitation or reinforcement strengthening.

4. Dual Scale Particle-strengthened Materials

It has recently been suggested (Rösler and Bäker 2000) that dual scale particle-strengthened materials, containing small and large particles in appropriate combination, may outperform dispersion-strengthened materials, containing only small particles, and composites, containing only large particles. The rationale is as follows: considering a dispersion-strengthened matrix to which large reinforcements are added, it is clear from the above discussion that the effective stress causing dislocation motion and, in particular, dislocation detachment from dispersoid particles is reduced by the factor Λ. Hence, the creep law for a material containing dispersoid particles and large reinforcements under detachment-controlled creep can be simply expressed as

$$\dot{\varepsilon}_{d,c} = \dot{\varepsilon}_0 \exp\left(-\frac{Gb^2 r[(1-\kappa)(1-\sigma/\Lambda\sigma_d)]^{3/2}}{kT}\right) \qquad (17)$$

where $\dot{\varepsilon}_{d,c}$ is the creep rate of the dual scale particle-strengthened material. For a given dispersion-strengthened matrix, particle radius r and relaxation factor κ are fixed, so that the critical factor determining creep strength is $\Lambda\sigma_d = \Lambda\sigma_0\sqrt{(1-\kappa^2)} \propto (1 + 2(2 + l/R)f_r^{3/2})\sqrt{f_d}$ (f_d: dispersoid volume fraction, f_r: reinforcement volume fraction). Interestingly, $(1 + 2(2 + l/R)f_r^{3/2})\sqrt{f_d}$ goes through a maximum at fixed total particle volume fraction $f_d + f_r$ under certain conditions. For example, setting $f_d + f_r = 0.2$ a numerical value of 0.45 is obtained if the material is entirely strengthened by dispersoids. However, if 15%

reinforcements are combined with 5% dispersoids, 0.54 and 0.30 are obtained as numerical values for $l/R = 10$ and $l/R = 1$, respectively. This means that a strength elevation of about 20% is predicted by dual scale particle strengthening for the example of high aspect ratio particles. In contrast, equiaxed particles are of no benefit. At this point, the prediction is merely theoretical and it remains to be seen whether the anticipated effect can be utilized in practice.

5. Conclusions

The effect of small and large particles on creep performance by direct and indirect strengthening mechanisms has been discussed. Small particles cause direct hardening by interaction with dislocations. Hereby, two barriers have to be considered: dislocation climb and dislocation detachment. Creep retardation by climb is caused because additional dislocation line length must be created in order to surmount particles. In the limiting case of low particle volume fractions, a back stress of the order 0.3 … 0.7σ results. This is the only direct strengthening mechanism of coherent particles. In contrast, incoherent dispersoids cause an additional detachment barrier because they exert an attractive force on moving dislocations. The creep curve is characterized by a remarkably high stress sensitivity, which should, however, not be mistaken as sign for the existence of a true threshold stress.

Large reinforcements do not cause strengthening by direct interaction with dislocations. Instead, load transfer from the softer matrix onto the harder particles is the underlying mechanism. The creep behavior can be readily described by the power law for steady-state creep of the unreinforced matrix, but the applied stress σ must be replaced by an effective stress σ/Λ. Hereby $\Lambda > 1$ is the strengthening coefficient which reflects the fact that the effective flow stress is reduced due to load transfer and built-up of hydrostatic stresses in the matrix. To make full use of reinforcement strengthening at high temperatures, it is important to select sufficiently large particle dimensions in order to avoid stress relaxation at the particle by diffusional creep.

CVD Monofilaments

Chemical vapor deposition (CVD) is a process in which one material is deposited onto a substrate to produce near-theoretical density and small grain sizes for the deposited material. CVD onto an appropriate fine filamentary substrate produces a thicker filament predominantly composed of materials that otherwise could not be made by drawing or other conventional processes. The fine and dense microstructure of the deposited material ensures maximum strength and Young's modulus. In the early 1960s, interest in the production of fibers that combined a high modulus with low density concentrated efforts on the lightest elements in the Periodic Table. This is because the ultimate strength and Young's modulus of a material are controlled by the outer electrons in the atoms and are not a function of atomic weight. The lightest element that possesses high mechanical properties is the fourth element in the Periodic Table, beryllium, which has a high Young's modulus of over 300 GPa and a density of 1.83. However beryllium is highly toxic, especially as an oxide, and interest centered on the other light elements, i.e., the fifth, sixth, and fourteenth elements, boron, carbon, and silicon.

Boron fibers were the first continuous high performance fibers to be produced. They are made by CVD onto a tungsten substrate or core, and possess a Young's modulus twice that of steel with the density of aluminum. The same technique is also used to produce silicon carbide (SiC) fibers. The latter fibers are produced on both tungsten and carbon cores. Boron and silicon carbide fibers are the only fibers made by CVD and find particular end uses. Their diameters, which are of the order of 20 times those of carbon fibers (i.e., of the order of 100 μm or more), ensure high compressive strength and allow them to be more easily embedded into metal matrices than many other fibers; however, as a result these filaments are also less flexible than other fibers used for reinforcement.

1. Chemical Vapor Deposition

The production of both boron and silicon carbide fibers by CVD takes place in a reactor that consists of a glass tube, which for commercial production is usually 1–2 m in length and most often vertical. Schematic representations of the arrangements for the production of both types of fibers are shown in Fig. 1. Several such reactors can be placed in series so as to allow staged deposition, but in practice this is avoided as the increase in the number of seals increases the risks of contaminants being introduced into the fiber. The wire substrate can run continuously through the reactor by the use of mercury seals at each end. These ensure that the reactive gases are contained in the reactor and also allow the substrate to be heated by electric current over the deposition length. The choice of the substrate is governed by the need to use a material that maintains its strength to around 1100 °C and is an electrical conductor. Heating the substrate, usually with a d.c. current, is a necessary part of the process that determines deposition rate, which must be constant or irregularities in the fiber diameter occur with a subsequent fall in
Figure 1

strength. Several potential substrate materials were investigated including molybdenum and tantalum but tungsten was chosen as it was available in the form of fine wire (produced for electric light filaments) and showed greater compatibility with boron, including having a similar coefficient of thermal expansion. Initial attempts to use carbon cores for the production of boron fibers were not successful due to differences in thermal expansion coefficients, which led to the breakage of the carbon filament. During production, such breakages produce hot spots due to the locally raised electrical resistance in the substrate; in turn, these result in locally enhanced deposition rates and weak spots. This was overcome by the deposition of pyrolytic carbon onto the substrate, which allowed the boron fiber to slide over the carbon fiber. Nevertheless, tungsten filaments are used for the commercial production of boron fibers, whilst both tungsten and carbon filaments are used as substrates for the production of silicon carbide fibers.

2.   *Boron Fibers*

Boron fibers can be made by CVD onto a tungsten core of 12 μm diameter. Several chemical routes are possible but commercially boron trichloride is mixed with hydrogen and boron is deposited according to the following reaction:

$$2BCl_3(g) + 3H_2(g) \rightarrow 2B(s) + 6HCl(g)$$
In commercial production the gas mixture is introduced at the top of the vertical reactor and flows in the drawing direction. The temperature along the reactor passes through a maximum at an early stage of deposition but as Wawner (1988) has shown, it must not exceed 1350 °C as this leads to increased grain sizes and a drop in filament strength. Passage through the reactor is of the order of one or two minutes and results in a fiber with a diameter of 140 μm. During the deposition process the small boron atoms diffuse into the tungsten core to produce complete boridization and the production of WB_4 and W_2B_5. This leads to an increase in diameter to 16 μm, which induces considerable residual stresses, putting the core into compression and the neighboring boron mantle into tension. A final annealing process puts the fiber surface into compression.

Boron fibers can be relatively easily used to reinforce light alloys but it is necessary to protect the fiber surface during contact with the molten metal to avoid chemical reactions occurring with a subsequent fall in strength. For this reason boron fibers have been commercially produced with both silicon carbide and boron carbide (B_4C) coatings.

Boron fibers coated with silicon carbide were originally made with a diameter of 106 μm but were found to split longitudinally due to low transverse strength (Kreider and Prewo 1972). This was avoided by increasing the diameter to 140 μm, but splitting due to localized high stresses when fibers touch during composite manufacture was found to occur even with these latter fibers (Bunsell and Nguyen 1980).

The tungsten wire substrates are produced by conventional wire drawing, which results in their surface being striated. The boron is deposited preferentially onto the highest peaks of the surface of the wire and grows as conical nodules, leading to a nodular surface to the fiber. Figure 2 shows the nodular appearance of a boron fiber. A smoother substrate such as a pitch-based carbon fiber leads to a smoother surface for the deposited fiber. The internal structure of the deposited boron is nanocrystalline with grain sizes of 2–3 nm consisting of α-rhombohedral and tetragonal polymorphs of boron (Bhardwaj and Krawitz 1983). The rate of deposition is strongly dependent on temperature so that any local hot spot will cause enhanced grain growth and surface irregularities, which lead to a fall in strength.

In the absence of such major defects three types of failure initiation processes have been identified. The stress-concentration which is produced by the joining of two neighboring nodules at the fiber surface is the most frequent failure initiation mechanism and surface etching to reduce rugosity results in an increase in strength (Vega-Boggio and Vingsbo 1976a). Two types of defects are associated with the boron mantle–core interface. The growth of neighboring nodules can cause radial defects that are due to the one nodule shadowing the deposition of the boron onto the
Figure 2
Boron is deposited on the tungsten wire substrate in the form of nodules, which leads to the nodular surface shown.

tungsten wire. Elongated voids can be formed at the interface by preferential deposition on each side of striations on the tungsten wire (Vega-Boggio and Vingsbo 1976b).

Boron fibers are not only strong in tension but also lead to composites that are very strong in compression, probably at least in part due to the large diameter, which inhibits buckling. The strength of the fibers in tension lies between 3.4 and 4.2 GPa with a coefficient of variation of 15% or less, a Young's modulus of 400 GPa, and a specific gravity of 2.54. The Poisson's ratio of boron fibers is 0.13 and their thermal expansion coefficient is $4.9 \times 10^{-6} \, ^\circ\text{C}^{-1}$ up to 325 $^\circ$C.

Boron fibers exhibit a linear axial stress–strain relationship at room temperature up to 650 $^\circ$C. Strength is retained in short-term tests to such high temperatures, but heating in air for periods of hours at temperatures above 300 $^\circ$C leads to large losses in room temperature strength. This strength loss is attributed to oxidation of the nodular boron surface.

At higher temperatures boron fibers exhibit anelastic behavior, which up to 800 $^\circ$C can be explained in terms of different strains induced in the boron mantle and the tungsten boride core (Ericksen 1974). A boron fiber formed into a loop and exposed briefly to an open flame, which is then withdrawn, retains its imposed curvature. On reheating, the fiber returns to its original shape, demonstrating that the deformation contains no permanent plastic component. Boron fibers also creep at high temperatures (DiCarlo 1977).

3. Silicon Carbide Fibers

Silicon carbide shows high structural stability and strength retention, even at temperatures above 1000 $^\circ$C. Passive oxidation begins at 1200 $^\circ$C but in bulk form silicon carbide is used up to 1600 $^\circ$C. It is therefore an attractive material to have in fiber form for reinforcement in high temperature composite materials. Silicon carbide fibers made by CVD are produced on both tungsten and carbon cores in similar reactors to those use for the production of boron fibers except that multiple injection points are used for the introduction of the reactant gases. Various carbon-containing silanes have been used as reactants. In a typical process, with MeSiCl$_3$ as the reactant, silicon carbide is deposited on the core as follows:

$$\text{MeSiCl}_3(\text{g}) \rightarrow \text{SiC}(\text{s}) + 3\text{HCl}(\text{g})$$

Silicon carbide fibers produced on a tungsten core of 12 μm diameter show a thin interfacial layer between the silicon carbide mantle and the tungsten core, caused by chemical interaction between the silicon carbide and tungsten, which forms reaction products of α-W$_2$C and W$_5$Si$_3$. Heating above 900 $^\circ$C leads to growth of this reactive layer and degradation

of the properties of the fiber. The carbon fiber cores, of 33 μm diameter, used for the CVD production of silicon carbide fibers, are themselves coated with a 1–2 μm thick layer of pyrolytic carbon, which covers surface defects on the core and produces a more uniform diameter. The fibers on a carbon core show a gradation of composition, which is richer in carbon near the interface and becomes stoichiometric silicon carbide towards the fiber surface. The fibers on a tungsten core have a mantle of stoichiometric silicon carbide. Both types of silicon carbide fibers have smoother surfaces than do boron fibers, which is due to the deposition of small columnar grains rather than conical nodules. The specific gravity of a 100 μm diameter SiC–W fiber is 3.35 whilst that of a 140 μm diameter SiC–C fiber is around 3.2.

Early silicon carbide fibers were found to have a wide scatter in tensile strengths, which was alleviated by coating them with a thin layer of carbon. This had the disadvantage, however, of reducing interfacial bonding, particularly with light alloys. To overcome this, the silicon carbide fibers made on a carbon core and destined to reinforce light alloys, are produced with a surface coating, the composition of which is made to vary from being carbon-rich to silicon carbide at the outer surface (Sattler *et al.* 1992). The fibers that are to be used to reinforce titanium have a protective layer that varies from being rich in carbon, to being rich in silicon, to a composition that is again rich in carbon at the surface (Ning and Pirouz 1991) as shown in Fig. 3. The outer sacrificial layer protects the fiber during contact with the molten and highly reactive titanium during composite manufacture. This type of fiber is called SCS-6, as the coating increases the fiber diameter by 6 μm. The fiber shows no degradation after 5 hours at 900 $^\circ$C when embedded in a titanium (6Al4V) matrix (Whatley and Wawner
Figure 3
The SiC-6 fiber produced on a carbon core for the reinforcement of titanium has a protective layer is 3 μm thick. This surface layer can be seen to be due to a first coating of carbon, which is then made richer in silicon, followed by a second carbon-rich layer, which plays a sacrificial role during composite manufacture.
Figure 4
A cross-section of a silicon carbide fiber, having a diameter of 103 μm, produced on a tungsten core and revealing a surface coating of carbon, which has allowed it to be used to reinforce a titanium alloy.

1985). A cross-section of a typical 100 μm diameter silicon carbide fiber on a tungsten core is shown in Fig. 4. This fiber has a surface coating 3–4 μm thick, which varies from being carbon rich to becoming a thin layer of less than 1 μm of TiB_2 at the surface (Shatwell 1999).

The room temperature strengths of the fibers are around 4 GPa. Low failure stresses are due to surface flaws, whereas higher strengths are controlled by defects at the core mantle interface. The strengths of CVD silicon carbide fibers have been shown to be anisotropic, with the radial strength being significantly lower than longitudinal tensile strength (Eldridge *et al.* 1993). Strength decreases in air when the fibers are heated to above 800 °C for long periods, most probably due to oxidation of the carbon-rich outer layers. At temperatures above 900 °C interfacial reactions between the tungsten core and mantle cause degradation of properties as explained above. At higher temperatures still grain growth in the silicon

carbide mantle may be the cause of further falls in strength.

4. Conclusion

Chemical vapor deposition has produced filaments with extremely high mechanical properties. However their large diameters and hence lack of flexibility limits the forms into which they can be arranged. In addition, the necessity to fabricate the fibers individually, so that one reactor is necessary for each fiber made, means that production costs are high. These aspects of the fibers inevitably means that their uses are restricted to applications for which their remarkable properties are fully required. One such application could be the reinforcement of titanium alloys by silicon carbide CVD fibers in rotating parts of aircraft jet engines. The use of such reinforcements would allow the titanium to be used up to 600 °C

whereas unreinforced the metal is limited by creep to a maximum of 450 °C.

Designing with Composites

The key principles and issues in designing with composites are summarized in this article. More comprehensive treatments of this topic can be found elsewhere (e.g., US Department of Defense [USDD] (1999), Gillespie and Carlsson (1990), Lubin and Peters 1998). Given the dominance of fiber-reinforced polymer matrix composites in commercial applications, the discussion that follows focuses on this class of materials. Many of the same generic principles apply to other classes of composites (e.g., metal and ceramic matrices).

The heterogeneity and anisotropy of composites play an important role in the design process. A key concept is that the response of composite structures is determined by mechanisms and geometric features that exist at several different characteristic length scales and that contribute to the overall structural behavior (see *Composite Materials, Microstructural Design of**). These length scales include fiber diameter, ply thickness, laminate thickness, length of structural details (i.e., joints, thickness transitions, and cut-outs), and the overall structural dimensions. The ability to design at multiple length scales simultaneously via the choice of constituent materials, fiber architecture, and laminate stacking sequence offers the potential for highly optimized design solutions. However, this results in a highly-coupled, complex, and potentially expensive design process. Efficient and effective design with composites requires a good understanding of these issues, allowing for simplification as appropriate. In addition, the multiplicity of manufacturing routes available (see *Polymer Matrix Composites: Matrices and Processing**, *Metal Matrix Composites: Matrices and Processing**, *Ceramic Matrix Composites: Matrices and Processing**) and the strong dependence of the resulting mechanical properties on the manufacturing route employed, implies that design for manufacturability must also be considered.

1. Overall Approach

Composite structural design generally progresses in one or more steps from a preliminary design to a detailed design. The means by which this progression is achieved depends to a large degree on the complexity of the structure and the manufacturing routes to be employed. Overall approaches that have evolved range from analysis of the structural requirements and proceeding directly to the fabrication of prototype parts (e.g., tennis racquets or golf club shafts) to a more deliberate, multistep process (e.g., the "Building Block" approach used for aerospace vehicles). This methodology, illustrated in Fig. 1, combines fabrication, testing, and analysis at defined levels of design. Material "allowable stresses" and other parameters are determined through extensive testing and these parameters are transferred to progressively higher levels of structural complexity and/or scale (e.g., laminate/coupon, subelement, element, subcomponent, component, and full-scale structure) to allow design at these higher levels of complexity and/or scale. Analysis is used at each step, mainly to determine the state of stress and strain, while the "allowables" are passed on with appropriate knockdown factors and other empirical and semiempirical modifications to account for issues introduced at the next level of structural complexity. By including these empirically-based modifications at each level (or scale), the effects at the full-scale structure can be taken into account through comparison to past experience. It is important to note that for this approach to be successful it is required that the failure and deformation mechanisms remain the same as the design progresses from testing at one length scale to the next.

The efficiency of the design process has increased over time. In both prototype-driven design, and the building block approach, designers currently benefit from the pervasive use of computer-aided design and finite element analysis. The ability to explore rapidly a range of geometrical and material possibilities simultaneously is a key to maximizing the use of composites.

2. Material System Selection

The selection of a material system generally occurs during the preliminary design phase. It is a key decision since the choice of materials directly affects the overall structural configuration and manufacturing route to be used, which in turn have a strong influence on the cost of the system. Given the wide range of available materials, including composites, it is important that materials selection is carried out in a systematic manner (see *Fibrous Reinforcements for Composites: Overview**, *Glass Fibers**, *Fiber Strength**, *Metal Matrix Composites: Matrices and Processing**, *Ceramic Matrix Composites: Matrices and Processing**). The basic structural considerations for material selection are described in detail elsewhere (*Composite Materials, Microstructural Design of* *). It is worth noting that generally the selection of a composite material system is based on estimates of homogenized directional material properties, whereas the subsequent detailed design requires consideration of the material architecture (i.e., laminate, weave,

Flow chart for the "Building Block" approach for structural composite design/certification.

sandwich panel, etc.). Clearly it is important that the initial estimates are accurate for the achievable laminate (or other architecture) properties.

3. Elastic Laminate Analysis

Well-established analytical tools are available in the form of anisotropic elasticity and laminated plate theory (see *Laminates: Physical and Mechanical Behavior**). The homogenized ply properties are used as the initial material input to the analysis. A number of comprehensive references on these theories are available (e.g., Jones 1998, Reddy 1997). These analytical tools are available to the designer in the form of commercially available software packages and in embedded routines within finite element codes. The analytical tools previously noted allow for an accurate prediction of the elastic response of composite structures as well as the stress distribution on a ply-by-ply basis. Care must be taken in applying them to ensure that the modeling assumptions are appropriate for the structural configuration in question. For example, in some cases, either a full three-dimensional elasticity model must be developed whereas in others the three-dimensional effects can be incorporated into modified plate theory (Barbero *et al.* 1990).

4. Design for Stiffness

A number of special issues must be considered when designing with composites for stiffness-limited applications. In-plane stiffness anisotropy permits the structural stiffness to be locally tailored to meet the design requirements. In addition, composite laminates allow for the coupling between deformation modes, i.e., extension–shear coupling and coupling between bending and torsional deformations. This offers the potential for novel design solutions. However, these effects are generally avoided by using balanced, symmetric laminates in order to simplify the design process. This results in laminates with only orthotropic properties and no out-of-plane coupling. An additional important consideration is that the anisotropic thermal expansion at the ply level can result in thermal distortions in unsymmetric or imbalanced laminates. In practice choices are frequently further restricted to balanced, symmetric laminates with only $0°$, $\pm45°$, and $90°$ plies, and optimization is achieved by varying the fractions of plies of each orientation within this family. This restriction of the choice of laminate stacking sequence allows the use of graphical methods, such as carpet plots (Gillespie and Carlsson 1990), to identify appropriate stacking sequences. The choice of fiber direction roughly

correlates with requirements for longitudinal, transverse, and shear loading.

5. Design for Failure

The ability to design against failure is less well developed. Numerous failure criteria have been proposed (e.g., Soden *et al*. 1998), but the resulting predictions are generally adjusted based on experimental data derived from mechanical testing together with "rules of thumb" accumulated from experience on previous projects and coupled with "factors of safety." The size of the test programs used in implementing the building block approach is largely determined by the uncertainties associated with predicting strength and probabilistic approaches have been developed (USDD 1999). Key issues in designing for failure include delamination, the role of free edges and stress gradients, the generally lower load carrying capacity in compression than tension, the effects of out-of-plane loading, and the importance of structural details. In addition damage tolerance and damage resistance requirements (particularly in terms of impact damage) have been regarded as a weakness of composites and require particular attention. These issues originate in the heterogeneous structure of composites and the resulting elastic anisotropy. Practical approaches to reducing the sensitivity of structures to these issues include: minimizing the number of adjacent plies with the same orientation (to suppress delamination); the use of internal ply drops to transition in thickness (to minimize free-edge stresses); and the use of through-thickness reinforcement (e.g., stitching) in areas susceptible to out-of-plane loading. The restriction of laminates to the $0/\pm45/90$ family also simplifies the process of designing against failure. No single analytical approach exists that can claim to allow for a sufficiently accurate predictive capability in order to permit simulation-based design against failure. This is a key limitation on the efficiency of the overall design process.

6. Other Issues in Design

In a similar situation to the case of designing against failure, several other issues in composite design are not amenable to analytical treatment. In particular, issues associated with the longevity and durability of composite parts have not proven to be amenable to analysis with sufficient accuracy to guide the design process. These include the effects of cyclic loading, moisture absorption, the effect of temperature, and the effects of active environments (see *Composite Materials: Environmental Effects**). As for the case of designing against failure, the approach taken has been to employ a combination of testing with heuristic knowledge gained from previous projects. A key difference for durability is that testing is not usually

conducted at all levels in the building block approach. Typically, durability testing will be performed initially at either the coupon or subelement level and subsequently at the full-scale structural level. Damage tolerance (i.e., the ability of a damaged structure to continue to carry load) is generally only verified at the element level or higher. This is a matter of ensuring the cost-effectiveness of the process. The requirements for design for damage resistance, damage tolerance, and durability have led to the development of woven and stitched composites to limit the effects of impact loading, the development of more moisture-resistant matrix materials, and the development of matrices with higher temperature limits.

7. Built-up Structure

The design of large structures typically progresses according to the building block approach or analogous processes. As for the unit issues of designing against failure and for damage tolerance and durability, a combination of analysis, testing, and experience is brought to bear in the process. One effect of the reliance on the building block approach is the tendency for designs to gravitate towards solutions in which the large structure is built up from component parts using extensive secondary joining processes. This is apparently at odds with one of the promises originally made for composites, namely that relatively large structures can be made by net-shape forming methods, thereby reducing the number of parts and the number of unit processes required. In addition, the designers of large composite structures have generally not fully embraced the use of the efficient structural configurations and concepts originally envisioned for composites, such as the extensive use of sandwich panels, the use of cocured adhesive bonding, and the elimination of discrete stiffeners and mechanical fasteners. This conservative approach has arisen, in part, because of practical considerations and some adverse experiences. Honeycomb sandwich panels can be more sensitive to impact damage, and particularly moisture ingress, than discrete-stiffened structures. Mechanical fasteners are advantageous if a structure must be disassembled for inspection and repair. Cocuring large pieces of structure also has serious economic implications for the capital cost of the equipment required and the sensitivity to any manufacturing considerations.

8. Summary

Design approaches for composite structures are well-established and draw on 30 or more years of experience and analytical tool development. Generally these approaches have been successful in creating safe and effective designs. In both prototype-driven design, and the building block approach, designers

currently benefit from the pervasive use of computer-aided design and finite element analysis. Further extension of this ability to include accurate predictive models and approaches for designing against failure and for durability and damage tolerance is a key requirement for increasing the efficiency of the overall design process.

Elastic Behavior of Cellular Solids

Cellular solids cover a wide range of multifunctional materials distinguished by low relative density. Familiar examples from nature and industry include cork, balsa wood, sponge, bread, and the flexible polyurethane foam that cushions our seats. More exotic foams manufactured from polymers, metals, and ceramics target high-technology aerospace and medical applications, and provide challenging opportunities to engineer new materials.

This article is concerned with the elastic properties of low-density cellular solids, which will also be referred to as foams. A micromechanical point of view provides a theoretical foundation for establishing structure–property–processing relationships, which guide the use and development of cellular solids. In general, stiffness and strength increase with the volume fraction, ϕ, of solid, $\phi = \rho/\rho_s$, which is synonymous with relative density; ρ is the foam density and the subscript s refers to the solid phase. The elastic constants exhibit strong dependence on microstructure when $\phi \ll 1$. Honeycombs and solid foams with open or closed cells, composed of slender struts or thin cell walls are used to illustrate the connection between macroscopic behavior, cell-level structure, and deformation mechanisms. All of the models used here are based on spatially periodic structures that involve a representative volume or "unit cell."

1. Honeycombs

The mechanics of "two-dimensional" honeycombs is a useful entry point into foam mechanics. The in-plane elastic constants of a regular hexagonal honeycomb with $\phi \ll 1$ are

$$\frac{K}{E_s} = \frac{1}{4}\phi \quad \frac{E}{E_s} = \frac{3}{2}\phi^3 \tag{1}$$

where K is the bulk modulus and E is Young's modulus. These results illustrate a common theme for low-density cellular solids. A linear dependence of properties on ϕ is the signature of stretching of individual members, such as cell walls or struts. Higher order dependence indicates bending of individual members that causes a much softer response. The cubic dependence of E on ϕ corresponds to bending of thin cell walls. A honeycomb is relatively easy to compress in the plane because of the bending mechanism. Since $K \gg E$, the plane–strain Poisson's ratio $\nu \approx 1$. Equation (1) illustrates another important feature of cellular solids: the elastic response does not depend on cell size. In other words, self-similar microstructures have identical elastic behavior.

2. Foams

The microstructure of a solid foam forms in the liquid state, where gas bubbles grow into polyhedral cells that deform under the influence of flow imposed by the manufacturing process. This motivates using liquid foams as templates to create models of solid foams (see *Foams, Microrheology of**). The main feature of open-cell foams, which do not have cell walls, is a network of slender struts meeting at rigid joints. The Kelvin cell shown in Fig. 1(a) is a natural starting point because it defines the geometry of a perfectly ordered three-dimensional (3D) foam, which is analogous to the honeycomb in two dimensions (2D). The struts are modeled as beams with uniform cross-section composed of linear elastic material. There are three independent elastic constants because the structure has cubic symmetry. They can be calculated in closed form and show that the response is nearly isotropic (Warren and Kraynik 1997). The effective isotropic elastic constants evaluated for different strut shapes are

$$\frac{K}{E_s} = \frac{1}{9}\phi \quad \frac{E}{E_s} = C\phi^2 \tag{2}$$

The bulk modulus of this highly symmetric structure only involves the stretching mechanism. However, strut bending and torsion have comparable effects on E in this case and for more realistic foam microstructures. When $\nu_s = 1/2$, the parameter C ranges from 0.59–0.98 as strut shape varies from circular to Plateau border, the space between three mutually tangent circles. The Plateau border shape is found in real foams. Experimental data for different solid
Figure 1
(a) Kelvin cell and (b) random monodisperse foam with 64 cells used as templates to produce the open-cell microstructures. "Pushing on a square and pushing on a hexagon" relate to the principal axes of the Kelvin cell. The deformed structures correspond to uniaxial compressive stress.
Figure 2
Stress–strain curves for uniaxial compression of the open-cell foams shown in Fig. 1 with struts of Plateau border shape and $\phi = 0.001$. The stress is scaled by $E_s\phi^2$. The two curves for the Kelvin foam correspond to pushing on a square face (100) or a hexagon (111); they have similar initial slopes but diverge at large compressive strains. ——, Random; ——, Kelvin 100; ······, Kelvin 111.

foams can be found in Gibson and Ashby (1997); they use $C = 1$ to correlate data for open-cell foams.

Open-cell foams with disordered structure can also be patterned after liquid foams (see Fig. 1(b)). The resulting finite-element models are subjected to large uniaxial compression. The corresponding stress–strain curves for the Kelvin and random foam are shown in Fig. 2. The strut material is linear elastic so the nonlinearity stems entirely from large deformation of the microstructure. The Young's modulus for the random foam is about 30% larger than the Kelvin foam—disorder leads to a stiffer not softer response. Foam structures based on less realistic Voronoi cells are even stiffer.

Finite element analysis using shell elements to model a closed-cell Kelvin foam with $v_s = 0.49$ gives

$$\frac{K}{E_s} = 0.44\phi \quad \frac{E}{E_s} = 0.31\phi \qquad (3)$$

Both properties scale with ϕ implicating the stretching mechanism and giving the stiffest response of any microstructure considered here. The foam has a Poisson's ratio $v = 0.38$. These results are typical of those obtained for more complicated foam structures.

Equation (3) neglects the effect of gas pressure P_g in the closed cells. Accounting for the gas would add the term P_g/E_s to the right-hand side of the bulk modulus. This contribution can be important when the solid phase is very soft or under large compression.

3. Concluding Remarks

This short survey can only hint at the rich mechanical behavior of real foams. Equations (2) and (3) are useful guidelines, but real foams often have intermediate microstructure and properties caused by the presence of cell walls and thick cell edges where struts form. When ϕ is a few percent, the struts and joints in open-cell foams can be quite thick, so asymptotic results developed for $\phi \ll 1$ must be kept in perspective. Other complications and imperfections abound.

Many applications of foams involve crushing. The stress–strain curves in Fig. 2 suggest but do not exhibit the extended plateau and lack the eventual sharp increases in stress that are often seen in laboratory measurements. The plateau defines material strength and is caused by "buckling" of the microstructure and strain localization, which have been analyzed for honeycombs (Papka and Kyriakides 1998) but not foams. This is just one example of the challenge and opportunity in foam mechanics.

Elastic Behavior of Composites

Other articles in this encyclopedia are devoted to composites covering reinforcing fibers, matrices of different natures (polymeric, metal, and ceramic), their processing, mechanical behavior at the micro- and macromechanical scale, designing principles, and miscellaneous applications of composite structures. Inevitably there is some degree of overlap, but the primary aim of this article is to cover elastic

properties and to emphasize the ways in which composites differ from other materials. It is for this reason that the following issues are concentrated on: the lamina as the building block with four elastic constants characterizing the stress/strain response, the directional nature of composite stiffness values, the coupling between normal stresses and shear strains and vice versa, the effect of stacking on the laminate stiffness, the unusual Poisson ratios outside the limit usual for isotropic materials, and the coupling phenomena between extension and bending for unsymmetrical laminates.

1. Lamina Stiffness Characteristics

The building block of a composite is called the lamina consisting of parallel, continuous, stiff, and strong fibers embedded in a matrix. The lamina properties are dictated by the constituent properties, typically by Young's modulus, E, and Poisson's ratio, v, and their concentrations, e.g., by the fiber volume fraction, v_f. Micromechanical modeling (see *Composites, Physical Properties of**) enables the lamina properties to be derived.

1.1 The Basic Stiffness Characteristics

As a lamina is transversely isotropic, there are two principal directions associated with extreme properties. These are the longitudinal direction parallel with fibers and the transverse direction perpendicular to the fibers. The former is denoted by the subscript 1, the latter by the subscript 2. On loading a lamina in either principal direction, its behavior is orthotropic. In other words, extension or compression is not accompanied by any distortion of angles.

Assuming further that the lamina finds itself under the plane stress situation, i.e., its thickness is negligible in comparison with the width and length, the stress/strain behavior involves two normal stresses, σ_1, σ_2, and one shear stress, σ_{12}, related to the corresponding normal (ε_1 and ε_2) and the shear strains, ε_{12}, by

$$|\sigma| = |Q| * |\varepsilon|$$
$$|\varepsilon| = |S| * |\sigma| \tag{1}$$

where the stiffness matrix, $|Q|$, and the compliance matrix, $|S|$, are of the type

$$|Q| = \begin{vmatrix} Q_{11} & Q_{12} & 0 \\ Q_{12} & Q_{22} & 0 \\ 0 & 0 & Q_{66} \end{vmatrix}; \quad |S| = \begin{vmatrix} S_{11} & S_{12} & 0 \\ S_{12} & S_{22} & 0 \\ 0 & 0 & S_{66} \end{vmatrix} \tag{2}$$

The four components of these matrices are related to the so-called engineering constants of the lamina, namely to the longitudinal, transverse, and shear

moduli, E_1, E_2, and G_{12}, supplemented by Poisson's ratio, v_{12}. Apart from the fact that these can be derived micromechanically, they can be also measured using a spectrum of dedicated tests (Tarnopolskii and Kincis 1985). The relationships for the elements of the compliance matrix are simpler and are:

$$S_{11} = \frac{1}{E_1} \quad S_{22} = \frac{1}{E_2}$$

$$S_{66} = \frac{1}{G_{12}} \quad S_{12} = -\frac{v_{12}}{E_1} \tag{3}$$

The lamina can be considered to be the composite entity of the highest anisotropy; extremely strong and stiff in the fiber direction, weak and soft in the perpendicular (matrix) directions. Plytron lamina based on polypropylene matrix reinforced with 50% (by weight) of E-glass fibers will be used in this article for illustrations of all points made. This is for two reasons: (a) this material type has already found its role in automotive applications; and (b) in the author's opinion Plytron lamina is likely to become one of the major composites used in the future. Engineering constants of the Plytron lamina have been determined as $E_1 = 21.7\,\text{GPa}$, $E_2 = 3.34\,\text{GPa}$, $G_{12} = 1.32\,\text{GPa}$, and $v_{12} = 0.35$.

1.2 Stiffness Characteristics of Lamina Loaded in an Off-axis Direction

If the lamina is subjected to a load at an arbitrary angle $0 < \Theta < 90°$, the stress/strain situation is much more complex because the axes related to the material symmetry system does not coincide with the coordinate system dictated by loading. Thus both the stress and strain components denoted 1, 2, and 12 and derived as above have to be transformed into x, y, and xy equivalents with the x-direction determining that of a load. The stress/strain behavior in the new coordinate system relevant to the structural response then involves the so-called reduced transformation stiffness/compliance matrices $|\underline{Q}|$ and $|\underline{S}|$ of the following format:

$$\begin{vmatrix} \sigma_x \\ \sigma_y \\ \sigma_{xy} \end{vmatrix} = |\underline{Q}| \begin{vmatrix} \varepsilon_x \\ \varepsilon_y \\ \varepsilon_{xy} \end{vmatrix} = \begin{vmatrix} \underline{Q}_{11} & \underline{Q}_{12} & \underline{Q}_{16} \\ \underline{Q}_{12} & \underline{Q}_{22} & \underline{Q}_{26} \\ \underline{Q}_{16} & \underline{Q}_{26} & \underline{Q}_{66} \end{vmatrix} \begin{vmatrix} \varepsilon_x \\ \varepsilon_y \\ \varepsilon_{xy} \end{vmatrix}$$

$$\begin{vmatrix} \varepsilon_x \\ \varepsilon_y \\ \varepsilon_{xy} \end{vmatrix} = |\underline{S}| \begin{vmatrix} \sigma_x \\ \sigma_y \\ \sigma_{xy} \end{vmatrix} = \begin{vmatrix} \underline{S}_{11} & \underline{S}_{12} & \underline{S}_{16} \\ \underline{S}_{12} & \underline{S}_{22} & \underline{S}_{26} \\ \underline{S}_{16} & \underline{S}_{26} & \underline{S}_{66} \end{vmatrix} \begin{vmatrix} \sigma_x \\ \sigma_y \\ \sigma_{xy} \end{vmatrix} \tag{4}$$

The elements $\underline{Q}_{ij}$ and $\underline{S}_{ij}$ can be derived from the elements of the stiffness/compliance matrices Q_{ij} and S_{ij} and trigonometric function of the loading angle Θ

between the fiber and loading directions:

$$\underline{Q}_{ij} = q(ij)[Q_{11}, Q_{22}, Q_{12}, Q_{66}, \sin^n\Theta, CP\cos^m\Theta]$$

$$\underline{S}_{ij} = s(ij)[S_{11}, S_{22}, S_{12}, S_{66}, \sin^n\Theta, CP\cos^m\Theta] \quad (5)$$

where $q(ij)$ and $s(ij)$ are explicit functions for the element ij. In addition, the elements $\underline{S}_{ij}$ and $\underline{Q}_{ij}$ can be related to the stiffness characteristics relevant to the structural response of the lamina, i.e., E_x (loading direction), E_y (direction perpendicular to the load), G_{xy}, and v_{xy} (shear modulus and the Poisson ratio in the lamina plane).

Figure 1 shows angular variation of these stiffness characteristics normalized by the appropriate engineering constants of the Plytron lamina. E_x/E_1 is seen to be a decreasing monotonic function of the loading angle Θ. The dependence of G_{xy} is a symmetrical function of Θ, $G_{xy}(\Theta) = G_{xy}(90-\Theta)$, passing through a maximum at $\Theta = 45°$. The angular dependence of v_{xy} satisfies the boundary conditions $v_{xy}(0)/E_1 = v_{xy}(90)/E_2$ and exhibits a maximum in the region of low loading angles. The area under the $E_x(\Theta)$ dependence represents composite potential contained in the lamina: it is relatively low for thermoplastic matrices reinforced with glass (the case of Plytron) and high for laminas containing a large concentration of high-modulus carbon fibers.

In conclusion, while the stress/strain behavior of the lamina loaded in the principal direction (orthotropic behavior) is described by four elements Q_{ij} (or S_{ij}), the anisotropic response of the lamina loaded at any other angle requires six elements $\underline{Q}_{ij}$ (or $\underline{S}_{ij}$). At the same time, they can be derived from the four basic engineering constants characterizing the lamina.

Two additional elements, Q_{16} and Q_{26} (S_{16} and S_{26}, respectively) are associated with another feature of the elastic response of composites, namely with the coupling between normal strains and shear stresses and vice versa. As this behavior is unique to composites, the coupling effects are further expanded in the following section.

1.3 Coupling Between Normal Stresses and Shear Strains

Tensile deformation of isotropic materials is associated with extension in the direction of the load and contraction in the lateral direction. If a lamina is loaded in an off-axis direction, deformation is anisotropic as it also involves changes in angles. This is owing to coupling of normal stresses with shear strains and shear stresses with normal strains. The extents of these couplings are quantified by the so-called coupling coefficients, v_{ij}, defined as

$$v_{ij} = \frac{\underline{S}_{ij}}{\underline{S}_{ii}} \quad (6)$$

Figure 2 shows the angular dependencies of v_{16} and v_{26} for the Plytron lamina and compares them with the dependence of Poisson's ratio, v_{xy}. While Poisson's ratio attains positive values only, the variation in the coupling coefficients is more dramatic. The functions involve both slightly positive and large negative values. In absolute terms, the effects appear more significant than those characterized by Poisson's ratio. There is an axial symmetry of 16 and 26 couplings: $v_{16}(\theta) = v_{26}(90-\theta)$.

Figure 1
Angular dependence of the off-axis stiffnesses normalized on the lamina characteristics of Plytron. Normalization: $E = E(\theta)/E_1$, $G = G(\theta)/G_{12}$, $v = v(\theta)/v_{12}$.
Figure 2
Angular dependence of the coupling coefficients and the Poisson ratio for the Plytron lamina.

It is this coupling owing to a combination of lamina anisotropy with geometric factors that leads to the state of combined stresses and that makes composites unique in their performance. The analysis of this unusual material behavior is simple although the mathematical apparatus needed is more involved than that which suffices for isotropic materials. Attention to all details is required so that the coupling effects may be exploited fully as an opportunity rather than ignored and their existence considered as a composite liability. The discussion of laminates reinforces this theme.

2. Laminates

2.1 Effective Stiffnesses in the Lamina Plane and the Coupling Coefficients

The analysis outlined in Sect. 1.2 can be easily extended to the behavior of laminates, i.e., structures containing a certain number, n, of laminas (plies) of thickness t stacked together in the direction z perpendicular to the laminate plane to form a monolithic structure of overall thickness $h = tn$. Furthermore, for any lamina i the fiber direction is offset by the angle Θ_i with respect to the loading direction and the space occupied by that is between z_i and z_{i-1}. The upper plane of the top lamina is thus situated at z_0 and the lower plane of the bottom lamina at z_n.

As a laminate is a layered structure with each ply characterized by its own stiffness, $E(\Theta_i)$, the whole construction is monolithic (no mutual slippage of adjacent plies allowed), the "state equation" of laminates involves another coupling, namely that between extension and bending (Reissner and Stavsky 1961):

$$|N| = |A||\varepsilon^0| + |B||\kappa|$$
$$|M| = |B||\varepsilon^0| + |D||\kappa| \tag{7}$$

A thermometer based on a bimetallic element serves as a good example of the principles involved.

With reference to *Laminates: Physical and Mechanical Behavior**, $|A|$ is defined as the extensional matrix, $|B|$ as the coupling matrix, and $|D|$ the bending matrix. The force matrix $|N|$, the moment matrix $|M|$, the middle-stack strain matrix $|\varepsilon^0|$, and the curvature matrix $|\kappa|$ are all obtained by appropriate integration of matrices defined by Eqn. (4) over the laminate thickness h. A discussion of the elastic behavior of laminates deserves a more detailed analysis of the matrices $|A|$, $|B|$, and $|D|$. These are 3×3 matrices based on six elements of the same indices as those contained in the reduced matrix $|\underline{Q}|$ (Eqn. (4)). Any element ij can be derived by summing up contributions of all plies from the corresponding $\underline{Q}_{ij}$ and taking into account the actual position of the kth ply

in the stack:

$$A_{ij} = \sum_{k=1}^{n} (\underline{Q}_{ij})_k (z_k - z_{k-1}) = t \sum_{p=1-n/2}^{n/2} (\underline{Q}_{ij})_p$$

$$B_{ij} = \frac{1}{2} \sum_{k=1}^{n} (\underline{Q}_{ij})_k (z_k^2 - z_{k-1}^2) = \frac{t^2}{2} \sum_{p=1-n/2}^{n/2} (\underline{Q}_{ij})_p [2p-1]$$

$$D_{ij} = \frac{1}{3} \sum_{k=1}^{n} (\underline{Q}_{ij})_k (z_k^3 - z_{k-1}^3)$$

$$= \frac{t^3}{3} \sum_{p=1-n/2}^{n/2} (\underline{Q}_{ij})_p [3p^2 - 3p + 1] \tag{8}$$

where p is the ply index expressing position of a given ply in another, more convenient, manner. The index $p = 0$ identifies the first ply below the midplane, $p = n/2$ the top ply, and $p = 1 - n/2$ the bottom ply. The weighting factor in the square brackets implies that if the stack is symmetrical with respect to the midplane the coupling matrix $|B|$ is zero. This means that extensions are decoupled from bending, i.e., an exerted force causes exclusively extensions and moments are responsible for bending.

Finally, defining the matrices $|A^*|$ and $|D^*|$ to be the inverse to matrices $|A|$ and $|D|$, all the laminate stiffness characteristics can be expressed as

$$E_x = \frac{1}{A*_{11}} h$$

$$v_{12} = -\frac{A*_{12}}{A*_{11}}$$

The effective moduli are seen to be arithmetic averages of stiffnesses of the constituent plies. However, two-dimensional composite properties expressed by the coupling coefficients differ significantly from two-dimensional properties of conventional isotropic materials. Coupling coefficients can be shown to be large and their origins not always obvious. Furthermore, they can be stated to represent the real potential of composites.

2.2 Some Important Symmetrical Stacks

(a) *Cross-plied laminates*. These are obtained by stacking $0°$ and $90°$ plies based on an identical lamina with a ply, p, being counterbalanced by the ply of the same orientation. Loading in either fiber direction results in an orthotropic laminate response and the coupling coefficients v_{16} and v_{26} are zero. An effective way of controlling the laminate stiffness is to vary the so-called ply ratio, M, i.e., the fraction of $0°$ plies in the stack. This is illustrated in Fig. 3 showing the dependence of the normalized (on the appropriate
Figure 3
Dependence of the stiffness characteristics on the construction of cross-plied laminates based on the Plytron lamina. Normalisation: $e_x = E_x/E_1$, $e_y = E_y/E_2$, $g = G_{xy}/G_{12}$, $v = v_{xy}/v_{12}$.

engineering constants of the lamina) stiffnesses in the longitudinal and transverse directions, shear modulus, and Poisson's ratio in the laminate plane. As the ply ratio increases, the $e_x = E_x/E_1$ dependence linearly increases, $e_y = E_y/E_2$ linearly decreases, and $g = G_{xy}/G_{12}$ remains independent of M. There is a marginal nonlinear increase in the relative Poisson's ratio $v = v_{xy}/v_{12}$ where $90°$ plies play a constraining effect. The simplest construction of the cross-plied laminate is the $\{0/90/90/0\}$ and associated with $M = 0.5$.

Loading a cross-plied laminate in a direction not coinciding with that of the fibers in plies is associated with an anisotropic response with $v_{16} \neq 0$ and $v_{26} \neq 0$. Figure 4 shows the variation of v_{16} with the loading angle $90° \geqslant \Theta \geqslant 0°$ and the ply ratio $1 \geqslant M \geqslant 0$. The coupling coefficient attains both the positive and negative values far exceeding unity. In addition, the variations are rather abrupt. This is particularly true for loadings at large angles and for low M values, i.e., a drastic change in the behavior owing to addition of a single $0°$ ply to the originally unidirectional laminate consisting of $90°$ plies.

(*b*) *Angle-plied laminates.* The symmetric stack consists of $+\omega$ and $-\omega$ plies. The absolute value of the ply angle, ω, controls the laminate stiffness values as illustrated in Fig. 5 showing the angular dependence of the four stiffness characteristics of angle-plied laminates $E_x(\omega)$, $E_y(\omega)$, $G_{xy}(\omega)$, and $v_{xy}(\omega)$ normalized on the stiffness characteristics representing the behavior of the uniaxial construction loaded in the corresponding $\Theta \equiv \omega$ direction. For Plytron laminates, the alternate stacking of plies enhances the

axial and transverse stiffness E_x and E_y by more than 80% and leads to a broader G_{xy} peak being 120% above the maximum level exhibited by the uniaxial construction. Poisson's ratio is seen to involve positive values exceeding the upper bound for isotropic materials of 0.5. In addition, $\omega = 70°$ construction is associated with negative values. With the loading directions bisecting the ply angles, the laminate behavior is orthotropic with $A_{16} = A_{26} = 0$.

A much wider range of Poisson's ratios is obtained when an angle-plied laminate is loaded along a direction different from the bisector of the two ply angles. This is illustrated in Fig. 6 showing a contour map of Poisson's ratio as a function of the ply angle, ω, and the load direction, Θ. Variation in Poisson's ratio conforms to the diagonal symmetry with the negative values attained by the $45°$ laminates at $\Theta = 30°$ and $60°$. The maximum positive values of Poisson's ratio are observed for $30°$ laminates at $\Theta = 0°$ and $60°$ laminates at $\Theta = 90°$, respectively.

(*c*) *Quasi-isotropic laminates.* A very popular laminate construction is achieved when the ply angle of two subsequent plies is rotated by π/n. The simplest laminate of this series of fourteen possible is $\{0/60/-60\}_s$ and the most popular is $\{0/45/90/-45\}_s$. The features of this laminate type are that E_x and E_y are independent of the loading direction and that coupling is absent by virtue of $A_{16} = A_{26} = 0$. The laminate stiffness cannot be altered unless a different building lamina is used. Thus this type of laminate represents the antipode to the unidirectional construction. It possesses minimum anisotropy, offers lowest performance, and may be qualified for lightweight replacement goals rather then for engineering ambitions. In composite technology, quasi-isotropic laminates represent the upper bound on weight and may be considered to be a useful starting point for a possible composite application with a possibility to optimize and to improve the design by enhancing anisotropy.

2.3 Asymmetric (unbalanced) Laminates

If the midplane symmetry is allowed to be absent, the elastic behavior of general laminates described by Eqn. (7) involves coupling between extension and bending and thus the full analysis that quantifies the interaction among forces, moments, extensions, and curvatures is required. The procedure is more cumbersome; nevertheless, the same methodology is used as already described.

An important issue that concerns this (general) laminate type is the way of controlling the coupling matrix $|B|$. Concentrating on laminates containing an even number of plies stacked alternately, the structural parameter of the laminate construction that controls coupling between extension and bending is
Figure 4
Variation in the coupling coefficient with the loading direction and the ply ratio of the cross-plied laminates based on the Plytron lamina.

the number of plies, n, as illustrated in Figs. 7 and 8. For the angle-plied laminates (Fig. 7), the extent of coupling quantified by B_{16}/A_{11} is correlated with the ply angle and the number of plies, n. At a fixed value of n characterizing this laminate type (so-called antisymmetric), the maximum coupling is achieved for the $+45/-45$ laminates. Coupling is seen to be reduced by the number of plies and thus the construction $\{+45/-45\}_T$ represents the case of the strongest coupling. For the cross-plied laminates (Fig. 8), the extent of coupling proportional to B_{11}/A_{11} is correlated with the structural parameter n and the lamina anisotropy expressed as the ratio E_2/E_1. For a given lamina, e.g., for that of Plytron characterized by $E_2/E_1 = 0.154$, the maximum coupling is again achieved for the construction $\{0/90\}_T$. If the laminate construction is fixed, the extent of coupling increases with increasing lamina anisotropy.

It is this combination of the material choice (lamina anisotropy) and the laminate construction that gives unique possibilities to a composite designer of structures such as the fan blade for which the centrifugal stress and the aerodynamic twist occur at the same time. Composites thus start fulfilling the role of tailored functional materials and this attribute defines their unique place in future technologies.

3. Concluding Remarks

Features of composites that make this material type different from all the others have been described. The transversely isotropic lamina acts as the building block and four engineering constants are required to describe its stress/strain behavior: longitudinal and transverse stiffnesses, E_1 and E_2, in the principal directions, and shear modulus, G_{12}, and Poisson's ratio, v_{12}, in the lamina plane all controlled by the constituent properties and their mutual concentrations. Lamina stiffness characteristics have been shown to

be dependent on direction and, in addition, there is a coupling between normal stresses and shear strains, and vice versa unless the loading happens in one of the principal directions. Stacking several laminas to form a monolithic laminate has been demonstrated to be the way towards simple structural elements exhibiting both Poisson's ratios and shear couplings not attainable by means of conventional materials. If the stacking arranges for midplane symmetry, the laminate behavior is relatively simple as the laminate extension is decoupled from the laminate bending. With the laminate midplane absent, the coupling matrix

$|B|$ is nonzero and the choice of a proper lamina, combined with its orientation and the way of stacking, opens ways towards structural responses in which composites behave as functional materials, which will be used in future technologies.

So in the terms of the concepts developed in this article the elastic behavior of composites is to be understood such that the lamina formulation controls the stiffness and compliance matrices $|Q|$ and $|S|$, the lamina orientation their reduced equivalents $|\underline{Q}|$ and $|\underline{S}|$, and the stacking sequence the three relevant matrices $|A|$, $|B|$, and $|D|$. This universal procedure

then allows either a simple stress/strain response to be orchestrated by eliminating anisotropy and working with quasi-isotropic laminates with the midplane symmetry, or, alternatively, to exploit fully the possible interaction of forces, moments, extensions, and curvatures to enter the domain of new materials.

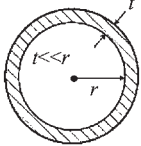
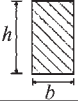
Elastic Structures in Design

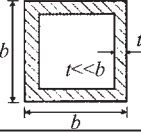
Structures may be broadly defined as engineering artifacts that support loads. The loading causes the material within the structure to become stressed, enabling loads to be transferred from where they are applied (including the weight of the structure itself) to the surroundings. The term "structures" usually brings to mind bridges and buildings. Taking a broader perspective than just civil engineering however, it can be seen that structures come in all shapes and sizes. For example, most modes of transport involve structural design, e.g., aircraft wings, car bodies, and bicycle frames. This also applies to many other familiar load-bearing products, such as chairs, tables, and sports products (vaulting poles, tennis racquets, oars, etc.).

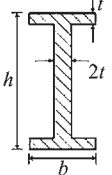
One design characteristic of any structure is its stiffness—that is, the deflection per unit of loading. Stiffness is controlled by both the geometry of the structure (the size and shape of its components) and the material used. Most structures are designed to remain elastic in service, so the maximum stresses must be analyzed to avoid failure by fracture or plastic collapse. Structural design can sometimes be concerned with large plastic deformations, e.g., for energy absorption in automotive crumple zones and crash barriers.

The subject of this article is elastic design and its interaction with material selection. The emphasis is on design for stiffness, although elastic design can have other aspects. For example, springs are designed to store elastic strain energy, while other structures are limited by vibration, either to reduce noise and interference (as in a vehicle engine or suspension), or because the structure is designed to generate sound (as in a musical instrument).

1. Elements of Elastic Design








The key material property in stiffness-limited design is Young's modulus, E (or the related shear modulus, G, for loading involving shear). However, an important aspect of determining the deflection per unit load is also the mode of loading: tension, bending, torsion, or compression. Each mode is characterized by particular structural elements (e.g., beams in bending, shafts in torsion), and the components of elastic structures can always be approximated to some combination of these. For example, the main down-tube of a diamond bicycle frame primarily experiences torsion from the pedaling action of the cyclist (along with some tension from the overall triangulated shape of the frame, and bending due to it being rigidly jointed).

For structures in which forces are carried axially, such as cables or the members in a truss, optimizing stiffness is a straightforward design problem. The elastic deflection of the overall structure is simply related to the extensions in its members, and for axial loading these extensions scale inversely with the cross-sectional area of the component and Young's modulus. In this case, the cross-sectional shape has no influence.

Bending is more complex and usually dominates deflection-limited design (since much smaller loads are required to produce distortion in bending than by axial loading). Closely related is *buckling*—an instability caused by axial compression on a structural member, when the member deflects sideways and is essentially loaded in bending. Buckling is discussed in *Elastic Instability*[#] and is not considered further here.

The loading on a beam in bending generates *bending moments* along its length. In classical theory, the moments cause a linear stress distribution from tension to compression across the section (with the "neutral axis" being the axis where the stresses change from tension to compression). The stresses

Table 1
Second moments of area and shape factors for standard structural sections (after Ashby 1999).

Section shape *(equal areas)*	Second moment of area	Shape factor in elastic bending, Φ	Typical values of shape factor, Φ
	$\pi r^4/4$	1	1
	$\pi r^3 t$	r/t	20–40
	$bh^3/12$	$(\pi/3) \times (h/b)$	2–10
	$\frac{2}{3}b^3 t$	$0.52 \times (b/t)$	10–20
	$\frac{1}{6}h^3 t\left(1+\frac{3b}{h}\right)$	$0.52 \times \frac{h}{t} \times \frac{(1+3b/h)}{(1+b/h)^2}$	30–80

cause curvature of the beam, with resulting deflection. The overall geometry also depends on the way the beam is supported, e.g., cantilever or end-supported, rigidly clamped or free to rotate, etc.

In the analysis of stresses and deflections in a beam, the most important characteristic is its cross-sectional shape. For a given applied bending moment, the section shape governs the slope of the stress gradient across the section and thus the curvature in a given material. Shape is characterized by the second moment of area, I, defined as

$$I = \int y^2 \mathrm{d}A$$

where y is the distance of the elemental cross-sectional area $\mathrm{d}A$ from the neutral axis. Table 1 summarizes formulas for I in standard structural shapes. Efficient shapes in bending are those that maximize I for a given cross-sectional area of material, such as I-beams. In these shapes most of the cross-section is located as far from the neutral axis as possible (large y).

A useful parameter has been defined to quantify the effect of shaping a given cross-sectional area for bending. This dimensionless "shape factor," Φ, is defined by

$$\Phi = \frac{4\pi I}{A^2}$$

The constant 4π is introduced such that $\Phi = 1$ for a solid cylinder, i.e., Φ measures the ratio of I for a given shape to I for the same area made into a solid cylinder. Typical values for Φ are included in Table 1.

For simple idealized loadings, the maximum deflection, δ, is given by

$$\delta = C_1 \frac{WL^3}{EI}$$

where the constant C_1 only depends on the detail of the way the load is distributed and the support arrangements. For a beam of given length, the deflection per unit load (or stiffness) varies inversely as the product EI, which is called the "flexural rigidity." This quantity has significant implications for the selection of materials in deflection-limited design in bending.

There are close analogies between the analyses of bending and torsion (for regular axisymmetric shapes such as tubes and circular shafts). In this case, an applied torque generates shear stresses that increase linearly with radial distance from the axis of the member, and the response of the member is to twist. The stiffness is defined by the twist per unit length divided by the torque. The "torsional rigidity" is now the important parameter—the product of the shear modulus, G, and the polar second moment of area, J, defined by

$$J = \int r^2 \mathrm{d}A$$

Now it can be seen that efficient shapes are those which arrange the material at a large radius from the section axis, i.e., hollow tubes. Shape factors for torsion have also been defined in a similar way to those for bending (Ashby 1999).

2. Lightweight Design in Bending

A common design requirement is to resist deflection in bending while minimizing the component mass (e.g., in sports equipment such as golf clubs, or in lightweight transport such as bicycles). Here material selection requires a trade-off between Young's modulus, E (which governs stiffness) and density, ρ (which governs mass). The mass, m, of a beam of given length L and cross-sectional area A is simply

$$m = \rho L A$$

The deflection, however, depends on the second moment of area, which can vary widely at constant A (as indicated by the shape factors in Table 1). Material selection must therefore take account of geometric constraints imposed on the area and shape. This is the basis of the approach described by Ashby (1999) for optimizing the selection of materials using "merit indices". As a simple example, consider the selection of material to minimize the mass for a square beam of dimensions $B \times B$ and fixed length L, with a specified allowable deflection per unit load δ/W. The dimension B is a free variable. It will need to vary from one material to another in order to provide sufficient stiffness. The area $A(= B^2)$ must therefore be eliminated from the expression for the "objective," mass, and this is achieved using an expression for the "constraint," deflection per unit load. Noting that, for a square section, $I = B^4/12$, we proceed as follows:

$$m = \rho L B^2$$

$$\frac{\delta}{W} = C_1 \frac{12L^3}{EB^4}$$

so

$$B^2 = \left(\frac{12C_1L^3}{E(\delta/W)}\right)^{1/2}$$

Hence, the mass of the beam is

$$m = \left(\frac{12C_1L^5}{(\delta/W)}\right)^{1/2}\left(\frac{\rho}{E^{1/2}}\right)$$

All of the parameters in the first set of parentheses are specified by the design, so the mass only depends on the group of material properties in the second set of parentheses. To minimize mass one needs to maximize $E^{1/2}/\rho$—this quantity is called a "merit index." An important point to note is that the result is not the "intuitive" answer, E/ρ, owing to the way mass and deflection depend independently on the cross-section geometry. Furthermore, if the constraints on geometry are modified, so is the merit index. For example, if the width of the beam is fixed but its depth is allowed to vary, the analysis yields the merit index, $E^{1/3}/\rho$. The significance of these results is best appreciated by illustrating the indices on a "material selection chart."

Figures 1 and 2 show a material selection chart—a plot of Young's modulus against density. Logarithmic scales are used since both properties span several orders of magnitude. Data for each class of material cluster into well-defined regions (reflecting the underlying atomic bonding and bond stiffness in each class).

On logarithmic scales, constant values of the merit indices plot graphically as straight lines, e.g., $E^{1/2}/\rho = constant$ is a line of slope 2. Guidelines of slope 1,
Figure 1
Material selection chart, showing Young's modulus against density for the material classes, with guidelines for three merit indices.
Figure 2
Material selection chart, showing Young's modulus against density for the material classes, with selected structural materials highlighted. Selection lines are shown for two merit indices.

2, and 3 (representing the merit indices E/ρ, $E^{1/2}/\rho$, and $E^{1/3}/\rho$, respectively) are shown in Fig. 1. Materials lying along a given line all have equal mass for the specified design constraints (but different cross-sectional sizes according to their respective Young's moduli). To maximize a given index, the line is translated across the chart to leave a subset of materials, as shown in Fig. 2. Hence for maximum E/ρ, composites

and some metals compete, while ceramics are the best (although unlikely to be used on the grounds of poor toughness). The ranking of materials changes significantly for a different index; e.g., woods have a clear advantage over all metals for panels of fixed width ($E^{1/3}/\rho$). Composites and metals do, however, compete in this situation by exploiting sandwich panel construction (see below). Having identified candidate materials that satisfy the stiffness constraint at low mass, the choice will be further narrowed by imposing other design limitations (strength, cost, etc.).

2.1 Structural Efficiency

The analysis above assumes a constant cross-sectional shape for all materials (e.g., a square section, or a panel of fixed width). Where possible, designers will use sections with an efficient shape factor—but not all materials are equally easy to make into efficient shapes, owing to manufacturing constraints. Woods can only be made into solid sections, or thick-walled hollow box sections, while steels can be made into very efficient I-beams, and composites fall somewhere in between. Table 2 indicates typical limits on shape factor for various structural materials.

Selection of materials for lightweight design in bending must take account of whether it is an option to use shaping. A partial solution can be obtained by an extension to the merit index approach. In certain circumstances, the merit index for constant shape (e.g., $E^{1/2}/\rho$) may be modified to allow for shape by incorporating the shape factor in the index, e.g., $(\Phi E)^{1/2}/\rho$. The effect of shaping can be visualized as enhancing the modulus of the material, allowing the denser materials (such as steel) to become more competitive again on account of their large shape factor. Table 2 shows typical values for the merit index without shape ($E^{1/2}/\rho$) and with ($\Phi E)^{1/2}/\rho$. In the first case wood comes out on top, while the effect of shape is to put aluminum first, closely followed by glass fiber-reinforced polymer (GFRP).

As noted above, other constraints will come into play—strength, size, manufacturing problems, and cost. The cost of a structural section is influenced by more than the initial material cost (e.g., manufacturing route), but an indication of the effect of material cost can be obtained by a further modification to the merit index. The index $E^{1/2}/\rho$ is inversely proportional to the mass of the beam (at constant shape). Dividing this by the cost per unit weight of the material, C_m, gives a merit index which is inversely proportional to the material cost of the beam: $E^{1/2}/(\rho C_m)$. Table 2 shows typical values for this index—steel now stands out clearly above the rest, and would do even better if shape were included. This helps explain the widespread use of steel for structural design where cost dominates.

Composites are difficult to make into efficient structural shapes, but they can be used efficiently by making a sandwich panel. Sandwich panels use thin skins separated by a core of low Young's modulus and density, such as a polymer foam or honeycomb. Composites are easy to fabricate in thin sheets, and also to join to the core using adhesives. Sandwich panels are structurally efficient as the core material makes a negligible contribution to weight or stiffness, but the stiff, load-bearing material is held at maximum distance from the neutral axis, giving the best possible magnitude of I. The role of the core is simply to hold the skins apart. Examples of products exploiting sandwich panel construction are skis, aircraft floor panels, and helicopter rotors, using high Young's modulus composites (such as carbon fiber-reinforced polymer (CFRP)).

The core in a sandwich panel contributes virtually nothing to the overall flexural rigidity, but it must be stiff enough to prevent the panel skins from collapsing together. Cellular solids, such as foams and honeycombs are an important class of materials for providing modest stiffness (and strength) at very low weight. Apart from sandwich panel cores, these materials are exploited in a wide range of packaging materials. The properties of cellular solids are usually defined by their relative modulus (E/E_s) and relative density (ρ/ρ_s), i.e., the Young's modulus and density of the cellular material divided by the values for the solid cell wall. Typically these properties are related by an expression such as

$$\frac{E}{E_s} = \left(\frac{\rho}{\rho_s}\right)^n$$

Table 2
Relative performance of different classes of structural materials.

Material class	Typical maximum shape factor, Φ_{max}	$E^{1/2}/\rho$	$(\Phi_{max}E)^{1/2}/\rho$	$E^{1/2}/(\rho C_m)$
Wood (oak)	8	**4.1**	11.5	1.5
GFRP composite	39	2.9	19.0	1.0
6061 Al alloy	44	3.1	**20.5**	2.1
Mild steel	65	1.8	14.7	**4.5**

where $n \approx 1$–2. On the material selection chart, Fig. 1, cellular solids will therefore appear to the left and below the solid from which they are made. For example, woods are natural cellular solids made of polymeric fibers, and fall on the left of the chart at low Young's modulus. The porous structure is responsible for enhancing the structural efficiency of woods. There are many examples in nature of cellular structures giving structural efficiency, e.g., bones, leaves, and feathers.

3. Future Challenges

There is much research effort into mimicking the performance of cellular natural materials using engineering materials. One development area is the manufacture of metallic foams (mostly in aluminum) for use as lightweight core materials for automotive structures. Medical engineering is another growth area, where artificial implant materials are being developed to have properties much closer to those of bone.

Steady improvements are being made in manufacturing techniques in composite materials, allowing more efficient and complex shapes to be made, e.g., hollow bicycle frames which are also shaped to enhance aerodynamic efficiency. Developments in polymer fibers are also leading to competition with steels for heavy-duty cabling and ropes, e.g., tethers for oil rigs and cables for suspension bridges.

Elasticity in Wood and Concrete: Hygromechanical Effects

Many materials absorb moisture in high-humidity environments. In order to account for moisture effects in the design of wood and concrete structures, as well as advanced composite materials, it is necessary to know both the total moisture content and its profile as a function of the service environment. Knowledge of the diffusion characteristics of materials is also necessary for the purpose of performing accelerated environmental conditioning prior to mechanical loading. In addition to swelling or shrinkage, moisture adsorption and desorption can change the mechanical properties of materials. Both non-symmetric moisture distribution and unsymmetric or antisymmetric material structure can cause hygromechanical warping. Therefore, understanding hygromechanical behavior is important not only for dimensional stability but also to ensure the safety of structures.

1. Moisture in Cellular and Porous Materials

Wood moisture may appear in four forms: (i) as water of constitution, (ii) as surface-bound water or water in an adsorbed monolayer with a high density ($1.3\,\mathrm{g\,cm^{-3}}$), (iii) as water adsorbed in multimolecular layers with a decreasing order of dipoles, and (iv) as capillary-condensed water. Constitutional water is due to the organic nature of cell walls. It cannot be removed without altering the chemical composition of the walls. Surface-bound water differs from the water of constitution and can be removed without altering the wood chemically. Since water is a polar liquid consisting of a negative hydroxyl $(OH)^-$ and a positive hydrogen fraction, it is assumed that hydroxyl groups are attached by valence bonds. Capillary-condensed water, as surface-bound water, can be freely evolved from wood.

The condition when all the cell-wall openings are filled with water, but no free water is present in the cell cavities, is the fiber saturation point (FSP). The movement of liquid water above the FSP is caused by capillary forces. Below the FSP bound water moves through the cell walls because of moisture gradients. The phenomenon is nevertheless complicated, because diffusion of moisture through the void structure, and bound water diffusion through the cell walls, occurs simultaneously (Kolmann and Côté 1968).

As in wood, the water contained in cement paste and concrete can be classified into types depending on the degree of difficulty of its removal. Chemically bound water is combined with the fresh cement in the hydration reaction and is not lost on drying but is only evaporated when the paste is decomposed by heating to high temperatures in excess of $1000\,^\circ\mathrm{C}$. Interlayer water is displaced in gel pores and can be removed only by strong drying. Adsorbed water is the water that lies close to solid surfaces under the influence of surface attractive forces. A large proportion of this water can be lost on drying to 30% relative humidity. Capillary water is located in the capillary and larger gel pores. The larger voids may only be partially filled with water but the remaining space contains water vapor. The movement of

moisture in concrete is caused by capillary forces and moisture gradients and depends on the rate of hydration reactions with cement.

Moisture diffusion models are based on Fick's law. Available data (Skaar 1988) indicate classical Fickian behavior in terms of total weight gains up to an apparent equilibrium level for both homogeneous materials and composites.

2. Hygrodeformation of Materials

2.1 Swelling and Shrinkage of Wood and Wooden Materials

In the living tree, the cell walls of wood are always in the fully swollen condition, at fiber saturation. When green wood dries, hygroscopic shrinkage takes place, the extent depending on a number of factors. These include the amount of moisture loss, the structural direction (tangential, radial, or longitudinal), the kind of wood, drying stresses caused by moisture gradients, etc. Wood is normally dried to a moisture content approximately equal to its anticipated mean equilibrium moisture content (EMC) in use. However, since environmental conditions are rarely constant the EMC is continually changing and the moisture content of wood is seldom equal to its anticipated EMC.

Hygroexpansion is given in terms of the percentage shrinkage or swelling. It depends on the deformation of wood itself and the fraction of air spaces in addition to cell-wall material. Hygrodeformation is not linear with moisture changes (Kolmann and Côté 1968).

The cell walls of wood are anisotropic, and therefore hygromechanical properties are also anisotropic. Typically, longitudinal shrinkage is least, usually 0.1–0.3% from the FSP to the completely dry condition. Total radial shrinkage ranges from 3% to 6% and tangential shrinkage from 6% to 12% for most woods over the same moisture range. This anisotropy is responsible for much of the warping of boards cut from various locations in the cross-section of a log.

In the production of wooden composites (plywood, flakeboards, fiberboards, etc.), plastic deformation is the major component of wood deformation that occurs during the hot-pressing process. When moistening, plastic deformation becomes recoverable and there is a large difference between swelling of the densified wood in the direction of pressing and in the transverse direction. The reconstituted wood structure means that the specific moisture strain of the densified wood in comparison with normal wood increases nonlinearly, when moisture content grows, in the direction of pressing but decreases in the transverse direction.

The methods of achieving dimensional stabilization of wood and wooden composites are: (i) cross-laminating of anisotropic sheets to restrain the dimensional changes; (ii) applying water-resistant surface and internal coatings to retard moisture adsorption or loss; (iii) reducing the hygroscopicity of the wood by heat treatment; (iv) introducing a nonvolatile material into the cell walls thus reducing their capacity for water uptake; and (v) cross-linking of the cellulose chains of the fibers by resin impregnation, acetylation, and treatment with polystyrene.

2.2 Shrinkage and Swelling of Concrete

There are two causes of shrinkage: drying and carbonation. Water can only be lost from the surface and therefore the inner core of a specimen constrains overall movement and hence the measured shrinkage varies with sample size. Maximum shrinkage occurs on the first drying, and a considerable part of this is irreversible, i.e., it is not recovered on rewetting (Illston 1998). During immersion in water, the water drawn into the material causes a net increase in volume. This is a characteristic of many gels, but in concrete the expansion is resisted by the skeletal structure so that the swelling is small compared to the drying shrinkage strains.

Four principal mechanisms have been proposed for shrinkage and swelling in cement pastes and concrete: capillary tension, surface tension, disjoining pressure, and movement of interlayer water. The drying shrinkage of concrete is less than that of neat cement paste because of the restraining influence of the aggregate. Apparently concrete has a shrinkage of 10–30% of that of the paste. A member with a large surface area to volume ratio will dry and therefore shrink more rapidly than a beam with a square cross-section of the same area. Carbonation shrinkage differs from drying shrinkage in that its cause is chemical, and it does not result from loss of water.

To minimize shrinkage of concrete it is desirable to: (i) keep the amount of mixing water to a minimum; (ii) cure the concrete well; (iii) use construction joints to control the position of cracks; (iv) use shrinkage reinforcement; and (v) use appropriate dense and nonporous aggregates.

2.3 Effect of Moisture on Advanced Composites

Fiber-reinforced epoxy laminates and other advanced composites absorb atmospheric moisture, apparently by instantaneous surface adsorption and subsequent diffusion through the interior. The absorbed water is not liquid, but exists as hydrogen-bonded molecules or clusters within the polymer. Liquid water may, however, be transported by capillary action along cracks and along fiber–matrix interfaces and may appear at interior voids. The absorbed water softens epoxy resins, and causes them to swell and deform (Gillat and Broutman 1978). The structural consequences of these effects are not yet fully quantified.

2.4 Hygroexpansion and Mechanical Stress

Materials swell to an extent that depends on the environmental conditions. One should expect, therefore, that elements restrained from swelling should exert a stress in the direction in which they are restrained. The swelling pressure of the material is limited by the crushing strength, which is a function of its density, moisture content, and temperature. The swelling pressure reaches a peak and then decreases with time. This is caused by simultaneous occurrence of swelling and stress relaxation with time.

The anisotropy of wood is responsible for the warping of lumber associated with initial drying and during subsequent use. The most important practical effects are different kinds of transverse warping caused by tangential/radial anisotropy in shrinkage. This effect can be reduced if the lumber is restrained from cupping and warping during drying by the application of weights or other restraints. However, hygrodeformation cannot be eliminated completely since some residual stresses are present.

3. Modeling of Hygromechanical Effects

For the estimation of mechanical properties, stresses, and deformation of a material under environmental effects, models are useful. In one approach, the material is divided into a system of elementary layers (real or conditioned) (Brauns and Rocens 1997). The hygromechanical properties of the layers are either determined from the properties of the components using analytical methods or found experimentally. In the general case, the stresses in elementary layers are different and the stress state of the material is inhomogeneous. By using a static equivalent system of average force stresses and couple stresses acting on a unit cube of material, the midplane strains and the curvatures depending on relative moisture content can be determined.

The force and couple stresses in the unit volume of material are calculated by averaging the stresses in the elementary layers of the material. Stresses in the layers are determined using specific environmental strains as well as the stiffness of the material determined analytically. The results calculated can be compared with values found experimentally of swelling deformation and curvatures (Fig. 1). The moisture profile perpendicular to the plane of layers is nonlinear, and the difference of moisture content of layers after seven days' exposure is 9.0%.

4. Concluding Remarks

Hygroexpansion and warping depend on the moisture content and profile within the material. Hygromechanical effects should be determined based on the configuration of the composite, precise stacking
Figure 1
Experimental and calculated values of curvatures (κ_i) and swelling deformations (ε_3) perpendicular to the plane of orthotropic wood laminate as a function of duration of unilateral exposure to moisture (after Rocens 1983).

sequence of the layers, as well as the ply stiffnesses. The optimum configuration for hygroeffects may not coincide with that for mechanical properties, and for every type of loading, specific composite structure should be used. Special methods of treatment have to be used for dimensional stabilization of wood and wooden composites as well as concrete used in structures.

Elastomers, Ceramic-modified

Many elastomers are generally compounded with a permanent reinforcing filler, particularly those which cannot undergo strain-induced crystallization (Medalia and Kraus 1994, Warrick *et al.* 1979). The two

most important examples are the addition of carbon black to natural rubber and to some synthetic elastomers, and the addition of silica to siloxane rubbers (Warrick *et al.* 1979). In fact, the reinforcement of natural rubber and related elastomeric materials is one of the most important processes in elastomer technology. Not surprisingly, there is an incredible amount of relevant experimental data available, with most of these data relating to reinforcement of natural rubber by carbon black (Donnet and Vidal 1986). However, other polymers such as poly(dimethylsiloxane), and other fillers such as precipitated silica, clays, metallic particles, and even glassy polymers, have become of interest (Calvert 1996, Giannelis 1996, Mark 1995, Mark 1996a, Mark 1996b, Mark *et al.* 1995, Schmidt 1996, Wen and Wilkes 1996). Some of these fillers can now be generated *in situ*, within elastomeric polymers, and this the main subject of the present article.

1. General Comments on In Situ *Reinforcement*

The polymer which has been used most extensively in studies of *in situ*-precipitated fillers is poly(dimethylsiloxane) (PDMS) $[-Si(CH_3)_2O-]_x$. It has been chosen in part because it is compatible with many of the organometallic materials used to generate ceramic-type phases, and also because it is an elastomer which requires considerable reinforcement from silica or some other filler before it is useful in most industrial applications (Warrick *et al.* 1979).

The idea of *in situ* generation of reinforcing fillers in polymers is based on an important advance in the ceramics area. It involves the use of preparative techniques that are heavily based on chemical reactions—for example the generation of ceramic-type materials by the hydrolysis of an organometallic compound (Cheetham *et al.* 1994, Mark *et al.* 1995). In the ceramics area, the advantages are the purity of the resulting products, the possibility of avoiding high temperatures (thereby permitting survival of organic guest molecules), the control of ultrastructure (at the nanometer level), the relative ease of forming ceramic "alloys," and the possibility of incorporating a different material into the resulting ceramic while it is still porous, prior to its densification. In the present application to elastomers, the new approach has the advantages of avoiding the difficult, time-consuming, and energy-intensive process of blending agglomerated filler into high-molecular-weight polymers, and simplifying the problem of obtaining good dispersions. The main disadvantage is the increased cost, and the reluctance of industry to carry out the major retooling required to introduce such a different technology. In any case, this approach has been investigated using a variety of fillers, for example silica (SiO_2) by hydrolysis of organosilicates, titania (TiO_2) from titanates, alumina (Al_2O_3) from aluminates,

zirconia (ZrO_2) from zirconates, etc. (Clarson and Mark 1993, Schaefer and Mark 1990).

The following sections consist mainly of descriptions of how some of these sol–gel ideas can be extended using concepts from the area of polymer chemistry (Mark 1996b). The modifications are generally carried out by using elastomeric polymer chains terminated with functional groups that can participate in the ceramic-generating reaction, typically hydroxy groups in the case of a hydrolysis reaction. This permits intimate bonding between the inorganic (ceramic) phase and the organic (polymer) phase in a way that is most likely to give rise to novel mechanical properties.

Although the reinforcement of elastomers by dispersed ceramic phases is of primary interest in the present context, the case where the ceramic predominates and becomes the continuous phase (Mark 1996b) is also mentioned. The elastomeric phase therefore becomes dispersed in it, improving its mechanical properties, such as impact resistance. Yet another approach to the novel reinforcement of elastomers involves some related systems in which there are either magnetically responsive particles or crystalline zeolites (Erman and Mark 1997).

2. Preparation

The most important reaction of this type involves the catalytic hydrolysis of tetraethoxysilane, also known as tetraethylorthosilicate (TEOS) (Erman and Mark 1997, Mark 1992, Mark *et al.* 1993):

$$Si(OC_2H_5)_4 + 2H_2O \rightarrow SiO_2 + 4C_2H_5OH \qquad (1)$$

In the original sol–gel technique, the gel thus formed is first dried to remove unreacted TEOS, ethanol, water, and catalyst (which is generally chosen to be volatile). It is then fired into a porous ceramic, which may then be densified into the final ceramic object.

In the simplest application of this approach to obtaining elastomer reinforcement, some of the organometallic material is absorbed into the cross-linked network, and the swollen sample placed into water containing the catalyst (typically a volatile base such as ammonia or ethylamine). Hydrolysis to form the desired silica-like particles proceeds rapidly at room temperature to yield the order of 50 wt.% filler in less than an hour (Erman and Mark 1997). Alternatively, hydroxy-terminated chains are blended with enough TEOS both to end link them and to provide silica by the hydrolysis reaction. Thus, curing and filling take place simultaneously, in a one-step process. In an alternative method, TEOS is blended into a polymer having end groups (e.g., vinyls) that are unreactive under the hydrolysis conditions. The silica is then formed in the usual manner (Eqn. (1)) and the product dried. The resulting slurry of polymer and silica is

stable and can be cross-linked later using any of the standard cross-linking techniques, such as vinyl–silane coupling or peroxide thermolysis (Erman and Mark 1997).

3. Electron Microscopy

Both transmission and scanning electron microscopy have been used to characterize these novel composite materials (Mark 1989). The information obtained in this way includes: (i) the nature of the precipitated phase (particulate or nonparticulate); (ii) the average particle size, if particulate; (iii) the distribution of particle sizes; (iv) the degree to which the particles are well defined (smoothness of the interfaces); and (v) the degree of agglomeration of the particles (Mark 1996b).

Such results show that the particles formed in this manner typically have a narrow distribution of sizes, with most diameters falling in the 200–300 Å range (Erman and Mark 1997, Xu *et al.* 1990). They are generally well dispersed and essentially unagglomerated, which suggests that the generation reaction may involve simple homogeneous nucleation. This is consistent with the fact that particles growing independently of one another and separated by cross-linked polymer would not agglomerate unless very high concentrations were reached. There is some evidence that at least in some cases, the pore size of the network constrains the growth of these particles, in that the average diameters observed seem to increase with decrease in cross-link density (Breiner and Mark 1998, Ulibarri *et al.* 1992).

One interesting result from characterization studies of this type is the conclusion that basic catalysts generally yield particles that are well defined, whereas acidic catalysts yield particles that are rather "fuzzy" (Erman and Mark 1997, Mark *et al.* 1985).

4. Scattering Techniques

A number of x-ray and neutron scattering studies has been carried out on these filled elastomers (Landry *et al.* 1995, Mark 1996b, McCarthy *et al.* 1998). In general, such data can provide estimates of average particle size and possibly particle-size distribution. In addition, the terminal slopes give an indication of the nature of the interfaces, with −3 corresponding to rough interfaces and −4 to smooth.

5. Nuclear Magnetic Resonance

Another way to characterize the *in situ*-generated particles is by nuclear magnetic resonance (NMR) imaging, using ^{1}H and ^{29}Si magic-angle spinning, with two-dimensional Fourier transform spin-echo techniques (Erman and Mark 1997, Mark 1996a).

The result of greatest interest is the distribution of particles within the elastomer, and how the precipitation reaction front moves into the sample with time. The method is obviously nondestructive, but slices taken from the sample can be further studied by density measurements in a gradient column, by electron microscopy, or by x-ray or neutron scattering. Elastomer which has been infiltrated into a silica aerogel can also be imaged in this way (Erman and Mark 1997).

6. Aging

Permitting precipitated silica particles to remain in contact with their aqueous catalyst solution can permit them to "age" or "digest" (Mark 1996b, Xu *et al.* 1990). Electron microscopy results suggest that some reorganization is occurring, with the particles becoming better defined, more uniform in size, and possibly even less aggregated. There seem to be interesting parallels with "Ostwald ripening" in the area of colloid science.

7. Densities

Comparisons between the values of wt.% filler obtained from density measurements and the values obtained directly from weight increases can yield very useful information on the filler particles. For example, the fact that the former estimate is smaller than the latter in the case of silica-filled PDMS elastomers (Erman and Mark 1997, Ulibarri *et al.* 1992) indicates that there are probably either voids or unreacted organic groups in the filler particles, and possibly both. Incomplete conversion of TEOS to silica is also indicated by ^{29}Si NMR measurements (Ulibarri *et al.* 1992).

8. Calorimetry

Differential scanning calorimetry measurements at low temperatures have been carried out on PDMS elastomers containing *in situ*-precipitated silica (Mark 1996a). The presence of the silica was found to reduce both the extent of crystallization and the rate of crystallization when the elastomers were in the unstretched state. This is in interesting contrast to similar studies of PDMS in the stretched state, where the filler may facilitate the crystallization process.

9. Thermogravimetric Analysis

In at least some cases, *in situ*-precipitated fillers may have the advantage of increasing thermal stability (Erman and Mark 1997). A possible mechanism for this improvement would be increased capability of the *in situ*-produced silica to tie up hydroxy chain ends that participate in the degradation reaction.

10. Mechanical Properties and Equilibrium Swelling

10.1 Uniaxial Extension

The reinforcing ability of such *in situ*-generated particles has been amply demonstrated for a variety of deformations, including uniaxial extension (simple elongation), biaxial extension, shear, and torsion (Erman and Mark 1997, Mark 1996b, Mark and Erman 1988). Illustrative results obtained for elongation (reciprocal elongation $\alpha^{-1} < 1$) and compression ($\alpha^{-1} > 1$) are depicted schematically in Fig. 1, where the modulus is plotted against α^{-1}. In the case of uniaxial extension, the modulus [f*] frequently increases by more than an order of magnitude, with the isotherms generally showing the upturns at high elongation that are the signature of good reinforcement (Erman and Mark 1997, Mark *et al.* 1992). As is generally the case in filled elastomers, there is considerable irreversibility in the isotherms, which is thought to be due to irrecoverable sliding of the chains over the surfaces of the filler particles. Some fillers other than silica, for example titania, do give stress–strain isotherms that are reversible, indicating interesting differences in surface chemistry (Mark 1996b).

10.2 Adhesion Between Phases

It is possible to interpret equilibrium swelling measurements obtained on unfilled and filled elastomers to estimate the degree of adhesion between elastomer and filler particles (Kraus 1965, Mark 1996b). Some typical results for *in situ*-generated fillers are presented schematically in Fig. 2, in which the ordinate is the ratio of the extent of swelling of a filled network relative to its swelling in the unfilled state. The results differ greatly from those expected for nonadhering fillers, indicating good bonding between the two phases. Resistance to separation from the surface in such swelling tests, however, does not necessarily contradict the conclusion that the chains have mobility along the surface, as was described in Sect. 10.1.

10.3 Biaxial Extension

Biaxial extension is one of the most important of the mechanical deformations other than simple elongation, and can be imposed by inflation of a sheet of the elastomer. Since biaxial extension is equivalent to uniaxial compression, both types of data can be combined in the same plot, as shown in Fig. 1. Very strong reinforcing effects from the precipitated silica occur for biaxial extension as well as for elongation. This is evident from both the large upward shifts of the isotherms as a whole and from the pronounced upturns at both high elongations ($\alpha^{-1} < 1$), and at high compressions (biaxial extensions) ($\alpha^{-1} > 1$). The pronounced maxima and minima in the isotherms for the filled elastomers in biaxial extension are not understood at present (Erman and Mark 1997), and

Figure 1
Schematic stress-strain isotherms for PDMS-silica in-situ reinforced elastomers in elongation (region to the left of the vertical dashed line, with reciprocal elongation $\alpha^{-1} < 1$), and in biaxial extension (compression) (to the right, with $\alpha^{-1} > 1$).
Figure 2
Plot of swelling ratio characterizing the swelling of a filled PDMS network relative to that of an unfilled PDMS network, against filler loading expressed as volume ratio of filler to rubber $\phi/(1-\phi)$ (where ϕ is the volume fraction of filler). The symbols represent experimental results obtained using silica, titania, or silica–titania mixed-oxide fillers.

represent challenges to theories on the origin of reinforcing effects in elastomers in general.

10.4   Shear

Pure shear is conveniently imposed by stretching a wide rectangular sheet in a direction perpendicular to its width. As in the case of uniaxial extension and compression, the addition of filler shifts the isotherms upwards to significantly higher values of the modulus. In the case of the filled networks there is an initial decrease in the modulus with increase in deformation. This may be due to stress-induced rearrangements of the chains in the vicinity of the filler particles (Erman and Mark 1997).

The filled samples have much higher shear moduli than the corresponding unfilled samples. Also, at high deformation, the filled samples show pronounced upturns in the reduced stress or modulus, which indicate very good reinforcement. The magnitudes of the upturns are much less pronounced, however, than those in uniaxial extension or compression.

10.5   Torsion

As was the case for the other deformations, an increase in filler content was found to shift the torsion isotherms upward, to significantly higher values of the shear modulus (Erman and Mark 1997). These curves are significantly different from the ones for the other types of deformation, however, in that there is little evidence for upturns in the modulus at high deformations. This could be due either to the nature of the deformation or to the inability, to date, of reaching sufficiently high torsional deformations.

10.6   Hardness

Another illustrative property of importance in such hybrid organic–inorganic composites is hardness. The case of the PDMS–SiO_2 system is illustrated in Fig. 3 (Mark 1996a). The hardness can be varied greatly by changing the organic-to-inorganic molar ratio, as measured by the molar ratio of organic R groups (in this case methyl) to silicon atoms. Low values of the R:Si ratio yield a brittle ceramic, and high values yield an *in situ*-reinforced elastomer. The most interesting range of values, where R:Si ~ 1, can give a hybrid material that can be viewed either as a ceramic of reduced brittleness or an elastomer of increased hardness, depending on one's point of view.

10.7   Dynamic Mechanical Properties

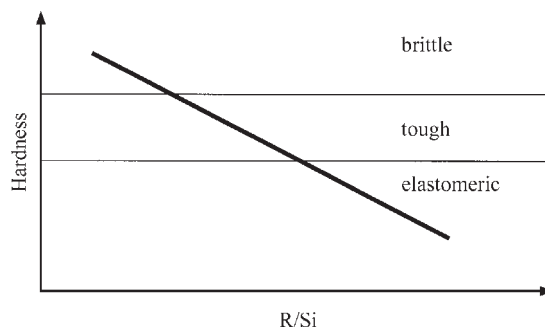
Measurement of dynamic mechanical losses can provide important information on transitions occurring in polymers, including filled elastomers. Such results,


Figure 3
Dependence of the D-scale hardness of PDMS composites on the molar ratio of alkyl groups to silicon atoms.

for example, document the effect of filler on an elastomer's glass transition temperature and melting point (Mark 1996b).

10.8   Cyclic Deformations

In a typical experiment of this type, silica-filled PDMS elastomers are subjected to cyclic compressions, with the modulus and sample dimensions monitored as a function of the number of cycles, the time period of cycling, or the power consumed (Mark 1996b). Of particular interest in such experiments is the decrease in fractional length of a sample with time, since this characterizes the amount of creep or compression set resulting from the cyclic deformation. Unfilled PDMS samples and those filled by blending with fume silica show considerable compression set, while the samples containing *in situ*-precipitated silica show relatively little (Erman and Mark 1997). This suggests that the *in situ* silica can retard the chemical changes caused by cyclic stresses as well as those caused by high temperatures, and is thus consistent with the thermogravimetric analysis results already cited (Mark 1996b).

10.9   Impact Resistance

Impact strengths of PDMS–SiO_2 samples have been determined by the Charpy pendulum impact test and by the falling-weight impact test (Erman and Mark 1997). The samples investigated were PDMS-modified SiO_2 and SiO_2/TiO_2 glasses with PDMS contents ranging from 0 to 65 wt.%. As expected, only samples with relatively high ceramic contents were sufficiently brittle to be studied in this manner. It was reported that the larger the amount of PDMS used, or the higher its molecular weight, the higher the impact strength of the composite. Thus, considerable toughening of the glass can be achieved by increasing the amount of PDMS introduced. The effect of increase

in PDMS molecular weight may be to increase the phase separation which leads to the energy-absorbing elastomeric domains (Erman and Mark 1997).

Microscopic observation of fracture surfaces can also provide useful information for interpreting impact strengths in terms of the physical processes involved. Specifically, smooth fracture surfaces are associated with completely brittle failure, with little effective resistance to either initiation or propagation of cracks. The samples with high PDMS contents had fracture surfaces showing some degree of "whitening" or shearing. This suggests a ductile, energy-absorbing response to the impacts, with increased resistance to crack propagation. Materials of this type are discussed in detail in the articles *Polymer-modified Ceramics** and *Polymer–Inorganic Composites, Properties of*[#].

10.10 Equilibrium Swelling

In a swelling experiment, the network is typically placed into an excess of solvent, which it absorbs until the dilational stretching of the chains prevents further absorption of solvent (Erman and Mark 1989, Mark and Erman 1988). Adsorption of some network chains on to the particles of a reinforced elastomer would, of course, reduce the extent of swelling at equilibrium (as described above) and lead to inhomogeneous strain fields. Characterization of such equilibrium swelling as a function of filler constitution, filler amount, and the method of generating and incorporating it into an elastomer are the issues of greatest interest with regard to this type of deformation.

11. Comparisons Among Various Silica-based Fillers

As is now obvious, there is a variety of ways to generate silica-type fillers useful for reinforcing PDMS networks, and the extent to which such fillers provide reinforcement has been characterized (Mark 1996a). The best mechanical properties seem to be obtained either by precipitating silica directly into a swollen PDMS network after curing, or by incorporating silica which has been prepared from partially hydrolyzed TEOS with incorporation of some PDMS. A better molecular understanding of filler reinforcement in general could provide a detailed interpretation of these results.

12. Other Elastomers

Most of the studies to date on elastomer–ceramic materials have involved PDMS, primarily because of its great miscibility with TEOS. Similar studies (Mark and Erman 1988) on the related polymer, poly(methylphenylsiloxane), however, are also of considerable importance because of the stereochemically irregular structure of this polymer which prevents it from undergoing strain-induced crystallization (Erman and Mark 1997, Mark and Erman 1988). Good *in situ*-generated reinforcement was also achieved in this polymer, demonstrating that such crystallization is not important for this type of reinforcement (Mark 1996a).

A large number of other polymers has been treated in this way (Mark 1996a, Mark 1996b). For example, the same techniques have been shown to give good reinforcement in polyisobutylene elastomers and in poly(ethyl acrylate). In the case of some hydrocarbon polymers, miscibility with the alkoxysilane $Si(OR)_4$ can be improved by choosing R groups that will make the molecule more hydrophobic than TEOS.

13. Other Ceramic-type Fillers

Silica particles in PDMS elastomers can be a problem at high temperature, since the silanol groups on their surfaces can cause degradation of the polymer (Warrick *et al.* 1979). Because of this, and for other reasons, a variety of other fillers has been precipitated into PDMS and other elastomers (Mark 1996a, Mark 1996b), including titania, alumina, and zirconia, and these nonsilica fillers also provide good reinforcement. One interesting difference, however, is the already mentioned observation that the stress–strain isotherms in these cases frequently have much better reversibility (Erman and Mark 1997, Mark and Erman 1988). The differences are presumably due to different interactions between the groups present on these particle surfaces and the PDMS elastomeric matrix.

There is now increasing interest in introducing fillers consisting of more than one oxide (Mark 1996a, Mark 1996b). One of the hopes is that there will be an advantageous "delegation of responsibilities" in these mixed oxides, with one type of particle improving one set of properties and the other improving a different set.

14. Preparation of Bicontinuous Systems

At some compositions and under some hydrolysis conditions, bicontinuous phases can be obtained (with the silica and polymer phases interpenetrating one another). Some of the evidence for such interpenetration is from small-angle x-ray scattering and small-angle neutron scattering profiles (Mark 1996b).

Other evidence is from stress–strain isotherms in elongation. Since the two networks interpenetrate one another, the mechanical properties exhibited by the material can be very peculiar. In the first deformation of the virgin material, the silica network can give a very high initial modulus, but once this structure is broken, additional deformation cycles

can indicate much lower values of the modulus. The mechanism for the generation of bicontinuous materials may be spinodal decomposition, occurring either before or after polymerization.

Elastomers, Reinforcement of

Finely divided particulate fillers have been used in the rubber industry for centuries, as cheap diluents and to increase the modulus of elasticity. Reinforcement, signifying an increase in tensile strength, abrasion resistance, and other ultimate (i.e., failure) properties as well as modulus, was reported in 1905 (with zinc oxide). Soon thereafter the much stronger reinforcement by carbon black was found with tires (see *Rubber Tires**), which at that time were based entirely on natural rubber. Noncrystallizing elastomers such as SBR are highly dependent on reinforcement, and the synthetic rubber industry of today could not exist without the use of reinforcing agents.

1. Reinforcing Fillers

Carbon black is the pre-eminent reinforcing filler. More than 30 grades of carbon black are manufactured for use in rubber; these impart a broad spectrum of properties to the rubber compound. Since

carbon black is discussed *in extenso* elsewhere (see *Networks, Failure of*[#]) only a brief review of the nature and important characteristics of carbon black is given here.

Carbon black consists of solid carbon entities of colloidal dimensions ($<1\,\mu m$) called *aggregates*. Each aggregate is composed of many particles fused together in a randomly arranged clustered (aciniform) morphology. The specific surface area is inversely proportional to the particle size (diameter), while the number and arrangement of particles in the aggregates determine the bulkiness, or ratio of the effective volume to the volume of carbon, which for historical reasons is called *structure*. Surface area is measured by adsorption of a gas (nitrogen) or of a surfactant (CTAB) in aqueous solution; adsorption of iodine is a convenient, though less accurate, method of measurement. Structure is measured by adsorption of a liquid (dibutyl phthalate), either on the carbon black as received (DBPA) or after a crushing and sieving treatment (CDBP). The surface of carbon black is composed of somewhat imperfect graphitic layers; these appear to be organized in a shingled arrangement, with exposed edges at which the carbon atoms may be bonded to hydrogen atoms or to oxygen groups, predominantly phenolic. The fraction of the surface covered by oxygen groups is low in most rubber-grade carbon blacks, and varies little from one grade to another, so the effect of the surface chemistry is generally minor.

Fumed silica, like carbon black, is produced in a flame (of silicon tetrachloride, hydrogen, and oxygen); thus its morphology resembles that of carbon black, though the aggregates may tend to be less tightly clustered than those of carbon black. Its surface contains hydroxyl (silanol) groups, in a concentration of 2–4.5 groups per nm^2; some nonpolar siloxane (Si–O–Si) groups are also present. The principal use in the elastomer industry is as a reinforcing agent for silicone rubber; the high cost of fumed silica precludes its usage in general purpose rubbers.

Precipitated silica is the second most widely used reinforcing filler, after carbon black. It is formed by controlled acidification of a solution of sodium silicate, stopping the reaction short of formation of massive silica gel. As with carbon black, precipitated silica exists in the form of aggregates, but these tend to be more highly clustered and some aggregates may resemble fragments of silica gel. The surface is covered with silanol groups, in a concentration of 8–12.5 per nm^2. Through these groups the aggregates tend to bond to each other, as well as to moisture; this makes the evaluation of some of the properties, such as bulkiness, difficult. Attempts to match the reinforcing performance of carbon black with precipitated silica have proven difficult owing to the different surface chemistry and morphology, but recently improved silicas, together with coupling agents (*vide infra*), have imparted excellent properties to tire

trends ((Rauline 1991), and this is an active field of study at present.

Mineral fillers, especially clay and calcium carbonate, are widely used in the rubber industry. They function as low-cost extenders and also raise the modulus and stiffness, but are not generally considered to be reinforcing agents since the ultimate properties of mineral-filled rubber compounds are poor. Some improvement in reinforcement can be achieved by surface treatment so as to improve interaction (bonding) with the elastomer (Dannenberg 1982).

Short fibers are used to a limited extent, generally together with a reinforcing filler, to increase the modulus and dimensional stability, as well as to impart anisotropy of properties where this is desired. These fibers may be of glass, cellulose, carbon, or organic polymers, and are generally precoated with a binder to aid in dispersion and to improve bonding to the elastomer.

2. Mixing and Dispersion: State of Filler in Compound

Reinforcement requires good dispersion of the filler. Because of the high viscosity of elastomers, this requires equipment of high power, imparting a great deal of shearing energy, most of which is converted to heat. Cooling is relatively ineffective in large-scale equipment, so care must be taken to avoid high temperatures at which "scorch," or premature crosslinking, would take place. Internal mixers, such as the Banbury mixer, are generally used, but two-roll mills may also be employed (see *Polymer Melt Mixing: Agglomarate Dispersion**).

In the filler as received by the rubber manufacturer the individual colloidal entities (aggregates) are associated by van der Waals forces (for carbon black) or hydrogen bonding (for silica) in the form of agglomerates, which are formed into tiny spherical pellets (of carbon black) or may be pressed to remove air and ground and sieved to facilitate shipping and handling (of silica). The first stage in mixing is the incorporation, in which elastomer is squeezed into the void space in the filler pellets or agglomerates and the filler is incorporated into the polymer mass. The next, and overlapping, stage is dispersion, in which the elastomer-filled agglomerates are broken down into the individual aggregates. At the same time distribution is taking place, resulting in uniformity on a scale of tens or hundreds of micrometers. At the loadings generally employed for rubber reinforcement, the dispersed aggregates remain in some contact with each other even after the dispersion step is carried to good reinforcement, and this contact may be increased by reagglomeration after mixing has been terminated. Interaggregate contact results in formation of a filler network which is manifested by

high dynamic modulus at low strains and (in the case of carbon black) by high electrical conductivity. Re-agglomeration and network formation are especially pronounced in silica, resulting in a large increase in stiffness of the uncured compound on standing.

As may be inferred from the above discussion, there are two types or aspects of dispersion: one (macro-dispersion) in which the initial compact agglomerates are broken down into aggregates, and the second (micro- or separation dispersion) which refers to the separation between the aggregates. Poor macro-dispersion, in which rubber-filled agglomerates or pellet fragments greater than about 2 μm in size are present, leads to poor ultimate properties, since the undispersed regions act as weak spots or stress concentration centers at which failure can be initiated. Macrodispersion is what is ordinarily referred to as "dispersion"; it can be measured by microscopic examination of thin sections, or by roughness of torn or cut or stretched surfaces. Separation dispersion can be judged, though not measured in an absolute sense, by the electrical conductivity (of carbon black filled compounds), or by the Payne effect (*vide infra*). Increased separation dispersion results in decreased hysteresis and heat generation during dynamic mechanical deformation of the compound.

The high shear and elongational flow during mixing can result in some breakdown of the aggregates themselves. Breakdown of carbon black aggregates results in decreased bulkiness or "structure," and since the properties of the compound depend on the structure of the aggregates *in the compound*, it is desirable to estimate this in quality control of the carbon black. This is the purpose of the CDBP test (*vide supra*) but since the extent of aggregate breakdown depends on the polymer and mixing conditions, there is not generally a 1:1 correspondence between breakdown on crushing and breakdown on mixing. Furthermore the crushing procedure tends to bring the DBP absorption values of different carbon blacks closer together, thus the *un*crushed DBP absorption remains of value for quality control.

3. Mechanical Behavior of Filled Vulcanizates

Reinforcement is manifested in various aspects of the mechanical behavior of the reinforced vulcanized (i.e. cross-linked) rubber compounds (Wolff and Wang 1993; Medalia and Kraus 1994). These will be discussed in a sequence corresponding to increasing complexity of their presumed mechanisms. The effects of carbon black will be reviewed first, followed by a comparison with silica.

3.1 Elastic Modulus

In general, a filler will increase the elastic modulus of a rubber compound. A hydrodynamic basis for this effect, based on the Einstein viscosity equation, is given in the widely used Guth–Gold Equation:

$$G' = G'_0(1 + 2.5\phi + 14.1\phi^2) \qquad (1)$$

where G' and ϕ are the modulus and volume fraction of the filler, respectively, and the subscript zero indicates the absence of filler. Equation (1) gives good results for systems with spherical particles, including N990 carbon black (a poorly reinforcing carbon black with low surface area and low structure, composed largely of individual spherical particles). However, reinforcing grades of carbon black give elastic moduli considerably higher than the predicted values. This can be accounted for, in the limit approached at high double strain amplitude (DSA), by considering that rubber is occluded within the convoluted carbon black aggregates and that this rubber acts to some extent as part of the aggregate rather than as part of the rubber matrix. By calculating the amount of occluded rubber from the DBPA, and assuming that one-half of it acts as part of the aggregate, the following expression can be derived for the effective volume fraction of filler, V:

$$V = 0.5\phi(1 + [1 + 0.02139(\text{DBPA})]/1.46) \qquad (2)$$

Substitution of V for ϕ in Eqn. (1) has given good results for a number of carbon blacks of different structure and surface area, at both low and normal loadings (Medalia 1973). For example, the predicted value of G'/G'_0 from Eqn. (1) is 2.02 for all carbon blacks at a loading of 50 phr or $\phi = 0.1945$, as normally used for reinforcement (the expression phr refers to the parts by weight of filler per 100 parts of rubber); whereas the value calculated for N568 (a carbon black of DBPA = 142) using V from Eqn. (2) is 3.81, in agreement with the experimental value.

3.2 Augmentation of Elastic Modulus by Network Formation

In reinforced rubber compounds, unlike gum (unfilled) rubber, the elastic modulus is generally dependent on the strain amplitude. G' approaches a limiting value at very low amplitude, which is higher than the limiting value approached at high DSA. The extent of this augmentation ($\Delta G'$) depends on the loading and surface area of the carbon black, but not significantly on structure (Medalia 1978). At a normal loading of a reinforcing black the augmentation can be substantial; for example, with N220 (iodine number 126) at 50 phr in SBR-1500, G' is 44% higher at a DSA of 0.5% than at a DSA of 10%, while with N568 (iodine number 47) the augmentation is only 13% (based on measurements at 25 °C and 0.25 Hz). The augmentation is less at higher temperatures, greater at higher frequencies.

The augmentation of elastic modulus—often referred to as the Payne effect—is attributable to the network of carbon black which is broken down at high amplitudes. Mixing procedures which improve the separation dispersion diminish $\Delta G'$; for example, a two-stage mix in the above formulation with N220 gives only a 29% augmentation. Confirmation of the network as the source of augmentation comes from the electrical conductivity, which is higher for higher surface-area carbon blacks, and decreases with improved separation dispersion.

3.3 Effect of Carbon Black on Hysteresis and Heat Generation

Conversion of mechanical energy to heat, or hysteresis, is an important aspect of the dynamic behavior of rubber products (Medalia 1978); for example, in tires (see *Rubber Tires**), where energy loss (rolling resistance) as well as temperature rise (heat build-up) are significant factors affecting performance. While unfilled elastomers exhibit significant hysteresis, in reinforced elastomers the contribution of the filler generally outweighs that of the elastomer. The hysteresis, H, is the mechanical energy loss per unit volume per cycle; related parameters include the phase angle, δ, and the loss modulus, G'', where $G'' = G' \tan \delta$.

The contribution of the filler to hysteresis is attributable to breakdown and re-formation of filler–filler bonds and thus of the filler network. At very low-strain amplitude $\tan \delta$ is no greater than that of the gum rubber, because there is little breakdown of the network. With increasing strain amplitude, $\tan \delta$ increases, as interaggregate bonds are broken and then re-formed in new positions. Tan δ reaches a maximum at approximately the midpoint of the decrease in G', and thereafter decreases somewhat, though not nearly to that of the gum rubber. Note that in comparing different compounds, H is proportional to $\tan \delta$ when the compounds are cycled at the same energy input, such as in a rebound experiment or (approximately) in tire treads; under equal strain conditions, H is proportional to G'', while under equal stress conditions, H is approximately proportional to $(\tan \delta)/G'$.

As may be expected, $\tan \delta$ is a function of $\Delta G'$. Under comparable mixing conditions, $\tan \delta$ has been found to be a linear function of a loading–interfacial area parameter, $\phi\psi$, where ψ is the interfacial area; thus $\phi\psi = \rho S\phi^2$, where ρ is the density of carbon black (1.85) and S is the specific surface area. A theoretical explanation for the relation between $\Delta G'$ and $\phi\psi$ has been derived by Kraus and subsequently refined (Ulmer 1996), on the basis of the kinetics of breakdown and re-formation of aggregate contacts, assuming that each such act dissipates energy.

In order to reduce rolling resistance, new elastomers have been developed in which the polymer chains are terminated by functional groups which can attach to the carbon black surface and thus impart better separation dispersion (Ulmer *et al.* 1998).

3.4 Stress–Strain Behavior: Stress Softening

A common test for mechanical properties is the uniaxial extension of a dumb-bell shaped specimen at a constant rate of strain to its breaking point. In comparison with the gum rubber, the initial slope of the stress–strain curve of a reinforced compound is much higher, owing to the hydrodynamic effect and to the filler network.

As the sample is stretched, the network is broken, but strain amplification contributes to a rapid rise in stress. Strain amplification refers to the increased strain on the rubber molecules linking rigid filler particles (aggregates). At very high strains, typically around 300% elongation ($\varepsilon = 4$), the rate of increase of stress starts to diminish, owing to several factors including polymer chain breakage, dewetting of the polymer from the filler–polymer interface, and slippage of the rubber molecules along the interface, until finally the specimen breaks. The stress at 300% elongation, based on the initial, cross-sectional area, is referred to as the 300% modulus (σ_{300}) and is widely used as a measure of stiffness while the stress at break, based similarly, is the tensile strength and is often taken as a practical measure of reinforcement. The 300% modulus depends on structure (compare N326, N330, and N347 in Table 1); the low modulus of the low-area black (N650) may be due to dewetting or molecular slippage, or to decreased shielding of the occluded rubber in the larger void spaces of this larger particle-size black.

If a filled rubber is stretched to a certain strain ε_1, then retracted to zero strain, then stretched again, the second stress–strain curve lies below the first one, but rejoins it at ε_1. Subsequent stress–strain cycles are progressively lower but to a much lesser degree. The mechanism of this stress softening or Mullins effect is not fully understood but may involve the same factors involved at higher extensions, or it may be due primarily to incomplete elastic recovery of the polymer, enhanced by strain amplification.

3.5 Ultimate Properties

The tensile strength depends on the surface area of the carbon black (compare N234, N347, and N650 in Table 1, the dependence being greater in SBR than in NR where self-reinforcing crystallites develop on stretching. (Note that in wear of tires the strain rates and temperatures are so high that crystallization cannot occur, thus reinforcement by carbon black is as important with NR as with noncrystallizing rubbers.) Tensile strength and elongation-at-break also depend on effective loading (i.e., volume fraction of

Table 1
Stress–strain properties of vulcanizates with various carbon blacks at 50 phr loading.

Carbon black	Surface area[a]	DBPA	Natural rubber			SBR-1500		
			300% Modulus	Tensile strength (MPa)	Elongation-at-break (%)	300% Modulus	Tensile strength (MPa)	Elongation-at-break (%)
N234	117	125	15.8	25.9	480	19.2	28.1	405
N330	80	102	14.4	25.2	520	17.7	26.9	435
N326	86	72	11.2	28.0	580	15.0	27.6	485
N347	86	124	16.3	25.2	480	20.1	26.9	420
N650	37	122	14.4	22.4	475	16.3	22.1	450

[a] By CTAB adsorption.

carbon black plus occluded rubber), going through a maximum at 50 phr of a low-structure black (N326), while higher structure blacks are to the right of the maximum of both properties at this loading.

Despite decades of research there is no generally accepted theory for the effect of carbon black on ultimate properties. Specimen breakage (tensile strength) occurs by propagation of an adventitious flaw or crack, generally at the edge of the specimen, and thus is related to fatigue crack growth, which can be measured separately but with much greater experimental difficulty (Young 1990). One school of thought focuses on dissipation of strain energy by the above-mentioned processes, including stress softening, thus leaving less energy available for the creation of new surface (Hamed 1994). However, studies of rubber tearing have shown that when tear deviation is prevented, strengthening by carbon black is relatively small. This and other evidence has led the author to conclude that reinforcement is due to formation of strands of carbon black aggregates on stretching, which act as barriers to tear propagation (Medalia and Kraus 1994).

Wear resistance is of vital importance in many applications, especially tire treads. The principal mechanisms involved in wear of rubber are abrasive wear and pattern abrasion. In abrasive wear, sharp asperities make scratches in the direction of abrasion and dig out the rubber while in pattern abrasion, adhesion of blunt asperities forms ridges normal to the direction of abrasion which are continually torn off. Abrasive wear resembles wear of plastics and is favored by high hardness of the rubber compound, while pattern abrasion, which is unique to rubber compounds, predominates with softer compounds (Veith 1992). Some widely used test machines favor one type of wear, some another type. Actual driving conditions may involve a mix of mechanisms, including mechanochemical degradation (see *Elastomers in Oxygen and Ozone, Degradation of*[#]); thus results from abrasion test machines are generally not considered reliable predictors of tire wear, which instead

is evaluated by actual road tests, although because of the different mechanisms involved these do not always correlate well with each other. In a general way it is well established that a high-surface area ("reinforcing") black is essential for good wear. The effects of structure and loading are complicated by the large effect of these variables on hardness, which is related to modulus, and thus to the predominant abrasion mechanism. Considerable effort has gone into development of carbon blacks with modifications in secondary characteristics such as aggregate morphology, aggregate size distribution, and surface activity (*vide infra*) in order to obtain some improvement in roadwear or in the balance of roadwear with other properties.

3.6 Comparison of Silica with Carbon Black

Precipitated silica, owing to its high coverage of silanol groups, interacts less strongly than carbon black with hydrocarbon rubbers, and forms stronger interaggregate bonds (network) and (Wolff and Wang 1992). This leads to higher hysteresis which does not set in until higher strain amplitudes. At high elongations silica compounds have low modulus, presumably due to slippage or detachment of rubber molecules. This slippage is beneficial in some applications, such as in imparting resistance to cutting and chipping of off-the-road tires.

The situation can be completely reversed by addition of a coupling agent which bonds the rubber to the silica. A widely used coupling agent is bis(3-[triethoxysilyl]-propyl)tetrasulfide, which reacts chemically via the triethoxysilyl groups with the silanol groups of the silica surface, and attaches to the elastomer molecules by way of the sulfide groups during vulcanization. Silica compounds with this coupling agent have *lower* hysteresis than carbon black compounds as well as high tensile strength and 300% modulus. With development of improved grades of silica, a good balance of tire tread

properties can be attained (Rauline 1990), which may be sufficient to compensate for the drawbacks of these systems such as high cost of coupling agent, high Mooney viscosity of the uncured compound, more sensitive curing systems, and low electrical conductivity (requiring addition of a conductive carbon black in tire treads).

4. Rubber–Filler Interaction

When carbon black is mixed into rubber some of the rubber becomes bonded to the filler. The bonding has been variously attributed to physical adsorption, to chemisorption, to free radical reactions of broken elastomer chains with active sites on the carbon black surface or with fractured carbon black aggregates, or to ionic reactions (with butyl rubber). In a good solvent the unbonded rubber can be extracted, while the bonded or so-called bound rubber and filler form a coherent mass which swells considerably but does not dissolve (at room temperature). (However, most of the bound rubber can be extracted at elevated temperatures, strongly supporting the physical adsorption mechanism (Wolff and Wang 1992), with a range of adsorption energies.) The amount of bound rubber has been used as a measure of filler "activity"; however, only small differences are found in specific activity, or bound rubber per unit surface area. The amount of bound rubber increases with surface area and (to a small extent) with structure, thus for a given type of filler it correlates with the degree of reinforcement.

Precipitated silica gives considerably less bound rubber than a carbon black of similar surface area (e.g., 32% vs. 52%, with natural rubber at 50 phr loading). With graphitized carbon black, in which surface imperfections and (to a large extent) layer edges have been removed by heating to 2700 °C, the amount of bound rubber is very small (<5%). The mechanical behavior with a graphitized black is similar to that with silica: low 300% modulus, high elongation-to-break, and fairly high tensile strength (23.4 MPa vs. 26.2 MPa) for the ungraphitized black (Medalia and Kraus 1994). Formation of bound rubber is especially important with butyl rubber, where it is actually facilitated by oxygen groups on the carbon black surface.

The polymer adjacent to the carbon black surface is to some extent immobilized, as shown by NMR measurements. Severe restriction of motion is confined to a layer ~ 0.5 nm thick, while a further layer estimated at 3 nm is affected to a lesser extent; thus T_g (glass transition temperature) of the compound is raised by no more than 2–3 °C. The immobilized rubber must not be confused with *bound* rubber, since the long-chain molecules of the latter extend from the filler surface (where the bonded segments are immobilized) far into the polymer matrix, where they are unaffected by the filler surface.

5. Summary

Reinforcement is necessary for the applications, including tires, in which most rubber is used. Carbon black is the pre-eminent reinforcing agent, but precipitated silica is of increasing importance. Reinforcing fillers increase the elastic modulus by a hydrodynamic effect, in which the filler volume is increased by rubber occluded within the filler, and (at low strain amplitude) by a filler network. Breakdown and re-formation of this network on strain cycling is a hysteretic process which causes conversion of mechanical energy to heat. Improvement of ultimate properties (e.g., tensile strength, wear of tires) is an important aspect of reinforcement which is still poorly understood and thus represents a challenge for future research.

Electronic Packaging: Conductive Adhesives

Electrically conductive adhesives perform two main functions. Like other adhesives, these materials provide a mechanical bond between two surfaces. In addition, they electrically interconnect the two bonded surfaces. This dual functionality is achieved by incorporating electrically conductive particles into a dielectric adhesive matrix. Conductive adhesives are used in electronic packaging applications when constraints such as process temperatures, stress levels, metallization options, contact pad pitch, or cost require an alternative to soldered interconnections.

1. Types of Conductive Adhesives

There are two principal types of conductive adhesives that are discussed in this article: isotropically conductive adhesives (ICAs), which conduct electricity uniformly in all directions, and anisotropically conductive adhesives (ACAs), which conduct electricity only in one direction (i.e., the direction perpendicular to the bond line). Conductive adhesives are the subject of many conferences (e.g., IEEE 1998) and publications. For a thorough review of conductive adhesives the reader is referred to Liu (1999).

1.1 ICAs

ICAs are prepared by the addition of conductive particles such that chains of particle-to-particle contacts span the material in all directions. For most common applications epoxies containing approximately 30 vol.% silver flakes are used which exhibit electrical conductivities of $1 \times 10^{-4}\,\Omega\,\mathrm{cm}$.

Increasing the concentration of metal particles in an insulating adhesive matrix changes the electrical properties of the composite in a discontinuous way. As the particle concentration begins to increase no significant bulk change occurs, because the particles are isolated from one another within the dielectric. Higher concentrations lead to the formation of agglomerates such that electrical conduction becomes statistically probable over a distance defined as the short-range percolation coherence length, ξ. At a critical concentration, called the percolation threshold (p_c), $\xi \to \infty$ and the composite becomes isotropically conductive.

The concentration of metal particles required to achieve p_c depends primarily upon the particle shape or aspect ratio (Bigg 1986). Increasing the aspect ratio from 1 (for spherical particles) to over 700 (for stainless steel fibers) decreases the percolation threshold from 38 vol.% to 1 vol.%. Other factors, such as the particle size distribution and material fabrication and processing techniques, can also have a significant

impact (Lyons 1991). Most ICAs employ metal particles in flake form. The relatively high aspect ratio of flakes reduces p_c, which permits the formulation of adhesives with good rheological properties. Other techniques for exceeding p_c at low metal concentrations include the use of metal particles that are significantly smaller than discrete adhesive particles. In this way, the metal particles are segregated into the boundaries between adhesive domains.

The electrical conductivity of some ICAs develops only after the adhesives are thermally cured, even though the concentration of silver flake is above p_c. This is owing to the presence of a fatty acid coating applied to the silver surface during flake manufacture. Cure at elevated temperatures and/or the presence of reactive diluents removes the coating from the metal surfaces and renders the adhesive conductive (Opila and Sinclair 1985, Lovinger 1979).

1.2 ACAs

The conductivity of ACA materials is restricted to the Z-direction (perpendicular to the plane of the board) while electrical isolation is maintained in the X–Y plane. In general, ACA materials are prepared by dispersing electrically conductive particles in an adhesive matrix at a concentration far below the percolation threshold. The concentration of particles is controlled such that enough particles are present to assure multiple electrical contacts between the assembled parts in the Z-direction while too few particles are present to achieve conduction via percolation in the X–Y plane. Because of the anisotropy, ACAs may be deposited over the entire contact region, greatly facilitating material application and increasing overall bond strength. These attributes make ACAs especially useful for fine-pitch electrical interconnections.

The most commercially significant ACAs are based on the single-particle bridging concept. Interconnections with pitches below $50\,\mu\mathrm{m}$ have been demonstrated with these materials. Figure 1 illustrates the principle of interconnections based on this technique. An ACA is applied to the substrate, covering an array of contact pads. After deposition, a component is aligned to the substrate and placed into the adhesive. Pressure and heat are applied simultaneously such that excess adhesive is displaced and single conductive particles are trapped between the substrate and component contact pads forming multiple discrete electrical interconnections. Shrinkage of the adhesive during cure, contraction of the adhesive during cooling, and robust adhesion at all surfaces maintain the compressive load on the particle–contact metallization interface that is essential for reliable electrical contacts. Spherical particles (aspect ratio = 1) are used to lower the probability of conduction in the X–Y plane. The use of narrow particle size distributions
Figure 1
Schematic illustration of the ACA assembly process. Application of heat and pressure displaces excess adhesive to create redundant single-particle electrical interconnections in the Z-direction.

Figure 2
Scanning electron micrographs of ACA interconnections between silicon chips and flex circuits. (b) Soft, nickel- and gold-plated polymer particle is plastically deformed between chip and flex circuit increasing the particle contact area.

also reduces the probability of percolation in this direction at a given concentration (Lyons 1991).

Many adaptations of this basic approach have been developed to form ACA interconnections at fine (50 μm) pitches. Usually these approaches strive to minimize conduction in the X–Y plane. Detailed discussions of these, and other, processes are reviewed elsewhere (Liu 1999); a brief description of four techniques is presented here. In some methods, aligning metal particles in a magnetic or electric field enhances anisotropy and permits higher particle loadings. Other methods coat the conductive particles with a thin polymer dielectric layer. The coating fractures only when it is compressed between two contact surfaces, rendering the particle surface conductive. Some adhesive films have been developed with two layers of adhesive. One layer, containing the conductive particles, has a relatively high viscosity that constrains the ability of the particles to flow and form shorts. The second layer, which contains no particles, flows easily and fills voids. Another approach to fine-pitch interconnections deposits particles only on top of contact pads. This localization occurs through either selective deposition of an ACA, or photodefinition of a tacky adhesive layer on the pads, followed by adhering the particles to these tacky regions.

(*a*) *Conductive particle types for ACAs.* The type of particle incorporated into an ACA significantly impacts on the conductivity and reliability of the electrical interconnection. Three classes of particles, all of which are spherical in shape, are commonly used: rigid, compliant, and alloy particles, each of which is discussed separately. Contact theory (Holm 1967) provides a basis for understanding the electrical interconnection at the particle–contact metallization interface as individual particles can be considered to be asperities in Holm's model.

Rigid particles are fabricated from pure metals (e.g., silver), plated metals (e.g., silver-plated nickel), or metal-plated glass spheres. Particle selection depends on conductivity requirements and cost. During the assembly process sufficient pressure is applied so
that particles penetrate into the contact surfaces forming intimate metal-to-metal contacts, as shown in Fig. 2(a). Plastic deformation occurs to a greater degree with softer contact metallizations.

Although they form stable interconnections, rigid particles can pose implementation problems. Some particulate materials with very broad particle size distributions contain numerous smaller particles that cannot form single-particle bridges. These "fines" may give rise to unintended conduction via percolation in the X–Y plane. Small concentrations of large, hard particles focus the force applied during assembly, resulting in excessive pressures that can crack brittle components.

Compliant particles are widely used as conductive fillers for ACAs and are typically composed of gold- and nickel-plated polymer spheres. During assembly, sufficient pressure is applied such that the particles themselves plastically deform and make contact over an area comparable to their initial diameter. An example of a deformed plated particle is shown in Fig. 2(b). As the size distribution of these particles is typically very narrow, with a range of sizes $<5\%$, most particles trapped between chip and substrate participate in the electrical interconnection to the same extent. The total force applied to an ACA joint, the number of contact pads (bumps), and the concentration of particles in the adhesive determine the

amount of particle compression. Interconnect resistance and stability can be optimized by controlling the amount of compression (Shiozawa *et al.* 1995). The most stable values, for interconnections tested at 85 °C and 85% relative humidity, are reported for 40% particle compression levels. Higher compression levels can lead to cracking and reliability problems.

Factors affecting the resistance of interconnections formed with compliant particles are similar to those for rigid particles and include the number of particles, the contact area of each particle, the resistance of the particles, and the presence of surface oxides or other contaminants.

Solder particles form metallurgical bonds to both the substrate and component metallizations. This mechanism eliminates the need for the polymer adhesive to maintain the particles under a compressive load. The quality of the bond depends strongly on the interaction between the filler particles and the component and substrate metallurgies.

Savolainen and Kivilahti have reported much of the work on flip-chip interconnections with solder-filled ACAs (Kivilahti and Savolainen 1995, Savolainen and Kivilahti 1995). They found that the metallurgy of both the solder particles and the contact metals must be carefully chosen to avoid the formation of a brittle intermetallic layer within the joint. To circumvent this problem, they developed a transient melting technique using SnBi particles and tin or SnPb contact surfaces. Bismuth diffuses into the tin surfaces until the melting temperature of the progressively tin-rich particles increases and the particles solidify at the bonding temperature.

Contact resistance values are low owing to the large particle diameters that result from applying pressure to the soft solder particles. Oxides on the solder particle, chip, or substrate metallizations can prevent solder wetting and thus significantly increase resistance values. It is found, however, that no added flux is necessary to achieve good solder particle–surface wetting (Kivilahti and Savolainen 1995, Savolainen and Kivilahti 1995). Other studies have found the addition of flux to be advantageous (Pennisi *et al.* 1992).

2. Adhesive Matrices

The intimate particle–substrate contacts formed during assembly are maintained in the final interconnection by curing the adhesive. The adhesive serves several functions including: (i) bonding a component to the substrate through chemical and/or physical processes, (ii) protecting the exposed surfaces from environmental degradation, and (iii) maintaining continuous contact force at the particle–contact metallization interface. The higher coefficient of thermal expansion (CTE) of the adhesive matrix, compared to that of the particles, exerts a load on the contacts

after cooling the assembly to ambient temperature (Lai and Liu 1996). Shrinkage of the adhesive during cure provides additional compressive forces on the particle contacts. Creep of the matrix would relax these loads. This explains, in part, why thermosetting matrices, which are less susceptible to creep owing to their high cross-link density, outperform thermoplastic-based conductive adhesives.

Two basic types of adhesives are used to formulate both ICAs and ACAs: thermoplastic and thermosetting. Thermoplastic adhesives are high molecular weight molecules that are rigid at temperatures below the glass transition temperature (T_g) of the polymer. Above this temperature, polymer flow can occur. When using this type of material, assembly temperatures must exceed T_g to achieve good adhesion. Thus, T_g must be sufficiently high to avoid polymer flow during use conditions, but must be low enough to prevent thermal damage to the electronic circuits during assembly. The principal advantage of thermoplastic adhesives is the relative ease with which the interconnection can be disassembled for repair operations. Block copolymers, such as styrene–butadiene–styrene have been used as the adhesive matrix. Newer systems employ linear polymers that can be cross-linked, improving performance.

Thermosetting adhesives are applied as mixtures of a curing agent with unreacted monomers of relatively low viscosity. Curing the mixture, typically with heat, causes a chemical reaction between curing agent and resin to form a three-dimensional cross-linked molecular network with a high T_g. Epoxies are the most widely used matrices for thermosetting adhesives owing to their ability to form robust adhesive bonds to a variety of surfaces over a wide range of environmental conditions. Details concerning the chemical formulation of conductive adhesives are reviewed elsewhere (Lyons and Dahringer 1994). Their tenacious properties can interfere with disassembly and interconnection repair steps.

Regardless of the type of adhesive matrix used, good adhesion is essential. This requires clean surfaces that can form chemical interactions with the adhesive. In addition, thorough wetting of the surfaces by the adhesive is required.

3. Assembly

The different conduction mechanisms of ICAs and ACAs mandate very different approaches to using these materials. ICAs require no external application of pressure during cure; however, the material must be placed only where needed. ACAs do require the simultaneous application of pressure during cure, but they may be applied over the entire surface to be bonded without creating unwanted short circuits.

Conductive adhesives come in two forms, films and pastes, regardless of the conduction mechanism

involved. Films are formed from polymers or resins that are solid at room temperature. Using liquid polymers, solvents, and/or elevated temperatures, a mixture of the adhesive system with conductive particles is spread onto a sheet, then dried, partially reacted, or cooled to form a freestanding film. Pastes are typically manufactured with low-viscosity thermosetting adhesive systems. Solvents are avoided in all adhesive systems as voids form during volatilization.

Assembly issues for the two classes of conductive adhesives are discussed separately.

3.1 ICA Assembly

The first step in assembling components with ICAs is dispensing the adhesive in the correct location. Commonly used techniques include syringe dispensing, stencil and screen printing, and dipping. Film adhesives are used for larger bond areas and employ manual or mechanical placement tools.

Syringe dispensing is the most commonly used method for die attach adhesives. An array of needles creates a specific pattern of adhesive on the substrate (lead frame). The adhesive pattern is designed to minimize the entrapment of air when the die is placed into the adhesive. Automated equipment controls the dispense time and pressure resulting in reproducible adhesive volumes.

Stencil and screen printing processes are best suited for assembly processes occurring over large areas. For example, surface mount assembly of components on flex or rigid PWBs is best accomplished with stencil printing an ICA as large numbers of adhesive dots of various sizes can be easily and reproducibly accommodated. Screen printing of circuit patterns on flexible PWBs with ICAs formulated as inks (low-viscosity pastes) is another commonly used process.

Interconnection of fine-pitch components with ICAs imposes severe tolerances on all application processes. The volume of adhesive necessary to interconnect very fine-pitch surface mount components is difficult to optimize as the volume required to ensure electrical isolation between adjacent leads may be insufficient to ensure the mechanical integrity of the bond, especially during drop tests (Zwolinski *et al.* 1996).

The use of ICAs for flip-chip interconnections is beginning to gain acceptance. A process developed by Matsushita (Kumano *et al.* 1999) employs ICA-coated stud bumps. Bumps formed with a wire bonder on integrated contact pads ($\lambda = 75\,\mu m \times 75\,\mu m$) are dipped into an ICA paste to a controlled depth. The paste coats the stud bumps and provides sufficient adhesive to comply with any nonplanarity resulting from either inconsistent bump heights or substrate flatness variations. Since the coating volume is low, insufficient adhesive is present to cause any shorting. To create a robust mechanical bond, an underfill

adhesive is required to fill the gap between chip and substrate and adhere to the exposed surfaces.

3.2 ACAs

ACAs are applied using the same methods as those described for ICAs; however, tolerances on the application area are significantly relaxed as the ACA can be applied to the entire interconnection area. This has numerous advantages, especially for fine-pitch interconnections, as sufficient adhesive is present to ensure robust adhesive bonds. Film-based ACAs (ACAFs) require special machines to cut, align, and tack the adhesive onto the substrate. Film thickness must be carefully selected to meet the requirements imposed on the assembly by the height of the contact pads, as well as the conductive particle diameter in the adhesive. Insufficient adhesive results in voids at the bondline whereas excessive adhesive can be difficult to displace thereby preventing particles from contacting the metal surfaces.

All ACA assembly processes require the application of pressure during adhesive cure. Maintaining alignment between component and substrate, while simultaneously applying heat and pressure, presents a challenge to developing a cost-effective assembly process.

For flip-chip bonding the alignment machine is commonly used to perform several functions including alignment of the chip to the substrate, application of sufficient energy to cure the adhesive, and application of pressure uniformly across the chip. Because of the multiple requirements and tight tolerances, machines are expensive to own and maintain. Cure time reduces throughput and significantly increases machine operating costs. This technique is widely used during the manufacture of LCD displays for either interconnecting bare die directly to the glass substrate or for bonding TAB packaged ICs to the glass substrate. The costs of assembling flip-chip interconnections with ACAs have limited the implementation of ACA materials to products with special materials or other constraints. Lower cost and higher throughput assembly processes are required to expand the use of ACA materials to applications beyond interconnections to glass substrates.

A new approach to using ACAs has been described (Lyons *et al.* 1996a, 1996b). In this process, the cure step is shifted from the alignment machine to a batch-curing fixture (BCF) where a conformal silicone bladder applies pressure uniformly to all assemblies. Many types of components, ranging from bare die to SMT packages, can be assembled with ACAs using this approach. A cross-sectional view of the BCF apparatus is shown in Fig. 3. Machines for evaluating the BCF process are commercially available (Fancort Industries, West Caldwell, NJ).
Figure 3
Schematic cross-section of the batch-curing fixture: (a)
after clamping the fixture to create a sealed sample
compartment; (b) after pressurizing the upper chamber,
forcing the bladder into conformal contact with the bare
and packaged ICs.

When implementing the BCF process, the first step
is to apply the ACA to the substrate. A paste adhe-
sive maximizes the throughput of the BCF process
for two reasons. Paste adhesives can be formulated
with specific rheological properties such that compo-
nents placed into an ACA paste are held securely
owing to their "tacky" nature. This eliminates the
need to supply heat to the component in the align-
ment machine. The second reason is that stencil
printing paste is an inherently less expensive process
than cutting, aligning, and tacking film-based adhe-
sives. Film materials can be used but component
tacking in the alignment machine is required.

After printing, components are aligned and placed
into the paste. The populated circuits are transported
from the placement machine to the BCF for cure. The
BCF sample chamber can be designed to accommo-
date single or multiple circuits, depending on sample
size and process flow.

In the BCF, the populated circuits are placed on a
heated plate, as shown in Fig. 3(a), and a stretched
silicone rubber bladder is placed above the circuits
to create a sample chamber. Pressure is initially ap-
plied to the interconnections by first evacuating the
sample chamber (Fig. 3(b)). Ambient pressure
above the bladder forces it into conformal contact
with the populated circuits. Compressed gas (100–
500 psi (6.9×10^5–3.4×10^6 Pa)) is introduced above
the bladder during the cure cycle to ensure inti-
mate particle–metal contact. Pressure can be main-
tained during cooling of the samples and is vented
before opening the BCF and removing the completed
circuits.

The chip-to-flex alignment achieved during the in-
itial placement step is maintained to within $\pm 5\,\mu$m
after final cure. This ability to reproduce closely in-
itial alignment accuracy is achieved, despite trans-
porting the populated circuits from the alignment
machine to the BCF, owing to the tacky nature of the
ACA paste as well as the compliance of the silicone
bladder. The bladder ensures that pressure is uni-
formly transmitted to the silicon chips regardless of
substrate–bladder coplanarity.

The principal advantage of the BCF process is that
it frees the alignment machine to *only* place die. Thus,
throughput in the machine is significantly improved,

approaching the rates achievable for flip-chip solder
interconnections (only the increased alignment accu-
racy slows the machine). Equipment costs are re-
duced, as the machine need not be constructed with
the ability to apply significant pressure levels, and
chip–substrate coplanarity requirements are relaxed.

Assembly considerations for SMT components
are similar to those described for flip-chip processes.
A thorough, step-by-step process description for very
fine-pitch flex to PWB substrates has been published
(Bruner 1995). Throughput is an even greater con-
cern, as placement times for SMT components are
even shorter than those for bare die. A BCF process
for SMT components has been developed to address
these concerns.

4. Reliability of ACA Interconnections

Optimization of materials, processes, and surfaces re-
sults in robust interconnections for both ICAs and
ACAs. The reliability of these conductive adhesive
interconnections depends on the specific formulation,
process, substrate, and component combination. No *a
priori* assumptions can be made, as each system must
be evaluated separately. The reliability of conductive
adhesive interconnections has been thoroughly doc-
umented for significant applications including die
attach (ICAs) and LCD assemblies (ACAs). As ex-
perience with these relatively new materials broadens,
and as fine-pitch requirements increase, the use of
conductive adhesives is expected to grow.

Electronic Packaging: Elastomer Conductive Polymers

Conductive elastomers (CEs) have been used for many years in switches in automobile horns and door open sensors, and automobile ignition wires are made of this material. CEs have found wide use in applications involving dissipation of static electricity. This includes many applications in hospital operating rooms where a spark could ignite highly explosive anesthetics. Automobile and truck tires, especially for vehicles carrying explosives, are made conductive to eliminate sparking. Many integrated circuit (IC) chips can be destroyed by static discharge. To prevent this, CE devices are used to electrically connect the chip leads during shipping and also ground those handling the chips. CEs have been used extensively in electro-magnetic shielding gaskets in military and nonmilitary applications.

CEs are used because of their ability to conform to substrate contours, their ease of fabrication into a wide variety of shapes and forms, and their versatility in electrical and mechanical properties.

1. Composition and Theory

A CE is generally produced by the incorporation of conducting particles in a rubber matrix. Inherently conductive polymers, such as polyacetylene, show promise for future applications, but their lack of stability and processing problems have limited their usefulness.

The conductivity of conductive particle-filled silicone rubbers results from intimate contact and electronic tunneling between particles. As shown in Fig. 1, there is a loading at which the conductivity will increase (resistivity will decrease) very rapidly with a small increase in filler content. This is the result of a process called percolation, in which a continuous chain of particles is required to produce conductivity (Wessling 1986). The conductivity of the filled rubbers varies with the metals used, shape and size of the particles, fabrication techniques, and cure time and temperature. The properties of the elastomer matrix also have a profound influence on the immediate and long-term properties of the material.

1.1 Matrix Composition

The elastomer matrix is generally silicone rubber because of its electrical and physical stability (Buchoff 1973). It maintains its properties over a wide range of temperature, humidity, radiation, and chemical environments. The modulus of a typical dimethyl silicone rubber varies little from $-45\,°C$ to $150\,°C$. It can
Figure 2
Logarithm of the percentage residual stress of a silicone elastomer held at constant strain as a function of logarithm of time at different temperatures.

withstand a temperature of 175 °C continuously and 300 °C for a few hours. Phenyl methyl silicones have the same high-temperature properties but remain flexible below −75 °C. Even when saturated with water, silicone rubbers maintain a volume resistivity greater than $10^{12}\,\Omega\,cm$. They have dielectric constants around 2.8 and very low loss tangents. Hydrocarbons and halogen-containing hydrocarbons cause silicone rubbers to swell, but will not chemically change them. When the solvent is removed from the silicone, the properties of the silicone rubber are the same as they were before solvent exposure.

Particle-filled silicone rubber exhibits classic stress relaxation (Buchoff 1983). That is, when the filled rubber is deflected and held at a constant strain, the stress decays with time as shown in Fig. 2. There is a linear relationship between logarithm of remaining stress and logarithm of time. This allows projection of the remaining contact pressure over a wide range of temperature and time. Extrapolating, this curve shows that, when held at a constant strain, silicone rubber loses only 50% of the original stress in 50 years at 25 °C (77 °F). There is also a linear relationship between logarithm of resistance and logarithm of time as shown in Fig. 3. The rate of this decay—termed relaxation—increases as the temperature increases. When the material is deflected, its volume increases

slightly, separating the particles. Also the particles tend to reorient, perpendicularly to the imposed force. These changes result in a decrease in volume conductivity. Over time, as the elastomer relaxes, the particles move closer together and they gravitate toward their original orientation. Thus, the conductivity increases. Because of the initial higher resistance, it is desirable to wait 15–20 seconds after deflection before imposing a voltage across the material.

1.2 Conductive Fillers

The most widely used conductive fillers are carbon, silver, nickel, stainless steel, and silver-plated copper, graphite, nickel, aluminum, and glass beads. Powder, flakes, beads, and filaments of various sizes and shapes are used (Roos-Kozel and Casavecchia 1984).

The initial conductivity of elastomers containing silver-coated copper is almost as high as those containing pure silver, but at a fraction of the cost of silver. Unfortunately, the copper migrates through the silver layer, where it oxidizes and sharply increases the resistivity. Elevated temperature greatly increases the rate of migration. Silver-coated aluminum particles are more stable than silver-coated copper particles, but they produce a lower conductivity.

355
Figure 3
Logarithm of percentage residual electrical resistance of a metal particle-filled silicone elastomer held at constant strain as a function of logarithm of time at different temperatures.

Carbon filler is employed if a volume resistivity greater than $1\,\Omega\,cm$ is required. Silver and silver-plated particles yield volume resistivities in the range 10^{-4}–$10^{-1}\,\Omega\,cm$.

2. Uses of CEs in Electronic Applications

CEs are used in electronic equipment such as shielding gaskets, pressure transducers, switches, keyboards, test contacts, shorting pads, and thermal coupling. A large and rapidly growing use is in connectors in digital watches, calculators, displays, chip carrier test contacts, military radar, cellular telephones, pagers, medical devices (Galton 1975, Pelt 1989), and space electronic gear (Markstein 1992).

3. Elastomeric Connectors

Elastomeric connectors are zero insertion force devices, i.e., there is no force used to install the connectors but pressure is necessary to establish and maintain electrical contact. A holder usually positions the element(s) and aligns the substrate contact pads (see Fig. 4). Pressure is applied with screws, rivets, headed plastic stubs, C-sections, etc. Often, the required deflection is produced during the assembly of a product (Buchoff 1987).

3.1 Advantages of Elastomeric Connectors

The continued pressure at the elastomer–pad interface effectively seals out moisture and other atmospheric contaminants. Even in highly corrosive environments the elastomer seal prevents the formation of insulating films that would increase resistance. This has been shown in a test in which mated elastomeric connectors are exposed to an atmosphere containing 5 ppm each of hydrogen sulfide, sulfur dioxide, and nitric oxide at $35\,°C\ (95\,°F)$ and 75% relative humidity for a 1000 h. There is no increase in resistance and the copper contact pads touching the connector elements are as shiny as before the test (Buchoff 1974).

Use of elastomeric connectors eliminates the heat of soldering and the necessity of removing flux and other contamination. Also, disassembly and reassembly is greatly simplified, and repair and upgrading of electronic equipment is fast and without damage to other components. Delicate parts, such as liquid crystal displays (LCDs), are shielded from shock and vibration. Also, the range of usable deflection of the elastomeric elements reduces the assembly tolerance requirements.

3.2 Types of Elastomeric Connectors

There are several configurations of elastomeric connectors employing conductive particles (Carlisle 1983).
Figure 4
Elastomeric metal ribbon connector element in a holder.

These include: (i) layered elements, (ii) buttons of conductive rubber molded into holes in plastic supports, (iii) conductive rubber inclusions into a nonconductive elastomeric support, and (iv) sheets of rubber containing metal particles at a concentration too low to produce isotropic conductivity.

(*a*) *Layered elements.* Layered elastomeric elements (LEEs) consist of alternating segments of conductive and nonconductive rubber, as shown in Fig. 5. LEEs are redundant components, i.e., the layers are much narrower than the substrate pads. Several of the conductive layers make contact with each pad regardless of the element position. This eliminates the need to align the conductive elements with the contacts, simplifying installation. The width of the conductive layers is typically 0.062 mm (0.0025 in) and they are on a pitch of 0.125 mm (0.005 in). Reliable contact is made to pads on 0.4 mm (0.016 in) or greater centers. Carbon-filled LEEs with a 0.040 mm (0.0016 in) pitch have been produced.

Carbon LEEs form the contact between the circuit boards and LCDs in the majority of digital watches (Buchoff 1974). The 100–5000 Ω resistance of the carbon-filled LEE is no problem because of the very

Solid or foam silicone for support or insulation

Alternating conductive and non-conductive silicone layers
Figure 5

high internal impedance of the LCDs. Where lower resistance is required the filler is silver. Resistances from 0.01 Ω to 0.5 Ω are common with silver-containing LEEs.
Figure 6
Interposer containing an array of conductive elastomeric button contacts.

(*b*) *Conductive buttons.* Conductive elastomer buttons molded into holes in carrier frames made the contacts in the earliest LCD watches. The frames containing the appropriate holes were molded in glass-filled nylon or glass-filled polyester. Thin Kapton sheets with punched holes also served as carriers. This configuration has also been used to make connections to pads for area matrices, as shown in Fig. 6. Pads having pitches as fine as 0.5 mm (0.020 in) have been connected. Conductive rubber buttons have been molded onto circuit paths, printed wiring boards (PWBs), flat cable, and flexible circuits.

Molded wiring boards containing conductive rubber contact balls have been produced where the hold-downs are molded as part of the board. Locating means for components are also incorporated, making automated assembly possible. Components can be replaced rapidly without disturbing the package.

A device has been developed to connect high I/O microprocessors to PWBs. Columns formed from a flexible conductive polymer material with embedded metallized particles make the contacts (Anonymous 1998).

(*c*) *CEs in nonconductive elastomer bodies.* An area of rapid growth is parts with conductive elastomers molded into nonconductive elastomer bodies (Maurer 1998). In one application, both silver and carbon LEEs are mounted onto a silicone rubber foam piece. The carbon LEE makes connections to a LCD and the silver LEE contacts the LCD heater. In another highly successful application, contacts are made between a PWB and a microphone. A nonconductive elastomer piece containing a CE insert forms the contact. The assembly is made by placing the elastomer part and the microphone into a positioning cavity followed by clamping.

(*d*) *Z-axis elastomeric sheets.* One of the earliest elastomeric connector elements used a silicone rubber sheet containing metal particles below the critical volume (Jin *et al.* 1988). That is, the particles are in too low a concentration to produce isotropic conductivity. When this sheet is sandwiched between two sets of pads, connections are established in the Z-axis between the opposing pads without creating conductive paths to adjacent pads. Z-axis material has been used in switches in automobiles for many years.

When the normally insulating Z-axis material is pressed, a conductive path is produced between two opposing pads. This type of switch has been used widely to sense door closure or activate the horn. It is also used in cameras to trigger camera shutters. The pads can be in a single row or over an area. One of the limitations of this approach is the dependence of the thickness of the sheet on the minimum separation of the pads. Generally electrical isolation between adjacent pads is maintained if the sheet thickness is less than 70% of the pad separation. This requirement leads to thin sheets, necessitating flat mating surfaces and high pressure to ensure low-resistance connections. The performance of this material can be improved by using silver-coated nickel particles that are vertically aligned in a magnetic field during production of the pad.

3.3 Elements Containing Metal Ribbons

In another family of elastomeric connector elements, thin, continuous metal strands run through, on one surface, or around the silicone rubber base (Buchoff 1983). The strands are wires or ribbons. Wires are usually stainless steel or nickel, often gold plated. The ribbons most often used are nickel, gold, or gold on nickel on copper.

Unlike LEEs, the metal traces of ribbon elastomeric elements (REEs) can be positioned accurately. Using REEs with ribbons on one flat surface of the silicone rubber core, contact has been made to pads on 0.1 mm (0.004 in) centers. These flat REEs produce minimum signal distortion at frequencies above 10 GHz when connecting sets of pads in the same plane separated by 0.125 mm (0.005 in). Position, width, and shape of the metal traces can be varied to contact pads on different pitches and/or produce specialized electrical properties. This configuration is used to connect circuit boards to bumped IC chips, circular IC chip probe boards, and high-frequency hybrid circuits.

Connections to medical implants with flat REEs operate well during long-term immersion in saline solution and have been implanted in several patients. This *in vivo* junction will simplify the implementation of advanced medical systems.

In another REE configuration, the metal traces run through the elastomeric body, making contact at the trace ends. The traces form a two-dimensional array as shown in Fig. 7. As there is a multiplicity of conductive paths, higher conductivity contacts are
Figure 7
Elastomeric connector element with metal traces running through the silicone rubber body.

produced. Also, multiple rows of contacts can be made with a single elastomeric element. This type of connector has proved to be highly reliable in a phased array radar system.

In wrap-around REEs, the metal traces encircle the rubber core (see Fig. 4). Contact is established between opposing sets of contact pads when they are pressed against the traces. Generally, as with LEEs, the wrap-around REE makes redundant contact. The traces have been produced on centers ranging from 0.1 mm to 0.5 mm (0.004–0.02 in). Resistance ranges from $0.005\,\Omega$ to $0.05\,\Omega$ depending on the dimensions of the contact pads and composition of the traces.

By changing the material of the core and its shape, clamping pressure can be adjusted from 10 psi to 100 psi (69×10^3–690×10^3 Pa).

4. Future Developments

As electronic packages and components get smaller and the pin counts increase, the use of elastomeric connectors will increase. Portable devices such as cellular telephones, pagers, calculators, computers, and data acquisition terminals will benefit the most. Elastomeric connectors will allow compact military devices to be smaller, have more closely spaced contacts, and be more reliable (Buchoff 1989). Connections will be made directly to chips and chip-scale packages.

Conductive elastomeric elements will simplify, improve, and reduce the cost of test and burn-in fixtures (Buchoff 1980). The majority of test fixtures employ spring-loaded metal pins or cantilevered metal arms. At close contact spacing, the elements in both techniques are fragile and easily damaged and become misaligned. Contacts spaced on 0.1 mm (0.004 in) centers have been successfully probed with metal-on-elastomer elements. When it becomes necessary to replace metal contact elements, the entire socket must be replaced. In contrast to this, individual elastomeric elements are easily replaced without removing the sockets.

New applications will be found such as sensors, switches, and even active devices. CE shapes will be

molded directly onto product cases and PWBs to form gaskets, conductive paths, pressure sensors, sockets, resistors, heaters, current limiters, and other devices. Conductive and nonconductive elastomers will be formed together to make complete assemblies.

Electronic Packaging: Heat Sink Materials

Heat sinks play two key roles in electronic packaging: thermal management and mechanical support. They are used in packages and with printed circuit boards (PCBs). Traditional heat sinks were primarily aluminum, copper, or unalloyed blends of two metals, such as copper/tungsten or copper/molybdenum. Because of the shortcomings of these traditional heat sinks, there has been considerable work on new materials, primarily composites reinforced with fibers

and particles. Advantages of these new materials include high thermal conductivities; low, controllable coefficients of thermal expansion; weight reductions; high strength and stiffness; and availability of net shape fabrication processes. In some cases the new materials are cheaper than the ones they replace.

1. Requirements for Heat Sink Materials

Heat sinks support electronic devices and provide a path for heat dissipation. For larger heat sinks, such as those used with PCBs, strength and stiffness are important properties (PCB heat sinks are also called thermal planes and cold plates). The continuing increase in packaging density has resulted in a need for materials with high thermal conductivities. In addition, to minimize thermal stresses that can cause component or solder failure, it is desirable that packaging materials have coefficients of thermal expansion (CTEs) matching those of the ceramic components, such as substrates and resistors, and semiconductors they support. Further, low density is desirable in many applications, especially transportable systems such as laptops, hand-held telephones, and avionics. Reducing weight also minimizes potentially damaging stresses resulting from shock loads that can occur during shipping and from other causes. Of course, low cost is also a key consideration. Traditional materials used in electronic packaging do not meet all of these requirements. In response to this need, new materials, especially composites, have been, and are continuing to be developed.

A composite material can be defined as two or more materials bonded together (Kelly 1988). Composites are nothing new in electronic packaging. For example, polymer matrix composites (PMCs) in the form of E-glass fiber-reinforced polymer PCBs are well-established packaging materials. Similarly, a variety of particles are added to polymers to reduce CTE and increase thermal conductivity, electrical conductivity, or both. These materials are particle-reinforced PMCs. Composites have been developed that provide unique combinations of properties making them outstanding candidates for heat sinks.

The four key classes of composite materials are PMCs, metal matrix composites (MMCs), ceramic matrix composites (CMCs), and carbon matrix composites (CAMCs), which include carbon/carbon composites (CCCs). PMCs, MMCs, and CCCs are the key composites of interest for thermal management.

Figure 1, which plots thermal conductivity as a function of CTE for a variety of materials used in electronics, illustrates the limitations of traditional packaging materials. In order to minimize thermal stresses in packaging, it is necessary to match the CTEs of semiconductors like silicon and gallium arsenide and ceramics used for substrates, such as alumina, beryllia, and aluminum nitride. These
Figure 1

materials have CTEs in the range of about $3–7 \, \mathrm{ppm K^{-1}}$ (shaded area). Aluminum and copper have good thermal conductivities, but, as Fig. 1 shows, CTEs that are much higher than desired.

Traditional materials with low CTEs include "Kovar," a nickel–iron alloy, and blends of copper and tungsten (Cu–W) or copper and molybdenum (Cu–Mo). Kovar has a low thermal conductivity and a density much higher than that of aluminum. To obtain low-CTE materials with higher thermal conductivities than Kovar, copper is blended with tungsten or molybdenum. Both liquid metal infiltration and powder metallurgy processes are used. As the two constituents are not truly alloyed, these materials can be considered composites. That is, they satisfy the definition of a composite material as two or more materials bonded together. For clarity, materials consisting of two distinct metals bonded together will be referred to as metal/metal composites. The term MMC is reserved for metals reinforced with carbon or ceramic fibers or particles. Table 1, which is based on data from Zweben (1998b), contains more detail about the properties of many of the materials in Fig. 1.

Note that although the thermal conductivities of Cu–W and Cu–Mo are much greater than that of

Table 1
Properties of selected electronic packaging materials.[a]

Reinforcement	Matrix or monolithic material	Thermal conductivity ($W\ m^{-1}\ K^{-1}$)	CTE (ppm K^{-1})	Modulus (GPa)	Specific gravity
	Silicon	150	4.1		2.3
	Alumina	20	6.7	380	3.9
	Aluminum	120	23	69	2.7
	Copper	400	17	117	8.9
	Epoxy	1.7	54	3	1.2

[a] CTEs and thermal conductivities for composites reinforced with continuous fibers are in-plane isotropic values. Fiber volume fractions for MMCs reinforced with continuous fibers are selected to achieve an in-plane CTE of 6.5 ppmK^{-1}.

Kovar, they are in the range of aluminum alloys. Higher values, along with low CTE and density, are desired for many applications.

There are several materials in Fig. 1 that have CTEs in the desired range and significantly higher thermal conductivities than traditional materials: carbon fiber-reinforced copper (C/Cu), carbon fiber-reinforced aluminum (C/Al), diamond particle-reinforced copper ((Diamond)p/Cu), and beryllia particle-reinforced beryllium ((BeO)p/Be). There are a number of other materials that have high thermal conductivities, but which lie outside the shaded area. In addition to silver, aluminum, and copper, they include pyrolitic graphite, carbon/carbon (C/C) composites, carbon fiber-reinforced epoxy (C/Ep) and, of course, diamond.

To compare packaging materials in applications for which both thermal conductivity and density are important, a useful figure of merit is specific thermal conductivity, which is defined as thermal conductivity divided by density (for simplicity, we use specific gravity, which is dimensionless). Materials with high specific thermal conductivities are desirable in weight-critical applications. Figure 2 shows specific thermal conductivity as a function of CTE for packaging materials. As Fig. 2 shows, the specific thermal conductivities of traditional low-CTE packaging materials like Kovar, Cu–W, and Cu–Mo are very low. However, the low densities of many composites, combined with their high thermal conductivities,

enhance their relative position. In fact, the specific thermal conductivities of some composites are more than an order of magnitude greater than those of traditional materials like Kovar, Cu–W, and Cu–Mo.

There is a rule of thumb to the effect that improving a critical property by an order of magnitude produces revolutionary change in a technology. It is not surprising, therefore, that composites are making significant inroads in electronic packaging.

A key advantage of some of the composites is that they can be used with processes that produce parts having the final desired shape (net shape processes) or which require only a small amount of machining (near-net shape processes). Minimizing machining enhances the cost effectiveness of these materials. This is particularly true for silicon carbide particle-reinforced aluminum, often called Al-SiC, which is one of the most important composite packaging materials.

In the following, the key types of reinforcements and composites used for thermal management, significant applications, and future directions are considered.

2. Reinforcements

There are several types of reinforcements used in composite materials: continuous fibers, discontinuous fibers, whiskers (elongated single crystals), and
Figure 2
Specific thermal conductivity (thermal conductivity divided by specific gravity) as a function of thermal expansion for materials used in electronic packaging (reproduced by permission of John Wiley and Sons from "Mechanical Engineers' Handbook," 2nd edn., 1998).

particles. Flakes can be included in the last category. The most important reinforcements for obtaining high thermal conductivity are pitch-based carbon fibers, which are used in continuous and discontinuous forms, and two types of ceramic particles, silicon carbide (SiC) and beryllia (BeO). As a rule, continuous fibers are much more efficient than discontinuous fibers and particles for achieving high thermal conductivity, stiffness, and strength.

Composites reinforced with discontinuous fibers or particles may have processing advantages in some instances. A key characteristic of particle-reinforced materials is that they tend to be isotropic. That is, their properties are the same in all directions. This is not true of materials reinforced with continuous fibers, which are almost always anisotropic, which means that their properties vary with direction.

If a composite is reinforced with discontinuous fibers that are truly randomly oriented, its properties are statistically isotropic. However, virtually all

processes produce some degree of preferred fiber orientation, and there are no strictly isotropic random-fiber composites. However, it is possible, and quite common, to make fiber-reinforced materials with properties that are approximately isotropic in a plane. These materials are called quasi-isotropic or pseudoisotropic materials.

A major advantage of using continuous fibers is that it is possible to vary directional properties significantly. For example, it is possible to produce composites with very high thermal conductivities, stiffnesses, and strengths in a particular direction by orienting a high percentage of fibers along this axis. In some instances, this can make fiber-reinforced composites more efficient than heat pipes for transporting heat over relatively short distances. In addition, solid-state methods of heat transfer are more reliable, and may be cheaper.

The most important types of commercial carbon fibers are made from polyacrylonitrile (PAN) and pitches derived from petroleum and coal. Figure 3 shows how thermal conductivity varies with electrical resistivity for selected metals and carbon fibers. As Fig. 3 shows, there are pitch-based carbon fibers, which are commercially available, with thermal conductivities more than twice that of copper. At the upper end of the spectrum are experimental fibers made by chemical vapor deposition (CVD), which have thermal conductivities in the region of $2000 \, \mathrm{W \, m^{-1} \, K^{-1}}$, five times that of copper.

The most thermally conductive commercial carbon fiber, designated K1100, has a nominal axial thermal conductivity of $1100 \, \mathrm{W \, m^{-1} \, K^{-1}}$ (Fleming *et al.* 1995).

Note that carbon fibers are generally strongly anisotropic, which means that their properties vary with direction. The radial thermal conductivity of thermally conductive pitch-based carbon fibers is at least an order of magnitude lower than the axial. In addition to their high thermal conductivities, pitch-based carbon fibers have other attractive attributes for packaging: elastic moduli as high as 965 GPa, more than an order of magnitude greater than that of aluminum, and very low densities. These reinforcements are used with polymer, metal, and carbon matrices to create light, stiff composites with extremely high thermal conductivities and low, controllable CTEs (Zweben and Schmidt 1989, Miller 1995, Fleming *et al.* 1995).

As previously noted, ceramic particles are used to increase the thermal conductivity and reduce the CTE of polymers. Although these particulate PMCs are significantly more thermally conductive than monolithic resins, their thermal conductivities are still an order of magnitude lower than that of aluminum. Since the early 1980s, however, ceramic particles have been added to metals to achieve the same objectives as for polymers, high thermal conductivity and low CTE, creating MMCs that are used in significant production applications. These composites also have
Figure 3
Thermal conductivity as a function of electrical resistivity for metals and carbon fibers (reproduced by permission of John Wiley and Sons from "Mechanical Engineers' Handbook," 2nd edn., 1998).

much lower densities than traditional low-CTE metallic materials used in packaging (Thaw *et al.* 1987, Zweben 1998a, Occhionero *et al.* 1999).

As mentioned above, the two key materials used as particulate reinforcements are silicon carbide and beryllia. Diamond particles also have been used to reinforce metals on an experimental basis (Zweben 1998). Because of the difficulty of measuring the thermal conductivity of particles, it is common to assume that they have values similar to those for bulk materials. However, there are considerable differences in published thermal conductivities for ceramics. In general, transport properties, like thermal conductivity, are more difficult to measure than bulk properties such as modulus.

3. Composite Heat Sink Materials

As discussed above, there are three key classes of composite materials used in electronic packaging thermal management: PMCs, MMCs, and CCCs.

3.1 PMCs

Polymers reinforced with continuous pitch-based carbon fibers have the highest thermal conductivity of all commercial PMCs. Table 1 gives the in-plane properties of quasi-isotropic epoxy-matrix composites reinforced with continuous K1100 fibers. Composite properties depend strongly on reinforcement content.

The fiber volume fraction here is 0.60. The in-plane thermal conductivity and elastic modulus of this composite are much higher than those of aluminum, and its density is much lower. The specific thermal conductivity of this composite is greater than that of copper. Note that the in-plane CTE is negative. In fact, most commercial carbon fibers have negative CTEs. Although the CTE of this composite does not fall in the desired range of 3–7 ppm K^{-1}, it is much closer than those of aluminum and copper.

Note that a K1100 carbon fiber-reinforced PMC with a fiber volume fraction of 0.6 having all fibers oriented in the same direction, which is called a unidirectional composite, would have a nominal axial thermal conductivity of 660 $Wm^{-1}K^{-1}$, over 150% greater than that of copper (about 400 $Wm^{-1}K^{-1}$).

Although continuous fibers offer the best properties, PMCs reinforced with discontinuous fibers can be used with relatively inexpensive net shape processes such as injection molding (Fleming *et al.* 1995). Table 1 gives representative properties of a composite with discontinuous K1100 fibers. Note that both thermal conductivity and elastic modulus are much lower than for composites reinforced with continuous fibers.

3.2 MMCs

The key electronic packaging MMCs are silicon carbide particle-reinforced aluminum (often called Al-SiC),

beryllia particle-reinforced beryllium, and carbon fiber-reinforced aluminum (Zweben 1998a). Table 1 lists properties of these materials.

A number of other MMCs have been developed, including beryllium–aluminum, "Invar"–silver ("Silvar"), and "Invar"–copper ("Cuvar"). A commercially available material consisting of 60% aluminum and 40% silicon also has been used for packaging. This material can be considered a type of particulate MMC, because of the low mutual solubility of silicon and aluminum at room temperature. A family of Al–Si materials with higher levels of silicon has been made by a powder spray process (Zweben 1998a). One formulation has a CTE in the desired range.

Perhaps the most successful of the newer MMCs is Al-SiC, which was first used in packaging in the 1980s (Thaw *et al*. 1987). Figure 4 shows how the CTE of Al-SiC varies with particle content. For particle volume fractions in the region of 0.7 it is possible to match the CTE of silicon. That, and its low density and net shape fabrication capability, have led to rapidly increasing use of this material (Occhionero *et al*. 1999, Zweben 1992, 1998a). Carbon fiber-reinforced aluminum also has been used in a limited number of highly specialized applications, such as spacecraft heat sinks and radiator panels.

Beryllia particle-reinforced beryllium also is used in commercial applications, although not as widely as Al-SiC because of its higher cost (Zweben 1998a).

Like common laminated metals used in electronic packaging, such as copper–"Invar"–copper and copper–molybdenum–copper, MMCs reinforced with continuous fibers may display significant hysteresis when subjected to large thermal excursions or mechanical stresses (Zweben 1989).

Other MMCs with high thermal conductivities are made by infiltrating porous CCCs with aluminum or copper. For copper matrix composites reinforced with highly oriented, thermally conductive carbonaceous fibrous materials, such as "ThermalGraph," axial thermal conductivities as high as $890\,Wm^{-1}K^{-1}$ have been reported (Miller 1995).

3.3 CCCs

There are a large number of materials that fall in this category, including "ThermalGraph," mentioned above. CCCs made from a pitch-based carbon fiber, P120, which has a nominal axial thermal conductivity of about $600\,Wm^{-1}K^{-1}$, are reported to have an in-plane isotropic thermal conductivity of $250\,Wm^{-1}K^{-1}$
Figure 4
CTE as a function of particle content for silicon carbide particle-reinforced aluminum (reproduced by permission of John Wiley and Sons from "Mechanical Engineers' Handbook," 2nd edn., 1998).

(Miller 1995). This, combined with a specific gravity of only 1.85, makes CCCs very attractive thermal control materials for weight-sensitive applications (Shih 1994).

4. Pyrolitic Graphite

As shown in Figs. 1 and 2, some forms of pyrolitic graphite, a monolithic material, can have very high in-plane thermal conductivity (values of $1200\,\mathrm{Wm^{-1}\,K^{-1}}$ are reported), combined with a relatively low specific gravity of 2.5 (Montesano 1996). However, this material is highly anisotropic, and the through-thickness conductivity is only about $25\,\mathrm{Wm^{-1}\,K^{-1}}$. Pyrolitic graphite is used in a form in which it is encapsulated with materials such as aluminum, copper, beryllium, "Kovar," and two composites, Al-SiC and C/Ep.

5. Applications

Advanced materials, especially composites, are now being used in a significant and increasing number of commercial and aerospace electronic packaging thermal management applications. Components include carriers; complex hermetic microwave packages (also called modules); power semiconductor packages; solid and liquid-cooled, flow-through PCB heat sinks; heat sink lids for central processor units; thermal straps; enclosures; and support structures. Pyrolitic graphite is also used in heat sink applications.

The components cited above are used in numerous commercial and aerospace products, including electric and hybrid vehicles; motor controllers; cellular telephone ground stations; laptop computers; and aircraft and spacecraft microwave and power supply subsystems. In addition, composites are key materials in developmental integrated multifunctional structural/electronic systems.

6. Summary

It is a virtual certainty that packaging density will continue to increase, and with it the need for continuing improvements in thermal management. This will require a variety of solutions, including use of heat pipes and active fluid cooling. However, it is unlikely that the latter two approaches will solve all thermal management problems. Further, a passive solution, such as use of materials with improved thermal conductivities, simplifies thermal management, improves reliability, and may reduce cost. In addition, use of active cooling and heat pipes does not eliminate the issue of thermal stresses resulting from thermal expansion mismatch.

Another important trend is the continuing competition to reduce the weight of transportable systems, such as laptop computers and hand-held devices such

as personal digital assistants and cellular telephones. In addition to these commercial products, the drive to reduce weight in electronics used in aircraft, spacecraft, and even shipboard applications is likely to continue.

Based on these facts, it seems likely that there will continue to be a need for improved materials having high thermal conductivities and low, controllable CTEs. In addition, there is a need for low-density materials in many applications.

It is clear that we are in the early stages of an important new materials technology. In the future, it is reasonable to expect continuing development of improved and new reinforcements, matrix materials, material systems, and manufacturing processes. Based on past experience, it is likely that increasing material production volumes and improved processes will reduce costs, making composites and other advanced packaging materials more competitive. For example, carbon fibers sold for US$500 kg^{-1} when they were first introduced commercially in the early 1970s. It is now possible to buy commercial structural-grade fibers for as little as US$4 kg^{-1}. Further price reductions appear likely as production volume increases.

Fatigue of Particle Reinforced Materials

The combination of a light metal (such as aluminum or magnesium) and a high-modulus reinforcement (typically a ceramic such as SiC or Al_2O_3) results in improved strength and stiffness over conventional light metallic alloys, while providing weight savings and allowing higher operating temperatures (Clyne and Withers 1993, Chawla 1997). Much of the driving force for engineering such metal matrix composites (MMCs) has been that monolithic lightweight alloys have inadequate fatigue resistance for many demanding applications. The use of a high-stiffness ceramic reinforcement in particulate form, such as SiC, can result in a substantial increase in fatigue resistance while maintaining cost at an acceptable level (Chawla and Shen 2001). This is an important design criterion in many applications, e.g., in automotive components. An example of an application where a lightweight, fatigue-resistant component is required is the connecting rod in passenger cars. The fatigue resistance of particulate MMCs depends on a variety of factors, including reinforcement particle volume fraction, particle size, matrix microstructure, the presence of inclusions or defects that arise from processing, and testing environment. The effect these factors have on the fatigue behavior of particle reinforced MMCs is summarized in this article (see also *Composite Materials, Overview*[#]).

1. Strengthening in MMCs

In general, strengthening in MMCs can be classified into direct and indirect strengthening. When a load is applied to a particulate composite, the load is transferred from the soft metallic matrix to the stiff ceramic reinforcement. This classical composite strengthening is an example of direct strengthening. The strength of the composite may also be enhanced by the influence reinforcement may have on matrix microstructure or deformation mode. For example, on cooling, there is a thermal mismatch between the low-expansion ceramic and the high-expansion metal. This thermal mismatch between the reinforcement and the matrix can result in the introduction of additional dislocations that strengthen the metal matrix. This is termed "indirect" strengthening, because the addition of the reinforcement indirectly strengthens the matrix of the composite. The indirect effect may be enhanced in precipitation hardened aluminum alloys where precipitate nucleation during aging takes place at dislocations. Thus, the intrinsic properties and microstructure of the matrix material in the composite may be significantly different from those of the unreinforced alloy.

2. Effect of Volume Fraction and Particle Size

Increasing the volume fraction and decreasing the particle size of the reinforcement both result in enhanced fatigue resistance, from a combination of direct and indirect strengthening. In the composite, most of the load is carried by the high-modulus, high-strength reinforcement, so for a given stress the composite undergoes a lower strain than the unreinforced alloy. Thus, the fatigue lives of particle-reinforced MMCs are generally longer than those of unreinforced metals. This is shown for a 2080 (Al–Cu–Mg) matrix composite reinforced with SiC particles in Fig. 1. These improvements are most pronounced at lower stresses, in the high cycle fatigue regime, while at high stress the differences between reinforced and unreinforced materials are reduced. With decreasing particle size, for a given reinforcement volume fraction, the reinforcement interparticle spacing decreases, resulting in more barriers for the reversible slip motion that takes place during fatigue, and a decrease in strain localization by cyclic slip refinement. Above a critical particle size, reinforcement fracture is predominant and contributes to premature fatigue life, because of the increased propensity for particle cracking as the particle size increases. Narrowing of the particle size range distribution also results in higher fatigue life, particularly when eliminating larger particles that are more prone to cracking.
Figure 1
Effect of reinforcement volume fraction (5 μm SiC particle size) on fatigue life of a 2080/SiC$_p$ composite (Chawla *et al*. 1998). Increasing volume fraction of the reinforcement results in enhanced fatigue resistance.

---

3. Effect of Matrix Microstructure

In addition to particle reinforcement, the matrix microstructure also significantly influences the fatigue behavior of the composite. Factors affecting the matrix microstructure include size, shape, and spacing of precipitates, grain size, and nonreinforcement dispersoids or inclusions (such as iron-rich inclusions that are formed during processing). The effect of grain size has not been explicitly examined, but composites follow the same trend as monolithic materials, i.e., for a given matrix alloy composition and volume fraction of reinforcement, finer grain sizes generally result in improved properties.

Contrary to conventional wisdom for monolithic materials, in MMCs high matrix yield and ultimate tensile strength do not necessarily reflect high fatigue strength (defined here as fatigue runout at 10^7 cycles). There is no significant difference in fatigue behavior between naturally aged and artificially aged MMCs, even though the naturally aged material typically has a much lower yield and ultimate strength. In age-hardenable matrix composites, thermal and thermomechanical treatments have a significant effect on the matrix microstructure and the resulting properties of the composite. A thermomechanical treatment (T8) typically produces a fine and homogeneous distribution of precipitates, while a thermal treatment only (T6) generally results in coarser and inhomogeneously distributed precipitates. Because of finer and more closely spaced precipitates, the composite that undergoes a T8 treatment usually exhibits higher yield strengths than that of T6 materials. Despite their lower yield strength, however, the T6 matrix composites have been shown to exhibit higher fatigue resistance than T8 matrix composites. This is shown in Fig. 2 for 2080/SiC$_p$-T6 and 2080/SiC-T8$_p$ of the same reinforcement volume fraction and particle size. The contrasting behavior between monotonic and cyclic loading in this composite can be attributed to the strong influence of the presence, stability, and morphology of S′ (Al$_2$CuMg) precipitates in the matrix of the composite. In fatigue, failure processes are affected by a variety of microstructural factors, which include resistance to dislocation motion and pileup at precipitates and/or reinforcement particles and cracking at slip bands. Throughout the fatigue process, dislocations either cut precipitates or loop around them during cyclic deformation, depending on precipitate coherency and size. In T8 materials, the precipitates are fine enough such that it is believed that the precipitates are cut by dislocations and localized slip takes place, which reduces the strengthening effect of precipitates, thereby impairing the fatigue strength. In T6 materials, the larger precipitate size allows them to retain their precipitate structure and strength during fatigue.

Overaging heat treatments also modify the matrix microstructure, resulting in coarsening of the precipitate structure, while retaining a homogeneous
Figure 2
Comparison of fatigue life of unreinforced and 2080/SiC$_p$ composites in peak-aged (T6) and rolled and peak-aged (T8) conditions. The T8 matrix microstructure consists of relatively fine and closely spaced precipitates that produce a material with high yield strength (Chawla *et al.* 2000b). The T6 matrix materials have relatively larger and more inhomogeneous distribution of precipitates, resulting in lower yield strength.

precipitate distribution, which directly influences fatigue life. Figure 3 shows the coarsening and increase in precipitate spacing in 2080/SiC$_p$-T8, from the strained and peak-aged condition, to a significantly overaged condition. Increasing precipitate spacing decreases both fatigue strength and fatigue lifetime (Fig. 4). This is to be expected since coarser precipitates mean a larger interprecipitate spacing and easier bypass of dislocations. For the composites subjected to higher overaging temperatures, the yield strength and fatigue strength also decrease with increasing precipitate spacing.

Processing-related defects in the form of intermetallic inclusions or particle clusters are also part of the matrix microstructure and play a role in fatigue strength, particularly in powder metallurgy processed materials. These defects act as stress concentrators that increase the local stress intensity in the material and promote easy crack nucleation. Crack initiation during fatigue takes place at these defects, which are typically located at the surface of the specimen. This is because inclusions at the surface are more highly stressed than inclusions completely within the matrix, so a higher stress concentration and, thus, higher probability for crack initiation is present at the surface. For a given inclusion size, the stress concentration in a composite, where the inclusion is surrounded by high-stiffness reinforcement particles, is lower than in an unreinforced alloy. Since more of the load is being "shared" by the high-stiffness SiC particles in the composite, an inclusion in the com-
Figure 3

Figure 4
Effect of overaging (increase in precipitate size and spacing) on fatigue life (Chawla *et al*. 2000b). Precipitate spacings are given in parentheses.

Figure 5
Ratio of cycles to initiation to cycles to failure (N_i/N_f) vs. fatigue life for two different composites systems (Lukasak and Koss 1993, Chawla *et al*. 1998). Notice the transition from crack propagation being dominant in the low cycle regime, compared to most of the fatigue life being spent initiating a crack in the high cycle fatigue regime.

posite will be subjected to lower stress than a similar inclusion in the unreinforced alloy. In extruded materials, the overall size of inclusions is also lower in composites since the ceramic reinforcement particles break the brittle inclusions into smaller sizes during extrusion.

It is interesting to note that in the low-cycle regime, cracks seem to originate relatively early in fatigue life (around 10% of total life). In the high-cycle regime, however, crack initiation can occur quite late (after about 70–90% of the life of the specimen). Figure 5 shows data for two different composites systems that

indicates the transition from crack propagation being dominant in the low-cycle regime, compared to most of the fatigue life being spent initiating a crack in the high cycle fatigue regime. While crack growth is relatively unimpeded in unreinforced materials (Fig. 6(a)), crack growth is hindered by mechanisms such as crack deflection and crack trapping in the composite (Fig. 6(b)).
Figure 6
Fatigue crack initiation and growth in (a) unreinforced 2080 Al and (b) 2080/SiC$_p$ composite (Chawla *et al*. 2000a). Notice that crack growth is hindered by mechanisms such as crack deflection and crack trapping in the composite.

4. Effect of Fatigue Testing at Elevated Temperatures

As described above, several MMC applications, such as the connecting rod in passenger cars, require fatigue resistance at elevated temperatures (of the order of 150–175 °C). Figure 7 shows the elevated temperature fatigue performance of 2080/SiC$_p$-T6 composites in comparison with the room temperature data shown in Fig. 1. The most significant loss of fatigue strength occurs between 25 °C and 150 °C. The incremental increase in temperature to 170 °C results in a modest decrease in fatigue strength. In applications where elevated temperature fatigue resistance is a criterion, the temperature at which the composite is aged becomes very important. At slightly higher temperatures than the aging temperature, a severe decrease in fatigue strength may take place because of significant matrix overaging. The fatigue strength in the composites seems to be directly proportional to the strength of the matrix, as shown by the fatigue ratio for an MMC tested at 25 °C and 150 °C (Table 1). Table 1 also shows that the decrease in fatigue strength owing to temperature is significantly higher than the decrease in yield strength. This may be caused by changes in matrix microstructure and decrease in matrix strength from a combination of long-term exposure and cyclic stress at elevated temperatures. Note that

Table 1
Effect of reinforcement volume fraction on fatigue properties of an MMC.

Material	Approximate fatigue strength (10^7 cycles), σ_{fat} (MPa)	Yield strength (0.2% offset), $\sigma_{0.2}$ (MPa)	Fatigue ratio ($\sigma_{fat}/\sigma_{0.2}$)
2080/SiC/30$_p$-T6, 25 °C	275	529	0.52
2080/SiC/20$_p$-T6, 25 °C	250	467	0.54
2080/SiC/30$_p$-T6, 150 °C	210	470	0.45
2080/SiC/20$_p$-T6, 150 °C	200	435	0.46
Figure 7
Elevated temperature fatigue performance of an MMC in comparison with the room temperature data shown in Fig. 1 (Chawla *et al*. 1999). The 2080/SiC/30$_p$ material with 5 μm particle size meets the stringent fatigue requirements for a connecting rod.

the composite meets the stringent connecting rod target of 210 MPa fatigue strength at 150 °C.

5. Summary

Some observations can be made about the key issues in designing MMCs for fatigue resistance. A high volume fraction of the particulate reinforcement is needed to obtain the desired elastic modulus of the composite for fatigue resistance, while relatively fine particle sizes also improve fatigue strength. The precipitate size, structure, and spacing in the matrix are very important in determining fatigue properties. Fine, closely spaced precipitates that provide high yield and tensile strength may be sheared by dislocations during the fatigue process. Relatively larger precipitates may retain their integrity during the fatigue process and provide a higher fatigue life, although

very large, incoherent precipitates, as observed in overaged microstructures, are not conducive to fatigue resistance. The minimization of the size and number of nonreinforcement inclusions or defects in the matrix also increases fatigue life. Thermal stability of the matrix is important, since a thermally stable matrix is required for long-duration applications such as the connecting rod in automotive engines. Finally, the quality of the fabrication process of the composites is extremely critical to obtain a composite with large volume fraction and fine particle size reinforcement, and a thermally stable microstructure with a minimum of defects. More importantly, low-cost processing routes are needed to implement these materials in high-volume applications.

Fiber Metal Laminates, Fatigue of

Fiber–metal laminates were developed as a family of hybrid materials that consist of bonded thin metal sheets and fibers embedded in adhesive, i.e., rubber-toughened epoxy (Fig. 1). This laminated layout creates a material with excellent fatigue, impact, and damage tolerance characteristics, and a low density (Vogelesang and Gunnink 1986, Vlot *et al.* 1999). The bondlines act as barriers against corrosion of the metallic sheets, and the metal layers protect the fiber/epoxy layers from picking up moisture. The laminate has an inherent high burn-through resistance as well as good damping and insulation properties. The material can be produced as semifinished sheet material; like monolithic aluminum, these sheets can be machined and formed into products. The laminate can also be cured in an autoclave into a complete structure: large, curved panels with co-cured doublers and stiffening elements. The so-called "splicing concept" makes a larger panel size possible compared to conventional aluminum structures, with consequent reduced assembly costs. The possible 20% weight reduction was the prime reason behind the development of these materials for aircraft structures.

1. Background and Different Types

The idea of fiber–metal laminates originated in the 1950s at the Dutch Fokker aircraft company. Instead of integral machined structures, it was chosen to adapt the local strength of laminated bonded structures, mostly for cost reasons. It turned out that as an added benefit, owing to the bending present in most structures, fatigue cracks in laminated aluminum-based structures remain mainly limited to the outer layer for a large portion of their life, while the remainder of the layers restrain crack opening. In the late 1970s the first tests were performed with fibers that were meant to reinforce the bondline; these attempts were not
Figure 1
Typical fiber–metal laminate lay-up.

successful. In the early 1980s, however, fiber–metal laminates were developed as an optimized, laminated, semifinished sheet product (Vogelesang *et al.* 1981). This was achieved by creating an optimized, carefully balanced mix of thin aluminum layers combined with fiber/epoxy layers. The optimal metal fraction relative to the fiber/epoxy content appeared to be crucial for an adequate fatigue performance. The first generation of laminates was based on aramid fibers and was named ARALL (aramid-reinforced aluminum laminate). These laminates had unidirectional fiber layers and were developed primarily for aircraft wing applications. ARALL reached maturity when its promising characteristics were finally demonstrated by testing a full-scale Fokker 50 wing panel in the period 1984–87, which proved that a weight saving of 20% was possible (Jongebreur *et al.* 1992). ARALL was selected for the cargo doors for the US Air Force's C-17 aircraft.

In 1987 the second generation of laminates was born with the name GLARE (glass reinforced), which was based on high-strength glass fibers (Roebroeks 1991). Whereas ARALL had unidirectional fiber layers because it was optimized for wing structures with a uniaxial stress state, GLARE was developed both in unidirectional and cross-plied variants. GLARE had to be developed for fuselage applications because fiber failure was found to occur in ARALL under realistic fuselage skin fatigue loading (i.e., a constant amplitude loading between zero and maximum load) owing to the bad compression properties of the aramid fiber. Because internal compressive stresses are present after curing the laminate at 120 °C owing to a mismatch of the coefficients of thermal expansion of the constituents, cyclic compression of the aramid fibers will occur even if the minimum stress on the laminate is zero. The glass fibers in GLARE do not show failure under realistic fuselage fatigue loads. GLARE soon appeared to be also superior for applications other than fuselage skins. The technology of GLARE was extended in close cooperation with Deutsche Airbus and extensively demonstrated in 1988–89 in Germany by testing a full-scale Airbus A330/340 fuselage barrel.

GLARE is manufactured by laminating the fiber/epoxy prepreg and aluminum layers, after which the laminate is cured for two hours in an autoclave at a temperature of 120 °C under an air pressure of 6 bar. After this curing, the laminate has an internal stress system with tension in the aluminum layers and compression in the fibers. This stress state can be reversed by plastically stretching the laminate. This causes a permanent elongation of the aluminum layers, whereas the fiber layers deform elastically. Therefore, after this operation the fibers impart a compressive stress on the elongated aluminum layers. Several GLARE variants are commercially available (see Table 1). Every grade can be built up in many different thicknesses, e.g., the lay-up of a GLARE 3

Table 1
Available GLARE variants.

| Variant | Aluminum layer | | Fiber layer | |
	Alloy	Thickness per layer (mm)	Orientation	Thickness per layer (mm)
GLARE 1	7475-T761	0.3–0.4	Unidirectional	0.25
GLARE 2	2024-T3	0.2–0.5	Unidirectional	0.25
GLARE 3	2024-T3	0.2–0.5	Cross-ply (50%–50%)	0.25
GLARE 4	2024-T3	0.2–0.5	Cross-ply (67%–33%)	0.375
GLARE 5	2024-T3	0.2–0.5	Cross-ply (50%–50%)	0.5

variant with a so-called "3/2 lay-up" as shown in Fig. 1 is:

$$[20\,24\text{-}T3/0°\text{glass}/90°\text{glass}/2024\text{-}T3/90°\text{glass}/$$

$$0°\text{glass}/2024\text{-}T3]$$

with the 0° direction as the L-direction (rolling direction of the aluminum layers).

2. Fatigue Behavior in Experiments

The key to the excellent fatigue performance is the so-called "crack bridging mechanism" (Fig. 2). The crack opening in the aluminum layers is restrained by the fibers. In other words, the stress intensity at the crack tip in the aluminum layers is reduced by effective crack closing stresses induced by the fibers on the crack flanks. The fibers do not fail during crack opening because cyclic shear stresses in the adhesive create a controlled delamination growth around the crack under fatigue loading. This balance of delamination and crack growth ensures a distribution of strain created by crack opening over a larger length of the fibers, which prevents fiber failure.

Figure 3 compares the fatigue performance of fiber–metal laminates and aluminum 2024-T3 under simulated fuselage loading from a central saw cut. While the crack growth rate of the monolithic material increases rapidly with increasing crack length, the laminates exhibit their characteristic, very slow crack growth behavior. Tests indicate that over a large range of crack lengths the crack growth rate is constant. Under realistic loading conditions, fiber–metal laminates exhibit crack growth rates of the order of 10–100 times slower than their monolithic aluminum constituents.

The longitudinal and circumferential riveted joints in a fuselage structure are the locations where fatigue damage will most probably occur. The residual strength of 2024-T3 and GLARE riveted lap joints
Figure 2
Crack bridging mechanism.
Figure 3
Crack length vs. number of cycles for GLARE and aluminum.

after fatigue is shown in Fig. 4. The GLARE lap joint shows superior behavior over the aluminum lap joint; a high initial residual strength and slow strength reduction are indicated. Cracks initiate in, and remain
Figure 4

limited to, one aluminum layer at the mating surface for a long portion of the life of the material. The 2024-T3 riveted lap joint shows a fast strength decrease once fatigue cracks have initiated. Relatively short inspection intervals are required for aluminum to prevent a situation in which unstable crack extension and reduced residual strength can occur. The results for the GLARE joints indicate that fracture of a riveted lap joint as a result of fatigue damage will never occur under realistic conditions. Damage tolerance is built into the material instead of having to rely on adequate inspection.

3. Fatigue Mechanism in Fiber–Metal Laminates

The fatigue process of fiber–metal laminates can be divided in three phases:

Crack initiation. Because of the lower stiffness of the fiber layers, the aluminum layers in fiber–metal laminates are more heavily loaded, and consequently the crack initiation period in GLARE is usually shorter than in monolithic aluminum. Since an internal stress system is present in the laminate, the initiation period also depends on the operating temperature. When the crack originates from a notch (e.g., hole or saw cut) the initial crack growth rate during the first 1–3 mm of the crack length measured from the notch edge is relatively high. This is related to the stress concentration induced by the notch, but also some crack length and crack opening is needed before the fibers become effective in slowing down the crack growth rate.

Crack growth. During the crack growth period the crack growth rate is almost constant and very low, while the crack growth rate in monolithic aluminum will increase rapidly. Whereas for monolithic aluminum the total fatigue life mainly consists of the crack initiation life, the life for fiber–metal laminates mainly consists of the crack propagation

period. Because general bending is present in the structure, e.g., in riveted lap joints, the crack will initiate and grow in one layer only. This fatigue crack remains in the outer layer for a very long time before the crack initiates in the layer underneath. The fibers and intact aluminum layers transfer a significant part of the load over the surface crack and restrain crack opening. If the internal stress system is reversed by a stretching operation after cure or by high peak loads, the crack growth rate will decrease with increasing crack length and crack growth is eventually stopped. High peak loads during variable amplitude fatigue loading are therefore more effective in slowing down crack growth in fiber–metal laminates compared to monolithic aluminum.

Failure. Because the fibers stay intact during fatigue, the residual strength of a cracked GLARE laminate is very high. The material can withstand very large cracks before failure occurs.

As already mentioned, fatigue crack growth in the aluminum layers is accompanied by growth of the delaminated area around the crack due to cyclic shear stresses present in the adhesive which transfer the load from the metal to the fibers (Fig. 2). The magnitude of the bridging stresses in the fibers is related to the crack opening displacement and the length over which the bridging fibers are elongated, i.e., the delamination length. Since the crack opening displacement decreases from a maximum at the crack center to zero at the crack tip, the crack bridging stresses also decrease to zero at the tip. Marissen (1988) introduced a relation for the contour of the crack opening displacement in accordance with a constant fiber bridging stress over the whole crack length. He assumed an elliptical delamination that grows in such a way that the fiber stresses become equal along the crack flanks. This is not unreasonable since a local higher fiber stress will cause locally more delamination which reduces the fiber stress. Although a decrease of the bridging stresses very close to the tips must take place, the fiber stresses will become constant away from the crack tips.

In an optimal situation, the crack opening should be minimal. This would be the case for an infinitely stiff bond between the aluminum and fiber layers. However, in a real situation, due to local shear deformation of the adhesive and delamination, more crack opening will occur. This is schematically represented in Fig. 5. During the fatigue process the adhesive is loaded with cyclic shear stresses which cause the delamination to grow. In most cases this delamination is found to be elliptical in shape. As a consequence, the bridging stress in the fibers will decrease, resulting in lower cyclic shear stresses in the adhesive. This means a reduction of the delamination growth rate. Increase of the crack length and crack opening will result in higher bridging stresses and shear stresses. This means that the crack growth in fiber–metal laminates is governed by a balance
Figure 5
Shear deformation in the adhesive layer.

between the delamination growth rate on the one hand and the bridging stress on the other.

4. Applications and Future Development

The first flying GLARE part was a bonded patch repair installed on a C-5A Galaxy aircraft by the US Air Force in October 1995. The first flying primary GLARE structure was a fuselage demonstrator panel on an Airbus A310 in 1999. The first civil series production applications were impact-critical cargo floors of Boeing and Airbus aircraft, the bulkhead of the Bombardier Learjet, and a blast-resistant aircraft container. New applications outside the aerospace industry will be explored and new variants will be added to the fiber–metal laminates family, e.g., high-temperature laminates with titanium and carbon fibers.

Fiber Orientation in Composites: Influence of Fluid Flow

A short-fiber composite consists of a polymer, metal, or ceramic matrix reinforced with short, discontinuous fibers. When a short-fiber composite is molded or extruded, the flow gives a pattern of preferential orientation to the fibers. This fiber orientation distribution determines the properties of the composite, since the fibers mainly reinforce the matrix along the axes.

This article discusses techniques for modeling flow-induced fiber orientation. The objective is to predict the orientation distribution in a processed part. This allows one to predict the mechanical performance of the part and, if necessary, alter the process to improve part performance. This type of calculation is already used for injection molded polymer matrix composites, to ensure suitable structural performance and dimensional accuracy before constructing a mold. More extensive reviews are provided by Tucker and Advani (1994) and Papathanasiou and Guell (1997).

1. Describing Orientation

The first step in modeling fiber orientation is to describe the orientation of the fibers at any point in a part. The fibers can usually be regarded as rigid cylinders, so the orientation of a single fiber is described by a unit vector **p** pointing along the fiber axis. The set of all possible directions **p** defines the orientation space, which is the surface of a unit sphere.

In fact, a single fiber direction is not an adequate description for most composites. Figure 1 shows a polished section of an injection molded composite. The glass fibers in this material are nearly perfect cylinders, so they appear on the cross section as dark ellipses. The near-circular ellipses are fibers whose axes are almost perpendicular to the section plane, and the highly elongated ellipses are fibers whose axes lie nearly parallel to the plane. Incomplete ellipses occur when the section plane passes through the end of a fiber.

Figure 1 demonstrates that the fibers in any small region of a short-fiber composite may have very different orientations from one another, so it is necessary to describe the *distribution* of fiber orientations. A very complete description is provided by the probability density function $\psi(\mathbf{p})$, defined such that $\psi(\mathbf{p})d\mathbf{p}$ is the probability that a fiber is oriented within the solid angle $d\mathbf{p}$ centered on the direction $\mathbf{p}$. ψ is defined on the orientation plane, i.e., on the surface of a unit sphere. Real composite parts also have significant spatial variations in fiber orientation, so ψ is typically taken to be a function of orientation $\mathbf{p}$, position $\mathbf{x}$, and time t.

The amount of information needed to describe $\psi(\mathbf{p}, \mathbf{x}, t)$ for a realistic part makes the calculation of ψ prohibitively expensive. Instead, the standard approach is to calculate moments of the distribution function. These moments are tensorial quantities, and are called the orientation tensors, configuration tensors, or moment tensors (Advani and Tucker 1987). The second-order orientation tensor is the average of the tensor product $\mathbf{pp}$ over all directions $\mathbf{p}$, weighted by the probability density function ψ:

$$A = \int \mathbf{pp}\,\psi(\mathbf{p})d\mathbf{p} \tag{1}$$

One may also think of A as the average value of $\mathbf{pp}$ for all the fibers in a small region. The discussion will also require the fourth-order tensor, which is:

$$A = \int \mathbf{pppp}\,\psi(\mathbf{p})d\mathbf{p} \tag{2}$$

The orientation tensors reveal the main directions of orientation (through the eigenvectors of $\mathbf{A}$) and show how aligned the fibers are about these directions. For example, if all of the fibers are aligned in the x_1 direction, then the second-order orientation tensor is:

$$\mathbf{A} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \tag{3}$$

while for a three-dimensional random orientation, the orientation tensor is

$$\mathbf{A} = \begin{bmatrix} 1/3 & 0 & 0 \\ 0 & 1/3 & 0 \\ 0 & 0 & 1/3 \end{bmatrix} \tag{4}$$

The off-diagonal components of $\mathbf{A}$ are nonzero when the principal axes of orientation are nonaligned with the coordination axes. $\mathbf{A}$ is a symmetric tensor and $A_{11} + A_{22} + A_{33} = 1$, so $\mathbf{A}$ has only five independent components. One must still solve for the five independent components of $\mathbf{A}$ as functions of $\mathbf{x}$ and t, but this is far less information than the probability density function ψ.

2. Orientation Dynamics

The basic solution for the rotational motion of a fiber in a deforming fluid was derived by Jeffery (1922). He considered a single, rigid ellipsoidal particle in a Newtonian fluid, with negligible inertia and body forces. Subsequent theoretical and experimental work showed that any rigid, axisymmetric particle will follow Jeffery's equation, provided the correct value of the axis ratio was used. Jeffery's result shows that the centroid of the fiber moves with the unperturbed fluid velocity, and the fiber axis $\mathbf{p}$ reorients according to

$$\dot{\mathbf{p}} = \mathbf{W} \cdot \mathbf{p} - \lambda(\mathbf{D} \cdot \mathbf{p} - \mathbf{D}{:}\mathbf{ppp}) \tag{5}$$

Here, the dot denotes a time derivative following the fiber, $D_{ij} = (\delta v_i/\delta x_j + \delta v_j/\delta x_i)/2$ is the rate-of-deformation tensor, $W_{ij} = (\delta v_i/\delta x_j - \delta v_j/\delta x_i)/2$ is the vorticity tensor, and $\lambda = (r_e^2 - 1)/(r_e^2 + 1)$ is a constant that depends on the fiber shape. r_e is called the equivalent axis ratio; for a slender fiber it is approximately equal to the fiber length divided by the fiber diameter.

Fibers in very dilute suspensions follow Jeffery's equation exactly. Shearing flows align fibers in the flow direction, while stretching deformations align fibers in the direction of stretching. This latter rule means that fibers in a converging flow rotate towards the flow direction, while fibers in a diverging flow rotate to lie across the flow.

Practical composites always involve high concentrations of fibers, where fiber–fiber interactions come into play. Theoretical modeling of these interactions

is quite difficult, and most computations use a phenomenological model proposed by Folgar and Tucker (1984). The effect of interactions is modeled as a rotary diffusion process (assuming that fibers bump into one another in a nearly random way), and the rotary diffusivity is assumed to be proportional to the scalar shear rate $\dot{\gamma} = (2\mathbf{D:D})^{1/2}$. Adding this term to Jeffery's equation and combining the result with Eqn. (1) gives an evolution equation for the second-order orientation tensor:

$$\dot{\mathbf{A}} = (\mathbf{A \cdot W} - \mathbf{W \cdot A}) + \lambda(\mathbf{A \cdot D} + \mathbf{D \cdot A} - \mathbf{D : A})$$

$$+ 2C_I\dot{\gamma}(\mathbf{I} - 3\mathbf{A}) \tag{6}$$

Here, the dot represents a material derivative and $\mathbf{I}$ is the unit tensor. C_I is the interaction coefficient, a dimensionless quantity describing the strength of fiber–fiber interactions that is adjusted to match experimental data. Increasing the value of C_I causes the steady-state orientation to be less perfectly aligned. C_I values between 10^{-2} and 10^{-3} are used to match data for fiber-reinforced polymers used in injection molding.

Equation (6) could be solved to follow the evolution of the second-order orientation tensor $\mathbf{A}$, except that it contains the fourth-order orientation tensor A. The corresponding evolution equation for A contains a sixth-order tensor, so some approximation is needed to close the set of equations. The usual strategy is to develop a closure formula that approximates A in terms of $\mathbf{A}$, and substitute it into Eqn. (6). The simplest useful form is the quadratic closure:

$$A = \mathbf{AA} \tag{7}$$

however, this is not always very accurate.

A variety of other closure approximations have been developed, the most accurate being the orthotropic family of closures (Cintra and Tucker 1995), and the natural closure (Dupret *et al.* 1997). Once a closure approximation has been chosen and the velocity field is known, Eqn. (6) can be integrated to find the orientation as a function of position and time.

3. Process Models

The preceding section showed that the fiber orientation is carried along with the flow of the fiber/liquid mixture, and that it evolves in response to the rate of deformation $\mathbf{D}$ and the vorticity $\mathbf{W}$. Thus, fiber orientation changes are driven by velocity and by velocity gradients. To model the orientation in a process like extrusion or molding, one must solve the flow problem to find the velocity field and then use those velocities in Eqn. (6) to solve for orientation.

Inertia, body forces, and density change are typically negligible in the process of interest, so the governing mass and momentum balance equations for the flow problem are

$$\nabla \cdot \mathbf{v} = 0 \tag{8}$$

$$-\nabla p + \nabla \cdot \tau = 0 \tag{9}$$

Here p is the fluid pressure and τ is the extra stress tensor. Many processing problems also involve significant temperature changes, temperature-dependent viscosity, and solidification, in which case the energy equation is also needed to provide the temperature field. Solving Eqns. (6), (8), and (9), subject to suitable initial and boundary conditions, provides the desired results. These solutions are usually found numerically.

Next, several example solutions will be shown. All of these calculations were performed by VerWeyst (1998), using a finite element code that uses pressure, velocity, and the components of the orientation tensor $\mathbf{A}$ as nodal degrees of freedom. The orientation calculations are all time-dependent and start from an initial condition of random orientation, but eventually the orientation solution reaches a steady state. The fiber orientation results are displayed here by drawing a line at each node, in the direction of the largest eigenvector of $\mathbf{A}$. The direction of this line is the principal direction of orientation, and the length of the line indicates the amount of fiber alignment around that direction: a long line corresponds to near-perfect alignment, while a very short line corresponds to nearly random fibers.

Figure 2 shows a steady-state solution for flow and fiber orientation in an axisymmetric contraction, where a tube of diameter 4.5 joins a tube of diameter 1. This is a prototype for flow in extrusion dies and capillary rheometers. The streamlines are for an isothermal Newtonian fluid with zero Reynolds number, and the computational mesh extends well upstream and downstream of the region shown in the figure. The converging streamlines at the contraction correspond to strong stretching in the flow direction, and the fibers become strongly aligned by this stretching flow as they approach the smaller tube. There is a slow recirculation in the corner, not apparent in the streamline plot, but easily seen in the fiber orientation pattern. The overall result of this flow is to produce a high degree of flow-direction alignment downstream of the contraction.

A second example concerns radial flow in a thin disk, entering from a tube connected to the center of the disk. Figure 3 shows the overall geometry, and Fig. 4 shows the streamlines and steady-state orientation pattern near the center of the disk. This flow is a prototype for injection molding, particularly for flow near a gate. The streamlines again correspond to an isothermal Newtonian fluid. The orientation pattern in this case is quite different from Fig. 2. Now, in the vertical tube, shearing has aligned the fibers in the flow direction. However, in the disk, the streamlines
Figure 2
Computed streamlines and fiber orientation pattern for an axisymmetric contraction. Flow is from top to bottom.
Figure 3
Geometry for the flow in a center-gated disk.

are diverging, which provides a strong stretching deformation in the hoop direction.

Figure 4 shows that, once the fibers enter the disk, they quickly rotate so that they are perpendicular to the flow. (Orientations perpendicular to the flow appear as dots in Fig. 4.) Near the upper and lower walls of the disk, the stretching effect is outweighed by shearing parallel to the walls (due to the no-slip boundary condition), and the fibers there begin to align in the flow direction. Further downstream of the area shown in the figure, an inner core of fibers transverse to the flow is sandwiched between outer shells of flow-aligned fibers. This shell/core structure is typical of injection-molded parts.

A more complex example is shown in Fig. 5 (VerWeyst *et al.* 1999). This is a short rib in a large plaque, 1.5 mm thick, that is injection molded. The rib is long in the direction perpendicular to the page, which allows this problem to be analyzed as a two-dimensional flow. This particular analysis includes all of the factors needed to accurately model injection molding: the polymer viscosity depends on temperature and shear rate, the energy equation is solved at

each time step to provide temperatures, and the analysis starts with an empty mesh and includes the moving flow front as the polymer/fiber mixture fills the mold cavity.

The orientation results in the plaque show the core/shell structure typical of injection molding, although in this case the fibers at the midplane are randomly oriented. Within the rib, the orientation pattern is more complex. Figure 5 shows a scanned image of a cross section from a molded part with this same geometry. The dark spots in the figure are glass fibers

and the white background is the polycarbonate matrix. The fibers in this image have the same orientation pattern as predicted by the calculations, a fact confirmed by more quantitative comparisons (VerWeyst *et al.* 1999).

The preceding examples solve the flow problem using the full two- or three-dimensional mass and momentum balance equations. However, in some processes, a simpler set of equations can be used to solve for the flow field. For polymer injection molding, one solves the generalized Hele–Shaw formulation (Hieber and Shen 1980). Gupta and Wang (1993) and Crochet *et al.* (1994) discuss how this type of flow solution is coupled with the fiber orientation equations.

In compression molding, the fibers are much longer than the part thickness, so the fibers are constrained to lie parallel to the mold surface. Then the orientation can be modeled as two-dimensional, and can be combined with a specialized solution of the flow problem. Advani and Tucker (1990) and Osswald and Tseng (1994) discuss models for compression molding.

4. Additional Issues

A number of other modeling issues must be addressed to make the simulation of fiber orientation useful. First, it is essential to be able to translate the orientation results into mechanical properties of the finished part. Consider an injection molded part, and suppose that a finite element mesh has been used to simulate mold filling and to predict fiber orientation. A micromechanics model is then applied to each element to predict its stiffness and thermal expansion,

after which one may perform a finite element structural analysis of the part. Fortunately, the orientation tensor provides exactly the information about fiber orientation that is needed to predict mechanical properties (Advani and Tucker 1987). Gupta and Wang (1993) and Zheng *et al.* (1999) give examples of this type of calculation.

A second issue is that changes in the fiber orientation alter the rheological properties of the fiber suspension. The examples in the preceding section ignored this phenomenon, calculating the flow field independently of the fiber orientation, and using that flow field to drive the orientation calculation. In fact, the presence of the fibers may alter the flow field, a phenomenon demonstrated experimentally by Libscomb *et al.* (1988). These same workers showed that the fiber suspension flow could be accurately modeled by using a constitutive equation for the extra stress τ that has the form:

$$\tau = 2\eta\mathbf{D} + 2\eta N_p A : \mathbf{D} \qquad (10)$$

Here, η is the viscosity of the fluid matrix, and N_p is a dimensionless quantity that depends on the fiber volume fraction and aspect ratio. Theories for
predicting N_p, as well as other aspects of fiber suspension rheology, are reviewed by Petrie (1999).

Figure 7 shows the velocity field and orientation pattern in an axisymmetric contraction for $N_p = 6$. This is a fully coupled equation: Eqn. (10) is used to compute stresses in the suspension, and the velocity field and orientation field are solved simultaneously. Comparing this to Fig. 2, which is the same geometry, shows that the presence of the fibers greatly enlarges and strengthens the corner vortex. The fibers resist stretching in the direction of their axes, but provide little resistance to shearing parallel to their axes. This causes the angle of the entrance streamlines to narrow, so that the elongational deformation is spread out over a greater length of the large tube. While the coupling between flow and orientation is important in this contraction flow, it is a weak effect for flows in narrow gaps (typical of injection and compression molding), and may be neglected in many problems of practical interest.

A third issue is the breakage of fibers during flow. Generally speaking, large stresses during flow lead to fiber breakage and reduction of the average fiber length, with attendant reduction in the mechanical properties of the composite. Some simple models provide a general understanding of the mechanisms of fiber breakage (Papathanasiou and Guell 1997). However, current practice is to design molds, runners, and gates to minimize fiber breakage, based on empirical rules, rather than to attempt a detailed prediction of breakage.

5. Other Modeling Approaches

This discussion has focused on the use of the second-order orientation tensor **A** as the primary variable for describing and calculating fiber orientation, an approach that has proved quite effective, and is incorporated in commercial software for modeling polymer injection molding. However, some other modeling approaches have been developed recently and deserve mention.

In the *Brownian configuration field* method (Fan *et al.* 1999), one calculates a field of orientation directions $\mathbf{p}(\mathbf{x}, t)$. The governing equation is Jeffery's equation, Eqn. (5), with an additional term representing the stochastic force from fiber–fiber interactions. The same stochastic force is applied to every fiber in the field. This method uses many fields of orientation, each with a different initial condition and a different stochastic force. By choosing the stochastic forces properly, the average result becomes equivalent to the rotary diffusion model proposed by Folgar and Tucker. Once the results have been calculated, the fiber directions from all fields at a given node can be combined to approximate the orientation distribution function ψ, or they can be averaged to compute the orientation tensor **A**. The

Figure 7
Computed streamlines and fiber orientation pattern for an axisymmetric contraction with fully coupled flow and orientation ($N_p = 6$). Flow is from top to bottom. Compare to Fig. 2, which corresponds to $N_p = 0$.

Brownian configuration field calculation is more expensive than calculating **A** directly, but it does not require a closure approximation so it is potentially more accurate.

A second, very different, approach is the *direct simulation* of a suspension with multiple fibers (Fan *et al.* 1999). Rather than using Jeffery's equation, the Navier–Stokes equation is solved at the microscopic level, in the spaces between the fibers. Each fiber is treated as a rigid cylinder that has translational and rotational motion. At each time step, the method solves for the velocity distribution between the fibers, as well as the rates of translation and rotation that cause each fiber to experience no net force or moment. This is an extremely challenging calculation, and direct simulations are presently limited to about 100 fibers in a box with periodic boundary conditions.

Thus, direct simulation is not useful for modeling entire extrusion or molding processes. The advantage of direct simulation is that it requires no approximations about fiber–fiber interactions. Instead, the effects of interactions arise naturally, as the fibers bump into one another or experience long-range hydrodynamic forces. Direct simulation provides a

way to make theoretical predictions of the interaction coefficient C_I, and recent calculations show promising agreement with experiments.

6. Summary

Flow-induced fiber orientation, generated during processing, determines the mechanical and physical behavior of short fiber composites. Fiber orientation distributions can be predicted by solving for the velocity field during flow, and by using a model of orientation dynamics. Current practice is to use the second-order orientation tensor (or moment tensor) **A** as the primary variable to represent local fiber orientation. This quantity captures both the principal directions of orientation and the extent of alignment about those directions. Governing equations for the evolution of **A** can be developed from the basic solution for single-fiber motion, and the resulting equations can be solved numerically for complex flow fields. The results of the orientation model can then be used to predict the mechanical properties and structural performance of the finished part.

Fiber Strength

Tensile strength is one of the most important physical characteristics of reinforcement fibers. Accurately quantifying strength and variability in strength is therefore of great importance. Fiber strength measurements are used by fiber and composite developers and manufacturers as a means of predicting composite properties and to assess the consistency of different lots of fibers.

Very high strength has been achieved by inorganic materials in fiber form. For instance, a tensile strength of $>1\,$GPa in monolithic ceramics is considered exceptional. By contrast, multifilament tows of SiC and Al_2O_3 are commercially available with strengths of 3–4 GPa. Commercial PAN-based carbon fibers exhibit even higher strengths of 5–7 GPa. Large-diameter monofilaments such as SiC fibers prepared by chemical vapor deposition (CVD) and single-crystal sapphire fibers also have strengths in excess of 5 GPa.

Two types of methods are used to measure fiber strength: single filament testing and dry bundle or tow testing. Single filament testing is the most direct route to determining fiber strength, and thereby provides the best data for understanding the fundamentals of behavior and variability. On the negative side, this technique is somewhat difficult because handling of small-diameter, high-modulus fibers and measuring small loads and small filament diameters requires special care to avoid errors that can compromise the accuracy of the test. Testing of tows is often used so that these issues can be avoided. Tow testing is attractive in that it allows the evaluation of hundreds or thousands of filaments simultaneously.

The variability of strength within a sample of fibers is very important. Models indicate that strength of composites is determined not only by the mean tensile strength of the reinforcing fiber, but also by the distribution of strength of fibers. This occurs since the failure of a few weak fibers within the composite at low loads can lead to failure of the entire composite. Weibull statistics are commonly used to predict strength at different tested volumes (gauge length, area), to predict the strength of bundles of fibers, and, ultimately, to predict the strength of fiber-reinforced composites.

1. Single-filament Strength Testing: Procedural Issues

Fibers used for the reinforcement of polymer, metal, and ceramic composites behave as brittle, elastic solids, i.e., fibers exhibit a linear stress–strain curve. Thus, strength is defined as the load at failure divided by the cross-sectional area of the fiber. Single-filament testing is performed as follows. A single filament is selected from the bundle of filaments,

carefully aligned and mounted on a special tab (typically of thin cardboard) with an open slot in the center corresponding to the gauge length, typically 25 mm. The filament is mounted on the tab with a suitable adhesive strong enough to prevent the fiber from pulling out during testing but not so stiff that fibers break at the edges of the adhesive. It is critical to mount high-modulus fibers with as perfect alignment as possible to prevent bending stresses which cause premature failure at the edge of the adhesive. The ends of the tab are gripped in a testing machine, the sides of the tab are carefully cut or burned away, and the fiber is tested to failure at a constant strain rate, usually 0.002–0.02 min^{-1}. For the testing of large-diameter monofilaments, the filament may be directly loaded into the grips of the test machine. The grips must be firm enough to grip the fiber and prevent it from pulling out during testing, but soft enough not to damage the fiber or create stress concentrations which cause premature failure in the grips. Soft aluminum foil is one suitable grip material. Direct gripping using rubber-faced grips has also been used for testing of small-diameter filaments (Wilson 1997).

The second part of single-filament testing is determining the cross-sectional area of the fiber. The measurement of fiber area, although conceptually simple, is not straightforward. A round-robin test undertaken by a joint government–industry task group has identified a number of shortcomings and concerns with the standard test method ASTM 3379-75 (Hurst *et al.* 1998). This study found that the measurement of filament diameter is the major source of error in fiber strength determinations.

The small size of fibers makes an accurate determination of fiber cross-section difficult. Most multifilament tow fibers are 7–15 μm in size; thus, a very small error in diameter measurement can have a large effect on calculated fiber strength. For instance, for a 12 μm diameter fiber, a measurement error of only 0.6 μm in diameter will change the calculated strength by 10%. If calibrated, scanning electron microscopy (SEM) can produce very accurate diameter measurements, but SEM is too time-consuming and costly for routine testing. Optical microscopes, often in combination with video image analysis systems, are frequently used for diameter measurement but are limited by their ultimate resolution of ∼0.5 μm. Laser diffraction patterns from opaque fibers can also be used for diameter measurement. The measurement of monofilaments is more straightforward because of their large diameter. Optical microscopy or mechanical micrometers can be used to measure the diameter of large-diameter monofilaments.

Additional complications in diameter measurement also exist. During testing, high-modulus fibers almost always shatter due to the release of stored strain energy at fracture, causing the original fracture location to be lost. The diameter of many, if not most, fibers

varies slightly down their length, so this effect can make it impossible to determine the actual stress at the point of fracture. A further complication is that fibers may not be round but oval or irregular in cross-section. In this case, it is critical to measure fiber cross-section end-on rather than longitudinally.

In many cases, for instance to assess lot-to-lot variability or to measure degradation of properties after exposure to certain process conditions, it is appropriate to use average strength. ASTM 3379-75 calls for the measurement of a "representative" number of filament diameters from planimetric sample cross-sections of composites to determine a mean filament diameter. The mean diameter is used to calculate the individual fiber breaking stresses. The use of mean diameter is sufficient for the determination of *average* fiber strength; however, the use of mean diameter rather than individual fiber diameters means that individual fiber strength values will not be strictly accurate. This effect must be taken into account during statistical analysis of the strength data.

2. Statistics of Fiber Fracture: Weibull Theory

As brittle materials, the strength of fibers is controlled by the strength of the "weakest link," i.e., fracture occurs at the largest flaw present in the sample. This type of behavior is described by Weibull statistics, in which flaws are assumed to be randomly distributed throughout the tested volume. The application of Weibull theory to high-modulus fibers has been reviewed by van der Zwaag (1989). The probability of failure of a material is given by:

$$P = 1 - \exp[-V/V_0(\sigma/\sigma_0)^m] \qquad (1)$$

where m is the Weibull modulus, V is the tested volume, σ is the failure strength, and V_0 and σ_0 are scaling constants.

Reinforcing fibers typically have a Weibull modulus between 4 and 15. The higher the Weibull modulus, the narrower the distribution of fiber strengths within a sample. A convenient method of estimating the Weibull modulus is the equation $m = 1.2/\mathrm{CV}$, where CV is the coefficient of variation of strength at a single gauge length. By rearranging and taking the natural logarithm of both sides of Eqn. (1), the following equation is obtained:

$$\ln[\ln(1/1 - P)] - \ln V/V_0 = m \ln \sigma - m \ln \sigma_0 \qquad (2)$$

For a constant tested volume (equivalent to constant gauge length for fibers), Eqn. (2) is reduced to:

$$\ln[\ln(1/1 - P)] = m \ln \sigma + k \qquad (3)$$

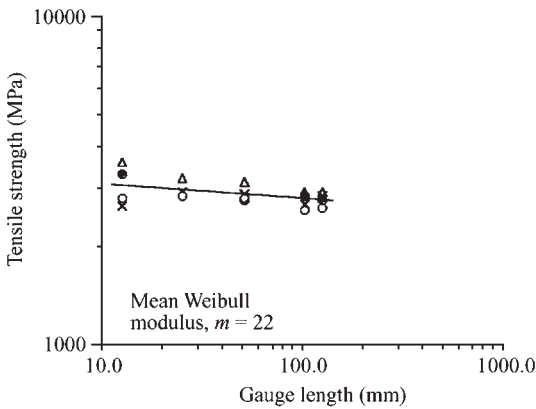
where k is a constant. The Weibull modulus, m, is then determined graphically as the slope of the "Weibull plot" of $\ln[\ln(1/1-P)]$ against $\ln \sigma$. For a set
Figure 1
Fracture probability and Weibull plot of Nextel 610 fiber. The fracture probability has sinusoidal form. The Weibull plot is linear with a slope equal to the Weibull modulus ($m = 12$).


Figure 2
Tensile strength of four lots of Nextel 610fiber at five different gauge lengths. The line is the least squares fit of the mean strength of all four lots ($m = 22$).

It is important to test a sufficient number of filaments to obtain an accurate Weibull modulus. One advantage of single-filament testing is that the number of samples available for testing is very large; however, fiber testing can be very time-consuming, so a tendency exists to minimize the number of fibers tested. Calculations from randomly generated data sets indicate that for a set size of 10 tests, the standard deviation in calculated Weibull modulus may be 30% or more (van der Zwaag 1989). It is recommended that a minimum of 20, and preferably 30 or more, filaments be tested to ensure an accurate statistical analysis of fiber strength.

Another method of determining Weibull modulus is to measure fiber strength as a function of gauge length. With increasing gauge length, the chance of finding a long flaw increases, so fiber strength decreases. If fracture probability, P, is held constant by measuring mean strength, then Eqn. (2) reduces to:

$$\ln \sigma = -1/m \ln V + k' \tag{4}$$

or, alternatively,

$$\sigma_1/\sigma_2 = (V_2/V_1)^{1/m} = (L_2/L_1)^{1/m} \tag{5}$$

where the strengths at tested volumes V_1 and V_2 are σ_1 and σ_2, respectively, and k' is a constant. For fibers, it is commonly assumed that the tested volume is proportional to gauge length, so gauge length, L, can be substituted for volume, V. Using this approach, the Weibull modulus, m, can be determined by plotting log of mean strength as a function of log of gauge length. The slope of the log–log gauge length plot is equal to $-1/m$. Figure 2 shows a log–log plot of tensile strength as a function of gauge length for

of fracture data, the samples are ranked from weakest to strongest, and the probability of fracture, P, is most accurately estimated as $P_i = (i-0.5)/n$, where P_i is the rank of the ith specimen and n is the number of specimens tested. If the statistics of fiber fracture conform to Weibull statistics, the strength data forms a straight line. Figure 1 shows the distribution of single-filament strength for Nextel 610 Ceramic Oxide Fiber, an alumina fiber made by 3M (Wilson 1997). On the strength plot, the data have a sinusoidal form. The Weibull plot is shown in Fig. 2: as can be seen, the data conform to Eqn. (2). The Weibull modulus for this fiber is 12.

Nextel 610 fiber. The Weibull modulus as calculated from Fig. 2 is 22.

Work carried out at the end of the 1990s has illuminated some issues concerning the classic Weibull analysis given in Eqns. (2) and (4) as applied to fibers. The Weibull modulus of fibers as measured by the strength distribution technique (Eqn. (2)) is usually lower than with the gauge length technique (Eqn. (4)) (Wilson 1997, Lavaste *et al*. 1995). This effect can be observed in Figs. 1 and 2. The reason for the discrepancy is not yet clear. One potential cause is incorrect diameter measurement, either due to the use of mean filament diameter rather than individual diameter or from measurement error. It can be shown that either effect will broaden the distribution of strength and therefore reduce the Weibull modulus. Another issue is the effect of natural variations in fiber diameter on tested volume. Since, for given gauge length, larger diameter fibers have larger tested volumes than smaller fibers, Eqn. (5) is not strictly accurate. Since large-diameter fibers would be expected to have lower strength than smaller fibers, this will also broaden the distribution of strengths at a single gauge length. Lastly, the assumption that flaws are distributed randomly with volume is most likely not accurate. For instance, as discussed below, fibers commonly fracture due to surface flaws rather than flaws distributed through the volume of the fiber. Other issues related to processing (e.g., surface damage) can also cause flaws to be nonrandomly distributed. To consider the effects of fiber diameter on fracture probability, Eqn. (1) can be expanded to:

$$P = 1 - \exp[-(\pi/4)LD^{\gamma}/V_0(\sigma/\sigma_0)^m] \quad (6)$$

where γ is a scaling constant and D is the fiber diameter. γ should in theory be 2, but several investigators have found that a lower value of γ generates a more accurate prediction of fiber strength (Wagner 1989, Zhu *et al*. 1997).

3. Strength of Fiber Bundles

The strength of an ideal bundle of fibers will be less than the mean strength of individual filaments. This occurs because the fibers in the bundle have a distribution of strength; therefore, some fibers will fail at a stress below the mean. The remaining stress will be transferred to the other fibers, increasing their load and reducing the overall load required for failure. The ultimate strength of a bundle of filaments which follow Weibull fracture statistics and have mean strength σ_0 was determined by Coleman (1958):

$$\sigma_u = \sigma_0/[m^{1/m}\exp(1/m)] \quad (7)$$

where m is the Weibull modulus. As the coefficient of variation in fiber strength increases (i.e., m decreases), the strength of the bundle decreases, as shown in

Fig. 3. For instance, for $m = 6$ the ideal bundle strength is 62% of the mean fiber strength.

The Weibull modulus of individual fibers in the bundle can ideally be determined from a single bundle test. Chi *et al*. (1984) derived an equation to calculate the Weibull modulus from measured parameters on a stress–strain curve of a bundle of fibers:

$$m = [\ln(\varepsilon_{max}S_0/L_{max})]^{-1} \quad (8)$$

where L_{max} and ε_{max} are the maximum load and strain, respectively, and $S_0 = EAN$, the initial slope of the stress–strain curve, where the number of filaments with modulus E is N having total area A.

Experimentally, it is often difficult to measure the "ideal" bundle strength. In an ideal bundle, each filament is continuous, evenly loaded, and exactly parallel to the load axis during testing; additionally, fracture in one filament is assumed not to affect neighboring fibers. These conditions are often not met with in commercial fibers. Loading hundreds or thousands of filaments equally is also not straightforward. Special arrangements are used to ensure uniform tension on fibers in the bundle. A common procedure is to stretch or hang the fiber tow on a frame under tension. The ends of the tow are infiltrated with epoxy or other suitable adhesive and attached to special end tabs for testing. For some fibers, even with this type of care, measured bundle strength is frequently lower than expected from single filament strength. Multifilament tows all have some degree of entanglement, leading to differences in load between filaments. For oxide fibers in which interfilament friction might be expected to be high, fracture of one filament may cause fracture in adjacent fibers. Oils or lubricants applied to tows have been shown to increase measured strength of oxide fibers; this suggests that friction between filaments causes premature fracture.
Figure 3
The strength of fiber bundles increases as Weibull modulus increases.
Figure 4
Fractographs of fibers with (a) linear surface defect and (b) spherical pore defect.

4. Microstructure–Strength Relationships in Fibers

Fibers are brittle, inelastic materials. Therefore, fiber strength is governed by the Griffith relationship:

$$\sigma = K_{Ic}/\sqrt{\pi c} \qquad (9)$$

where K_{Ic} is the fracture toughness of the fiber and c is the flaw size. Fracture toughness of fibers is no higher than bulk materials; in fact, the opposite is more likely. For instance, analysis of mirror-mist-hackle radii of SiC fiber fracture surfaces found that fiber fracture toughness was lower than in bulk SiC ceramics (Matsuo *et al.* 1992). In alumina, fracture toughness decreases with decreasing grain size. Thus, the very high strength that can be achieved by reinforcing fibers can only occur in fibers with very small grain and, hence, minimal flaw sizes. The Griffith equation predicts that a material with a fracture toughness of 3 (as expected for SiC or Al_2O_3) can achieve a fracture strength of 3 GPa only when the critical flaw size, c, is $<0.3\,\mu m$. Thus, not only must defect sizes be kept low by careful fiber processing, high fiber strength requires a very small grain size. The grain size of commercial fibers is usually below $0.1\,\mu m$.

Fiber defects can be identified by SEM observation of fracture surfaces captured during fractography testing. Fiber fracture is carried out in a damping medium such as grease to avoid secondary fracture and loss of the origin of fracture. Flaws in fibers are generally classified as two types: surface or internal flaws. Surface flaws occur due to abrasion, impacted particles, or other damage during processing. Figure 4(a) shows a Nextel 610 fiber that fractured at a linear surface defect caused by interfilament welding. Common internal flaws include porosity or regions of large grains.

Figure 4(b) shows a Nextel 610 fiber that fractured at an internal pore.

Fiberglass

Glass fibers have valuable properties as a result of their geometric shape and the uniqueness of glass

itself. The room-temperature properties of glass make it well suited for many applications but it is its unusual viscous characteristics in the molten state and its resistance to crystallization that allow glass to be so easily formed into many shapes and, in particular, drawn into fibers.

Most metals, metal oxides, and salts form an extremely low-viscosity, almost water-like, liquid when melted; they also tend to crystallize rapidly at a specific temperature upon cooling. Any attempt to draw such low-viscosity, molten materials into fibers is thwarted by the surface tension overcoming the low viscous forces and causing the fiber to break up into spherical droplets to minimize surface energy. A few substances tend to form high-viscosity liquids when melted and have attendant low crystallization rates; such melts become progressively more viscous as they cool and they solidify into a glass. Uniform fibers can be drawn from these higher viscosity liquids since there isn't time during fiber formation for the relatively high viscous forces to be overcome by the surface tension.

Stable inorganic glasses can be made from a number of oxides and salts, but the most useful glasses are oxides. Silica (SiO_2), B_2O_3, P_2O_5, and GeO_2 are examples of some of the most common glass-forming oxides. Although silica is a valuable glass in its own right for both high-temperature low-expansion ware and low-loss optical fibers, most commercial glasses are a compound of silica and other oxides. The amounts and types of glass-forming and nonglass-forming oxides added to silica generate a range of glasses with widely varying properties in both the molten and solid state.

This article covers the basics of the manufacturing processes for fiberglass, of which there are two major forms.

(i) *Continuous glass fibers* (also referred to as reinforcement or textile glass fibers). These are constant-diameter, continuous glass threads or filaments which are attenuated from the molten state, usually by winding on to a rotating drum. Such fibers are, typically, processed into multifilament strands, mats, or woven cloths for use in composite materials.

(ii) *Insulation wool fibers*. These are discontinuous filaments, of random length and a range of diameters, produced by the attenuation of molten glass streams in a high-velocity gas, where the interaction of the gas with the glass stream is a primary attenuating factor. The pack of random, wool-like fibers so produced usually undergoes further processing and is then widely used for various forms of heat and sound insulation.

1. Continuous Glass Fibers

1.1 Compositions, Properties, and Uses

The composition ranges of a number of glasses used to produce continuous fibers are given in Table 1 with some attendant typical properties. E-glasses, and similar compositions containing little or no boron or fluorine, are the commonly produced glasses for reinforcement applications. They have an excellent

Table 1
Composition ranges in wt.% and typical properties for glass fibers.

combination of physical, electrical, and chemical properties. Glass fibers produced from these glasses are commonly found in fiber-reinforced plastics (FRP) used in electrical applications, automobiles, trucks, boats, pipes, and storage tanks. The other compositions in the table are used for more specialized applications.

S-glass is probably one of the more technically important glasses. It has the highest strength, stiffness, and softening point of any commercial reinforcement glass fiber. This glass is used in very demanding products such as FRP lightweight armor.

A-glass is a soda–lime–silica glass that is similar to common bottle glass and is sometimes used where mechanical performance and water durability are less critical.

C-glass is designed to have a high acid resistance and is used in such products as battery plate separators.

AR-glass has a high alkali resistance and was developed for use in the reinforcement of Portland cement.

1.2 Processing

Modern large-scale production of continuous glass filaments involves several steps (see Fig. 1). These include the weighing and mixing of batch materials (e.g., finely ground silica sand, clay, limestone, and colemanite or boric acid), the reaction and melting of the mixed batch at about $1500\,°C$, usually in a gas-fired or an electrically-boosted gas-fired furnace, the refining/homogenizing of the molten glass, the conditioning/cooling of the glass in the forehearth, and the subsequent drawing of fibers at about $1250\,°C$.

The actual formation of the fibers occurs through a platinum alloy "bushing," which is an electrically heated container situated below the forehearth of the furnace. The base of the platinum alloy bushing contains hundreds of short hollow tips arranged in rows, these tips having bores of about 1–2 mm in diameter. Molten glass at a viscosity of approximately $1000\,P$ (100 Pa s) exudes from each tip and is attenuated into fibers by winding on a rapidly rotating drum at fiber drawing speeds typically between 20 and $70\,ms^{-1}$. The diameter of the fibers is determined by the glass viscosity, tip bore dimensions, depth of the glass above the tips, and drawing speed. Usual commercial diameters range from $5\,\mu m$ to $20\,\mu m$. Chilled metal fins are placed between the rows of tips creating a uniform environment for the tips and greater process consistency. Throughputs for a single bushing may be as high as $100\,K\,gh^{-1}$ with several tens of bushings being supplied from a single furnace.

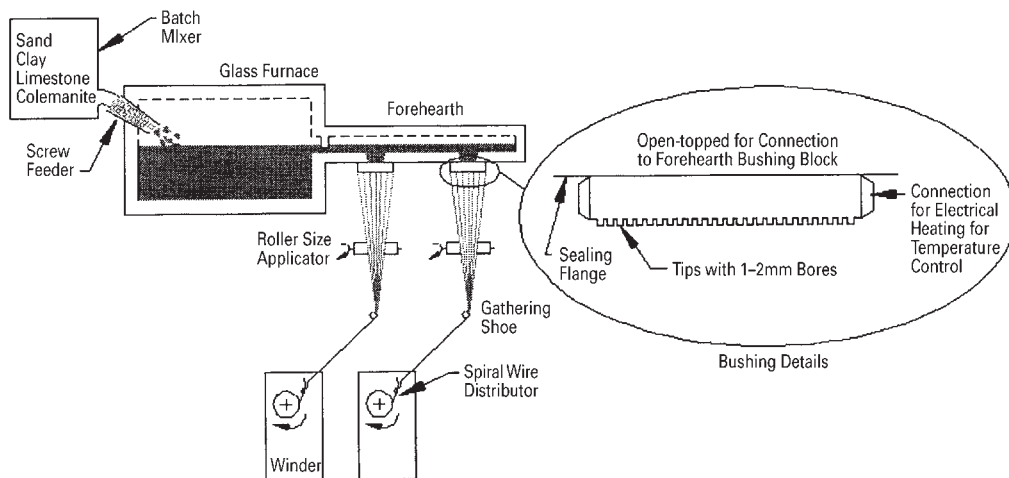
Water-based coatings (or "sizes") are usually applied to the fibers with a roller–applicator situated between the bushing and the winder. The applicator is immediately preceded by a water spray or mist which cools the fibers to prevent the chemical size from being applied to a hot glass surface. The coating on the fibers is subsequently dried and cured when the fiber package is removed from the winder and passed through an oven. The coating generally serves two functions: it protects the fibers from mechanical damage during the various process steps, and it also controls the interface properties between the fibers and the polymer matrix when they are formed into a composite material. Because of this, coatings are usually complex mixtures which invariably contain a coupling agent, in the form of a silane, to maintain the mechanical performance of


Figure 1
Continuous glass fiber manufacturing process.

subsequently made fiber/polymer composites in wet conditions.

Some specialty fibers are manufactured on a smaller scale using a resistively-heated, platinum-alloy melter situated directly above each fiberizing bushing to melt the batch materials. This process is commonly used for such glasses as S-glass. Other processes in use include those where the glass is made in a large furnace and then formed into marbles, which are subsequently remelted in small platinum alloy melters situated directly above each fiberizing bushing.

2. Insulation Wool Fibers

2.1 Composition, Properties, and Uses

Most commercial insulation glasses fall within the range depicted in Table 1. They invariably contain significant amounts of sodium and boron oxides to lower both the liquidus and working temperature, the latter to a level compatible with the operating temperature of the base metal spinners. An important requirement is that the fibers have good water durability to ensure that they do not deteriorate in shipping or service, requiring a balance between the amount and type of oxides needed for lower working temperature and those giving improved weatherability.

Insulation wool glasses find global use in commercial and residential buildings in both thermal and acoustical insulation as well as in the area of filtration.

Other important insulating fibers like rockwool, slagwool, and refractory ceramic fibers are, technically, glass fibers, too; the description of their processing is omitted here but can be found elsewhere (Eastes 1993).

2.2 Processing

In typical fiberglass insulation production the reaction and melting of the batch raw materials are carried out at 1400 °C to 1500 °C either in a gas-fired furnace or a submerged-electrode "cold-top" furnace. The batch ingredients, ground minerals such as silica sand, limestone, soda-ash, borax, and, increasingly, crushed post-consumer bottle and plate glass, are weighed, premixed, and fed into the furnace by a belt conveyor or a screw-feeder (see Fig. 2). Firing arrangements in the furnace coupled with stirring using bubblers and appropriate dwell times create a homogenous melt which is cooled to close to the working temperature in a forehearth channel before being drawn off as a glass stream. The primary division of this glass stream occurs while it is at a viscosity of about 1000 poise; the glass flows through several thousand holes in the vertical wall of a rotating bowl called a spinner (see inset in Fig. 2). The thousands of coarse primary fibers so produced are immediately attenuated further to the desired fineness by an annular external burner and/or a high-velocity turbulent gas stream which surrounds the spinner; typical final nominal fiber diameters range from 4 μm to 15 μm. A furnace may supply glass to as many as 10 spinners, with the throughput of each spinner being 450 Kg h^{-1} or more. The spinners operate at temperatures as high as 1050 °C and have to withstand hoop stresses of about 27 MPa with minimal distortion or creep in a severely corrosive environment.

The fibers produced by the above process are sometimes used as-made but are more commonly bonded together *en masse* by being sprayed with a water-based resin binder, typically phenol–formaldehyde (PF) based, which is subsequently dried and cured in an oven to give coherence to the fibrous material to allow for handleability. Continuous slitting and high-speed guillotining cuts the moving pack into appropriate dimensions for in-line compression packaging as rolls or batts. The importance of compression packaging, for economy in storing and shipping, may be appreciated when it is realized that
Figure 2
Insulation fiberglass manufacturing process.

approximately 98% of the volume of a typical uncompressed insulation batt is air space.

A specialty fibrous wool product of some technical significance, which is used for aircraft insulation and filtration, is produced by a flame-blowing technique. For this, marbles that have been produced by a furnace melting system similar to that described earlier are remelted in a platinum bushing and drawn into coarse filaments about 1 mm in diameter which are fed into a horizontally directed, high-energy gas burner. The extremely fine fibers produced in the turbulent gas jet are collected on a sloping conveyor.

3. Recent Developments

3.1 Processing

The most significant broad change in technology in recent years is the ongoing conversion to a new method of firing furnaces. This has been largely driven by environmental concern over nitrogen oxide (NO_x) emissions. The new firing technique, which is also being used in other segments of the glass industry, uses pure oxygen instead of air in fossil fuel-fired systems. Dramatic reductions in NO_x emissions are achievable but, due to higher flame temperatures, refractory brick changes are necessary. In addition, electrostatic precipitators have to be added to the furnace exhaust to capture the increased particulate volatilization from the molten glass surface.

3.2 Products

A product innovation with unique process challenges appeared with the commercial introduction of Miraflex® fibers in the mid-1990s. These fibers, which have remarkable curl and tortuosity, bear some analogy with the bimetallic strip. Two glasses, with markedly different coefficients of thermal expansion, are fused into a single fiber at the point of fiberization. The process requires two adjacent glass melting furnaces and forehearths, each with a different glass composition, to enable two separate glass streams to be dropped into a single insulation wool spinner. A system of baffles keeps the glasses separate until they are brought together at the spinner holes where they fuse, are attenuated, and then solidify without significant mixing of the compositions. A backscatter electron micrograph of the cross-section of the fibers (see Fig. 3) shows the delineated boundary between the two compositions. An interesting feature of this unbonded product is the process simplification brought about by the lack of need for a traditional resin binder application system and curing oven in manufacture.

3.3 Stewardship

As a consequence of much research in the last two decades or so of the twentieth century, the desirability
Figure 3
Backscatter scanning electron micrograph of Miraflex® fibers.

of having low biopersistence in potentially respirable fibers was recognized. Regulations were developed within the European Union to ensure that insulations which contained respirable fibers were tested in animals and their compositions certified to have low biopersistence. The global nature of the industry has meant that most companies have compositional guidelines to ensure that this facet of the technology is appropriately controlled. Process implications are minimal since control is simply effected by adjusting the input batch materials to control glass chemistry.

Fibers: Superabsorbent

Absorbent fibers such as cotton, rayon, and wood pulp, have been used for a long time in articles ranging from diapers to surgical sponges. The transport of water in these cellulosic fibers is accomplished mainly by capillarity without significant swelling of the fibers. Since the 1970s, superabsorbent fibers have been developed that absorb many times the amount of water taken up by the earlier cellulosic fibers. These newer fibers with their unique structure swell on absorbing large quantities of water and become hydrogels capable of retaining most of the water even when they are exposed to pressure. The early superabsorbent fibers were produced by esterification or etherification reactions of the hydroxyl groups of cellulosic fibers along with cross-linking. One of the most popular superabsorbent cellulosic fibers is sodium carboxymethylcellulose that has been cross-linked.

An example of one of the newer synthetic superabsorbent fibers is Lanseal F produced by the Japan Exlan Company (now Toyobo). Lanseal F has an acrylic core with a superabsorbent outer layer that is claimed to swell about 12 times its initial size when it contacts water. Another acrylic superabsorbent fiber called Fibersorb developed by Arco Chemical Company has been manufactured by DuPont. A third synthetic superabsorbent fiber is reported to be a joint development of Allied Colloids and Courtaulds Fibers in the UK.

1. Mechanism of Water Absorption by Superabsorbers

Superabsorbent polymers are materials which, in the presence of water, exist in a gel state and as the name implies absorb large quantities of liquid. Although the definition is not strict, polymers are considered to be superabsorbent if they imbibe 20 times or more of their weight of aqueous fluid. Many are water soluble before being cross-linked, and the greatest uptake of water is usually at the lowest cross-linking density that provides water insolubility. This point is

illustrated by Fig. 1, a plot of water absorbency vs. amount of cross-linking for poly(sodium acrylate).

The transport of water through a superabsorbent is complex and believed to occur by both capillary and diffusion mechanisms. Initial transport, when the water first contacts the superabsorbent, is primarily by capillarity. As a result of the initial sorption of water, the surface layer develops into a slowly permeable superabsorbent gel layer, which impedes the diffusion of water into the interior of unswollen polymer mass; this phenomenon is known as gel blocking. Cross-linking reduces gel blocking by preventing excessive surface swelling (Chen *et al.* 1985).

The water absorbency of polyelectrolyte superabsorbers is affected by the concentration of electrolytic salts in the water and the pH, as shown in Fig. 2 for sodium carboxymethylated cotton cross-linked in the
Figure 1
Water absorbency vs. cross-linking (after Chen *et al.* 1985; also Nukushin 1980) for poly (sodium acrylate).
Figure 2
Water retention of cross-linked sodium carboxymethylated cotton (after Grignon and Scallan 1980).

wet state with epichlorohydrin. The swelling increases with pH to that characteristic of a weak acid, reaches a maximum near neutrality, then decreases at a pH of about 10. The whole curve is lowered as the concentration of added salt is increased. The effects of both pH and salt concentration are, of course, important in such practical uses of superabsorbents as diapers and incontinence products.

According to (Chen *et al.* 1985), superabsorbent polyelectrolyte gels generally have the greatest ability to absorb water when the pH of the water is between 8 and 10. The neutralization "acts to unravel and straighten out the polymer chains in aqueous fluids so that the final absorbent composition is more swellable in the presence of such fluids." Neutralization of ionic groups can be accomplished with a suitable base, including alkali metal hydroxides such as sodium hydroxide.

2. Cellulosic Fibers

Superabsorbent fibers may be prepared from cellulose by chemically modifying cotton, rayon, or wood fibers, or by extruding chemically modified cellulose. Cellulose ethers are the predominant cellulosic fiber superabsorbers. Methyl, ethyl, and carboxymethyl cellulose fibers are usually prepared from cellulosic fibers under alkaline conditions by treatment with alkyl chlorides. The cellulose ether can then be cross-linked to form a superabsorber. Alternatively, cross-linking may be accomplished prior to formation of the cellulose ether or even during formation. Cross-linking is normally carried out in the wet state because the fibers are then swollen and tend to maintain this swollen state with its high moisture absorbency.

Carboxymethyl cellulose (CMC) can be prepared by treating alkaline cellulosic fibers with monochloracetic acid. The degree of substitution (DS) achieved in this reaction is of critical importance. Although absorbency increases rapidly with an increase in DS, at a DS of about 0.35, the CMC fiber starts to become water soluble. Various methods have been employed to preserve the water insolubility of the fiber, including (i) cross-linking, (ii) heat treatment, and (iii) conversion of the ionic state (from metal salt to free acid). The increase in absorbency and water solubility due to an increase in DS has to be balanced by the decrease in solubility produced by any one or a combination of these methods so as to obtain optimum absorbency with sufficient insolubility to preserve the fibrous state of the superabsorbent fiber.

Other cellulose ethers that have provided superabsorbents are hydroxyethyl cellulose, carboxymethyl hydroxyethyl cellulose, and methylhydroxyethyl cellulose. Still another is phosphonomethylcellulose. In order to cross-link cellulose, a chemical must contain groups that will react with the hydroxy groups in cellulose and have a functionality of at least two.

Formaldehyde, epichlorohydrin, and dichloro-2-propanol are commonly used cross-linkers.

Reid (1968) describes heat treatment of modified polysaccharides including cellulose ethers containing both carboxyl and hydroxyl groups capable of inter-reacting to form an ester cross-link at elevated temperatures. CMC is cross-linked by heating it at a low pH where there are free carboxyl groups to react with hydroxyl groups. The resulting absorbent CMC with a DS of about 0.7 and 65–70% of the carboxyl groups in the sodium salt form has good water absorbent properties. Hercules marketed a self-cross-linked CMC absorbent fibrous product based on Reid's work. The Aqualon subsidiary of Hercules is producing two such fibers called Aquasorb FC and FR, the latter being more highly cross-linked (Hercules 1986).

In addition to the superabsorbent fibers formed by cross-linking cellulose chains by esterification using a heat treatment, superabsorbent cellulosic fibers containing phosphorus have been prepared by the urea phosphate process, in which the fibers were treated with an aqueous solution of urea and orthophosphoric acid. Another cellulose ester, cellulose sulfate, has been used as a superabsorber as well.

Superabsorbent cellulosic fibers can be prepared by grafting onto cellulosic fibers hydrophilic groups or groups capable of being converted to hydrophilic groups after grafting. The former method, using acrylic and methacrylic acids, for example, has not produced fibers as highly absorbent as the latter method, which is illustrated by the grafting of acrylonitrile followed by saponification to sodium polyacrylate.

Takebe and Yamazaki (1978) disclosed the formation of highly absorbent fibers by spinning lower alkyl or lower hydroxyalkyl substituted cellulose ethers by wet or dry spinning methods. They spun fibers of methyl cellulose, ethyl cellulose, hydroxyethyl cellulose, hydroxypropyl cellulose, and hydroxypropylmethyl cellulose.

Superabsorbent cellulose ester fibers have also been made by wet spinning the maleic, succinic, and phthalic acid monoesters of cellulose (Diamantoglou and Meyer 1988). The alkali metal salts of the resulting fibers have superabsorbent properties.

3. Synthetic Superabsorbent Fibers

Burrow and Laity (1987) describe superabsorbent cross-linked polysaccharide fibers. These fibers can be produced by dissolving a carboxylate ester of a polysaccharide, such as a mixture of acetylated and benzoylated dextran, in a solvent, such as *N*-methyl pyrrolidone, with a latent cross-linking agent, such as epichlorohydrin, extruding the solution through a jet into an aqueous medium, and subjecting the fibers to conditions leading to hydrolysis of the ester groups and cross-linking of the resulting hydroxyl groups.

Gross (1976) spun superabsorbent fibers from an organic solvent solution of a copolymer of maleic anhydride and a vinyl aromatic monomer, such as styrene, with a cross-linking agent, such as an adduct of glycerine with ethylene oxide and propylene oxide, by dry spinning or wet spinning into a water bath. The resulting fibers were heated at an elevated temperature to complete the cross-linking and then were made water swellable by reaction with ammonia. Similarly, Bashaw and Atkins (1976) prepared superabsorbent fibers with copolymers of maleic anhydride and a vinyl monomer but used a polyfunctional cross-linking agent, such as a glycol or alkylene diamine, that will react with a carboxylic acid anhydride; the cross-linking was completed by heating at an elevated temperature followed by treatment with ammonia or an alkali metal hydroxide.

Holst *et al.* (1982) prepared superabsorbent fibers by hydrolyzing polyacrylonitrile or copolymer fibers at temperatures exceeding 100 °C in alkaline aqueous solutions, which could contain an organic solvent miscible with water.

Tanaka (1982, 1983) of the Toyobo Company has issued two patents that claim superabsorbent fibers containing an outer cross-linked hydrogel layer and an inner acrylonitrile core, and a process for producing them. The outer superabsorbent hydrogel layer is produced by exposing acrylonitrile fibers to an alkali metal hydroxide or ammonia. It is believed that Lanseal F, Toyobo's superabsorbent fiber, is covered by these patents. In the first, US Patent No. 4,366,206, fibers of polyacrylonitrile or acrylonitrile copolymer are partially hydrolyzed in an aqueous medium with (i) a high concentration of alkali metal hydroxide or ammonia, or (ii) a lower concentration of alkali metal hydroxide or ammonia in conjunction with an "electrolytic salt." The hydrolysis is carried out "… for a sufficient time to cross-link and render the outer layer of the fibers hydrophilic, thereby producing fibers having said hydrophilic cross-linked outer layer and a non-cross-linked, nonhydrophilic acrylonitrile inner layer." The patent claims fibers with less than 55% by volume of the outer hydrogel layer; it is preferred that the hydrogel layer is between 5% and 40% by volume. Although the patent claims fibers with water absorbency of up to $300 \, cm \, g^{-1}$, the fibers with useful physical properties given in the examples have lower water absorbency values. The second patent, US Patent No. 4,374,175, is similar to the first but in addition claims superabsorbent fibers with "latent or visualized crimps" and includes a final step of wet heating the fibers at temperatures of 100–250 °C. This patent also claims "… an industrially advantageous process for producing …" the fibers.

Lanseal F is described as a "… double layer structure, with the outer layer of the superabsorbent substance … and an … inner layer of acrylic fiber …" (Toyobo Company). The rate of water absorbency and the absorbency in electrolyte solutions are given

in Fig. 3. It is produced in two forms, a 5 denier fiber 51 mm long, and a 3 denier fiber 3 mm long. Lanseal F fibers, alone or in blends with other fibers, are recommended for a wide range of applications including feminine care products and disposable diapers.

Le-Khac (1988a, 1988b, 1989, 1990) of Arco Chemical Company has patented several superabsorbent fiber compositions. These patents cover superabsorbent fibers containing a copolymer of an α, β-unsaturated monomer, such as maleic anhydride, a suitable co-monomer, such as isobutylene, and a material capable of cross-linking the copolymer by means of a curing step at an elevated temperature after the fiber is spun. The preferred copolymer has 20–80% pendant carboxylic acid groups and 80–20% pendant carboxylate salt units from partial neutralization with a metal hydroxide. Fibers are formed from aqueous solutions by dry spinning. The cross-linking agents include compounds with at least two hydroxyl groups, which supposedly cross-link by reacting with the carboxylic acid groups of the copolymer, alkylene glycols with 2–10 carbons, for example, such as glycerol and its ether; other cross-linking agents include disaccharides such as sucrose and oligosaccharides.

Le-Khac (1988c, 1989, 1990) also patented superabsorbent fibers made from copolymers similar to those just described, but in place of the agents used as
Figure 3
Absorbency behavior of Lanseal **F** fibers after Toyobo Company; (a) rate of water absorbency and (b) absorbency in electrolyte solutions.

cross-linkers he claimed polyethers derived from C_2 to C_{10} alkylene oxides "... wherein ... at least a portion of the oxide groups on the polyether are inter-reacted with the carboxyl hydrogen atoms on the pendant carboxylic acid units such that the copolymer and the polyether are associated through hydrogen bonds."

The composition of the superabsorbent fiber Fibersorb, developed by Arco Chemical Company, is unknown, but it may be covered by one of the Arco patents mentioned above. It is manufactured in three grades of fibers (Arco Chemical Company). The rate of water absorption of one of the fibers, SA-7000M, and its absorption under various pressures in water and in brine are shown in Fig. 4. Early in 1991, Arco Chemical Company announced that it was discontinuing Fibersorb development and offering to sell the Fibersorb operations.

There is little literature on another synthetic superabsorbent fiber being developed jointly by Allied Colloids and Courtaulds Fibers in the UK. The fiber is reported to be based on acrylate technology but uses a polymer system different from that of any other superabsorbent fiber. The fiber is said to have a saline absorptive capacity of up to 40 times its own weight. Allied Colloids' European Patent 0-268-498 describes superabsorbent polymers that can be made into fibers. The patent covers a substantially linear polymer formed by polymerization of a water-soluble ethylenically unsaturated monomer blend. This polymer contains both carboxylic acid and hydroxyl groups which cross-link to form an ester. The new fiber being developed by Allied Colloids and Courtaulds could possibly be based on this patent.

4. Uses

Superabsorbent fibers have a wide range of uses. The more important applications are in products for sanitary purposes—in feminine care products, baby diapers, surgical dressings, hospital disposables, and incontinence fabrics for adults. They may be used alone but often are blended with other fibers not only to get the most favorable properties but also to economize, since superabsorbent fibers are usually more expensive. For example, blends with cellulose fluff give improved rates of absorption as well as more economical products. Superabsorbent fibers may be used in fiber form or in fabric structures containing superabsorbent polymer particles. One of the advantages of using fibers over polymer particles is that they usually migrate less in structures like diapers.

Superabsorbent fibers are used for the prevention of condensation; for example, Lanseal F fibers are used in a nonwoven fabric called Dew Stopper to absorb moisture in containers that carry coffee beans. They may be used to absorb water in oil and in organic solvents, although they will not absorb dissolved water. They are used in fabric form for gardening and agriculture. They may be used in fire prevention or in fire extinguishing operations. They also are used in filters for absorbing water. Attempts are being made to use superabsorbents for absorbing water in household goods, food products, pharmaceutical products, and medical devices.

Other uses for superabsorbent fibers will doubtlessly be developed in the future. Future improvements in absorbency and reduced costs of superabsorbent fibers might well open up for these fibers the large market now enjoyed by particulate superabsorbers.

Fibrous Reinforcements for Composites: Overview

The fibrous form of matter is very common in nature. This is because matter in this form is highly flexible and thus can be used to make complex and multifunctional parts (Chawla 1998a). Modern usage of synthetic fibers as reinforcement for polymers, metals, and ceramics to make composite materials can be traced to the use of glass fibers for reinforcement of polyester and epoxy thermoset matrix materials in the first half of the twentieth century. High-stiffness and high-strength fibers (organic and inorganic) came about in the second half of the twentieth century, more particularly in the last quarter of the twentieth century. This can be attributed to advances in synthesis and processing as well as to an understanding of the importance of a processing–structure–property triad. This triad implies that the processing of a material into a fibrous form determines its microstructure, which determines the ultimate properties of the fiber.

1. A Brief Historical Perspective

In the late 1930s and early 1940s it was discovered that silica-based glass could be drawn into a very high-strength fiber. The stiffness of the glass fiber does not differ from that of the bulk glass. This is because glass is an amorphous material, and therefore there is no preferential orientation after the fiber-drawing operation. The stiffness of glass is, however, quite high compared to that of most polymers and therefore glass fiber is used as a reinforcement fiber for polymeric materials.

The last quarter of the twentieth century saw a large body of work that led to the commercial production of high-stiffness and high-strength fibers, organic as well as inorganic. In the 1950s it was realized that the carbon–carbon bond in the backbone chain of polymers is very strong and that if one could only orient the molecular chains, one should get a high-modulus fiber from the organic fibers. This was attempted at first by applying ever-increasing stretch or draw ratios to the spun organic fibers. This resulted in some improvement in the stiffness of the fiber, but no better than was available with glass fibers, i.e., a tensile or Young's modulus of about 70 GPa in the fiber direction. It was at this stage that a major structure–property relationship in polymers was realized, namely that one needs orientation *and* extension of the molecular chains in order to realize the full potential of the carbon–carbon bond. Aramid and ultrahigh molecular weight polyethylene fibers, with a Young's modulus over 100 GPa, epitomize this oriented and extended chain structure.

The last quarter of the twentieth century also saw an increasing amount of work in the area of ceramic fibers having low density, high stiffness, and high strength, but more importantly possessing these characteristics at high temperatures (as high as 1000 °C and higher). Examples of such high-temperature fibers include boron, carbon, alumina, silicon carbide, etc. Some very novel and innovative techniques based on the sol–gel process and the use of polymeric precursors to obtain inorganic or ceramic fibers such as silicon carbide, alumina, etc., came into being. The driving force for this development was the use of these fibers as reinforcements for metals and ceramics, i.e., at medium to very high temperatures.

2. Stiff and Strong Fibers

The use of fibers as high-performance materials in structural engineering applications is based on three important characteristics:

(i) *High strength*. This is achieved through several mechanisms. Because materials in fibrous form feature a small diameter with respect to the grain size or other microstructural units of the material, in some systems this allows a higher fraction of the theoretical strength to be attained than is possible with the same material in bulk form. This is also known the size effect, i.e., the smaller the size, the lower the probability of having an imperfection of a critical size that would lead to the failure of the material. Then, for a material in its fibrous form, the strength decreases as its diameter increases. In highly oriented carbon or polymeric fibers, as mentioned above, orientation of atomic bonds in the material along the fiber axis results in a fibrous material having far higher strength and, sometimes, even a higher elastic modulus than in the bulk form. In some fibers, particularly when produced via the sol–gel route or by conversion of preceramic polymers, high strength is achieved because microstructural units of the material, such as grain size and with which strength-limiting defect dimensions are scaled, can be produced with a particularly small dimension. In fibrous form, then, these materials are intrinsically stronger.

(ii) *A very high degree of flexibility*. This is really a characteristic of a material having a high modulus and a small diameter. Even materials that are brittle in their bulk form such as glass, alumina, silicon carbide, etc., when given the form of a fine-diameter fiber, can become quite flexible. This flexibility allows a variety of techniques to be employed for producing yarns from continuous fibers, which in turn can be braided, knitted, or woven into fabrics, ropes, cords, and other complex shapes and forms for use as reinforcement in a matrix material.

(iii) *A high aspect ratio (length/diameter, R/d)*. This allows a very large fraction of applied load to be transferred via the matrix to the stiff and strong fiber in a fiber-reinforced composite (e.g., Chawla 1998b).

Thus, in summary, the most distinctive feature of a fibrous material is that its properties are highly biased along its length. Fibers in general, and continuous fibers in particular, are hence very attractive reinforcements for composite materials. These characteristics have led to the development of fiber-reinforced composites with a variety of matrix materials such as polymers, metals, glasses, and ceramics (e.g., Chawla 1993, 1998b, Clyne and Withers 1993, Hull and Clyne 1996, Piggott 1980, Taya and Arsenault 1989, Suresh *et al.* 1993).

3. Important Definitions

Several important terms, definitions, parameters, and features serve to characterize the wide variety of existing fibers and products made from fibers (other than fiber-reinforced composites). These definitions and features are generally independent of fiber type, i.e., polymeric, metallic, glass, or ceramic fibers. They depend on the geometry rather than any material characteristics.

A fiber can be defined as an elongated material having a more or less equiaxed and uniform transverse cross-section of diameter or thickness less than $250\,\mu m$, and an aspect ratio, defined as the ratio of fiber length to fiber cross-sectional diameter or thickness, greater than about 100. This definition is a purely geometrical one in that it applies to any material. Often, however, the aspect ratio falls below this value but the material is still, by virtue of its elongated cylindrical shape and fine diameter, clearly fibrous in form; in such cases, fibers are designated as short fibers, chopped fibers, whiskers, or staple fibers depending on their nature and geometry (see below).

A fiber is the fundamental unit in making textile yarns and fabrics. Fibers can be naturally occurring or synthetic. There are many natural fibers, organic and inorganic. Examples include organic fibers such as silk, wool, cotton, jute, sisal; and inorganic fibers such as asbestos and basalt. There are a large variety of synthetic fibers available commercially. Polymer fibers such as polypropylene, polyethylene, polyamides, poly(ethylene terephthalate) (PET), polyacrylonitrile (PAN), polytetrafluoroethylene (PTFE), aramid, etc., are well-established fibers. Metallic wires or filaments have been available for a long time. Examples include steel, aluminum, copper, tungsten, molybdenum, gold, silver, etc. Among ceramic and glass fibers, glass fiber for polymer reinforcement has been available since the 1940s; optical glass fiber for telecommunication purposes made its debut in the 1950s, while ceramic fibers such as carbon, silicon carbide, alumina, etc., became available from the 1960s.

One can transform practically any material, polymer, metal, or ceramic, into a fibrous form. Historically and traditionally, fibers were used in the textile industry for uses such as clothing, upholstery and draperies, sacks, ropes, cords, sails, containers, etc. Gradually, their use entered the realm of more engineered items such as conveyor belts, drive belts, geotextiles, etc. With the advent of high-modulus fibers, the use of fibers has extended to highly engineered materials such as composites. Understandably, therefore, the terms commonly used with fibers have their origin far more often in textile technology terminology than in terminology specifically developed for or by the materials community. Relevant definitions include:

Aspect ratio. The ratio of length to diameter of a fiber (see above).

Braiding. Two or more yarns are intertwined to form an elongated structure. The long direction is called the bias direction or machine direction.

Chopped strand. Fibers in a strand are chopped to various lengths, 3–50 mm, for mixing with resins.

Continuous fibers. Continuous strands of fibers, generally available as wound fiber spools.

Denier. A unit of linear density. It is the mass in grams of a 9 km long yarn. This unit is commonly used in the US textile industry.

Fabric. A kind of planar fibrous assembly. It allows the high degree of anisotropy characteristic of yarn to be minimized, although not completely eliminated.

Filament. Continuous fiber, i.e., fiber with an aspect ratio approaching infinity.

Fill. See weft.

Monofilament. A large-diameter continuous fiber, generally with a diameter greater than 100 μm.

Roving. A bundle of yarns or tows of continuous filaments (twisted or untwisted).

Spinneret. A vessel with numerous shaped holes at the bottom through which a material in a molten state is forced out in the form of fine filaments or threads.

Staple fiber. Fibers having short, discrete lengths (10–400 mm long) that can be spun into a yarn are called staple fibers. This spinning quality can be improved if the fiber is imparted a waviness or crimp. Staple fibers are excellent for providing bulkiness for filling, filtration, etc. Frequently, staple natural fibers, e.g., cotton or wool, are blended with staple synthetic fibers, e.g., nylon or polyester, to obtain the best of both types.

Tenacity. A measure of fiber strength that is commonly used in the textile industry. Commonly, the units are gram-force per denier, gram-force per tex, or newtons per tex. It is a specific strength unit, i.e., there is a factor of density involved.

Tex. A unit of linear density. It is the weight in grams of 1 km of yarn. Tex is commonly used in Europe.

Tow. Bundle of twisted or untwisted continuous fibers. A tow may contain tens or hundreds of thousands of individual filaments.

Twist. The angle of twist that individual filaments may have about the yarn axis. Most yarns have filaments twisted because it is easier to handle a twisted yarn than an untwisted one.

Warp. Lengthwise yarn in a woven fabric.

Weft. Transverse yarn in a woven fabric. Also called *fill*.

Whisker. Tiny, whisker-like fiber (a few millimeters long, a few micrometers in diameter) that is a single crystal and almost free of dislocations. Note that this term involves a *material* requirement. The small size and crystalline perfection make whiskers extremely strong, approaching the theoretical strength.

Wire. Metallic filament.

Woven fabric. Flat sheet able to be draped made by interlacing yarns or tows.

Woven roving. Heavy fabric able to be draped woven from continuous rovings.

Yarn. A generic term for a bundle of untwisted or twisted fibers (short or continuous).

4. Fiber Flexibility

The flexibility of a fiber, i.e., its ability to be bent to an arbitrary radius, is one of the most important attributes of a fibrous material and worth discussing in some detail. It is easy to visualize that many operations such as weaving, braiding, winding, etc., depend on the ability of a fiber to be bent without breaking. This flexibility is also of great importance in composites because it permits a variety of techniques to be employed for making composites with these fibers. If we treat the fiber as an elastic beam of circular cross-section, then we can easily see that the fiber flexibility corresponds to the ability of the elastic beam to be bent to an arbitrary radius of curvature. A high degree of flexibility is really a characteristic of a material having a low modulus and a small diameter (Dresher 1969). The flexibility of a given fiber is a function of its stiffness or elastic modulus, E, and the moment of inertia of its cross-section, I.

The elastic modulus of a material is quite independent of its form or size. It is generally a material constant for a given chemical composition and fully dense material. Thus, for a given composition and density, the flexibility of a material is determined by its shape, the size of its cross-section, and its radius of curvature, the maximum attainable value of which is a function of the strength of the material. We can use the inverse of the product of bending moment (M) and the radius of curvature (R) as a measure of flexibility. From elementary strength of materials, we have the following relationship for a beam in bending:

$$M/I = E/R$$

Rearranging, and remembering that the moment of inertia, I, for a beam of circular cross-section of diameter d is equal to $\pi d^4/64$, we can write:

$$MR = EI = E\pi d^4/64$$

The product term EI ($= MR$) is known as flexural rigidity. So, we can define the flexibility of a fiber as:

$$1/MR = 64/E\pi d^4 \approx 20/Ed^4$$

This equation indicates that ($1/MR$), a measure of flexibility, is a very sensitive function of diameter, d. If we take a 25 μm diameter nylon fiber as a classical example of a flexible fiber, we can compute the diameter of various other fibers that will be required to have a flexibility equal to this 25 μm diameter nylon fiber, see Fig. 1. It follows from this curve that, given a sufficiently small diameter, it is possible to produce, in principle, an equally flexible fiber from a polymer,
Figure 1
Diameter of various fibers with a flexibility equal to that of a 25 μm diameter nylon fiber. Given a sufficiently small diameter, it is possible to produce, in principle, an equally flexible fiber from a polymer, a metal, or a ceramic.

a metal, or a ceramic. In other words, one can make a very flexible fiber out of a ceramic such as silicon carbide or alumina provided one can produce it with a fine enough diameter.

5. Fiber Processing

It is possible to process a variety of materials into a fibrous form; in particular, tremendous progress has been made in processing high-stiffness and high-strength organic fibers (e.g., aramid, polyethylene) and inorganic fibers (e.g., silicon carbide, alumina

The process of producing a fibrous form from the liquid state is called spinning. There are quite a few variants of the basic fiber-spinning process. The most common is called melt spinning, which as the name implies means that the fiber is produced from a melt. This process is used for producing fibers from organic polymers and inorganic silica-based glasses. An appropriate thermoplastic polymer, generally in the form of dry pellets, is fed into an extruder where it is melted and then pumped through a spinneret to form filaments. A spinneret has multiple holes through which the molten material exits as fine filaments. Figure 2 shows a schematic of a generic fiber-spinning process. Suffice it to mention here three important types of polymeric fiber-spinning processes: dry spinning, wet spinning, and dry jet–wet spinning. In the dry spinning process the polymer melt or solution is extruded into an evaporating gaseous stream. In the wet-spinning process molten jets are extruded into
Figure 2
Schematic of a generic fiber-spinning process.

a precipitating liquid medium. In dry jet–wet spinning the extruded solution passes through an air gap before entering a coagulation bath.

The following process variables are very important in any fiber-spinning process: (i) flow rate of the melt, (ii) take-up velocity of the wound filaments, (iii) extrusion temperature, (iv) dimensions and shape of the spinneret holes, and (v) cooling conditions.

The production of metallic fibers from the melt is generally difficult, mainly because of the high temperatures often involved and also because the high surface tension of molten metals implies a higher tendency towards destabilization of metallic melt streams. Metallic wires are, therefore, generally produced by taking advantage of their high ductility in the solid state, by drawing through a die. This very old process has the further advantage of leading to a microstructure featuring grains or second phases that are strongly oriented along the fiber axis, which generally confers on drawn metallic wires elevated tensile strengths along their axes.

Processing of carbon or of ceramics other than glass into fibrous form generally requires very high melt temperatures and the melts generally do not have the rheological characteristics suitable for the melt-drawing process. Thus, to make such fibers one must use other methods. One such method is chemical vapor deposition (CVD). Silicon carbide and boron monofilaments are typically made by CVD on a substrate heated to around 1300 °C (DeBolt *et al.* 1974). The substrate can be tungsten or carbon. The reactive gaseous mixture contains hydrogen and alkyl silanes for SiC or BCl_3 for boron and very high frequency (~ 60 MHz) to obtain an optimum temperature profile. To obtain a 100 µm SiC monofilament, it generally takes about 20 s in the reactor. The filament is wound on a spool at the bottom of the reactor.

The exhaust gases (95% of the original mixture + HCl) are passed around a condenser to recover the unused silanes. Efficient reclamation of the unused reactant gases is very important for a cost-effective production process. This process results in a fiber structure featuring elongated grains along the radial direction, at times producing a fiber surface that is somewhat nodular, the nodules on the surface of SiC being smaller than those seen on boron fibers. Such CVD processes result in composite monofilaments which have built-in residual stresses. The process is, of course, very expensive.

The SiC fiber obtained via CVD is very large in diameter, and thus not very flexible. An alternative route to obtain a fine, continuous, and flexible SiC fiber was developed in the mid-1970s by Yajima and co-workers (Yajima *et al.* 1976, Yajima 1980). They used a polycarbosilane precursor to make a nominally silicon carbide fiber, which is manufactured under the trade name of Nicalon. Actually, Nicalon fiber consists of SiC, SiO_2, and some free carbon. This method of using silicon-based polymers to produce a family of ceramic fibers having good mechanical properties, good thermal stability, and oxidation resistance has enormous potential. In any process involving ceramic fiber fabrication via a polymer route, the following are the critical steps (Wax 1985):

(i) polymer characterization (yield, molecular weight, purity, etc.);

(ii) melt-spin the polymer into a precursor fiber;

(iii) cure the precursor fiber to cross-link the molecular chains, making it infusible during the subsequent pyrolysis. This step may not be required under certain conditions, see below; and

(iv) controlled pyrolysis.

Carbon fiber is also often fabricated by controlled pyrolysis of an organic fiber precursor such as PAN. Depending on the precursor and processing, one can obtain a variety of carbon fibers with different strength and modulus. Important types are high strength (HS), high modulus (HM), intermediate modulus (IM), and super high modulus (SHM). There are certain essential steps common to all processes of

carbon-fiber manufacture that use conversion of a polymer precursor.
These are:

(i) *Fiberization*. This involves converting the precursor material into a fibrous form, i.e., extrusion of a polymer melt or solution into a precursor fiber.

(ii) *Stabilization*. This treatment renders the precursor infusible during the subsequent high-temperature processing. This involves preoxidation or cross-linking of the polymer by thermosetting and is done at relatively low temperatures (200–450 °C), usually in air.

(iii) *Carbonization*. This step involves conversion of the stabilized precursor fiber into a carbon fiber. This is carried out in an inert atmosphere (generally pure N_2) at a temperature between 1000 °C and 2000 °C. At the end of this step the fiber has 85–95% carbon content.

(iv) *Graphitization*. This is an optional treatment. It is done in argon or N_2 at a temperature between 2400 °C and 3000 °C. This step increases the carbon content to more than 99% and imparts a very high degree of preferred orientation to the fiber.

Alternatively, carbon fibers can be produced from pitch-based precursors. Pitch is a generic term. Asphalt pitch is a product of oil refining while coal tar pitch can be obtained by mixing coal with appropriate organic fluids. Pitch is converted into a liquid crystal or mesophase pitch, which is a mixture of aromatic hydrocarbons with generally high molecular weights but with a distribution of molecular weights. The mesophase pitch is melt-spun into a fibrous precursor form. The pitch precursor fiber is then pyrolyzed under controlled conditions to obtain a highly oriented graphitic fiber. Pitch-based carbon fibers can have a very high elastic modulus and exceptionally high thermal conductivity.

Unlike glass fibers, many oxide ceramic fibers cannot be spun directly from the melt because the temperatures involved are far too high for the process to be economical (tooling and energetic requirements then become prohibitive). Therefore, to produce fibers of oxide ceramics such as alumina or mullite, one generally spins a slurry or other precursor of the ceramic at temperatures far below its melting temperature, after which the process comprises a sintering or firing step. A low firing or sintering temperature will result in a small grain size but is very likely to lead to an unacceptable level of residual porosity. At higher processing temperatures, one can eliminate porosity but excessive grain growth may result. Control of this step of the process is, thus, important in this fiber-processing route. Another approach for the production of refractory oxide fibers is the sol–gel route. Many companies have commercialized alumina or alumina-based fibers produced by sol–gel processing. An important series of such fibers, produced by 3M Co., goes by the name of the Nextel series of fibers.

Finally, we should mention an important form of short fiber, namely whiskers. These are monocrystalline, short fibers with extremely high strength. Strength levels approaching the theoretically expected values have been measured in many whiskers. Typically, whiskers have a diameter of a few micrometers and a length of a few millimeters. Thus, their aspect ratio (length/diameter) can be very high, varying from 50 to 10 000. This makes it attractive to use these high-strength whiskers as reinforcements. Whiskers do not have uniform dimensions or properties. This is perhaps their greatest disadvantage, i.e., the spread in properties is extremely large. It should be also recognized that preservation of a defect-free surface during processing of a composite is a very difficult task, i.e., handling and alignment of whiskers in a matrix to produce a composite are rather difficult. Whiskers are normally obtained by vapor phase growth.

Early in the 1970s a new process was developed, starting from rice hulls, to produce SiC particles and whiskers (e.g., Chawla 1998a). The SiC particles produced by this process are of a fine size. Rice hulls, a waste by-product of rice milling, contain cellulose, silica, and other organic and inorganic materials. Raw rice hulls are heated in the absence of oxygen at about 700 °C to drive out the volatile compounds. These coked rice hulls, containing about equal amounts of SiO_2 and free carbon, are heated in an inert or reducing atmosphere (flowing N_2 or NH_3 gas) at a temperature between 1500 °C and 1600 °C for about 1h to form silicon carbide:

$$3C + SiO_2 \rightarrow SiC + 2CO$$
When the above reaction is over, the residue is heated to 800 °C to remove any free carbon. Generally, both particles and whiskers are produced together with some excess free carbon. A wet process is used to separate the particles and the whiskers. Typically, the average aspect ratio of the as-produced whiskers is 75.

A vapor–liquid–solid (VLS) technique can be used to grow exceptionally strong and stiff silicon carbide whiskers. The catalyst forms a liquid solution interface with the growing crystalline phase while elements are fed from the vapor phase through the liquid–vapor interface. Whisker growth takes place by precipitation from the supersaturated liquid at the solid–liquid interface. The catalyst must take in solution the atomic species of the whisker to be grown. For SiC whiskers, transition metals and iron alloys meet this requirement.

6. Skin–Core Structure

Melt or solution spinning is one of the most common methods of giving a fibrous form to a material. Even
Figure 3
Schematic of a skin–core structure in a high-speed spun fiber showing a greater degree of crystallization in the skin than in the core.

in the case of ceramic fibers that are produced from polymeric precursor fibers, high-speed spinning is used to produce the precursor fiber. This high-speed spinning process can have some important effects on the resultant fiber structure and, consequently, on its properties. The process of extrusion through a spinneret leads to a certain chain orientation in the filament. Generally, the molecules in the surface region undergo more orientation than the ones in the interior because the solution in contact with the sides of the spinneret hole suffers more frictional resistance than the solution in the center of the spinneret hole. In other words, high-speed spun fibers show a skin–core structure, i.e., there are radial variations in the microstructure of a fiber (Fig. 3)

Microstructurally, these variations correspond to a higher degree of molecular orientation and crystallinity in the near-surface region (skin region) than in the core region of the fiber (Perez 1985, Vassilatos *et al*. 1985). Another reason for this skin effect is the presence of a radial temperature variation (lower temperature in the near-surface region than in the interior) due possibly to cross flow of the quench air. Such a radial temperature variation results in a higher viscosity and higher stress in the skin region than in the core. Consequently, most fibers spun at high speed show a greater degree of crystallization in the skin than in the core. This skin effect can affect many other properties of the fiber, e.g., the adhesion with a polymeric matrix or the ability to be dyed.

7. Stretching and Orientation

As pointed out above, the spinning process of making a fiber results in some chain orientation but this occurs together with a skin effect. Generally, the as-spun polymeric fiber is subjected to some stretching, causing further chain orientation along the fiber axis and consequently better tensile properties, such as stiffness and strength along the fiber axis. The amount of stretch is generally described in terms of a draw ratio, which is the ratio of the initial diameter

to the final diameter. The higher the draw ratio, the higher the degree of chain alignment, the higher the degree of crystallinity, and consequently the higher will be the elastic modulus of the fiber along its axis. This can affect a number of fiber characteristics, e.g., the ability of a fiber to absorb moisture: the higher the degree of crystallinity, the lower the moisture absorption. Du Pont produces a series of aramid fibers under the trade name of Kevlar. In particular, Kevlar 149 fiber has a higher degree of crystallinity than Kevlar 49. Consequently, Kevlar 149 has a higher elastic modulus and absorbs less moisture than Kevlar 49. In general, one can say that a higher degree of crystallinity in a polymeric fiber translates into a higher resistance to penetration by foreign molecules, i.e., a greater chemical stability.

There is, however, a limit to the amount of stretch that can be given to a polymer because the phenomenon of necking can intervene and cause rupture of the fiber. In other words, in a polymeric fiber there is a limit to the modulus enhancement that can be obtained by subjecting it to an ever-higher draw ratio.

8. Cross-sectional Shape and Surface Roughness

Although many fibers are more or less circular in cross-section, fibers can have variety of cross-sectional shapes. Natural fibers, in particular, mostly have noncircular cross-sections. For example, cotton fiber has a cross-section that appears like a collapsed circle. The cross-sectional shape of a spun synthetic fiber can be varied by changing the shape of the spinneret holes through which the polymer is extruded. In fact, one can even produce hollow fibers. Synthetic fibers can have dog bone, kidney bean, or trilobal cross-sectional shapes. Most melt-spun fibers, however, have initially a circular cross-section; however, solution spinning can still result in lobed or dogbone-type cross-sections even though the spinneret orifice may be circular. The reason for this is that although the jet emerging from the orifice is circular, it collapses as the solvent is removed by drying (in dry spinning) or by solution (in wet spinning). Such noncircular fibers can provide a greater density in a fabric than circular fibers.

The surface texture of fibers can also vary considerably. Vegetable fibers such as cotton, jute, sisal, etc., have an irregular surface, while most animal fibers such as hair have scales. Compared to the natural fibers, synthetic fibers generally have relatively smooth surfaces; however, synthetic fibers can also show a large degree of variation in their surface texture. Striation markings due to drawing are commonly observed on the surface of metallic filaments. Similar markings, but on a finer scale, are observed on the surface of carbon fibers. As mentioned above, fibers produced by CVD show a somewhat nodular surface. Very fine-grained ceramic fibers can show surface roughness that scales with the grain size of the

Table 1
Properties of some important synthetic fibers.

Material (fiber)	Tensile modulus (GPa)	Tensile strength (GPa)	Compressive strength (GPa)	Density (gcm^{-3})
Steel	200	2.8		7.8
Al alloy	71	0.6		2.7
Ti alloy	106	1.2		4.5
Alumina	350–380	1.7	6.9	3.9
Boron	415	3.5	5.9	2.5–2.6
SiC	200	2.8	3.1	2.8
S-glass	90	4.5	>1.1	2.46
Carbon P100 (pitch-based)	725	2.2	0.48	2.15
Carbon M60J (PAN-based)	585	3.8	1.67	1.94
Kevlar 49	125	3.5	0.39–0.48	1.45
Kevlar 149	185	3.4	0.32–0.46	1.47
PBZT	325	4.1	0.26–0.41	1.58
PBZO	360	5.7	0.2–0.4	1.58
Spectra 1000	172	3.0	0.17	1.0
Vectran	65	2.9		1.4
Technora	70	3.0		1.39
Nylon	6	1.0	0.1	1.14
Textile PET	12	1.2	0.09	1.39

fiber (Chawla *et al.* 1993). Such surface roughness characteristics can have an important bearing in regard to mechanical bonding of fibers with matrix materials in different composites (Chawla 1993).

9. Density

The density of fibers is a very important attribute. Mentioned above was the use of linear density or mass per unit length. That term is really suitable for giving an idea of the fiber size. Bulk density or mass per unit volume tells us how heavy a material is. Bulk density values of some important fibers are given in Table 1. It can be easily verified that if we divide the linear density of a fiber by its bulk density we get the cross-sectional area of the fiber. Most polymeric fibers have bulk densities varying between $0.9\,\mathrm{g\,cm^{-3}}$ and $1.5\,\mathrm{g\,cm^{-3}}$ (polypropylene, $0.9\,\mathrm{g\,cm^{-3}}$; polyethylene, $0.97\,\mathrm{g\,cm^{-3}}$; polyester, $1.4\,\mathrm{g\,cm^{-3}}$; cotton, $1.5\,\mathrm{g\,cm^{-3}}$). Ceramic fibers have densities varying between $2\,\mathrm{g\,cm^{-3}}$ and $4\,\mathrm{g\,cm^{-3}}$ while metallic fibers can have densities in the range 2–$20\,\mathrm{gcm^{-3}}$. The closer the value of the density of a fiber to its theoretical value, the smaller will be the amount of microvoids in the fiber and the closer it will be to its theoretical composition. For example, the theoretical bulk density of carbon is $2.1\,\mathrm{g\,cm^{-3}}$, while the actual bulk density of carbon fiber can range from about 1.6–$1.8\,\mathrm{g\,cm^{-3}}$ to close to $2\,\mathrm{g\,cm^{-3}}$ for highly aligned graphitic fibers obtained from a pitch precursor. The reason for this is that the pitch-based graphitic fibers have fewer noncarbon atoms and microvoids than other carbon fibers.

10. Mechanical and Thermal Properties

A summary of the mechanical characteristics of important fibers is given in Table 1. It should be pointed out that these values refer to the axial direction of the fiber. As mentioned above, most fibers have characteristics that are heavily biased along their axis, i.e., they are highly anisotropic. In some cases (carbon fibers in particular) they are stronger and stiffer along their axial direction than in the transverse or radial direction. Note also that the properties in compression generally differ from those in tension. Some fibers conduct: obviously copper wires, but also some carbon fibers. Carbon fibers also have a negative coefficient of thermal expansion.

11. Conclusions

Materials in a fibrous form have been used for a long time. Fiber yarns have been used for making fabrics, ropes, cords, etc., since prehistoric times, long before people had any idea of the internal structure of these materials. By any measure, fiber-related industrial activity worldwide represents a very important sector of the world's economy. Fibrous materials are, in one

form or another, part of our daily life. In particular, the availability of strong and stiff fibers has resulted in very important developments in the field of fiber-reinforced composites, spanning the fields of sporting equipment, marine and civil construction, the aerospace industry, and defense applications involving aircrafts, rocket nozzles, and nose cones of missiles and space vehicles.

Foams, Microrheology of

Foams are low-density cellular materials, formed by introducing gas bubbles into liquids through physical or chemical means. They are encountered daily in

food, beverage, personal care, and household items, and are used in firefighting, mineral processing, and petroleum recovery, all of which illustrate the broad range of materials and applications that motivates the development of foam science and technology (Bikerman 1973, Kraynik 1988, Prud'homme and Khan 1996, Weaire 1996, Gibson and Ashby 1997, Sadoc and Rivier 1999, Weaire and Hutzler 2000, Perkowitz 2000). Foams are prototypical multiphase materials; their structure involves multiple length scales and their behavior embodies many physical mechanisms. A micromechanical point of view provides a theoretical foundation for establishing structure–property–processing relationships to guide the use and development of foams. Cellular solids that begin life as gas–liquid foams retain much of the structure that evolves in the liquid state. Polyhedra packed to fill space underlie the geometry of all low-density foams.

This article focuses on the structure and rheology of soap foams under quasistatic conditions. Dry soap foams consist of polyhedral gas bubbles separated by thin liquid films. They can be modeled as networks of minimal surfaces. Even though these foams are composed primarily of two Newtonian fluids—water and air—they behave like soft solids because the cells are jammed together. Elastic response occurs when the foam is strained and the network of thin films deforms without changing topology; strain energy is stored as increased surface area. Plastic response occurs when the film network loses stability as it deforms, which provokes irreversible cascades of topological transitions that release energy. The foam stress and energy density scale as $\sigma/V^{1/3}$, where σ is surface tension and V is average cell volume. Foams with smaller cells are stiffer and stronger as measured by the shear modulus, G, and yield stress, σ_y, respectively (Saint-Jalmes and Durian 1999). Foams are far from equilibrium: films rupture, gravity encourages liquid drainage (Verbist *et al.* 1996), and gas diffuses between cells causing coarsening.

1. Foam Structure

Under static conditions, the local geometry of dry soap foams satisfies Plateau's laws: (i) each face on a polyhedron is a minimal surface with uniform mean curvature that balances the pressure difference between neighboring cells; (ii) three faces meet at each cell edge, a degenerate Plateau border, at equal dihedral angles of $120°$; (iii) four edges meet at each cell vertex at equal tetrahedral angles of $\cos^{-1}(-1/3) = 109.47°$. These conditions imply that no face can be a flat polygon with straight edges because no such polygon has all vertex angles equal to the tetrahedral angle. Lacking analytical solutions for the shape of the minimal surfaces, the Surface Evolver (Brakke 1992) has become the standard computer

software for calculating foam structures (it is available from: http://www.susqu.edu/facstaff/b/brakke/evolver/). All foams discussed here are modeled as spatially periodic structures with N cells in a representative volume or "unit cell."

The Kelvin cell shown in Fig. 1 is a natural starting point for modeling three-dimensional foams because it is the only polyhedron known to form a perfectly ordered structure that satisfies Plateau's laws. It sits on a b.c.c. lattice and has 14 faces: 6 flat quadrilaterals with curved edges and 8 nonplanar hexagons. The Williams foam contains two 14-hedrons with the same shape but different orientations. These cells arrange into alternating layers and have two quadrilateral, eight pentagonal, and four hexagonal faces. The Weaire–Phelan foam uses less surface to divide space into equal-volume cells than any known structure. It contains two pentagonal dodecahedra and six 14-hedrons, and belongs to a class of structures known as tetrahedrally close packed (t.c.p.) to crystallographers and Frank–Kasper to materials scientists (Rivier 1994). All t.c.p. foams are composed of only four types of cells with 12, 14, 15, or 16 faces. Each cell has 12 pentagons; the other faces are hexagons that do not touch each other. The three t.c.p. foams with cubic symmetry are shown in Fig. 1; they and their alternative names are Weaire–Phelan (A15), Friauf–Laves (C15), and Bergman (T).

Ordered foams are useful models of three-dimensional structure but real foams are disordered. Matzke (1946) carefully prepared and examined monodisperse foams (equal-volume cells) and classified the different polyhedra according to face content. Data on 600 cells from the foam interior are summarized in Fig. 2. The first step in modeling random foams involves molecular dynamics simulation to produce a random close packing of N hard spheres with adjustable size distribution. The center and radius of each sphere are used to construct weighted Voronoi polyhedra whose size distribution reflects that of the spheres. The Surface Evolver is then used to relax the Voronoi structures under the constraint of fixed cell volumes. This process involves many topological transitions before structures that satisfy Plateau's laws are achieved. Random, monodisperse foams are produced by starting with equal-size spheres and using equal cell volumes as constraints. Typical distributions of polyhedra with F faces and polygons with n edges are shown in Fig. 2. Matzke (1946) found averages of $\bar{F} = 13.70$ and $\bar{n} = 5.124$. Ten simulations with $N = 1000$ produced excellent agreement with experiment: $\bar{F} = 13.86$ and $\bar{n} = 5.134$. Triangular faces are common among the Voronoi cells but very rare in fully relaxed monodisperse foams. Matzke did not find any triangular faces or a single Kelvin cell. The simulations produced a few Kelvin cells but they are very rare (0.2%), which is not surprising since pentagonal faces are so common. Figure 2 shows some of the more common cells. The
Figure 1

predominant polyhedron recorded by Matzke (19.7%) was a 13-hedron (1, 10, 2); the notation (n_4, n_5, n_6) indicates the number of n-gons. There is only one way to assemble this cell: the two hexagons are attached to opposite sides of the quadrilateral. Among the more common cells in the simulations (13.2%) were 14-hedrons (2, 8, 4) that include the

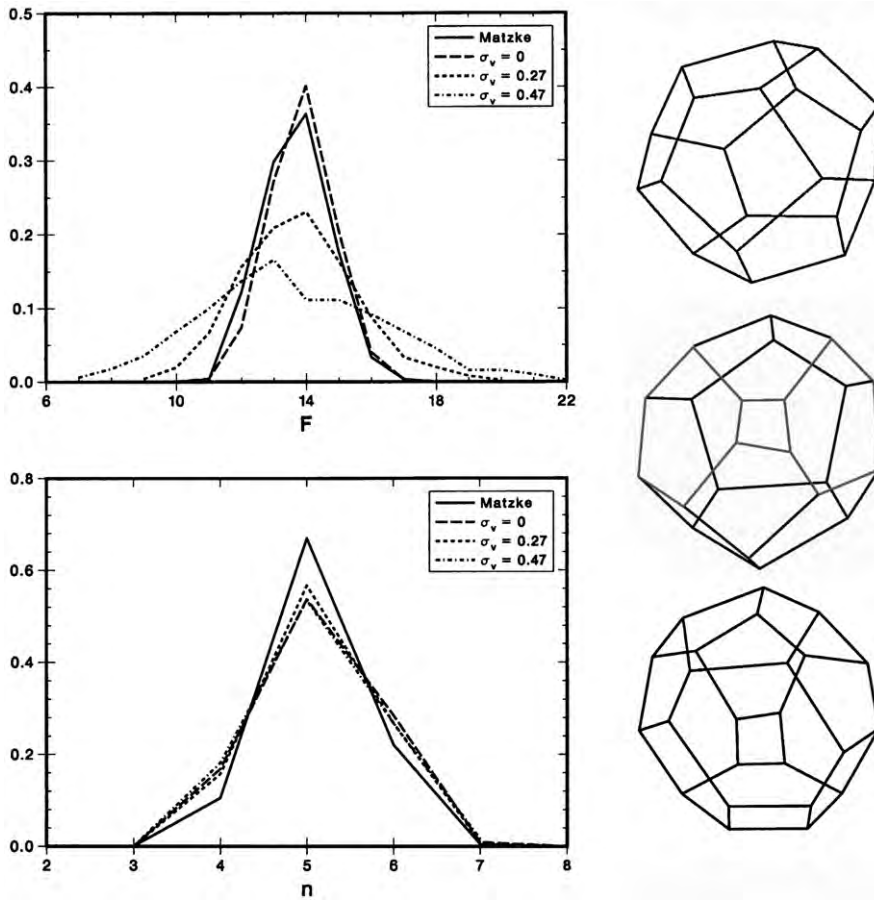
Williams cell but the faces can be combined in 11 different ways. Pentagonal dodecahedra, which are often considered to be the prototypical foam cell, are well represented but not the most common. Figure 2 also contains F and n distributions for two polydisperse foams whose cell volumes vary by over a factor of 10. They contain a broader distribution of


Figure 2
Distributions of polyhedra with *F* faces and polygons with *n* edges in random foams. Some common cells in random monodisperse foam: pentagonal dodecahedron, 13-hedron (1, 10, 2), and 14-hedron (2, 8, 4).

F-hedrons than monodisperse foams; smaller cells tend to have fewer faces and vice versa. The distribution of *n*-gons is surprisingly similar to monodisperse foams. Most of the faces have four to six edges when the cell-size distribution is not too broad. A large number of extremely small tetrahedral cells would significantly increase triangular faces.

2. Rheology

The Surface Evolver can be used to deform spatially periodic foams, compute the minimal structures, and evaluate the stress. The *effective isotropic* shear modulus of ordered foams ranges from $G = 0.78\sigma/V^{1/3}$ for the Kelvin foam to $G = 0.87$ for t.c.p. foams. Calculations for random monodisperse foams with $N \leqslant 216$ give $G = 0.80 \pm 0.02$; polydisperse foams are slightly softer. Experimental studies on wet foams and concentrated liquid–liquid emulsions provide consistent estimates of the shear modulus in the dry limit: $G = 0.82$, which is in excellent agreement with simulations. No dependence on polydispersity has been reported from measurements. Coincidentally, the shear moduli of Kelvin and random foams are very close. By contrast, a calculation based on affine deformation predicts $G > 1.4$

Elastic–plastic behavior occurs when a dry foam is subjected to quasistatic simple shearing flow. Figure 3 shows the evolution of shear stress and surface energy density with strain for a random monodisperse foam with 64 cells. The fluctuations correspond to storage and release of strain energy. The jumps occur when cell edges go to zero length, which violates Plateau's laws and triggers cascades of local topological transitions called *T1*s. The irreversible sequence of events that defines a *T1* cascade and dissipates energy is a fundamental mechanism for plasticity in jammed
Figure 3
Evolution of shear stress and surface energy density for a random foam in simple shearing flow.

fluid–fluid systems. The stress saturation at large strains determines the viscometric functions of a dry foam in the limit of zero shear rate. The shear stress "plateau", in particular, determines a yield stress σ_y, which is different from the elastic limit defined by the first *T1* avalanche. Measurements of yield stress vary significantly, $\sigma_y = 0.11$–0.22. Simulations suggest a slightly higher value: $\sigma_y \approx 0.3$. Considering the uncertainties that surround the measurement of nonlinear rheology in these relatively fragile fluids, the agreement is reasonable. Stress–strain curves for Kelvin and Weaire–Phelan foams exhibit much larger fluctuations and strong dependence on foam orientation (Reinelt and Kraynik 2000). Nonlinear properties obtained from simulations on small systems are unreliable.

3. Diffusive Coarsening

Gas diffusion between cells causes foam coarsening, a prevalent destabilizing mechanism related to Ostwald ripening. A scaling argument suggests that R, the average cell "radius," grows with the square root of
Figure 4
Average growth rate of *F*-hedrons in a polydisperse foam compared against the mean-field theory (solid line) for $\mathscr{G}(F)$ discussed in the text.

time in two or three dimensions; therefore, diffusive coarsening causes a foam to soften with time since stress scales as σ/R. In two dimensions, the growth rate of a polygonal cell with n sides is given by von Neumann's law:

$$\frac{\mathrm{d}A}{\mathrm{d}t} = D(n - 6) \tag{1}$$

where A is the cell area and D is an effective diffusion coefficient. This exact relationship shows that the growth rate is independent of cell size and solely dependent on n. Cells with six sides, the average in two dimensions, neither grow nor shrink. The situation in three dimensions is not as simple. The growth rate of individual cells does not depend on F alone, so efforts have focused on finding an *average* growth law. Dimensional analysis and physical arguments suggest

$$V_F^{-1/3}\frac{\mathrm{d}V_F}{\mathrm{d}t} = D\mathscr{G}(F) \tag{2}$$

where V_F is the average volume of cells with F faces and $\mathscr{G}(F)$ is some dimensionless function of bubble shape that depends on F and other features of the foam structure. The instantaneous growth rate of individual cells can be evaluated from Surface Evolver calculations, which provide cell pressures and geometry. Figure 4 shows average growth rate plotted against F for a polydisperse foam with 512 cells. The data are well represented by a mean-field theory for which $\mathscr{G}(F \to \infty) \sim \sqrt{F}$ (Hilgenfeldt *et al.* 2000).

4. Wet Foams

Unlike the dry limit, a perfectly ordered wet foam can have different structure besides a wet Kelvin cell, e.g., the wet rhombic dodecahedron associated with f.c.c. packing (see Fig. 5). This indicates that Plateau's laws do not pertain to wet foams with finite liquid volume
Figure 5
Wet Kelvin cell, $\phi = 0.01$; Plateau border segments from a Kelvin cell, $\phi = 0.001, 0.01$; wet rhombic dodecahedron, $\phi = 0.06$.

fraction ϕ. The connectivity of Plateau borders that form along cell edges can exceed four, permitting a richer variety of foam topologies. Wet Kelvin cells on a b.c.c. lattice can be stretched to form wet rhombic dodecahedra on an f.c.c. lattice (Kraynik *et al*. 1999). The topological transition between the two types of cells also occurs during simple shearing flow. Surface Evolver models of perfectly ordered wet foams capture some qualitative features of real systems, such as the shear modulus and yield stress decreasing with ϕ. However, accurate calculations for wet foams with random structure and large N are beyond current computing resources.

5.   *Summary*

This brief survey of static foam structure and rheology from a micromechanics point of view reveals a firm theoretical foundation for developing structure–property–processing relationships for foamed materials. The interplay between viscosity and surface tension and its influence on foam microrheology exemplifies further challenge and opportunity in modeling foam processing. The fluid mechanics of bubbles growing and deforming in a viscous fluid provides a link to the micromechanics of cellular solids by setting microstructure.

Functionally Graded Materials

A functionally graded material (FGM, or sometimes also "gradient material") is characterized by a gradual change of material properties with position. The

property gradient in the material is caused by a position-dependent chemical composition, microstructure, or atomic order. The spatial extension of the gradient may differ: in a bulk FGM the property variation extends over a large part of the material, whereas in a graded coating or joint it is restricted to the surface of the material or a small interfacial region.

Although FGMs attracted scientific interest only towards the end of the twentieth century, these materials are not new. In fact, spatial variations in the microstructure of materials have been exploited for millions of years by living organisms. In many structures found in plants, microstructural gradients are formed in order to produce optimum structural and functional performance with minimum material use. An example is the culm of bamboo, which consists of high-strength natural fibers embedded in a matrix of ordinary cells (Fig. 1(a)). The fiber content is not homogeneous over the entire cross-section of the culm but decreases from outside to inside (Fig. 1(b)). This gradation in fiber content is a natural adaptation of the plant to flexural loads—the fiber content is high only in those sections where the highest stresses occur.

There are also some examples of early synthetic materials taking advantage of property gradients such as case-hardened steels in which a hard surface is combined with a tough interior. Nevertheless, it was only in 1987 that Japanese scientists conceived graded materials as a new concept and defined an FGM as an "inhomogeneous composite, in which the material's mechanical, physical, and chemical properties change continuously, and which have no discontinuities within the material" (Hirai *et al.* 1987).

Meanwhile it has become common practice to use the term FGM not only for composites, but also for all materials with a macroscopic property gradient (see definition at the beginning of the article). Thus, materials containing only one phase such as graded glasses or graded single crystals are also FGMs. In such materials the spatial property variation is caused by a gradient in chemical composition. Nevertheless, the vast majority of FGMs are composite materials with a macroscopic microstructural gradient. For example, the composite may contain a spatially varying volume fraction of one of the phases (Fig. 2(a)). In this case, the gradient material can be conveniently described by the use of a transition function $f(x,y,z)$, where f is the volume fraction of one of the phases as a function of position. In many practical cases the compositional variation will be restricted to one coordinate, z, and the different gradients can then be described by a so-called transition function of the type:

$$f(z) = \left(\frac{z}{d}\right)^p \qquad (1)$$

where f denotes the volume fraction of one of the phases, d is the thickness of the graded region, and p is the so-called gradation exponent. However, a composition gradient is not inherent to all FGMs. Microstructural gradients may also be obtained in composites by changing the shape (Fig. 2(b)), orientation (Fig. 2(c)), or size (Fig. 2(d)) of the dispersed phase.

1. Functions of Property Gradients in Materials

Properly designed property gradients in materials lead to a performance that cannot be achieved with a homogeneous material or by the joining of two different materials. The gradient can thus be regarded as an additional material design parameter which may be adapted and optimized to meet the requirements of a particular application. This leads to the unusual situation that the performance of the material is strongly influenced by geometric factors such as the shape of the material, and the extension and profile of the property gradient. Thus, a gradient material cannot be fully characterized by materials constants only, and already comprises certain aspects of the design of a component.

Most of the theoretical research on FGMs has been devoted to their macroscopic mechanical and thermal behavior and there has been considerable progress in understanding the effects of gradients on the stress distribution within such materials (reviewed by Suresh and Mortensen 1998). A gradation of the elastic modulus and/or of the thermal expansion coefficient changes the stress distribution in a component when it is mechanically or thermally loaded. A simple but illustrative example is a trilayered beam of infinite length in the x-direction, and unit width in the z-direction. In the y-direction it consists of two homogeneous layers of thickness h_1 and h_2 and a graded interlayer of thickness g (Fig. 3). For this simple geometry the stresses inside the beam can be conveniently calculated using classical continuum mechanics. It is assumed that plane stress conditions prevail in the center of the beam. If the beam is subjected to a uniform temperature change from a stress-free temperature, a strain gradient in the thickness direction y will evolve due to the difference in thermal expansion of the two materials and the beam will bend. The only nonzero stress in the center of the beam is $\sigma_{xx}(y)$. The stress distribution $\sigma_{xx}(y)$ for a Cu/Al$_2$O$_3$ beam of 5mm thickness after a uniform temperature change of 100 K is shown in Fig. 4. In the case of a simple bimaterial ($g = 0$, $h_1 = h_2 = 2.5$mm) a large stress jump with high compressive stresses in the Al$_2$O$_3$

and high tensile stresses in the copper is predicted near the interface. If a layer that possesses a linear variation of composition from copper to Al$_2$O$_3$ is introduced in the central part of the beam ($h_1 = h_2 = 1$mm, $g = 3$ mm, exponent p of the transition function = 1), the stresses $\sigma_{xx}(y)$ will be substantially reduced and the abrupt change in sign of the stress disappears. Instead, a gradual transition from tensile to compressive stress is observed and the stress becomes zero in the center of the beam. If desired, the exact location y_0 where $\sigma_{xx}(y)$ vanishes can be shifted to a different position by choosing an appropriate transition function. If the linear gradation of the thermal expansion coefficient extends over the whole plate thickness ($h_1 = h_2 = 0$, $g = 5$ mm), the thermal stresses will even vanish completely. However, a graded layer that is thin compared to the homogeneous layers ($g \ll h_1 + h_2$) cannot affect the force balance inside the whole beam and the stress reduction in the nongraded part will be negligible.

It should be pointed out that a stress reduction in bimaterials is not a general feature of FGMs. For
Figure 4
Stresses σ_{xx} along the y-axis of a thin Cu/Al$_2$O$_3$ bar after a temperature change of 100K from the stress-free temperature: ↑, direct joint; —, with graded layer of 3mm thickness in the center; - - -, linear gradation across the entire thickness of the bar.
Figure 3
Geometry of FGM bar used for stress calculation.

arbitrary geometry and loading situation, the gradient will not always lead to a decrease in stress. However, a properly chosen gradient in thermoelastic properties can aid in redistributing stresses in a favorable manner. This can be an important feature in situations where the size or shape of a component is restricted.

So far, only stresses in the interior of an FGM have been considered. There is another important effect of the gradient on the stresses at the free edge of the beam, in particular at the locations where the interface intersects the free boundaries. Assuming elastic material behavior, the stresses σ become singular (infinite) at these locations according to:

$$\sigma_{ij}(r, \Theta) = \frac{K}{r^{\lambda}} f_{ij}(\Theta) \qquad (2)$$

where K is a constant, $f(\Theta)$ is a function describing the angular distribution, r is the distance from the free edge, and λ is the stress exponent. A similar stress singularity for the stress σ_y and the shear stress τ_{xy} is also predicted at an elliptical pore located at the interface of dissimilar materials (Yang *et al*. 1997). The stress concentrations at the free edges or pores are sites where the nucleation of critical cracks (leading to delamination) is likely to occur. If a graded zone with continuously varying mechanical properties is introduced, the stresses at the free edge of the interface become finite (Yang 1998). It was also demonstrated that the introduction of a gradient leads to finite values of σ_y and zero shear stresses τ_{xy} at a pore located at an interface. It is therefore expected that delamination cracking in bimaterial joints or coatings can be substantially reduced or suppressed by the introduction of a property gradient. Indeed, delamination of a TiC/Ti coating on a silicon substrate was shown to be suppressed by a properly chosen gradient (Dahan *et al*. 1999).

In the above, only the effect of a gradient in elastic and thermal properties on the stress distribution in a crack-free material was discussed. However, a gradient will not only affect crack initiation, but also the mechanical energy release rate of an existing crack. Fracture mechanical calculations show that an edge crack propagating along the interface of a homogeneous coating possesses a higher mechanical energy release rate compared to a crack in a graded coating (Erdogan 1995). Furthermore, a suitable local variation of fracture toughness and subcritical crack growth behavior can improve the fatigue life of a component considerably. It was demonstrated that a gradual transition from a fully aged, brittle, high-strength titanium alloy at the surface to a ductile, low-strength titanium alloy is produced by roller burnishing and a subsequent heat treatment. The graded structure retained by the surface treatment improves considerably the high-cycle fatigue strength of the titanium alloy (Berg and Wagner 1999).

The advantages of gradients are not restricted to structural applications. Gradient materials can display functional properties that cannot be achieved by a homogeneous material or directly joined material. Indeed, one of the earliest uses of property gradients in functional materials were graded refractive index lenses and graded refractive index glass fibers for data transmission which allow outstanding transfer rates even for long transmission paths (Uchida *et al*. 1970). Additionally, the absence of sharp interfaces in FGMs offers the chance to eliminate undesired effects of interfaces such as reflections of electromagnetic or acoustic waves or pile-up of dislocations in heteroepitaxy. Such tailor-made properties make FGMs attractive for many acoustic, optic, electronic, magnetic, piezoelectric, thermoelectric, and photovoltaic applications (see Sect. *3*).

2. *Processing of FGMs*

A large part of the research work on FGMs has been dedicated to processing and a large number of production methods have been developed (reviewed by Suresh and Mortensen 1998, Neubrand and Rödel 1997). Most of the processes for FGM production are based on a variation of conventional processing methods which are already well established. Methods that are capable of accommodating a gradation step include powder processing, thermal spraying, melt processing, and coating processes. Which of these production methods is most suitable depends mainly on the material combination, type of transition function required, and geometry of the desired component (Table 1).

In powder processing, the gradient is generally produced by mixing different powders in variable ratios and stacking the powder mixtures in separate layers. The thickness of the separate layers is typically between 0.2 mm and 1 mm. However, even thinner layers with a quasicontinuous composition can be obtained by employing centrifugal powder metallurgy (Delfosse and Ilschner 1992). In this process the powder mixtures and a liquid binder are projected by centrifugal forces onto a support ring, where a solid green body is produced. Quasi-continuous gradients may also be formed by spraying powder suspensions or slip casting having a variable slip composition. The major problem in powder processing of FGMs is the sintering step, as the sintering rates of the different components may differ by orders of magnitude leading to cracking or warping of the compacts. Numerous efforts to counterbalance unequal sintering activity have been undertaken, including adaptation of particle size of the powder components in such a way that the sintering rate becomes similar over a wide range of temperature, and addition of a sintering aid to the more refractory component to increase its sintering rate. Local sintering rates can also be

Table 1
Characteristics of processing methods for FGMs.[a]

equalized by sintering in a temperature gradient which can be produced by laser surface heating or plasma-activated sintering in a stepped or tapered die. Hot pressing is also an efficient means to prevent deformation.

Thermal spraying has been frequently used to produce FGM coatings. Thermal spraying of FGMs offers the possibility to combine highly refractory phases with low-melting metals and allows for direct setting of the gradation profile. The powders for each component can be delivered through multiple feeders using a single torch or using separate torches. Materials produced by thermal spraying have a porosity between 5% and 20%. It is thus particularly attractive for applications where this porosity can be tolerated or is even advantageous such as in graded NiCrAlY/YSZ thermal barrier coatings. Thinner graded coatings have been produced by vapor deposition processes such as conventional physical vapor deposition (PVD), electron beam physical vapor deposition (EBPVD), magnetron sputtering, chemical vapor deposition (CVD), and galvanic plating. In all of these processes the composition gradient is produced by a controlled release of the components from a source such as an anode, ingot, liquid, or gas reservoir.

Bulk FGMs containing a low-melting metal can be favorably produced by melt processing. Particles of the more refractory phase are added to the melt and the gradient is produced by sedimentation or centrifuging during solidification. The more refractory phase can also be provided as a graded preform which is infiltrated with the melt. Processes used to prepare graded preforms include sequential slip casting of dispersions with a variable content of short fibers, weaving long-fiber preforms with a variable content of spacer particles, electrochemical generation of porosity gradients in homogeneous preforms, and inhomogeneous compression of polymer foams.

3. Potential Applications

Due to the development of the FGM concept only in the 1990s, the practical use of FGMs is still very limited. There are, however, a few examples of early applications of materials that are FGMs by definition. Already in the 1960s glass/metal joints with a gradient in thermal expansion coefficient were used to reduce thermal stresses at the interface of the two materials and thus prevent failure of the joint. Glasses with graded refractive index were developed in the early 1970s and were probably the first materials in which a very specific and precise gradation profile was essential for application. A circular plate with a gradient in refractive index can act as a miniature focusing lens with no spherical aberration. Glass rods with a radial index gradient drawn to a fiber can be used in wide-band optical fiber cables. Another well-established application of FGMs is in polymer skin foams with a dense surface layer and an increasing porosity towards the interior. These foams can provide high impact strength at low weight in applications such as instrument panels.

All the materials mentioned above are graded glasses or polymers, which are comparatively easy to manufacture. Gradient composite materials consisting of components with strongly different properties, i.e., graded ceramic/metal or ceramic/ceramic composites, have been manufactured only since the 1990s and tests of graded components from such materials in a real environment are still a rarity. Therefore, they are not widely used in commercial products. Nevertheless, they are expected to provide useful solutions for challenging engineering problems (Miyamoto *et al.* 1999). A few promising examples of FGMs for structural applications are given below. Table 2 gives examples of some proposed functional applications.

Table 2
Proposed applications of FGMs as functional materials.

Proposed application	Proposed FGM	Function of gradient

Graded heteroepitaxial structure	$Si/SiGe$	Reduction of dislocation density
Graded capacitor	$BaTiO_3/SrTiO_3$	Zero-temperature coefficient of capacitance

3.1 Wear Protection

The wear resistance of tools can be substantially increased by a hard surface layer in a compressive stress state (Lin *et al.* 1998). However, if a coating is under compressive stress the risk of delamination is considerable for many material combinations. A WC/Co FGM with a gradual variation in cobalt binder content from the surface to the interior will develop a compressive stress state at the surface. However as explained in Sect. 1 spallation of the top layer is unlikely to occur. Sandvik AB and Sumitomo Electric Industries already use this concept in tools for special applications such as drill bits and throwaway chips. The improved resistance to delamination of an FGM coating was also exploited in an FGM cutting tool where a diamond surface layer was applied to a SiC substrate. Such a tool has a very high cutting precision due to its high stiffness compared to a tool based on a metallic alloy substrate (Li *et al*. 1994).

3.2 Thermal Protection Systems

One of the earliest applications of the FGM concept was the thermal protection of space re-entry vehicles. A SiC/C FGM nose cone for a space plane was developed at the Japanese National Aerospace Laboratory. A nose cone with a SiC protection layer on a C/C composite exposed to a supersonic gas flow at 1900°C deteriorated after the first thermal cycle. In contrast, a nose cone with an additional graded SiC/C interlayer did not show any change after 10 cycles (Sohda *et al.* 1993). Turbine blades of gas turbines must withstand high stresses at elevated temperatures and are thus made from superalloys. The efficiency of the turbine increases with increasing gas inlet temperature and

thus the superalloy is coated with a bond coat of Ni-CrAlY and a heat-insulating layer of ZrO_2 in state-of-the-art gas turbines. The major mechanism limiting the lifetime of such a thermal barrier coating (TBC) is the growth of an oxide layer of alumina at the interface of the bond coat and the ZrO_2 which causes stresses and, ultimately, spallation of the TBC. A gradation of the zirconia coating and the bond coat improved considerably the resistance of the coating to spallation in thermal cycling experiments (Kawasaki and Watanabe 1999). However, it is expected that the oxidation resistance and thus the long-term stability of such a graded system will be insufficient due to the dispersed metal particles in the graded layer. It has therefore been proposed to introduce an additional graded alumina layer between the bond coat and the zirconia. It is not clear yet whether such a design will provide a substantial improvement compared to conventional TBCs. Future use of graded TBCs in turbines is thus uncertain. Likewise, TBCs can be applied to piston crowns and cylinder heads of diesel engines. A 5% reduction in fuel consumption can be achieved by a 2mm thick graded TBC, the lifetime of the graded TBC being much higher than that of an ungraded TBC. Whether graded TBCs will be used in large diesel engines in the future depends presumably on the development of fuel prizes.

3.3 Medical Implants

It is generally acknowledged that a porous surface of a bioactive material such as hydroxyapatite is ideal for rapid bone ingrowth and good mechanical bonding in prosthetic devices. However, for the sake of mechanical stability it is often necessary to use metals as load-carrying materials in implants. As a result,

titanium coated with hydroxyapatite is used as an implant material. The adhesion of hydroxyapatite on titanium is only moderate and failure of the interface may occur after implantation. However, it has been demonstrated that the bonding of certain glasses to titanium is quite strong. Therefore, a coating of glass on a Ti–6Al–4V substrate possessing an increasing volume fraction of hydroxyapatite and pores close to its outer surface is an excellent material for cementless artificial joints and dental implants. Such a graded composite showed a good apposition *in vivo*, and the pull-out strength of dog femur implants was three times higher than that of a sandblasted titanium implant (Maruno *et al.* 1999). The pull-out strength increased with time due to bone growth into the interior of the coating layer, and after 76 months of implantation no separation of the glass layer from the titanium was observed. A graded composite of this type therefore has a considerable potential as a cementless artificial joint or endosseous dental implant.

4. Summary

FGMs can be used to avoid problems associated with the presence of an interface in a material: stress singularities due to elastic or thermal property mismatch, poor adhesion, or unwanted reflections at the interface. They can also serve to introduce a designed property profile into a material providing an optimum response to an external field in functional applications. FGMs have been produced successfully with a variety of processing methods including powder, melt and spray processing, as well as various coating techniques. However, for most processing techniques there is a lack of information on the reproducibility of the gradient and the reliability of the produced materials.

This may explain why FGMs are still rare in commercial products despite a considerable number of potential applications that have been proposed in the field of structural and functional materials. An even more important drawback is the additional cost that a gradation process adds to component fabrication. Therefore, in the early years of the twenty-first century it is likely that FGMs will only find applications in components under severe external thermal or mechanical loads where the limits of conventional materials are difficult to advance: thermal protection systems for space vehicles, jet engines or turbines, tools, or medical implants may be candidates. A more widespread application will largely depend on advancements in cost-effective processing of FGMs.

G

Glass Fibers

The term glass or a glassy material represents a rather large family of materials with the common characteristic that their structure is noncrystalline. Thus, rigorously speaking, one can produce a glassy material from a polymer, metal, or ceramic. An amorphous structure is fairly common in polymeric materials. It is less so in metals, although metallic glass, generally in the form of a ribbon, can be produced by rapid solidification, i.e., by not giving enough time for crystallization to occur. In this article the focus is on silica-based inorganic glasses because of their great commercial importance as reinforcement fibers for polymer matrix composites.

1. Fabrication

The characteristic ability of glasses to be drawn stems from their viscoelastic nature, or in other words the fact that their deformation under stress is a strong function of time and deformation rate. Glassy materials, above the glass transition temperature, T_g, show Newtonian viscosity, i.e., the stress is linearly proportional to the strain rate. This property is exploited in the drawing of glass fibers. We can write, in terms of normal stresses and strains:

$$\sigma = \eta\dot{\varepsilon} \tag{1}$$

where σ is the stress, η is the viscosity, and $\dot{\varepsilon}$ is the strain rate. The deformation proceeds at a constant volume, i.e., an increase in length is accompanied by a decrease in the cross-sectional area. If an incremental increase in length is dl, and the corresponding decrease in cross-section is $-$dA, then:

$$\frac{\mathrm{d}l}{l} = \mathrm{d}\varepsilon = -\frac{\mathrm{d}A}{A}$$

where l and A are the instantaneous values of length and cross-sectional area, respectively. We introduce the strain rate by dividing throughout by incremental time, dt. Thus:

$$\dot{\varepsilon} = \frac{\mathrm{d}\varepsilon}{\mathrm{d}t} = -\frac{\mathrm{d}A}{A}\frac{1}{\mathrm{d}t} = -\frac{\mathrm{d}A}{\mathrm{d}t}\frac{1}{A} = -\frac{\dot{A}}{A}$$

$$A\dot{\varepsilon} = -\dot{A} \tag{2}$$

If F is the applied load, then from Eqns. (1) and (2) we can write:

$$F = \eta\dot{\varepsilon}A = -\eta\dot{A} \tag{3}$$

Equation (3) states that the rate at which the fiber becomes thinner is proportional to the applied force *not the applied stress*. This means that thinner and thicker regions suffer cross-sectional reduction at an equal rate; hence, there is no tendency for preferential thinning of the drawn glass where the stress is locally raised by a local decrease in fiber cross-sectional area. Thinning of drawn viscous fibers is, thus, uniform and stable. This is different from tensile thinning of most materials, which becomes interrupted by rupture after a certain strain due to a preferential local thinning instability, known as necking.

The stability of glass fibers against localization of deformation, and hence against necking, is further reinforced by the fact that for a given load, as the viscosity increases the strain rate decreases. This has indeed very important implications in fiber drawing. In order to understand these implications we need to examine the temperature dependence of viscosity. This temperature dependence is given by:

$$\eta = A\exp(Q/RT)$$

where Q is the molar activation energy, A is a preexponential constant, and R is the universal gas constant. This equation indicates that the viscosity varies inversely in an exponential manner with the temperature. As thinner regions of the fiber cool more rapidly, the viscosity of such regions increases resulting in a decrease in the rate at which the thin region gets thinner. This allows the thicker regions to catch up and increases further the resistance of the drawn fiber material against necking.

2. Glass Fibers for Reinforcement of Polymers

A schematic representation of the conventional fabrication procedure for glass fibers is shown in Fig. 1. The raw materials are heated in a hopper and the molten glass is fed into electrically heated platinum or platinum–rhodium bushings having multiple holes. Typically, each bushing contains 200 holes at its base. A constant head of molten glass is kept in the tank. The molten glass flows by gravity through these holes forming fine continuous filaments which are gathered together and passed around a fast-rotating collet, followed by drawing at a speed of $1–2\,\mathrm{km\,min^{-1}}$. Glass flows out of a platinum bushing at a rate given by:

$$q = \frac{khr^4}{\upsilon l}$$

where r is the radius, l is the length, υ is the kinematic viscosity (i.e., dynamic viscosity, η, divided by density, ρ), and h is the hydrostatic pressure generated by

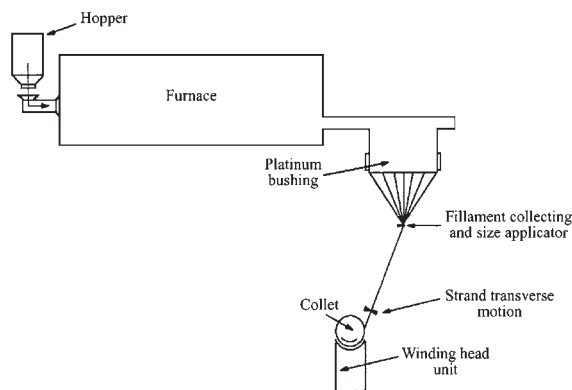
---


Figure 1
Schematic of the conventional fabrication procedure for glass fibers.

the head of glass in the bushing. The fibers exiting the bushing are cooled, subjected to a surface treatment (using an organic size such as a starch oil), and given a stretching treatment by the take-up spool. A size, consisting of an aqueous polymer emulsion, is applied before winding on a drum.

Typically, the glass fibers have a diameter between $5\,\mu m$ and $20\,\mu m$. The final glass fiber diameter is a function of the bushing orifice diameter, viscosity (itself a function of composition and temperature), and the head of glass in the hopper. The viscosity is generally around $100\,Pa\,s$ for good fiberization. During the glass fiber stretching treatment by the take-up spool, the take-up speed is 50–$60\,m\,s^{-1}$, which is slightly higher than the drawing speed, and thus the as-wound glass fiber suffers a stretch.

Glass filaments are easily damaged by the introduction of surface defects. The sizing treatment provides for ease of handling, protects against surface damage, and binds the filaments into a strand. In almost any fiber drawing process from a melt, the melt viscosity is by far the most important process control parameter. If a single glass filament breaks, the glass will drip across other filaments and cause a breakdown of the whole drawing process. Filament breakage can occur because of undissolved particles in the glass, abrasion, devitrification, or any instability due to changes in viscosity/winding speed (Proctor 1971).

An important characteristic of glass fiber is its extreme flexibility, which of course stems from its fine diameter and low modulus. Textile processes of weaving, knitting, etc. can be used with fine, flexible glass fibers to produce fabrics, tapes, sleeves, and ropes. E-glass fiber has a diameter between $3\,\mu m$ and $20\,\mu m$ and is commonly used for insulation purposes as well as for reinforcement of polymers. Frequently, glass fibers are chopped to obtain short, staple fibers.

3. Sol–Gel Processing of Glass Fibers

The conventional processing of glass fibers, as described above, involves direct melting of raw materials, followed by drawing of the molten glass through electrically heated platinum bushings. A major problem with any direct melting process is that the temperatures involved are very high. Quite frequently, the melt viscosity at reasonable temperatures is too high to allow proper homogenization. At times the oxides show large differences in volatility and direct melting results in large losses of some of the constituents. All these problems have led to processing of ceramics and glasses via a chemical route. This allows a high degree of homogeneity on a molecular scale and consequently high-purity glasses or ceramics can be obtained. In particular, the sol–gel technique of making glass fibers has become important.

Essentially the sol–gel route for making any glass or ceramic involves the formation of the appropriate glass or ceramic structure by chemical polymerization of suitable compounds in the liquid state (sol) at low temperatures. A sol is a colloidal suspension in which the individual particles are so small that no sedimentation occurs. The particle size in a sol generally varies between $1\,nm$ and $100\,nm$. A gel is a suspension in which the liquid medium is viscous enough to behave more or less like a solid.

The precursor material for glass fibers in the form of a gel is obtained from the sol. The unwanted residues (water, organic compounds, etc.) are removed from the gel by heating at temperatures much lower than those used in direct-melting processes, and the desired glass or ceramic is obtained in an appropriate form (powder, film, fiber, etc.). As the solvent liquid is lost, the sol viscosity increases until it becomes rigid, i.e., it gels. A well-controlled rate of drying is required because of the large shrinkage that accompanies the drying process.

Fiber drawing is carried out in the course of sol-to-gel conversion. The gelled fibers are then heated to produce glass fibers. There are some very general but important points to be considered in sol and gel spinning. Spinning of dilute solutions into gels results in a minimum of polymer chain entanglement. Gelled fibers are then highly porous and elastic, and should be stretched by drawing while in a temperature gradient. This removes the solvent and decreases the porosity. The viscosity of sols and gels can also be a function of time at constant temperature; e.g., when a tetraethoxysilane $[Si(OC_2H_5)_4]$–water–hydrochloric acid–alcohol solution of appropriate composition is held at near room temperature, hydrolysis and polycondensation occur and the solution viscosity increases. Fibers can be drawn at a viscosity of about $10\,Pa\,s$, which occurs during the course of sol-to-gel transition. It should be pointed out that for an alkoxide solution to be spinnable (Sakka 1982) the solution must have linear polymers and an appropriate

ratio of $[H_2O]/[Si(OC_2H_5)_4]$, called the *r*-ratio. An *r*-ratio < 2 gives a spinnable solution.

4. Chemical Composition

Silica-based glass fiber has been around for a long time. Common glass fiber is readily available commercially in a variety of different chemical compositions. Most glass fibers are silica based (~ 50–60% SiO_2) and contain a host of other oxides of calcium, boron, sodium, aluminum, iron, etc. They are commonly used for reinforcement of thermosetting and thermoplastic polymers. Table 1 gives the compositions of some commonly used glass fibers in composites. The designation E stands for electrical as E-glass is a good electrical insulator besides having good strength and a reasonable Young's modulus; C stands for corrosion as C-glass has a better resistance to chemical corrosion; S stands for high silica content and S-glass is able to withstand higher temperatures than others. Most continuous glass fiber produced is of the E-glass type.

5. Structure

Silica-based glass is a generic term representing an interesting and versatile class of materials. Glasses of various compositions can be obtained and they show very different properties. Structurally, however, all silica-based glasses have the same basic building block: a tetrahedron made up of four oxygen ions bonded covalently to a silicon ion at the center. The composition of a single tetrahedron is thus SiO_4. Each oxygen ion is, however, shared by *two* tetrahedrons, giving the bulk composition of SiO_2. It is this basic building block that is repeated in three dimensions in silica and silica-based materials. Different repeat patterns result in different structures for the same composition. The addition of other oxides of metals such as sodium, calcium, aluminum, magnesium, etc., to silica serves to alter the network structure and the bonding, and consequently the properties, mainly a reduction in viscosity which makes for easy processing. The presence of crystalline

regions is undesirable in a glass because such regions act as stress raisers. Glass fibers are quite isotropic; Young's modulus and thermal expansion coefficient are the same along the fiber axis and perpendicular to it. This, of course, is a result of the amorphous, three-dimensional network structure of glass, i.e., there is no preferential alignment of any structural units such as polymer chains along the fiber axis.

6. Properties

Compared with most other inorganic fibers, silica-based glasses generally have a comparatively low density. The strength can be quite high, but the elastic modulus is not very high. Thus, while the strength-to-weight ratio of glass fibers is quite attractive in comparison with other inorganic fibers, their modulus-to-weight ratio is only moderate. Typical properties of different glass fibers are summarized in Table 2.

Although resistance to fire and many chemicals are very attractive features of glass, moisture can decrease the strength of glass fiber. In particular, the adsorption of moisture by freshly made glass fiber results in a drastic decrease in its strength. Glass fibers are also susceptible to what is called static fatigue, i.e., they cannot withstand loads for long periods of time. This is due to the phenomenon of stress corrosion induced by the ambient moisture.

Common glass fiber such as E-glass becomes severely corroded in an alkaline atmosphere such as in cement or concrete. Some special alkali-resistant glass fibers have therefore been developed. The properties of one such fiber, called Cemfil, are given in Table 2.

7. Fracture

Many brittle, amorphous materials such as thermosetting polymers and silica-based inorganic glasses show some tell-tale markings on their fracture surfaces (Mecholsky *et al.* 1977, Chandan *et al.* 1994). Typically, the fracture surface of a glass fiber shows four distinct regions. These regions surrounding the origin point of fracture are: a smooth mirror region, a mist region of small radial ridges, a hackle region

Table 1
Chemical composition of some common glass fibers.

Compound	E-glass	C-glass	S-glass	Cemfil
SiO_2	55.2	65.0	65.0	71.0
Al_2O_3	8.0	4.0	25.0	1.0
CaO	18.7	14.0		
MgO	4.6	3.0	10.0	
Na_2O	0.3	8.5	0.3	$Na_2O + K_2O = 11$
K_2O	0.2			
Li_2O	7.3	5.0		< 1.0

Table 2
Typical properties of some glass fibers.

Glass fiber type	Density (g cm^{-3})	Tensile strength (GPa)	Young's modulus (GPa)
E-glass	2.54	1.7–3.5	69–72
S-glass	2.48	2.0–4.5	85
C-glass	2.48	1.7–2.8	70
Cemfil	2.70		80

consisting of large ridges, and finally a region of extensive crack branching. It turns out that the product of strength, σ, and the square root of the distance of each of these regions from the origin of fracture is a constant. One can write:

$$\sigma R_i^{0.5} = A_i$$

where R_i are the radii of the mirror-mist, mist-hackle, or crack-branching boundaries. These radii can be related to the initial flaw depth, a, or the half-width, b, through the fracture mechanics analysis:

$$\frac{c}{R_i} = \frac{K_{Ic} Y^2}{2 A_i^2}$$

where $c = (ab)^{0.5}$, Y is a geometrical constant, and K_{Ic} is the critical stress intensity factor or fracture toughness.

8. Applications

Glass fiber is available in a variety of shapes and forms. Some of the important ones include continuous fiber and roving, staple fiber, and chopped strand mat. Staple fibers are strands of individual filaments 200–400 mm long and are excellent for providing bulkiness for filling, filtration, etc. Chopped strand glass fibers consist of fibers chopped to various lengths, 3–50 mm, mainly for the purpose of mixing with a resin for making composites. Glass fiber mats consist of randomly dispersed chopped fibers or continuous fiber strands, held together with a resin.

Glass fibers find applications in a vast array of markets.

8.1 Automotive Market

The automobile industry is one of the largest users of glass fiber. Polymer matrix composites containing glass fibers are used to make external body panels, bumper beams, pultruded body panels and air ducts, engine components, etc. Parts made of glass-fiber-reinforced polymers are much lighter than metallic ones, making the automobile more fuel efficient.

8.2 Aerospace Market

Glass-fiber-reinforced composites are used to make aircraft parts such as wings, helicopter rotor blades, engine ducts, etc. Glass fiber has a relatively low elastic modulus. Hence, it is more common to use glass-fiber-reinforced polymer composites in the interior of an airplane rather than in primary structural parts. The radar transparency characteristic of glass has given it some key uses in the radar-evading stealth technologies.

8.3 Marine Market

Sailing boats and hulls and decks of commercial fishing boats and military mine-hunters are frequently made of glass-fiber-reinforced polymers. Glass-fiber-reinforced polyester is commonly used in making boats of all sizes.

8.4 Civil Construction

This is another large market where glass fiber is widely used. Typical applications include the use of glass fibers in polymeric resins for paneling, bathtubs and shower stalls, doors, windows, etc. Glass fibers are also used as reinforcement in a variety of household items such as paper, tapes, lampshades, etc. Some special alkali-resistant glass fibers have been developed for reinforcement of cement and concrete. Commonly, steel bars are used for such purposes. Cement, however, is very alkaline. An ordinary glass fiber such as E-glass will be severely corroded in an alkaline atmosphere, hence the need for special, alkali-resistant glass fibers (Majumdar 1970, Hannant 1978). The bonding between glass fiber and cement is mainly mechanical and has its origin in the shrinkage that occurs when the cement is set.

8.5 Sporting Goods

Not surprisingly, the sporting goods industry was one of the first to make use of glass-fiber-reinforced composites. Examples include bicycle frames, tennis rackets, golf-club shafts, cricket bats, skis, etc. Braided fibers in a resin matrix give high torsional stiffness to skis.

8.6 Electrical/Electronic Market

Glass fibers are used extensively in printed circuit boards, industrial circuit breakers, conduits for power cables, etc.

9. Conclusions

Glass fibers are a very versatile class of materials. They are used extensively as a reinforcement fiber for polymeric resins such as epoxy and unsaturated polyester. The stiffness of glass fiber is lower than that of other reinforcement fibers, but it possesses the distinct advantage of combining a very high strength with low density and, most of all, a very reasonable cost. Glass fiber will continue to be used as a major reinforcement fiber well into the future.

H

Hard Tissues, Mechanical Properties of

Bone has a varied arrangement of material structures at many length scales, which work in concert to perform diverse mechanical, biological, and chemical functions such as, structural support, protection and storage of bone cells, and mineral ion homeostasis. In order to understand the mechanical properties of hard tissues, it is important to understand the mechanical properties of its component phases, and the structural relationship between them at the various levels of hierarchical structural organization (Ziv *et al*. 1996). For example, a piece of writing chalk and a clamshell are chemically almost identical in composition, but the chalk will break far more easily. The difference in the performance of these two materials originates in their microstructure. This hierarchically organized structure has an irregular, yet optimized, arrangement and orientation of the components, making the material of bone heterogeneous and anisotropic (Fig. 1).

It has been shown that the mechanical properties of bone vary at different structural levels. For example, the Young's modulus of large tensile cortical specimens has been shown to be in the 14–20 GPa range (Reilly *et al*. 1974) (wet specimen, macrostructural property), while that of micro-bending cortical specimens was 5.4 GPa (wet specimen, microstructural property; Choi *et al*. 1990). However, it is unclear whether this discrepancy is due to the testing method or due to the influence of microstructure. Recently, the Young's modulus of osteon lamellar

bone measured by nanoindentation was approximately 22 GPa (dry specimen, submicrostructure property; Rho *et al*. 1997) close to that for the macrostructure. There are, at present, no data in terms of Young's modulus for the nanostructure. The basic building blocks (apatite crystals and collagen fibrils) are extremely small, making mechanical testing nearly impossible. Therefore, it seems of primary importance to break down the mechanical testing of bone according to the various levels or architecture within bone material.

1. Macrostructural Properties: Cortical and Cancellous Bone

Some workers (Carter and Hayes 1977, Keller *et al*. 1990) consider cortical and cancellous bone to be a single morphological material, which can be characterized by a highly variable porosity or apparent density (mass/total volume, including pores). Others consider these two types to consist of two different materials (Choi *et al*. 1990, Rho *et al*. 1993). In general, cancellous bone material is much more active metabolically, is remodeled more often than cortical bone, and is, therefore, "younger" on average than cortical bone. Therefore, even though cancellous and cortical bone may be of the same kind of material, the maturation of the cortical bone material may alter the mechanical properties at the microstructural level.

At the macrostructure level, bone is distinguished into the cortical (or compact) and cancellous (or
Figure 1
Hierarchical structural organization of bone: (a) macrostructure—cortical and cancellous bones, (b) microstructure—osteons and trabeculas, (c) sub-microstructure—lamellas, (d) nanostructure—mineralized collagen fibrils, (e) sub-nanostructure—mineral, collagen, and noncollagenous organic proteins.

# Cross references marked by a hash can be found by consulting the Encyclopedia of Materials: Science and Technology.

trabecular) types. In cross-section, the end of a long bone such as the femur has a dense cortical shell with a porous, cancellous interior. Flat bones such as the calvaria have a sandwich structure composed of dense cortical layers on the outer surfaces and a thin, reinforcing cancellous structure within. Although both types of bone (cortical and cancellous) are most easily distinguished by their degree of porosity or density, true differentiation comes from histological evaluation of tissue microstructure.

The mechanical properties of bone are influenced greatly by the porosity and the organization of the microstructure. It is, therefore, difficult to predict micro-properties *in vivo* by measuring mechanical properties at the macrostructural level. In general, values for mechanical properties of bone at the macrostructural level vary from one bone to another as well as within different regions of the same bone (Rho *et al.* 1995, Goldstein 1987). The lesser regional heterogeneity observed in cortical bone is the result of the lower turnover rate for this material, which engenders changes at the microstructural level. Overall, the differences between the mechanical properties in cancellous bone are much broader than those in cortical bone and indeed they may vary by a factor of 2–5 from bone to bone. To a great extent, differences between whole bones may be explained by the variance in their structure and mechanical function (Burstein *et al.* 1976, Yamada 1970, Cezayirlioglu *et al.* 1985, Martens *et al.* 1983, Linde *et al.* 1989, Keaveny *et al.* 1997). However, the properties of a particular type of bone can not be adequately expressed in single values; our best estimates can only be given in a range of values reflecting both the experimental difficulties and the observed regional heterogeneity (Table 1).

2. Microstructural Properties: Osteons and Trabeculas

Mineralized collagen fibers form into planar arrangements called *lamellas* (3–7 μm wide). In some cases these sheets (lamellas) of mineralized collagen fibers wrap in concentric layers (3–8 lamellas) around a central canal to form what is known as an *osteon*. The osteon looks like a cylinder about 200–250 μm in diameter running roughly parallel to the long axis of the bone. Other forms of cortical bone, where the mineralized collagen fibers are less well registered and no pattern can be distinguished, are called *woven* bone. In some forms of bone, the lamellas are overall tangential to the outer surface of the bone (without forming osteons), and together with woven bone tissue, form a larger plywood-type stacking of thicker layers (150–300 μm) around the complete circumference of the bone. Cancellous bone is made of an interconnecting framework of trabeculas in a number of combinations all comprising of the following basic cellular structures: rod–rod, rod–plate, or plate–plate. A trabecular rod is about 50–300 μm in diameter.

Over the years Ascenzi and co-workers have examined the mechanical properties of single Haversian systems in bending (Ascenzi *et al.* 1990), tension (Ascenzi and Bonucci 1967), compression (Ascenzi and Bonucci 1968), and torsion (Ascenzi *et al.* 1994; Table 2). Osteons with longitudinal lamellas are better for tension and torsion and perhaps stronger in bending as well, while osteons with alternating lamellas are more suited for compression. The stiffnesses produced from torsion testing of individual osteons were much higher than those for the whole bone. Ascenzi *et al.* do not justify or explain this

Table 1
Mechanical properties of human cortical and cancellous bones tested by compression, tensile, and torsional testing.

Bone	Specimen		Strength (MPa)	Elastic modulus
Human cortical bone	Femur[a]	Compression	179–209	15.4–18.6 GPa
	Tibia[a]		183–213	24.5–34.3 GPa
	Femur[a]	Tensile	120–140	15.6–17.7 GPa
	Tibia[a]		45–170	18.9–29.2 GPa
	Femur[b]	Torsional	54 ± 0.6	3.2 GPa
	Tibia[c]		66–71	–
	Femur[d]	Bending	103–238	9.82–15.7 GPa
Human cancellous bone	Femoral head[e]	Compression	9.3 ± 4.5	900 ± 710 MPa
	Femoral neck[e]		6.6 ± 6.3	616 ± 707 MPa
	Intertrochanteric[e]		3.6 ± 2.3	263 ± 170 MPa
	Proximal tibia[f]		5.3 ± 2.9	445 ± 257 MPa
	Vertebral body[g]		–	165 ± 110 MPa

[a] Burstein *et al.* 1976, [b] Yamada 1970, [c] Cezayirlioglu *et al.* 1985, [d] Keller *et al.* 1990, [e] Martens *et al.* 1983, [f] Linde *et al.* 1989, [g] Keaveny *et al.* 1997.

result. However, this effect may be explained by the use of Cosserat micropolar elasticity, which allows for local rotation at cement sheaths and other internal boundaries (Lakes 1995). Katz (1981) confirmed that there is a majority of fibers in the longitudinal direction in osteons and also along the long axis of trabeculas in cancellous bone, but the situation in general is muddled. Marotti (1993) claims that fibers in general follow two patterns which constitute thin and thick lamellas; the thin ones are more oriented and compact, the thick ones are more diverse and sparse (somewhat microporous) in their elements.

The trabecular properties are easier to study in isolation. However, in spite of recent reports (Choi *et al*. 1990, Rho *et al*. 1993) there remains some controversy regarding the value of the elastic modulus of single trabeculas (Table 3). Trabecular bone material properties are important for characterizing various bone pathologies, and the remodeled bone adjacent to various joint implants, because they are affected by disease sooner than cortical bone. In the past it was assumed that individual trabeculas, single osteons, and a thin cortical shell possessed the same mechanical properties as those of large cortical bone specimens regardless of their type or size (Wolff 1892). However, many investigators produced values for the elastic modulus of individual trabeculas, single osteons, and a thin cortical shell that were considerably less than that for whole bone (Choi *et al*. 1990, Rho *et al*. 1993, Ashman and Rho 1988). Mechanical testing of cortical osteonal samples has shown a similar modulus, while individual trabeculas show a lower modulus of elasticity than that of large cortical bone specimens. This issue needs further clarification.

A literature survey of measured and estimated values of the modulus of trabecular bone material shows that moduli values range from 1 GPa to 20 GPa (Table 3). Rho *et al*. (1993) showed that the relationship derived from this data, between elastic moduli and density in cancellous bone material, could not be extrapolated from similar data from

Table 2

Mechanical properties of single osteons and trabeculas. Longitudinal (L) osteon has marked longitudinal spiral course of fiber bundles in successive lamellas. Alternate (A) osteon has fiber bundles in one lamella making an angle of nearly 90° with the bier bundles of the next one.

Test method	Elastic modulus (GPa)
L osteon, three-point bending[a]	2.32 ± 1.20
A osteon, three-point bending[a]	2.69 ± 0.93
L osteon, tension[b]	11.7 ± 5.8
A osteon, tension[b]	5.5 ± 2.6
L osteon, compressive[c]	6.3 ± 1.8
A osteon, compressive[c]	7.4 ± 1.6
T osteon, compressive[c]	9.3 ± 1.6
L osteon, torsion[d]	3.3 ± 0.5
A osteon, torsion[d]	4.1 ± 0.4
T osteon, torsion[d]	4.1 ± 0.4

tests on cortical bone material and its density. This led the authors to conclude that the materials of the two bones were intrinsically different. However, the data are not definitive, as the dependence of the modulus on other parameters such as location, microstructure, or density variation was not considered. The most recent studies by use of nanoindentation (Rho *et al.* 1999) and by finite element analysis (FEA) simulation (vanRietbergen *et al.* 1996) suggest that in fact the elastic properties of single trabeculas are very similar to the properties of nearby cortical tissue. This matter requires further clarification because imprecise values may lead to misinterpretations of the structural function of each type of bone material or misinterpretation of the role of trabecular bone in the mechanical behavior of normal and implanted joints.

3. Submicrostructural Properties: Lamellas

Bone lamellas are 3–7 μm thick, but the detailed anatomy of lamellas is still a matter of dispute. Gebhardt (1906) all lamellas are dense fibrous layers in which collagen fibers lie parallel; the difference between successive lamellas consists only in the orientation of the fibrils, which may vary through an angle of 0° to 90°. Ziv *et al.* (1996) proposed a model in which adjacent lamellas have roughly the same structure, but their layers are aligned in different orientations. There are transitional regions between the neighboring lamellas in which the orientation of the collagen and its associated mineral changes rapidly but smoothly over a few microns. In other models, the lamellar pattern of the bone is held to depend on the alternation of layers of heterogeneous structure (Reid 1986). The models propose that lamellar bone is made up of alternating collagen-rich (thin lamellas) and collagen-poor (thick lamellas) layers, all having an interwoven arrangement of fibers. By means of x ray microprobe analysis, Marotti (1993) found that the calcium and phosphorus content of thick lamellas was 10–15% higher than in thin lamellas. Reid (1986) also observed that thin lamellas are more rapidly removed during polishing than thick lamellas.

With nanoindentation, it is possible to measure properties at the micron and submicron levels and thus study the properties of bone microstructural components having dimensions of only a few microns or less. For example, nanoindentation has recently been used to determine the elastic modulus and hardness of individual trabecular struts (Rho *et al.* 1997, 1999) and small filler particles in resin composites and other dental restoratives (Townsend *et al.* 1975). The nanoindentation technique is theoretically able to measure mechanical properties with a resolution of better than 1 μm. To the best of our knowledge,

in only one previous study has an investigation on the tensile properties of individual lamellas within osteons been carried out (Ascenzi *et al.* 1982). It met with little success due to the inhomogeneity in thickness of single lamellar samples along their length and width. They observed that there was usually a wide, continuous range of variation in thickness even along the length of single osteonic lamellas. However, the dimensions of these substructural building blocks of osteons, a few microns or less, were well within the capabilities of nanoindentation measurement.

The mechanical properties of the osteonal thick lamellas (19.7 GPa) have been successfully measured using nanoindentation. However, the properties of thin lamellas, which some investigators (Gebhardt 1906, Ziv *et al.* 1996) believe to have a quite different microstructure compared with that of the thick lamellas, still remain to be measured in order to gain a better understanding of the properties of lamellar bone.

4. Nanostructural Properties: Collagen Fibers and Crystals

The most prominent structures seen at this scale are the collagen fibers, surrounded and infiltrated by mineral. The attachment sites of macromolecules onto the collagen framework are not distinctly known, although several immunohistological studies have shown preferential labeling of some macromolecules in a periodic fashion along the collagen molecules and fibers (Glimcher 1989). The subnanostructures of the three main materials are crystals, collagens, and noncollagenous organic proteins.

Some studies, which used selective demineralization and acoustic methods, have come up with most intriguing theories about the complementary role of the collagen and the mineral (Turner *et al.* 1995, Pidaparti *et al.* 1996). These workers have suggested that isolated collagen is more or less isotropic and by the impregnation of mineral it reaches the anisotropic ratios that are known for whole bone (1.7–2.1) in two normal directions. Experimental methods that can resolve the issue of absolute and relative (anisotropy) values for the elastic modulus of microscopic bone tissue would be invaluable. There is still no reliable data regarding the elastic properties of the mineral crystals and the collagen matrix of bone. Isolated crystals retaining all of the native features of bone mineral can be obtained using low-temperature and nonaqueous methods; however, it is not clear how the mechanical properties of these crystals can be measured at this time. Most likely, the elastic properties of bone mineral crystals are different from those of pure hydroxyapatite due to the vacancies and substitutions in the natural

crystals. Examination of the highly mineralized rostrum bone of a Mesoplodon whale (it has only 2–3% collagen w/w) shows that bone fully compacted with mineral retains the same anisotropy ratios (roughly 2:1 in elasticity and toughness) as less mineralized ''normal'' bone. This seems to underline the importance of the shape, geometry, and material properties of the crystals for determining the behavior of whole bone.

The elastic properties of the collagen of bone have been assumed to be the same as that for tendon or ligament collagen. However, unlike the collagen of soft tissues, it is normal to assume that bone collagen will not show a reorientation under stretch and also will not (does not) have the crimp pattern and straightening out effect. Examining the organic remnant after crystal dissolution appears to be the customary method for obtaining the properties of the collagen of bone (Bowman *et al.* 1996). However, no one can be certain of the constitution and any conditional changes of the phase (either mineral or collagen) that is left behind (Aerssens *et al.* 1994). Therefore, it is very difficult to imagine what the bone-collagen properties may be, and certainly the intimate relationship of mineral and collagen and their interplay makes measurement and predictions even more difficult. Further investigations are warranted for a more complete understanding as to how mineral–matrix interactions are related to their effects on mechanical properties at the various hierarchical levels of tissue structure and organization.

5. Concluding Remarks

Additional research would advance our understanding of bone as a structure and as a material. The following questions remain unanswered: Is there a size effect in bone? What is the hierarchical level at which homogenized material properties can be obtained that are similar to the ones observed macroscopically in whole bone samples? What is the nature of the interfaces between the constituents of bone at all length scales? If we are successful in answering these questions, various pathophysiological conditions may be easier to understand. Aging, osteoporosis, osteoarthritis, and other degenerative diseases all are expected to influence, and be influenced by, the microstructure to different degrees. It may just be possible that certain diseases affect the constitution and quality of only one level of the hierarchical organization of bone, and, therefore, they may become easier to understand and treat. Therefore, further investigations of mechanical properties at the ''materials level'' in addition to the studies at the ''structural level'' are needed to fill the gap in our present knowledge and to achieve a better understanding of the mechanical properties of hard tissues such as bone.

High-performance Fibers

1. Fiber Development

High-performance synthetic fibers often resemble textile fibers in appearance and some are of the same chemical composition; however, they are produced so as to optimize their mechanical properties to achieve enhanced performance (Bunsell A R 1988, Hearle J W S 2001, and Moncrieff R W 1979). Such fibers are used in structures for which their flexibility, lightness, and very high mechanical properties, compared to bulk materials, make them indispensable. These fibers have higher strengths and often higher elastic moduli than conventional textile fibers due to the manufacturing processes employed and also, in many cases, due to their molecular or atomic structures. In the case of some high-performance fibers, their properties can attain almost the limits of what is physically possible so that very high moduli, even up to that of graphite, can be achieved. Some fibers have been developed to possess great thermal stability for use at temperatures above the limits at which high-performance metals can be used. Although stiff along their lengths, fibers are flexible when bent because of their small diameters, which are usually of the order of 10 μm. They are used in applications that include high-performance tethering ropes, flexible architectural structures, reinforced elastomers, and fiber-reinforced composites.

The commercial development of synthetic fibers began in the 1930s with the production of glass fibers in the US. Glass and glass fibers have approximately the same Young's modulus and density as that of aluminum. Although fibers made from regenerated cellulose, from wood, or other plants, were produced, first in France, toward the end of the nineteenth century and are known as rayon or viscous rayon, the first truly synthetic polymeric fibers were produced in 1938. These were polyamide 6.6 (developed in the US) and polyamide 6 fibers (developed in Germany). These polyamide, or "nylon" fibers, together with polyester fibers, developed in Great Britain in the 1940s, are the most important synthetic textile fibers produced. Although of low stiffness, they were the first of a family of organic fibers, which have been developed with elastic moduli rivaling and even exceeding that of steel, but with only a fifth or less of the weight. These organic fibers find, however, many industrial applications as in tyre reinforcement and anchor lines for off-shore oil platforms. Boron and silicon carbide fibers made by chemical vapor deposition onto a filament of tungsten or carbon were first produced in the early 1960s in the US and then in France and Russia (Kostikov VI 1995). They have the density of glass but Young's modulus twice that of steel. Carbon fibers, with a density of a quarter of

that of steel, were first produced in Great Britain in the mid-1960s. They are made by the pyrolysis of polyacrylonitrile precursor fibers and commonly have moduli up to one and half times the modulus of steel but can be up to three times stiffer. An alternative process developed in the 1970s in the US uses the pitch residue from oil refining or the coking of coal to give fibers with moduli approaching that of graphite. Fine ceramic fibers, for structural applications, started to appear at the end of the 1970s and in the 1980s (Bunsell A R and Berger M-H 1999). One group of these fibers, developed in Great Britain and in the US, is based on alumina, whereas others developed in Japan are based on silicon carbide. These fibers have Young's moduli ranging from that of steel to twice this value with densities less than half that of steel.

Most fibers have diameters of the order of 10 μm, which can be compared to the diameter of a human hair, which is 70 μm. Exceptions, however, are the boron and SiC fibers made by Chemical vapor deposition (CVD) onto cores, which are twice as thick as hair. The fineness of fibers allows even the stiffest of materials to be made in a flexible form as bending stiffness is related to the cube of the diameter. However, many high-modulus fibers are completely elastic, at least at room temperature, and are therefore brittle in tension and in bending. They are most suited to be used as reinforcements in composite materials. The high-performance polymer fibers are also used as reinforcements, such as in tyres and other composites, but they are not brittle as they deform plastically in compression. They show great toughness which can be exploited (Chawla K K 1998) in structures such as cables and structures, which must resist impacts.

1.1 Organic Fibers

Polyamide (PA) or "nylon" fibers were developed in 1938 by Du Pont in the US and in Germany by I.G. Farben. These fibers are based upon amide groups (–C(O)NH–) contained within a chain of carbon atoms making up a backbone of atoms linked by strong covalent bonds (Table 1). However, the molecules are linear and can bend and rotate at each bond so that the molecules are not perfectly aligned parallel to the fiber axis, which results in a low Young's modulus. Around 1947, polyethylene terephthalate (PET) or "polyester" fibers were produced in Great Britain and have become the most widely produced synthetic fibers. Table 1 shows that the polyester molecule contains an aromatic ring, which stiffens the molecule compared to the very flexible polyamide structure. Both polyamide and polyester fibers melt at around 260 °C. Although both of these latter fibers melt at around the same temperature, it is significant that the polyester fiber, which contains the aromatic rings,

shows much higher resistance to discoloration at raised temperatures than the polyamide fiber. A fiber which is related to PET fibers is the polyethylene-naphthalate (PEN) fiber. Table 1 shows that this latter fiber is based on a molecule which has two aromatic rings, which further increases the rigidity of the fiber. The three fibers mentioned above are made by drawing from the melt through a spinneret. The drawing rate determines the final properties. An undrawn fiber will have a strain to failure of some hundreds of a percent and tensile loading will produce not only a very high strain to failure but deformation will involve striction of the filament. Striction is when the diameter of the filament is locally reduced under load and in this region the molecular structure becomes aligned parallel to the fiber axis and the loading direction. Further loading induces an increase in the striction until the specimen is reduced in cross section and the molecular structure is largely oriented parallel to the fiber axis. Fibers for textile end-uses are drawn during production so as to produce filaments with enhanced molecular orientation, higher strengths, and longitudinal stiffness but with reduced strains to failure, generally of the order of 30%. Striction is not usually seen with this type of fiber. High-performance versions of PA and PET fibers, which are utilized for industrial applications, are more highly drawn with further reduced strains to failure in the region of 20% for the former and 15% for the latter. PEN fibers are only produced as high-performance industrial fibers and have strains to failure of around 6%. The molecular morphology of these fibers consists of microfibrils, with transverse dimensions of around 5 nm, arranged more or less parallel to the fiber axis. Regions within the microfibrils are composed of well-ordered arrangements of molecules which are folded as in a concertina. The rest of the structure is made up of less well-ordered regions so that the overall molecular structure is semi-crystalline with a crystalline content generally of the order of 40%.

A typical tensile fracture morphology of one of the above thermoplastic fibers is shown in Fig. 1(a). It can be seen that the fracture surface consists of two regions, an initial inclined region corresponding to initiation at the surface and slow crack propagation normal to the fiber axis. The crack opens because of plastic deformation ahead of the crack. Rapid failure finally occurs when the remaining part of the section can no longer support the applied stress. Under particular cyclic conditions, the same fiber fails in fatigue and one half of the fatigue break is shown in Fig. 1(b). The crack has initiated at or near the surface but instead of running normal to the fiber axis it has been deviated to run at a slight angle to the fiber axis, penetrating into the fiber section so that the remaining section finally fails by the tensile process. A particularity of this type of failure is that the minimum load has to be lower than a threshold level so that

Table 1
Molecular composition of high-performance organic fibers.

Fiber type	Repeat unit in the macromolecule	Maximum elastic modulus (GPa)	Melting or decomposition temperature (°C)
Polyamide 6 [Nylon 6]	$[NH-CH_2-CH_2-CH_2-CH_2-CH_2-CO]_n$	4	230
Polyamide 6/6 [Nylon 6.6]	$[NH-CH_2-CH_2-CH_2-CH_2-CH_2-CH_2-NH-CO-CH_2-CH_2-CH_2-CH_2-CO]_n$	5	260

raising the cyclic loading pattern can stop fatigue failure.

Higher melting points or decomposition temperatures and much higher Young's moduli have been achieved by including more aromatic rings in the molecular main chain and by aligning these very rigid molecules parallel to the fiber (Table 1). These types of polymers are made by the technology of liquid crystal spinning, as illustrated in Fig. 2. Overall, within the melt or solution, the molecular alignment is random; however, orientation is achieved not by drawing but through the shearing of the solution when the solution passes through the spinneret. Molecular alignment in these fibers occurs because of the very stiff molecules that are aligned preferentially parallel to the fiber axis by the shear forces in the spinneret and held together by hydrogen or van der Waals' bonds. The straighter the molecule the higher the modulus achieved. These liquid crystal polymers do not usually lend themselves to melt spinning and are usually spun from a solution although the Vectran fiber, produced since the 1970s by Hoechst-Celenese, is melt spun.

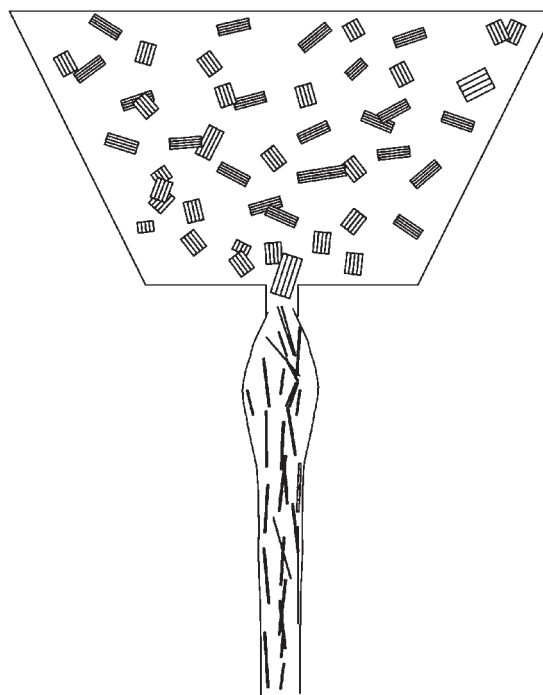
Vectran is a liquid crystal polyester-based fiber, which, as can be seen from Table 1, has a molecular structure that is not perfectly straight. It is produced by the acetylation polymerization of *p*-hydroxybenzoic acid and 6-hydroxy-2-naphthoic. The good alignment of its molecular structure gives higher rigidity than that found with other polyester fibers but the form of the molecule determines its ultimate rigidity. The fiber is the only melt spun liquid crystal fiber, which is available and finds uses in applications such as sail cloth because of its rigidity and resistance in bending.


Figure 2
Spinning from a liquid crystal solution.

The aramid family of fibers are made up of aromatic PAs. Nomex was the first fiber of this family, produced in the 1960s by Du Pont. Nomex is a *m*-aramid, which accounts for an elastic modulus

little different from high-performance PET but with a higher temperature resistance. Nomex is widely used for clothing for potentially hazardous conditions where fire is a danger. It is also widely used in paper form as a honeycomb structure in the aeronautical industry. *p*-Aramids can possess remarkably high Young's moduli, more than 20 times that of conventional PA fibers and twice that of glass, as shown in Table 2. This group of fibers, first introduced as the Kevlar fiber from Du Pont, has been available since 1972. These fibers are made from a mesophase or liquid crystal solution of poly-(*p*-phenylene terephthalamide) (PPTA) dissolved in concentrated sulfuric acid. If an appropriate concentration is made, the solution consists of locally organized PPTA molecules, which align with one another. The structure of aramid fibers is very well ordered; however, they are highly anisotropic, which results in them being weak in all directions except parallel to the fiber axis. As a consequence failure of these fibers is nearly always highly fibrillar.

Under tension, Kevlar fibers are 5 times as strong as steel in air for the same weight. Under tension, the fibers show little tendency to deform plastically, but when they are bent, the side experiencing compression undergoes plastic deformation, which allows them to accommodate the imposed strain. This results in the fiber being difficult to cut as well as giving great tenacity and resistance to impact loading. Their highly anisotropic behavior means that the fibers are not used in primary loading structures subjected to compressive forces. Aramid fibers, other than Kevlar, that are commercially available are the Twaron fiber developed by Akzo in Holland, now produced by Teijin Twaron, also in Holland and the Technora fiber from Teijin in Japan. Technora is derived from poly-*p*-phenylene/3,4′-diphenylether terephthalamide, which, as can be seen from Table 1, is not a straight molecule and as a consequence the fiber has an intermediate modulus of ~ 65 GPa.

In 1998 the Toyobo Company began the commercial production of the Zylon fiber. Its chemical composition is poly(*p*-phenylene benzobisoxazole) (PBO). The fiber has remarkable properties in tension, as can be seen from Table 2. It has a Young's modulus, which is 40% higher than that of steel, with the density of an engineering plastic. Its Young's modulus is twice that of Kevlar, since unlike Kevlar, the PBO molecule, shown in Table 1, is completely straight thus making the most of the covalent bonds in its structure. PBO fibers, however, suffer from poor compressive strength as molecular interchain cohesion is assured by van der Waals' bonds. As can be seen from Fig. 3, the fiber fibrillates on failure due to its inherent anisotropy.
Figure 3
Detail of the splitting of a Zylon PBO fiber.

Table 2
Comparison of organic fiber properties.

Fiber	Diameter (μm)	Specific gravity	Young's modulus E (GPa)	Strength σ (GPa)	Strain to failure ε (%)	Specific modulus E/ρ (GPa g^{-1} cm^3)	Specific strength σ/ρ (GPa g^{-1} cm^3)
Polyamide 66	30	1.14	<5	1	20	4	0.9
Polyester	20	1.38	15	1	15	10	0.7

Polyethylene	38	0.96	117	3	3.5	120	3.1

Magellan International in the US has taken over the development of a fiber created by the researchers at Akzo, which at present is called M5. The fiber is said to possess a Young's modulus of 330 GPa, but, above all, superior compressive properties, such as molecular interchain cohesion, are ensured by hydrogen bonds. This leads to a slightly higher specific gravity of 1.7. Compressive strength is said to be 4 times higher than that of the PBO fibers and nearly 3 times higher than Kevlar fibers.

The production of aramid fibers involves complex and expensive chemistry; however, the high-performance properties of the fibers are a result of the molecules being aligned parallel to the fiber's axis. Simpler polymers could, if all their molecules were aligned parallel to one another, give materials with the characteristics of high-performance materials. Such fibers can be made using a sol-gel, in which polyethylene is dissolved in a solvent to make a very dilute solution, which is then spun. Such fibers were first produced in Holland by DSM, under the name Dyneema, and then by Allied (now Honeywell) in the US under the name Spectra. The fibers consist of polyethylene molecules, which are aligned parallel to the fiber axis with molecular interchain cohesion assured by van der Waals' forces. They have properties in tension rivaling those of the aramid fibers with a lower specific gravity (0.97). However their properties in compression are poor. These fibers are limited in temperature to a maximum of $120\,°C$ as they melt around $150\,°C$ and suffer from creep.

1.2 Glass Fibers

In 1931 two American firms, which were later to fuse to make the Owens Corning Fiberglas Corporation, developed a commercial method of spinning glass filaments from the melt through spinnerets. The melting point of the most widely used glass is around $1200\,°C$ and the spinnerets are made from platinum. The holes in the spinnerets have diameters of $1–2\,mm$ and drawing the filaments produces fibers having diameters usually between 5 and $15\,\mu m$. The spinnerets usually contain several hundreds of holes so that a strand of glass fibers is produced. Several types of glass exist but all are based on silica (SiO_2), which is combined with other elements to create specialty glasses. The compositions and properties of the most common types of glass fibers are shown in Table 3. The most widely used glass for fiber-reinforced composites is E-glass. S-glass, which contains a greater amount of alumina, is used to make glass fibers with superior mechanical properties whereas type C has a much reduced alumina content and resists an acid environment. Type D, which has no alumina, but a high content of boron oxide is used for its dielectric properties.

The strength of glass fibers is usually much higher than that of bulk glass as they contain far fewer

Table 3

Compositions (wt.%), density, and mechanical properties of various glasses used in glass fiber production.

Glass type	E	S	R	C	D
SiO_2	54	65	60	65	74

Failure strain (20 °C) %	4.5	5.3	5.3	4.0	4.5

weakening flaws. However to prevent damage by abrasion, they are coated with a protective size which also holds the strand together, acts as a bonding agent with resins and sometimes as an antistatic agent. The structure of glass fibers is amorphous with ionic bonds linking the atomic structure. There appears to be no appreciable residual stress within the fiber and the structure is isotropic, which means that the Young's modulus of glass in fiber form is the same as in bulk form. Glass fibers are cheaper than most other relatively high-modulus fibers and do not require very specialized machines or techniques to handle them. Their elastic modulus is, however, low compared to many other fibers and the specific gravity of glass is relatively high. Glass fibers are most commonly used to reinforce resins that limit their use to $\leqslant 300\,°C$ (usually $\leqslant 120\,°C$). Above this range densification of the glass occurs and the fibers become increasingly susceptible to slow crack growth from surface defects. Strength increases with decreasing temperature.

1.3 Deposited Fibers

Boron, the fifth element in the periodic table, is the lightest element with which it is practical to make fibers and they were first produced in the US at the beginning of the 1960s. Boron fibers are made by chemical vapor deposition, in which a mixture of boron trichloride (BCl_3) and hydrogen (H_2) at around $1000\,°C$ passes over a continuous tungsten filament heated by electric current. Boron is

Table 4
Properties of ceramic fibers produced by chemical vapor deposition.

Fiber	Manufacturer	Trade mark	Composition	Diameter (μm)	Density (g cm^{-3})	Strength (GPa)	Strain to failure (%)	Young's modulus (GPa)
SiC	Specialty materials (formerly Textron)	SCS-6	SiC on carbon	140	2.7–3.3	3.4–4.0	0.8–1	427
	DERA	Sigma	SiC on tungsten	100	3.4	3.4–4.1	0.8	400–410
B	Speciality materials (formerly Textron)		Boron on tungsten	100–140	2.57	3–6	1	380–400

deposited on the tungsten filament, which has a diameter of 12 μm.

The fibers have Young's moduli exceeding 400 GPa as shown in Table 4 and very high strength both in tension and in compression. This latter quality is enhanced by their large diameter of 140 μm. A cross section of a boron fiber reveals its tungsten core and boron mantle. Boron fibers have proved to be a good reinforcement for light metal alloys particularly when the fiber was protected by a coating of SiC or B_4C. However, their high cost of production has limited the wide use of this type of fiber.

Silicon carbide fibers are also produced by CVD using various chlorosilanes, such as $CH_3\text{-}Si\text{-}Cl_3$, which gives 3HCl and SiC, which is deposited onto a tungsten or carbon core. They are of primary interest for the reinforcement of titanium and intermetallic matrices. Fibers with diameters of between 100 and 140 μm are made. These fibers, until recently produced by Textron and now produced by Speciality Materials Inc., are known as SCS-*n*, where *n* is the number of microns of surface coating added onto the diameter to protect it during composite manufacture. SiC fibers have a Young's modulus $\geqslant$ 400 GPa, as shown in Table 4 and can be used to around 1000 °C. Figure 4 shows the cross section of an SiC fiber made by CVD showing the tungsten core.

1.4 Carbon Fibers

Carbon is the sixth lightest element and the carbon–carbon covalent bond is the strongest in nature. Many fibers can be converted into carbon fibers, the basic requirement being that the precursor fiber carbonizes rather than melts when heated. The carbon fibers developed in the US in the 1950s and early 1960s used fibers regenerated from cellulose. This proved a slow process, as the carbon yield from cellulose is only 24% and mechanical properties were
Figure 4
Cross-section of an SiC fiber made by CVD showing the tungsten core.

not high. However, such fibers have high thermal conduction properties and are still used in carbon–carbon heat shields and brake pads.

Most carbon fibers though are made by a process developed first in Great Britain and then in Japan in the late 1960s based on the conversion of a modified form of acrylic textile fiber. Polyacrylonitrile (PAN) has a carbon yield of 49% and the properties of

carbon fibers made by this method depend on the temperature of pyrolysis. The PAN fibers, held in tension, are first heated to about 250 °C in air, which cross links the structure and makes it infusible. Further heating in an inert atmosphere to above 1000 °C eliminates most of the elements other than carbon and around 1500 °C a fully carbon fiber is achieved. At this temperature the strength of carbon fibers reaches a maximum. Above this temperature, the basic carbon structural units increase in size, which results in a fall in strength whereas the Young's modulus increases continuously with increasing temperature up to around 3000 °C. The structure, which results from the pyrolysis of PAN, is highly anisotropic, with the basic structural units formed by the carbon atom groups aligned parallel to the fiber axis. There is complete rotational disorder in the radial direction and the relatively poor stacking of the carbon atoms means that a graphite structure is never achieved. The structure contains pores that account for the density of the fibers being less than that of fully dense carbon. Table 5 shows some typical properties of carbon fibers; however, there exists a considerable range of properties for these fibers. Figure 5 shows a PAN-based carbon fiber.

Carbon fibers made from pitch-based precursors were developed in the US in the early 1970s and in Japan in the 1980s. The high carbon yield of pitch, which approaches 90%, makes it an attractive and cheap source for making carbon fiber precursors. However, cost is increased by the purification processes by which the pitch is converted into a mesophase or liquid crystal solution, which is then spun giving precursor fibers with aligned microstructures. From this point the fabrication route is the same as that for the PAN-based fibers. Unlike PAN-based

fibers, there is no peak in strength at 1500 °C. Pitch-based precursors heated to around 2300 °C give fibers with Young's moduli as high as those obtained with PAN-based fibers at 2900 °C and heating to these higher temperatures gives even greater stiffness of up to four and a half times that of steel. It is therefore more economical to produce high-modulus carbon fibers from pitch than from PAN. The properties are due to a less disordered, more graphitic microstructure of the pitch-based fibers, which leads to lower compressive strength and increased costs in producing high-strength carbon fibers.

In the absence of oxygen, carbon fibers are the ideal reinforcement and can be used above 3000 °C. However, the fibers suffer from oxidation from around 400 °C so that they can be used for short exposure times, such as in carbon–carbon composite rocket nozzles or heat shields for atmospheric re-entry vehicles, but not for long-term applications above this temperature.

1.5 Oxide Fibers

The oxide of aluminum, alumina, is a hard brittle material with excellent refractory properties up to 1600 °C. The atomic structure of this material is assured by a mixture of covalent and ionic bonds. Fibers for structural applications based on forms of alumina were developed first in the UK and in the USA in the 1970s. Alumina exists in a range of phases of which the most stable and crystalline form, to which every other phase is converted around 1200 °C, is alpha alumina which has a Young's modulus of around 400 GPa. Several manufacturers have produced continuous α-alumina fibers as can be seen

Table 5
Typical characteristics of carbon fibers.

Fiber type	Manufacturer	Trade mark	Diameter (μm)	Density (g cm^{-3})	Strength (GPa)	Strain to failure (%)	Young's modulus (GPa)

A PAN-based carbon fiber.

from Table 6. These fibers are made from slurries consisting of α-alumina particles, in an aqueous solution of aluminum salts which is spun and sintered. The control of grain growth and porosity in the production of α-alumina fibers is difficult so that the different manufacturing routes adopted have produced fibers with different Young's moduli. The Almax fiber, for example, contains considerable porosity, which accounts for its lower modulus than that of Nextel 610.

The difficulties in producing pure α-alumina fibers can be overcome by the inclusion of silica in the structure and the development of intermediate alumina phases. The Young's moduli, around 200 GPa, of these fibers are lower compared to that of pure α-alumina and such fibers are produced at a lower cost. This, added to easier handling due to their lower stiffness, makes them attractive for thermal insulation applications, up to at least 1500 °C and as reinforcements for aluminum alloys in the temperature range of 300–350 °C. α-Alumina fibers and those of other phases containing silica resist oxidation at high temperature but the high diffusion rates of the elements in their structures above 1000 °C means that they creep and also lose strength around this temperature.

A series of fibers based on a mullite composition consisting of a ratio of 3 moles of alumina to 2 of silica has been developed by 3 M. Mullite has a complex crystallographic structure, which is highly resistant to creep at high temperatures. The Nextel 720 fiber from 3 M consists of both α-alumina and mullite phases. The microstructure of the fiber is composed

Table 6

of mosaic grains of 0.5 μm with wavy contours, consisting of several slightly mutually misoriented grains and elongated grains. Its Young's modulus is 260 GPa. At high temperatures, above 1000 °C and up to 1500 °C, the microstructure of the Nextel 720 fiber leads to a dramatic reduction in creep rate compared to pure alumina fibers. However, the fiber surface is particularly reactive to alkaline contamination above 1100 °C, which leads to the development of a granular surface and a subsequent fall of strength occurs.

1.6 SiC-based Fibers

Fibers, based on silicon carbide, became available from Japanese producers in the early 1980s. They are made by the pyrolysis of organo-silicon precursor filaments based on polycarbosilane, which consists of cycles of six atoms arranged in a similar manner to the diamond structure of β-SiC. The early Nicalon fibers made by Nippon Carbon and the Tyranno fibers from Ube Industries were prepared by cross-linking the precursor fibers by heating in air, which introduced oxygen into the structure. The Tyranno fibers already contained some oxygen as it was introduced with a small amount of titanium into the precursor to control spinning. The presence of the oxygen resulted in the SiC grains, about 2 nm in size, which were developed during pyrolysis, being surrounded by an amorphous Si–C–O phase and the fibers had Young's moduli of around 200 GPa. This intergranular phase caused the fibers to creep above 1000 °C and its degradation above 1200 °C limited their use. Cross-linking of the precursors by electron irradiation eliminated the need for introducing additional oxygen into the precursors. This process gave rise to the Hi–Nicalon fiber, which had no significant oxygen-rich amorphous phase, but considerable excess free carbon. The grain size of the Hi–Nicalon fiber is around 10 nm and its Young's modulus is in the range of 265–290 GPa. The fiber is more stable than its predecessors at temperatures above 1000 °C although grain growth occurs. Both the Japanese manufacturers and Dow Corning have produced a near stoichiometric SiC fiber by extending the above technology and heating the fibers to temperatures of around 1800 °C. The fibers differ in detail, which leads to different ultimate properties, as can be seen in Table 7, but all three have grain sizes greater than 50 nm and up to 200 nm. This leads to Young's moduli of up to 400 GPa. These fibers retain their properties in short-term tests to around 1400 °C.

2. Concluding Remarks

A wide range of very different high-performance fibers have been developed. Many have low densities making them attractive engineering materials, either

embedded in a matrix to form a composite, or by themselves as ropes or other structures. These materials, which are still being improved, are destined to find a wide range of uses some of which would be impossible without the extraordinary properties of high-performance fibers.

Inorganic and Inorganic–Organic Aerogels

Aerogels are highly porous solid materials with very low densities and high specific surface areas. Their structure consists of a filigrane solid network with open, cylindrical, branched mesopores. This results in interesting physical properties, such as extremely low thermal conductivity and low sound velocity, combined with high optical transparency. Aerogels can be obtained as monoliths, granulates, films, or powders. There are several review articles (Ayen and Iacobucci 1988, Fricke and Emmerling 1992, Gesser and Goswami 1989, Heinrich *et al.* 1995, Hüsing and Schubert 1998) and symposium proceedings on aerogels (Fricke 1986, 1992, Pekala and Hrubesch 1995, Phalippou and Vacher 1998).

1. Network Formation

A gel consists of a sponge-like solid network, the pores of which are filled with a gas or a liquid. When gels are prepared from solutions of molecular precursors (through the sol stage), the pores are filled with the solvent ("wet" gels). Aerogels are obtained when the pore liquid in the wet gel is replaced by air without decisively altering the highly porous network structure or the volume of the gel body. In contrast, xerogels (see *Xerogels**) are formed by conventional drying of the wet gels with concomitant large shrinkage (and mostly destruction) of the gel body.

The procedures for the preparation of xerogels and aerogels are the same up to the wet gel stage, but the drying process is different. However, because the properties of aerogels very critically depending on the structure of the gel network, the chemical parameters governing the network formation have to be controlled more deliberately than required for most xerogels.

Inorganic or inorganic–organic gels are prepared by sol–gel processing (Brinker and Scherer 1990) from purely inorganic precursors (hydrolyzable metal salts or oxide sols) or from metal or semi-metal alkoxides and their organically substituted derivatives (see *Sol–Gel Reactions: Theory[#]*). The network and thus the pore structure of gels is formed by the aggregation of small primary colloidal or polymeric (sol) particles with typical diameters of 1–3 nm. In colloidal gels, dense colloidal primary particles are interconnected like a string of pearls. In polymeric gels, linear or branched polymer chains are formed by condensation of small clusters (the oligomeric species formed during sol–gel processing). There are several theoretical models for the aggregation of the primary particles to three-dimensional networks (Brinker and Scherer 1990, Schaefer 1989).

Aerogel networks are usually formed from colloidal particles. However, each aerogel has its own structural characteristics because the microstructure strongly depends on the preparation conditions.

1.1 Silica-based Aerogels

The term "SiO$_2$ gel" (correspondingly for other gels) is used to characterize the type of inorganic skeleton. "SiO$_2$ gels" and the corresponding aerogels often have the composition SiO$_x$(OH)$_y$ or, if they are prepared from alkoxides, SiO$_x$(OH)$_y$(OR)$_z$, where the values of y and z can be rather high.

Most laboratory preparations of silica aerogels use tetraalkoxysilanes (Si(OR)$_4$) as the silica source. The less expensive aqueous sodium silicate solutions (water glass) are used for larger-scale technical applications. The sodium silicate solution is ion-exchanged and the resulting silicic acid solution gelled by lowering the pH.

The kind of inorganic network formed by sol–gel processing depends to a large extent on the relative rates of the hydrolysis and condensation reactions. Hydrolysis is the rate-determining step under basic conditions, where reaction at central silicon atoms of an oligomeric unit is favored. The network of the resulting colloidal gels consists of big particles and large pores. The clusters mainly grow by the condensation of monomers, because condensation of clusters is relatively unfavorable. Acidic conditions (pH = 2–5) favor hydrolysis, and condensation is the rate-determining step. A great number of monomers or small oligomers with reactive Si–OH groups is simultaneously formed. Reactions at terminal silicon atoms are favored. This results in polymer-like networks with small pores.

Complete removal of the pore liquid from the smaller pores in polymeric gels is more difficult, resulting in a larger shrinkage during drying. For this reason, silica aerogels are usually prepared by base-catalyzed reaction of Si(OR)$_4$.

A modification of this procedure is to prehydrolyze Si(OR)$_4$ with a small amount of water under acidic conditions. In a second step, a defined amount of aqueous acid or base is added. Base catalysis in the second step results in a stiffening of the network that stabilizes the gels. This two-step procedure allows a more deliberate control of the microstructure of the SiO$_2$ gels.

The macroscopic properties of SiO$_2$ aerogels differ widely, due to structural differences. Silica aerogels with bulk densities as low as 0.003 g cm^{-3} (99.8% porosity) have been prepared. Typical values are in the range 0.1–0.2 g cm^{-3} (85–90% porosity). Skeletal densities are in the range 1.7–2.1 g cm^{-3}, mean pore

[#] Cross references marked by a hash can be found by consulting the Encyclopedia of Materials: Science and Technology.   437

diameters are in the range 20–150 nm, and specific surface areas are in the range 100–1600 $m^2 g^{-1}$. Silica aerogels are always amorphous.

The spectrum of properties can be widened by modification of silica aerogels with organic entities. For example, the hydrophobicity and the elastic properties of SiO_2 aerogels are improved by incorporation of organic groups, and new applications can be envisioned by the integration of functional organic moieties. Any modification should retain the gel network and the pore structure, because the interesting physical properties of aerogels result from these. Possibilities of postsynthesis doping or modification of aerogels with organic compounds are limited. Therefore, the organic groups have to be incorporated during sol–gel processing. Embedding molecules or polymers in gels is achieved by dissolving them in the precursor solution. The gel matrix is formed around them and traps them. The doped wet gels can be converted to aerogels. However, the probability is very high that the organic groups are leached out during the drying process.

A more general route for the organic modification is to use hydrolyzable and condensable precursors for sol–gel processing in which the organic group is covalently attached to the silicon atom and will therefore be bonded to the inorganic network. Silica aerogels modified by non-functional or functional organic groups are prepared by sol–gel processing of $R'Si(OR)_3/Si(OR)_4$ mixtures followed by supercritical drying of the wet gels. The process can be controlled in such a way that the organic groups cover the inner surface of the gel network without influencing its basic structure.

1.2 Metal Oxide Aerogels

The principles for network formation of non-silicate inorganic gels are the same as for SiO_2 gels. Aqueous salt solutions or metal alkoxides are employed for sol–gel processing. Metal alkoxides are much more reactive towards water than alkoxysilanes. This is due to the lower electronegativity and higher Lewis acidity as well as the possibility of increasing the coordination number. Whereas the reactivity of alkoxysilanes has to be promoted by catalysts, the reaction rates of metal alkoxides must be moderated to obtain gels instead of precipitates. The most common method is the substitution of part of the alkoxy groups by bidentate anionic ligands, such as carboxylates, β-diketonates, etc.

Unlike silica aerogels, their non-silicate counterparts can also form crystalline primary particles. As a general rule, the crystalline portion is favored by a large excess of water in the hydrolysis reaction. For example, TiO_2 aerogels can be prepared totally amorphous or with a network of mesoparticles (about 50 nm in diameter) formed by aggregation of crystalline anatase nanoparticles of about 5 nm diameter. Amorphous and partially crystalline ZrO_2 aerogels are found to have a branched, polymer-like fractal structure consisting of small primary particles with average diameters of 5.2 nm (partially crystalline) or 2.5 nm (amorphous).

One-component oxide aerogels include titania, alumina, and zirconia (mainly prepared from the propoxides and butoxides), V_2O_5 (prepared from $VO(OR)_3$), Cr_2O_3 (prepared from CrX_3, $X = NO_3$, Cl, or OAc), Fe_2O_3 (prepared from $FeCl_3$ or $Fe(acac)_3$), MoO_3 (prepared from $MoO_2(acac)_2$), and Nb_2O_5 (prepared from $Nb(OEt)_5$).

Mixed-metal, binary, or ternary aerogels can be prepared from the same types of precursors. Typical examples are TiO_2/SiO_2, mullite, Fe_2O_3/SiO_2, Fe_2O_3/Al_2O_3, V_2O_5/MgO, PbO/Al_2O_3, PbO/ZrO_2, BaO/Al_2O_3, Li_2O/B_2O_3, $PbTiO_3$, $NiO/SiO_2/MgO$, and cordierite. Many of these were prepared for catalytic applications (Schneider and Baiker 1995, 1997; Pajonk 1991, 1997).

When mixtures of two or more precursors with very dissimilar hydrolysis and condensation rates are reacted, the microstructure of the product may become rather heterogeneous, and phase separation may even occur. The faster reacting compound may form sol particles, which are coated by the slower reacting component. This effect can be avoided by moderating the reaction rate of the faster reacting component by the already discussed bidentate ligands. Alternatively, the slower reacting precursor can be prehydrolyzed and the faster reacting component added afterwards.

In mixed-oxide aerogels, the SiO_2 and Al_2O_3 portions are always amorphous. However, crystalline aluminates are observed (e.g., $NiAl_2O_4$). The structural data and properties of non-silicate aerogels depend very strongly on the particular system and on the preparation conditions. Typical densities are in the range 0.1–0.3 $g cm^{-3}$, and typical porosities in the range 80–95%. Pore radii range from 1 to 25 nm, specific surface areas from 80 to 800 $m^2 g^{-1}$, and primary particle diameters from 2 to 50 nm.

1.3 Metal–Aerogel Composites

A second metal component in the gels may not necessarily yield a binary oxide aerogel. The use of alcohols for supercritical drying can, under the applied conditions, result in the reduction of oxides to metals. Metal particles can also be generated by subsequent reduction of the aerogels with hydrogen at high temperatures or by mixing hydrogen into the autoclave during supercritical drying.

Postsynthesis doping of aerogels with metals is achieved by impregnation with the alcoholic solution of a suitable metal salt. The solvent has then to be removed again by another supercritical drying step in

order to prevent destruction of the aerogel network (two-step process). Composites prepared by this approach include Cu/SiO_2, Cu/MgO, Pt/MoO_3, Pd/Al_2O_3, and Pd/CeO_2. Alternatively, suitable metal compounds can be mixed into the precursor solution, which results in the incorporation of the metal compounds in the gel during sol–gel processing. Examples of metal-containing aerogels prepared by this approach include Pt/TiO_2, Pt/Al_2O_3, Pd/Al_2O_3, V/SiO_2, and Cu/SiO_2.

2. Drying Methods

The evaporation of the liquid from a wet gel is a very complex process. When wet gels are conventionally dried, the slower shrinkage of the network in the interior of the gel body results in a pressure gradient. Furthermore, the meniscus of the liquid drops faster in larger pores. The walls between pores of different size are therefore subjected to uneven stress and cracking (Brinker and Scherer 1990). The capillary forces exerted by the meniscus of the pore liquid and the pressure gradient exerted by the large shrinkage of the network are the main reasons for the collapse of the filigrane structure upon conventional drying. For the production of aerogels, methods must be applied which conserve the pore structure of the wet gels.

2.1 Supercritical Drying

In this procedure, the pore liquid is put into the supercritical state, where the liquid/gas interface disappears. The wet gel is placed in an autoclave and both the temperature and the pressure are adjusted to values above the critical point of the corresponding solvent (p_c, T_c). The fluid is then slowly vented at constant temperature, while the pressure drops. When ambient pressure is reached, the vessel is cooled to room temperature. Often the vessel is pre-pressurized by nitrogen to avoid evaporation of the solvent. The gas/liquid phase boundary must not be crossed during the drying process.

The pore liquid itself, which is usually an alcohol or acetone from the wet gel preparation, can be put into the supercritical state; about 250 °C and 7000 kPa are required. Problems arise from the combination of high temperatures and high pressures, and the flammability of these solvents. Furthermore, rearrangement reactions in the gel network are highly probable because of the high temperatures. As a consequence, the resulting aerogels have a lower specific surface area, a more narrow pore radii distribution (elimination of microporosity), and a stiffer network. Organic groups may be destroyed during drying. Phase separation and loss of stoichiometry or crystallization may occur in multicomponent gels.

An alternative is the use of liquid CO_2. This has the advantage of a low critical temperature ($T_c = 31.1$ °C) at a moderate critical pressure ($p_c = 7392$ kPa). However, a time-consuming solvent exchange is necessary before the actual drying step. Another requirement is the miscibility of the pore liquid with carbon dioxide. Structural changes only take place to a minor extent with CO_2 as the supercritical fluid.

2.2 Freeze Drying

Another possible way to avoid the gas/liquid interface during drying is by freeze drying. The pore liquid is frozen and then sublimed *in vacuo*. However, the aging period has to be extended to stabilize the gel network, the solvent must be exchanged by another with a low thermal expansion coefficient and a high pressure of sublimation, and low freezing temperatures have to be achieved by addition of salts. Another disadvantage is that the network may be destroyed by crystallization of the solvent in the pores. Therefore, only powders are obtained.

2.3 Ambient Pressure Drying

Drying of the gels at ambient pressure requires strengthening of the network by exact control of the aging conditions to avoid its collapse.

One approach involves a series of solvent exchange processes and a modification of the inner surface. The water/alcohol mixture in the pores of the gel is first exchanged for a water-free solvent, and the Si–OH groups at the inner surface are silylated. The gel surface is thus hydrophobized and its reactivity reduced. In the first stage of the drying process the gel shrinks strongly, as expected. However, no irreversible narrowing of the pores by formation of Si–O–Si bonds is possible because of the silylation. Therefore, the gel expands to nearly its original size in the final stage of the drying process ("spring-back" effect). The network of the modified gels must be stable enough to tolerate a reversible shrinkage of up to 28% of its original volume.

In another strategy, the strength and stiffness of the network is increased by aging the wet gels in solutions of tetraalkoxysilanes in aqueous alcohols. The monomers condense in the smallest pores and at the particle necks, the microporosity of the gels is lost, and shrinkage during drying can be completely avoided. The gels can be dried at ambient pressure at temperatures of 20–180 °C due to the stiffer network.

With the ambient pressure drying technique for the preparation of aerogels, a simpler and therefore less expensive preparation method is available, which makes the industrial application of aerogels economically more interesting. Ambient pressure drying also facilitates the possibility of preparing aerogel films.

3. Postsynthesis Modification of Aerogels

Postsynthesis treatment with a liquid is difficult because wet gels are again formed. Doping with metal salts by impregnation has already been mentioned in Sect. 1.3.

Another, more general possibility for the postsynthesis modification of aerogels is their reaction with gaseous compounds. Organic compounds can be sublimed into the network as shown for a porphyrin derivative. Carbon was deposited on the inner surface of aerogels by decomposition of gaseous organic compounds to improve the thermal properties of aerogels.

The chemical vapor infiltration method has been employed to prepare Si/SiO_2 nanocomposites by reaction of SiH_4 or $HSiCl_3$, and for the deposition of iron or tungsten particles from ferrocene, $Fe(CO)_5$ or $W(CO)_6$. In an oxidizing atmosphere, amorphous iron oxide particles in SiO_2 aerogels were obtained which in subsequent reactions were transformed to Fe_3O_4 or Fe_9S_{10}-doped SiO_2 aerogels. WN or WS_2 particles in aerogels were formed by post-treatment of the tungsten-doped aerogels with ammonia or sulfur.

The coating of the inner aerogel surface with carbon structures can also be achieved by pyrolysis of organic groups covalently bonded to the gel network.

4. Properties

A big problem with unmodified SiO_2 aerogels, particularly for technical uses, is their long-term stability in humid atmospheres. Owing to the large number of silanol groups on their inner surface, adsorption and capillary condensation of water and eventually cracking of the gel body by the resulting capillary forces results. Hydrophobation of the aerogels is achieved by silylation reactions via the gas phase, or by treatment of the wet gel with a silylating reagent or by using organically modified precursors during sol–gel processing.

The optical properties of aerogels strongly depend on their chemical composition. SiO_2 aerogels and the derived inorganic–organic hybrid aerogels vary between transparent and translucent. They appear yellowish under light and bluish against a dark background due to Rayleigh scattering. Objects viewed through a silica aerogel tile appear slightly blurred. For most applications a high optical transmission is desirable. Improvements were, *inter alia*, achieved by optimizing the drying procedures and the synthesis conditions.

Although the rigidity of aerogels is low due to their structure and the brittleness of the SiO_2 particles, it is sufficient for most applications. The compressive strength of monolithic SiO_2 aerogels is between 0.15 and 0.30 Nmm^{-2}, depending on the density, with an elastic compression of about 2–4%. The rigidity in vacuum is distinctly higher. The tensile strength is about 0.020 Nmm^{-2} and the modulus of elasticity 0.002–100 MPa.

One of the decisive parameters for mechanical properties is the connection of the primary particles of the gel network. Silica aerogels with covalently bonded organic groups have improved elastic properties because the organic groups at the surface of the particles impair stiffening of the particle necks by Ostwald ripening.

The sound velocities in SiO_2 aerogels of 100–300 ms^{-1} are among the lowest for inorganic solids due the particular network structure. SiO_2 aerogels have the lowest acoustic impedance of all solid materials ($Z = 104–105\,k\,gm^{-2}\,s^{-1}$).

Aerogels have the lowest thermal conductivities of all solids (0.017–0.021 $Wm^{-1}\,K^{-1}$ at 300 k in air). The solid conductivity portion increases with increasing bulk density, whereas the reverse is true for gas and radiative transport. Heat transport via the gas phase can be avoided by evacuation of the system. For example, an evacuated SiO_2 aerogel at about 300 k shows a thermal conductivity of only 0.010 $W\,m^{-1}\,K^{-1}$. Reduction of the radiative heat transport is important for high-temperature applications of aerogels, because the radiation maximum is then in a wavelength range in which SiO_2 does not sufficiently absorb (3–5 μm). This is achieved by doping the aerogels with infrared opacifiers, such as carbon soot or TiO_2.

5. Applications

SiO_2 aerogels are the best investigated aerogels with regard to their preparation, structure, and properties, and they can also be prepared at lower cost than other aerogels. There are already commercial applications. Non-silicate aerogels increasingly play an important role, particularly as novel catalysts.

SiO_2 aerogels are installed in several Cherenkov detectors worldwide. Their refraction indices (1.007–1.024) are in a range not covered by the previously used compressed gases or liquids. Aerogels as solid materials additionally allow easier construction of the detectors.

Aerogels belong to the best thermal insulation materials currently available. Additional advantages are their nonflammability and their transparency. However, since the production of large aerogel panels is still a big problem, conventional window systems cannot be equipped. The commonly prepared granulate, which is not transparent due to the roughness of its surface, can only be used for "daylight windows" (e.g., bathroom, staircase, or ceiling windows). In addition to transparent thermal insulation, applications for a variety of other insulation problems are conceivable, for example in cooling or heating systems, high-temperature batteries, insulation for piping, heat and cold storage appliances, automotive

exhaust pipes, transport vehicles, and vessels. Aerogels can also be utilized for passive use of solar energy, for example for paneling of house walls or for coating solar-energy collectors. A layer of the transparent aerogel allows the penetration of the sun's radiation to the blackened wall, but not the escape of the heat generated there.

All the advantages of sol–gel processing for preparing catalysts or catalyst supports—in particular, the controllable dispersion of the active component and the possibility of deliberately influencing the microstructure—also apply for aerogels. Additionally, the very high and accessible inner surface, the large pore volumes, an excellent temperature stability, and the high selectivities in catalytic processes predestines them for these applications. Nearly all oxides relevant for catalytic applications can be prepared as aerogels, including binary and ternary compositions, mixtures of metal oxides, and metal particles on oxide carriers. The investigated systems are summarized in special reviews (Schneider and Baiker 1995, 1997, Pajonk 1991, 1997).

The high porosity and very large surface area of silica aerogels can be utilized for applications as absorbing and encapsulation media, and hydrogen fuel storage. Partially sintered aerogels that show a strengthened texture can be used for the storage, thickening, or transport of liquids, for example rocket fuels.

Aerogels can be sintered at low temperatures and can therefore be processed to extremely pure and totally homogeneous glasses. The inner surface area and the porosity decrease during sintering and the pore structure can be modified in a controlled way by partial sintering. This was used, for example, for producing gas filters with pores in the range of 20–100 nm. Doping of aerogels with dyes or rare earth elements allows the fabrication of glass for various applications including lasers and radioluminescent light sources.

Aerogel films can be exploited as optical coatings for solar cells because of their low refractive index, and can thus replace the currently used glass layers with high refractive indices. More light reaches the active surface because of the lower Fresnel scattering losses. These films have also been applied as coatings for fiber optics to improve the light collection and propagation efficiency.

Aerogels are excellent materials for low dielectric constant applications. While bulk aerogels can be used for microwave electronics and high-voltage insulators, thin aerogel films can compete with existing technologies in microelectronics, where the low dielectric constant of <2.0 plays a particularly important role. In addition, the dielectric constant is easily controlled because it is directly correlated with the porosity and thus the density of the materials.

Some metal oxide aerogels exhibit superconducting, thermoelectric, or piezoelectric behavior.

Aerogels are efficient sound insulation materials. They have very low acoustic impedances and can therefore be used as $\lambda/4$ layers for matching the high acoustic impedance of piezoceramics to the low impedance of air.

SiO_2 aerogels are currently one of the standard media for collecting cosmic dust. They are fixed on the outside of spacecraft. Aerogels have the advantage that they are extremely light. The unique mesostructure enables a ''soft landing'' of very fast extraterrestrial particles hitting with a velocity of more than $3 \, km \, s^{-1}$, and also allows their later investigation by optical methods.

6. *Future Perspectives*

The unique optical, thermal, acoustic, and mechanical properties of aerogels originate from the combination of a solid matrix (the chemical composition of which can be modified) and nanometer-sized pores filled with air. There is a direct connection between the chemistry of the sol–gel process and the structure of the gels on one hand, and between the structure and the properties of the aerogels on the other.

The most important area for the application of aerogels is thermal insulation, while important acoustic insulation applications are emerging. There is no doubt about the physical and ecological advantages (nontoxic, nonflammable, easily disposed) of SiO_2 aerogels compared with most other materials on the market.

Apart from special applications in which material costs only play a minor role, the rather high price of supercritically dried aerogels has prevented a broader range of applications. The new ambient pressure drying techniques will probably make the technical preparation much cheaper and will thus make aerogels more competitive. They will also allow the preparation of aerogels with standard laboratory equipment.

Inorganic Nanotube Materials

The original article, which was published earlier, was focused mostly on the structural principles underlying the formation of nanotubes and fullerene-like nanostructures from layered (2-D) compounds (IF). This area witnessed a remarkable upshot over the years with numerous articles appearing in scientific literature, reporting new synthetic strategies which yielded these substances. Not less importantly though, new physical measurements have been carried out and the number of potential applications has increased dramatically.

Generally speaking, the concept of nanotubes and fullerene-like nanoparticles being the most stable phase of layered compounds in the nanodomain, which was proposed and first demonstrated for WS_2 (Tenne *et al.* 1992, see Fig. 1) and MoS_2 (Margulis *et al.* 1993) and their respective selenides, is well established by now. It was verified through numerous experiments and quantum chemical calculations. Using density functional theory (DFT) calculations, Rubio *et al.* proved in 1994 that single-wall BN nanotubes are stable compared to their unfolded analogs. More recently, a combined experimental and DFT tight-binding (DFT–TB) study demonstrated that multi-wall WS_2 (MoS_2) nanotubes of (outer) diameter between 10 nm and 20 nm (4–7 layers) are more stable than any conceivable unfolded structure with the same number of atoms (Seifert *et al.* 2002). In the absence of experimental evidence, DFT calculations proved to be very informative in this respect. Thus, single-wall phosphorus nanotubes were shown to be stable compared to their unfolded analogs (Seifert and Hernandez 2000, Cabria and Mintmire 2004), while phosphorous fullerenes were found to be unstable (Seifert *et al.* 2001). Numerous examples for different inorganic nanotubes have been worked out recently, providing strong evidence for the stability of such systems in the nanoregime. Despite the absence of stable layered type phases, it was argued that compounds exhibiting metastable sp^2-like hybridization, like GaN (Lee *et al.* 1999), or AlN (Zhang and Zhang 2003) can form stable nanotubes and even fullerene-like structures (Chang *et al.* 2001).

New synthetic approaches have been devised to promote the growth of nanotubes from various compounds. Perhaps, the most versatile and successful series of strategies were based on "chimie douce" (soft chemistry), and in particular, the hydrothermal synthesis which was extensively used for the synthesis of numerous new nanotube phases. Thus, Ce(H-$PO_4)_2 \cdot H_2O$ nanotubes were synthesized by heating a 6 M solution of phosphoric acid at 50–110 °C and
Figure 1
A bundle of three WS_2 nanotubes.

subsequently adding 0.02 M cerium diammonium nitrate solution dropwise with continuous mixing (Tang *et al.* 2004). WO_2Cl_2 nanotubes, the first oxyhalide nanotubes to be synthesized, were obtained by dissolving and stirring the ball-milled WO_2Cl_2 powder in $LiPF_6$ in a nonaqueous solvent for a few days (Armstrong *et al.* 2004). $CuSiO_3 \cdot 2H_2O$ and $Mg_3Si_2O_5(OH)_4$ nanotubes were synthesized by hydrothermal synthesis from an ethanol–water–ammonia solution of the respective nitrate salts and Na_2SiO_3 at 200 °C (Wang *et al.* 2004). Crystals consisting of bundles of single-layer uranyl selenate nanotubules were recently prepared at room temperature by a reaction of uranyl nitrate, butylamine, and H_2SeO_4 in an aqueous solution (Krivovichev *et al.* 2005). Titanate nanotubes have, over the years, received much attention, mainly due to their numerous potential applications. Most notably, Peng and his co-workers found that these nanotubes are formed by first a chemical transformation of the original TiO_2 crystal into the layered $(Na, H)_2Ti_3O_7$ lattice, and then its subsequent exfoliation into molecular sheets of the compound and folding into nanoscrolls (Zhang *et al.* 2003, see also Fig. 2). TiS_2 nanotubes were prepared by the reaction of a nonaqueous solution of Na_2S with $TiCl_4$, followed by solvothermal synthesis at 200 °C (Chen *et al.* 2003a). It should be borne in mind that nanoscrolls, which are halfway in stability between the unstable nanosheets and the fully bonded and stable nanotubes, are a typical product of low-temperature chemistry. This short account presents a few examples from the large body of data dedicated to the low-temperature synthesis of inorganic nanotubes.

Many reports were dedicated to the high-temperature synthesis of inorganic nanotubes, or processes involving a combination of low- and high-temperature synthesis (see, e.g., Li *et al.* 2002). Following the synthesis of nested nanoparticles of WS_2 with fullerene-like structure by the fluidized bed reactor, the same reactor was used for the large-scale synthesis of multiwall WS_2 nanotubes with lengths up to a fraction of a millimeter (Rosentsveig *et al.* 2002). High-temperature synthesis of various metal chalcogenide (MX_2) nanotubes from the MX_3 precursor was reported first by Nath and Rao (2001) and reviewed by Rao and Nath (2003). Chemical vapor transport (CVT) with iodine was used to synthesize single-wall MoS_2 nanotubes with diameter of <1 nm which self-assemble into hexagonal closed-packing bundles (Remskar *et al.* 2001). The role of iodine in these superstructures has not been fully clarified. CVT has been used also by Chen *et al.* (2003b) to synthesize TiS_2 and other MX_2 nanotubes. WS_2 (Whitby *et al.* 2002) and ReS_2 (Brorson *et al.* 2002) nanotubes were obtained by soaking carbon nanotubes in the respective metal–salt solution and subsequent firing the dried powder at elevated temperatures in H_2S atmosphere. Generally speaking, high-temperature processes yield perfect crystalline nanotubes.
