While many nanotubes have been prepared from different kinds of layered compounds, recent efforts were also directed to the synthesis of crystalline nanotubes from quasi-isotropic (3-D) compounds. Such nanotubes are not expected to be fully stable and their surfaces are usually passivated by reaction with the ambient. Most frequently, sacrificial templates are used to endow the lattice with a tubular structure. Thus, GaN nanotubes (zincblende structure with sp^3 bonding) were prepared by chemical vapor deposition of trimethylgallium and ammonia vapor onto ZnO nanowires with hexagonal cross-section at 600–700 °C
Figure 2

(Goldeberger *et al.* 2003). The ZnO nanowires were later removed by reductive annealing at 600 °C. An alternative strategy was developed by the Golberg-Bando group (see, e.g., Li *et al.* 2003). Here indium metal and In_2O_3 powders were heated to 1300 °C in the presence of a carbon source (carbo-thermal synthesis). The product contained crystalline In_2O_3 nanotubes which grew out of the oxide grains. Much of the nanotubes' core was filled with indium. This growth mode suggests that metallic indium droplets served as templates for the vaporized oxide nucleation and growth. This strategy, where the molten droplet was obtained from the oxide by solvo-thermal reduction using reactive carbon powder[2], was further developed and documented by this group in a number of recent publications. In another study, magnetite (Fe_3O_4) was deposited onto MgO nanowires by pulsed laser ablation process (Liu *et al.* 2004). Subsequently, the MgO template was removed by wet chemical etching in a solution of ammonium sulfate, leaving behind the hollow magnetite nanotubes.

The synthesis of nanotubes from various inorganic compounds permits a systematic study of their properties. The Young's modulus of BN nanotubes was measured to be about 1 TPa (Chopra and Zettl 1998). The mechanical properties of WS_2 nanotubes have been investigated in detail through both, experiment and theory (Kaplan-Ashiri *et al.* 2004, 2005). Tensile and buckling experiments of individual nanotubes were carried out using both atomic force microscope (AFM) and high-resolution scanning electron microscope (HRSEM). The Young's modulus, yield strength, and elongation to yield are 150–170 GPa, 15.7, and >10%, respectively, putting these nanotubes in a unique position of being both very strong yet flexible material. Furthermore, in contrast to macroscopic objects, the mechanical behavior of the nanotubes was shown to be dictated mostly through their intrinsic properties, that is, the strength of the chemical bonds. DFT–molecular dynamic calculations of MoS_2 nanotubes showed that the nanotube is deformed elastically through most of the elongation and its failure is effected through rapid propagation of an atomic defect along the circumference of the nanotube. In a different kind of experiment, bundles of single-wall (3,3) MoS_2 nanotubes were suspended over porous alumina substrate. Using the AFM tip, the nanotubes were deflected vertically into the pores. Using a well-established model and the experimental parameters, the Young's and shear moduli of the nanotube were calculated as being 120 GPa and 0.16 GPa, respectively (Kis *et al.* 2003). The low value of the estimated shear modulus of the MoS_2 nanotube as compared to that of graphite (4.5 GPa) is indicative of its suitability for solid lubrication (*vide infra*).

The effect of shockwave impact on the structural integrity of WS_2 nanotubes (Zhu *et al.* 2002) and MoS_2 nanoparticles with fullerene-like structure (Zhu *et al.* 2005) was evaluated. While the WS_2 nanotubes were stable to impacts of 21 GPa, the MoS_2 were found to withstand impacts as high as 30 GPa with minimal destruction. Furthermore, fullerene-like WS_2 and MoS_2 nanoparticles were recently found to be stable under compression in a diamond anvil cell to pressures of 20 GPa and 30 GPa, respectively (Joly-Pottuz *et al.* 2005). The extraordinary resilience of the nanoparticles against shock and compression offers numerous applications in high-strength materials.

The electronic structure of BN and BC_2N nanotubes was investigated first by the Louie–Cohen group (Rubio *et al.* 1994, Miyamoto *et al.* 1994). BN nanotubes were shown to be large-gap semiconductors with the gap decreasing with the shrinking diameter of the nanotube. BC_2N nanotubes arranged in two different configurations were studied: one a large-gap semiconductor, while in the other, the carbon atoms formed a continuous coil within the hexagonal BN network, giving the nanotubes a metallic character. Seifert *et al.* (2000) carried out a systematic theoretical study of the structure and properties of metal–dichalcogenide nanotubes using DFT-TB calculations. In their earlier papers, they made three important observations: (i) Nanotubes which are derived from semiconducting compounds remain so after being folded into nanotubes. (ii) In contrast to usual nanoparticles, the bandgap of these nanotubes decreases with shrinking diameter of the nanotube. (iii) While (*n*,*n*) armchair nanotubes, like their bulk predecessor, exhibit indirect lowest gap, (*n*,0) zigzag nanotubes exhibit a direct gap. These calculations are so far supported only partially by experimental measurements (see, e.g., Scheffer *et al.* 2002). More recently, the stability and band structure of nanotubes of III–V compounds, like AlN, which generally crystallize in the stable zincblende (diamond-like) structure, was studied. In the present calculations however, a network of sp^2 (graphite-like) bonded aluminum and nitrogen atoms was assumed (see, e.g., Zhao *et al.* 2003). Interestingly, not only were the nanotubes found to be stable against unfolding (though not globally stable), but their electronic structure too was not very different from those of the other inorganic nanotubes as summarized in the three points above.

Various applications have been proposed for the inorganic nanotubes and fullerene-like nanoparticles. The preliminary observation that IF-WS_2 (IF-MoS_2) can serve as high-performance solid lubricants (Rapoport *et al.* 1997) was followed by a detailed investigation that elucidated the complex mechanism underlying the action of these nanoparticles as solid lubricants (for a short summary, see Rapoport *et al.* (2005)). It is believed that under relatively low loads (<0.5 GPa), the main benefit of these nanoparticles emerges from sliding and rolling. Under higher loads, the spacing between the reciprocating pair of surfaces

becomes smaller than the size of the nanoparticles, leading thus to their gradual collapse and the transfer of WS_2 nanosheets onto the asperities. Consequently, the WS_2-coated surfaces slide past each other with minimum friction and wear. These findings led to substantial interest in these materials in automobile, aerospace, machining, microelectronics, medical, and other industries. Hence, a major effort for the large-scale commercialization of this technology is now well under way.

The use of inorganic nanotubes for cathode materials in rechargeable batteries has been contemplated. It was shown (Nordlinder *et al.* 2003, Tao *et al.* 2004) that large amounts of the guest atoms can be intercalated within the van der Waals gap of the host nanotubular lattice, giving rise to substantial electrical capacity. Furthermore, the kinetic stability of the nanotubular structures allows for many charge/discharge cycles with only moderate losses in the electrical capacity. Potential applications of inorganic nanotubes in catalysis (Chen *et al.* 2002), hydrogen storage (Chen *et al.* 2003), solar cells (Adachi *et al.* 2003), and in organic light emitting diodes (Qian *et al.* 2004) have been demonstrated. The wide variability of these materials and their rich chemistry offers countless opportunities for a vast number of studies and applications in various technologies.

Laminates: Physical and Mechanical Behavior

A composite laminate is a perfectly bonded assembly of individual plies of a unidirectional composite for which the fibers are parallel in a direction that defines the orientation of the ply within the laminate (Fig. 1 shows a cross-ply laminate having separated the individual plies). Various methods have been used to develop an understanding of damage growth in such laminates. Parvizi *et al.* (1978) developed the first so-called shear lag model of ply cracking in a cross-ply laminate, while Nuismer and Tan (1988) adopted the optimum shear lag approach that is recommended for use. More accurate analyses based on the application of variational techniques to ply crack problems have been given by Hashin (1985, 1987, 1988) and by Nairn (1989, 1995, 1997) and Nairn and Hu (1992). The most accurate methods consider multilayer models of laminates where through-thickness stress and deformation variations are modeled by subdividing each ply of the laminate into subplies. Examples of

this approach are the variational approach applied to cross-ply laminates by Pagano (1991), Pagano and Schoeppner (1997), Schoeppner and Pagano (1998), and the technique developed by McCartney (1998b, 2000) for both cross-ply and general symmetric laminates which is consistent with variational mechanics but provides the complete stress and displacement fields within the laminate.

There are three types of behavior that need to be considered when designing composite components. First of all, for relatively low applied loadings, the composite deforms as a linear elastic solid without the formation of any type of microstructural damage. Many models predicting the thermoelastic constants of laminated composites have been developed for this type of behavior (see *Elastic Behavior of Composites**). For larger applied loads, the composite experiences the second type of behavior where microstructural damage formation occurs leading to the progressive degradation of material properties, and to non-linear stress–strain behavior. Engineering components usually exhibit stress concentrations arising from geometrical features such as holes,
Figure 1
Computer image of the structure of a cross-ply laminate.

---

changes of section, etc. Such concentrations cause localized microstructural damage formation and localized property degradation that leads to the macroscopic redistribution of stress within the component. This is a very important phenomenon that is largely responsible for composite components out-performing their expectations, based on designs using laboratory coupon data for relatively simple loading modes, e.g., uniaxial loading. Following the progressive stable growth of microstructural damage, the third type of behavior ensues where instability and catastrophic failure of the structure occur. Important design objectives are to delay the occurrence of microstructural damage, to extend the progressive microstructural damage growth phase of deformation, and to delay the onset of catastrophic failure thus leading to engineering components that fail "gracefully," i.e., with plenty of warning.

The methodology to be described here is aimed at fulfilling these objectives. It can be applied to any fiber-reinforced composite whose constituents can be regarded as deforming in a linear elastic manner, such as, thermosetting polymer composites and ceramic matrix composites. The methodology can be applied to monotonically loaded, fiber-reinforced thermoplastic and metal composites only if matrix yield and creep are not significant; otherwise, extensions of the methodology must be sought. It can also be applied to fatigue-damaged fiber-reinforced metal laminates when assessing the effect on effective properties of ply cracks that have formed as a result of fatigue loading, and the growth of such damage during cyclic loading.

1. Assumptions of the Methodology

The assumptions on which the methodology is based are:

(i) laminates are symmetric (i.e., ply orientations are balanced about mid-plane of laminate) and constructed of any number of plies that can be made of different anisotropic materials having directional properties, and are perfectly bonded together at all points on the interlaminar interfaces.

(ii) laminates are subject only to loading in the plane of the laminate. Bend deformation of the laminate is not considered.

(iii) there exists a stress-free temperature T_o at which laminates, when in an unloaded state, are free of any internal stresses arising from thermal expansion mismatch between plies. The temperature difference, $\Delta T = T - T_o$, where T is the current temperature, appears in the stress/strain relations and, when non-zero, leads to thermal residual stresses in the composite.

(iv) the undamaged plies of laminates have directional properties and linear stress/strain behavior.

(v) cracks in any ply of the laminate are planar such that the entire ply cross-section is cracked.

2. Undamaged General Symmetric Laminates

In order to characterize the properties of laminates it is useful to introduce orthogonal directions for a ply of the laminate. These are the axial y-direction, the transverse z-direction which is normal to the axial direction lying in the plane of the laminate, and the through-thickness x-direction. The stress and strain components referred to these directions are denoted by σ_{xx}, ε_{xx}, σ_{xy}, ε_{xy}, etc.

2.1 Stress/Strain Relations for Individual Plies in a Laminate

The stress/strain relations for any ply in the *undamaged* laminate whose fibers are parallel to the axial y-direction are of the following form where the superscript, i, is a label denoting the ply being considered

$$\varepsilon_{xx}^i = \frac{\sigma_{xx}^i}{E_t^i} - \frac{v_a^i}{E_A^i}\sigma_{yy}^i - \frac{v_t^i}{E_T^i}\sigma_{zz}^i + \alpha_t^i \Delta T, \qquad (1)$$

$$\varepsilon_{yy}^i = -\frac{v_a^i}{E_A^i}\sigma_{xx}^i + \frac{\sigma_{yy}^i}{E_A^i} - \frac{v_A^i}{E_A^i}\sigma_{zz}^i + \alpha_A^i \Delta T, \qquad (2)$$

$$\varepsilon_{zz}^i = -\frac{v_t^i}{E_T^i}\sigma_{xx}^i - \frac{v_A^i}{E_A^i}\sigma_{yy}^i + \frac{\sigma_{zz}^i}{E_T^i} + \alpha_T^i \Delta T, \qquad (3)$$

$$\varepsilon_{xy}^i = \frac{\sigma_{xy}^i}{2\mu_a^i}, \varepsilon_{xz}^i = \frac{\sigma_{xz}^i}{2\mu_t^i}, \varepsilon_{yz}^i = \frac{\sigma_{yz}^i}{2\mu_A^i} \qquad (4)$$

where E_A, E_T, E_t, v_a, v_t, v_A, μ_a, μ_t, μ_A, α_t, α_A and α_T are material properties known as the Young's moduli (E), Poisson's ratios (v), shear moduli (μ) and thermal expansion coefficients (α) for the undamaged laminate. The upper case suffices A (axial), T (transverse) indicate that the property to which it is attached is for a direction of the laminate lying within the plane of the laminate. Lower case suffixes are attached to properties involving out-of-plane deformation. When the fibers of an individual ply are oriented in the axial direction, and the ply is isotropic in directions normal to the fibers, the stress/strain relations are given elsewhere (see also *Continuous Parallel Fiber Composites: Deformation and Strength**), together with formulae that can be used to estimate the thermoelastic constants of undamaged plies from the fiber and matrix properties.

For other orientations of the plies, where the fibers in the ith ply are parallel and inclined so that the angle between the fiber direction and the y-axis is ϕ_i, the stress/strain relations are of the form (McCartney 2000).

$$\varepsilon_{xx}^i = g_{11}^i\sigma_{xx}^i + g_{12}^i\sigma_{yy}^i + g_{13}^i\sigma_{zz}^i + g_{14}^i\sigma_{yz}^i + \alpha_1^i \Delta T \quad (5)$$

$$\varepsilon_{yy}^i = g_{12}^i\sigma_{xx}^i + g_{22}^i\sigma_{yy}^i + g_{23}^i\sigma_{zz}^i + g_{24}^i\sigma_{yz}^i + \alpha_2^i \Delta T \quad (6)$$

$$\varepsilon_{zz}^i = g_{13}^i \sigma_{xx}^i + g_{23}^i \sigma_{yy}^i + g_{33}^i \sigma_{zz}^i + g_{34}^i \sigma_{yz}^i + \alpha_3^i \Delta T \quad (7)$$

$$2\varepsilon_{yz}^i = g_{14}^i \sigma_{xx}^i + g_{24}^i \sigma_{yy}^i + g_{34}^i \sigma_{zz}^i + g_{44}^i \sigma_{yz}^i + \alpha_4^i \Delta T \quad (8)$$

$$\varepsilon_{xy}^i = a_{11}^i \sigma_{xy}^i + a_{12}^i \sigma_{xz}^i, \quad \varepsilon_{xz}^i = a_{12}^i \sigma_{xy}^i + a_{22}^i \sigma_{xz}^i \quad (9)$$

where, in terms of $m_i = \cos\phi_i$, $n_i = \sin\phi_i$, the coefficients appearing in Eqns. (5)–(9) are:

$$\left. \begin{aligned} g_{11}^i &= \frac{1}{E_t^i}, \quad g_{12}^i = -m_i^2 \frac{v_a^i}{E_A^i} - n_i^2 \frac{v_t^i}{E_T^i}, \\ g_{13}^i &= -m_i^2 \frac{v_t^i}{E_T^i} - n_i^2 \frac{v_a^i}{E_A^i}, \\ g_{14}^i &= 2m_i n_i \left(-\frac{v_t^i}{E_T^i} + \frac{v_a^i}{E_A^i} \right) \end{aligned} \right\} \quad (10)$$

$$\left. \begin{aligned} g_{22}^i &= m_i^2 n_i^2 \left(\frac{1}{\mu_A^i} - \frac{2v_A^i}{E_A^i} \right) + \frac{m_i^4}{E_A^i} + \frac{n_i^4}{E_T^i}, \\ g_{23}^i &= m_i^2 n_i^2 \left(\frac{1}{E_A^i} + \frac{1}{E_T^i} - \frac{1}{\mu_A^i} \right) \\ &\quad - m_i^4 \frac{v_A^i}{E_A^i} - n_i^4 \frac{v_A^i}{E_A^i} \end{aligned} \right\} \quad (11)$$

$$\left. \begin{aligned} g_{24}^i &= m_i n_i (m_i^2 - n_i^2) \left(\frac{1}{\mu_A^i} - \frac{2v_A^i}{E_A^i} \right) \\ &\quad - \frac{2m_i^2}{E_A^i} + \frac{2n_i^2}{E_T^i}, \\ g_{33}^i &= m_i^2 n_i^2 \left(\frac{1}{\mu_A^i} - \frac{2v_A^i}{E_A^i} \right) + \frac{m_i^4}{E_T^i} + \frac{n_i^4}{E_A^i} \end{aligned} \right\} \quad (12)$$

$$\left. \begin{aligned} g_{34}^i &= m_i n_i \left[(m_i^2 - n_i^2) \left(-\frac{1}{\mu_A^i} + \frac{2v_A^i}{E_A^i} \right) \right. \\ &\quad \left. + \frac{2m_i^2}{E_T^i} - \frac{2n_i^2}{E_A^i} \right], \\ g_{44}^i &= \frac{(m_i^2 - n_i^2)^2}{\mu_A^i} + 4m_i^2 n_i^2 \left(\frac{1}{E_A^i} + \frac{1}{E_T^i} + \frac{2v_A^i}{E_A^i} \right) \end{aligned} \right\} \quad (13)$$

$$\left. \begin{aligned} \alpha_1^i &= \alpha_t^i, \quad \alpha_2^i = m_i^2 \alpha_A^i + n_i^2 \alpha_T^i, \\ \alpha_3^i &= m_i^2 \alpha_T^i + n_i^2 \alpha_A^i, \quad \alpha_4^i = 2m_i n_i (\alpha_T^i - \alpha_A^i) \end{aligned} \right\} \quad (14)$$

$$\left. \begin{aligned} a_{11}^i &= \frac{1}{2} \left(\frac{m_i^2}{\mu_a^i} + \frac{n_i^2}{\mu_t^i} \right), \\ a_{12}^i &= \tfrac{1}{2} m_i n_i \left(\frac{1}{\mu_t^i} - \frac{1}{\mu_a^i} \right), \\ a_{22}^i &= \frac{1}{2} \left(\frac{m_i^2}{\mu_t^i} + \frac{n_i^2}{\mu_a^i} \right) \end{aligned} \right\} \quad (15)$$

2.2 Macroscopic Effective Stress/Strain Relations for Any Undamaged Symmetric Laminate

A symmetric laminate has a ply geometry that is symmetric about the mid-plane of the laminate. Consider a laminate of total thickness $2h$ comprising $2N$ plies. The plies in one half of the laminate are labelled $i = 1 \dots N$. The characteristic property of undamaged symmetric laminates subject to in-plane loading is that the axial, transverse and in-plane shear strains, ε, ε_T and γ respectively, are uniform throughout those parts of the laminate that are not affected by the presence of laminate edges, and that the through-thickness stress, σ_t, is also uniform in all plies of the laminate. In addition the stress components σ_{xy}, σ_{xz} are zero everywhere. When the laminate as a whole is considered the stress/strain relations (Eqns. (5)–(8)) are applied to each ply in the laminate such that $\varepsilon_{yy}^i = \varepsilon$, $\varepsilon_{zz}^i = \varepsilon_T$, $2\varepsilon_{yz}^i = \gamma$, $\sigma_{xx} = \sigma_t$. The effective applied axial, transverse and in-plane shear stresses σ_{yy}^i, σ_{zz}^i, τ_{yz}^i will be uniform in each ply but will be discontinuous at ply interfaces.

The effective axial stress σ, transverse stress σ_T, and in-plane shear stress τ are defined by total normal and shear loads acting on the laminate edges divided by the total area of cross-section of the edges over which the load is acting. The through-thickness displacement on the laminate faces is divided by the half-thickness of the laminate when defining the through-thickness strain ε_t. It is then possible to calculate the effective stresses σ, σ_T and τ in each ply together with the effective through-thickness strain ε_t using:

$$\left. \begin{aligned} \sigma &= \frac{1}{h} \sum_{i=1}^N h_i \sigma_{yy}^i, \quad \sigma_T = \frac{1}{h} \sum_{i=1}^N h_i \sigma_{zz}^i, \\ \tau &= \frac{1}{h} \sum_{i=1}^N h_i \sigma_{yz}^i, \quad \varepsilon_t = \frac{1}{h} \sum_{i=1}^N h_i \varepsilon_t^i \end{aligned} \right\} \quad (16)$$

where ε_t^i is the uniform through-thickness strain in the ith ply. These values are then used to calculate the effective stresses σ, σ_T and τ and through-thickness strain ε_t for the laminate as a whole. Stress/strain relations for the laminate may then be derived (McCartney 2000) which are of the same form as the relations (Eqns. (5)–(8)) assumed for individual ply properties.

The laminate stress/strain relations are written in the following form that generalizes the notation given in Eqns. (1)–(4):

$$\varepsilon_t = \frac{\sigma_t}{E_t} - \frac{v_a}{E_A}\sigma - \frac{v_t}{E_T}\sigma_T - \frac{\lambda_t}{E_A}\tau + \alpha_t \Delta T \quad (17)$$

$$\varepsilon = -\frac{v_a}{E_A}\sigma_t + \frac{\sigma}{E_A} - \frac{v_a}{E_A}\sigma_T - \frac{\lambda_A}{E_A}\tau + \alpha_A \Delta T \quad (18)$$

$$\varepsilon_T = -\frac{v_t}{E_T}\sigma_t - \frac{v_A}{E_A}\sigma + \frac{\sigma_T}{E_T} - \frac{\lambda_A}{E_A}\tau + \alpha_T \Delta T \quad (19)$$

$$\gamma = -\frac{\lambda_t}{E_A}\sigma_t - \frac{\lambda_A}{E_A}\sigma - \frac{\lambda_T}{E_A}\sigma_T + \frac{\tau}{\mu_A} + \alpha_S \Delta T \quad (20)$$

The parameters λ_A, λ_T and λ_t are ratios associated with the effect of shear stress on axial and transverse strain respectively. The parameter α_S is the thermal expansion coefficient associated with the effect of temperature changes on the shear strain.

3. Effects of Ply Cracking on Thermoelastic Constants of Damaged Laminates

The first damage mode encountered when laminates are subject to multi-axial loading is the formation of ply cracks in plies whose fiber direction is transverse to the principal loading direction. Ply cracks usually form suddenly and completely crack the ply cross-section. Increasing loads lead to the progressive formation of ply crack arrays. When a ply crack forms in an undamaged laminate the load it carried is transferred to neighboring plies which are intact as the fibers are usually in a different direction to those in the cracked ply. The stress transfer occurs through the action of shear tractions on the interfaces between the cracked ply and its neighbors. The nonuniform stress field that results has a significant effect on the values of the thermoelastic constants of the laminate.

Recently, ply crack formation has been studied in quasi-isotropic laminates, (Crocker *et al.* 1997, McCartney 1998b, 1999, 2000) including finite element analysis of cracked laminates for the case of generalized plane strain deformation (Tong *et al.* 1997). For laminated systems, a methodology has been developed (McCartney 1999, 2000) that is capable of predicting accurately the stress and displacement distributions at all points in a cross-ply laminate containing arrays of ply cracks. Such solutions have been used to predict the dependence of the laminate properties, such as Young's moduli, Poisson's ratios, and thermal expansion coefficients, on the degree of cracking, and more importantly, the dependence of these properties on the state of loading. The important result of this analysis is that the stress/strain relations for a damaged laminate (where all ply cracks are stress-free) are of the form given by Eqns. (17)–(20). The occurrence of ply cracking does not alter the form of the stress/strain relations. Only the values of the thermoelastic constants are affected by the damage.

3.1 Macroscopic Effective Stress–Strain Relations for a Laminate

Consider a general symmetric laminate subject to multi-axial loading whose damage, in the form of stress-free ply cracks (as illustrated in Fig. 2 for the case of a cross-ply laminate), is characterized by the damage parameter ω. This parameter is a single label that is used to represent a series of damage modes (and associated variables), for example the effective crack densities in each ply. It is assumed that the

distribution of damage is homogeneous when viewed at the macroscopic level. When any physical parameter f is damaged its value is denoted by $f(\omega)$ and when undamaged it is denoted by f. In order to simplify the analysis it is assumed that ply cracking occurs only in the 90° plies of a general symmetric laminate for which any ply (in one half of the laminate) having orientation θ has a corresponding $-\theta$ ply in the same half of the ply made of the same material and having the same thickness as the θ ply. For this special case the shear coupling terms λ_t, λ_A and λ_T, and the expansion coefficient α_S, in the stress–strain equations for a damaged laminate may be neglected. As a result, the shear stress–strain relations for a damaged and undamaged laminate have respectively the following simple forms:

$$\tau = \mu_A(\omega)\gamma, \quad \tau = \mu_A\gamma \tag{21}$$

McCartney (2000) has considered more general laminates where shear coupling terms are included in the analysis. For the special case when in-plane shear deformation is absent, the effective stress/strain relations of the *damaged* laminate may be expressed in the form:

$$\varepsilon_t = \frac{\sigma_t}{E_t(\omega)} - \frac{v_a(\omega)}{E_A(\omega)}\sigma - \frac{v_t(\omega)}{E_T(\omega)}\sigma_T + \alpha_t(\omega)\Delta T \tag{22}$$

$$\varepsilon = -\frac{v_a(\omega)}{E_A(\omega)}\sigma_t + \frac{\sigma}{E_A(\omega)} - \frac{v_A(\omega)}{E_A(\omega)}\sigma_T + \alpha_A(\omega)\Delta T \tag{23}$$

$$\varepsilon_T = -\frac{v_t(\omega)}{E_T(\omega)}\sigma_t - \frac{v_A(\omega)}{E_A(\omega)}\sigma + \frac{\sigma_T}{E_T(\omega)} + \alpha_T(\omega)\Delta T \tag{24}$$

The values of the thermoelastic constants in Eqns. (22)–(24) may be determined by detailed stress analysis (McCartney 2000) for any distribution of ply cracks. It has been shown, by considering the crack closure conditions for a laminate subject to uniaxial loading in the axial, in-plane transverse, and though-thickness directions, that:

$$\frac{\alpha_t(\omega) - \alpha_t}{\frac{v_a}{E_A} - \frac{v_a(\omega)}{E_A(\omega)}} = \frac{\alpha_A(\omega) - \alpha_A}{\frac{1}{E_A(\omega)} - \frac{1}{E_A}} = \frac{\alpha_T(\omega) - \alpha_T}{\frac{v_A}{E_A} - \frac{v_A(\omega)}{E_A(\omega)}} = k_1 \tag{25}$$

$$\frac{\frac{v_t}{E_T} - \frac{v_t(\omega)}{E_T(\omega)}}{\frac{v_a}{E_A} - \frac{v_a(\omega)}{E_A(\omega)}} = \frac{\frac{v_A}{E_A} - \frac{v_A(\omega)}{E_A(\omega)}}{\frac{1}{E_A(\omega)} - \frac{1}{E_A}} = \frac{\frac{1}{E_T(\omega)} - \frac{1}{E_T}}{\frac{v_A}{E_A} - \frac{v_A(\omega)}{E_A(\omega)}}$$

$$= \frac{\alpha_T(\omega) - \alpha_T}{\alpha_A(\omega) - \alpha_A} = k \tag{26}$$
Figure 2
Computer image of the ply cracking that occurs in a cross-ply laminate during loading.

$$\frac{\dfrac{1}{E_t(\omega)} - \dfrac{1}{E_t}}{\dfrac{v_a}{E_A} - \dfrac{v_a(\omega)}{E_A(\omega)}} = \frac{\dfrac{v_a}{E_A} - \dfrac{v_a(\omega)}{E_A(\omega)}}{\dfrac{1}{E_A(\omega)} - \dfrac{1}{E_A}} = \frac{\dfrac{v_t}{E_T} - \dfrac{v_t(\omega)}{E_T(\omega)}}{\dfrac{v_A}{E_A} - \dfrac{v_A(\omega)}{E_A(\omega)}}$$

$$= \frac{\alpha_t(\omega) - \alpha_t}{\alpha_A(\omega) - \alpha_A} = k' \tag{27}$$

where

$$k_1 = \frac{E_A[\alpha_A + B\alpha_T - C]}{1 - v_A B}, \quad k = \frac{E_A}{E_T} \frac{B - v_A \dfrac{E_T}{E_A}}{1 - v_A B},$$

$$k' = \frac{E_A A - v_a - v_t \dfrac{E_A}{E_T} B}{1 - v_A B} \tag{28}$$

and where A, B and C are constants calculated from unidirectional undamaged ply properties (in bold).

$$A = \frac{\boldsymbol{v_t}}{\boldsymbol{E_T}} + \frac{\boldsymbol{v_a v_A}}{\boldsymbol{E_A}}, \, B = \boldsymbol{v_A}, \, C = \boldsymbol{\alpha_T} + \boldsymbol{v_A \alpha_A}.$$

The parameters k_1, k and k' are laminate constants that are independent of the state of damage.

3.2 Thermo-elastic Constants for Damaged Laminates

It can be shown from Eqns. (25)–(27) that the thermoelastic constants of a damaged laminate are of the form (McCartney 2000)

$$\left.\begin{array}{l} \dfrac{1}{E_A(\omega)} - \dfrac{1}{E_A} = \Phi(\omega), \\[2mm] \dfrac{1}{E_T(\omega)} - \dfrac{1}{E_T} = k^2 \Phi(\omega), \\[2mm] \dfrac{1}{E_t(\omega)} - \dfrac{1}{E_t} = (k')^2 \Phi(\omega) \end{array}\right\} \tag{29}$$

$$\left.\begin{array}{l} \dfrac{v_a}{E_A} - \dfrac{v_a(\omega)}{E_A(\omega)} = k' \Phi(\omega), \\[2mm] \dfrac{v_A}{E_A} - \dfrac{v_A(\omega)}{E_A(\omega)} = k \Phi(\omega), \\[2mm] \dfrac{v_t}{E_T} - \dfrac{v_t(\omega)}{E_T(\omega)} = k k' \Phi(\omega) \end{array}\right\} \tag{30}$$

$$\left.\begin{array}{l} \alpha_A(\omega) - \alpha_A = k_1 \Phi(\omega), \\[2mm] \alpha_T(\omega) - \alpha_T = k k_1 \Phi(\omega), \\[2mm] \alpha_t(\omega) - \alpha_t = k' k_1 \Phi(\omega) \end{array}\right\} \tag{31}$$

451

where all the effective thermoelastic constants of a damaged laminate can be calculated in terms of the single damage dependent parameter $\Phi(\omega)$ that characterises the change in the values of all thermoelastic constants resulting from damage formation. They enable an exact and simple means of fully characterizing the effects of microstructural damage on the effective thermoelastic constants of laminates, requiring only the value of the parameter $\Phi(\omega)$ which depends upon the axial modulus, that is frequently measured in practice or can be estimated from a suitable model. It is emphasizd that the above relations can be derived without having to solve for the stress and displacement distributions in a cracked laminate. Such solutions are needed only to derive values for the effective thermoelastic constants. Nairn (1997) has reached a similar conclusion for a limited set of elastic constants in the case of cross-ply laminates. The results are in fact valid for any damage in laminates where the damage is in the form of cracks or delaminations that are stress-free. The results can also be applied to the degraded properties of laminates that arise during fatigue loading.

4. Predicting Progressive Ply Crack Formation in Multiple-ply Laminates

Consider a laminate that already contains ply cracks in some (but not necessarily all) 90° plies such that the damage is characterized by the parameter ω_1. Then consider the simultaneous formation of new ply cracks in the 90° plies such that the resulting damage state is characterized by the damage parameter ω_2. The locations of the ply cracks are assumed to be such that the overall deformation of the laminate is governed by the effective stress/strain equations (Eqns. (22)–(24)). This means that the crack distribution is regarded as being sufficiently uniformly distributed for shear and out-of-plane bending deformations to be negligible. The new crack surfaces are assumed to form quasi-statically under conditions of fixed effective applied tractions and fixed temperature. From energy balance considerations and the fact that kinetic energy is never negative, the criterion for crack formation under these conditions has the form (McCartney 1998a)

$$\Delta\Gamma + \Delta G < 0 \qquad (32)$$

where the energy absorbed in volume V of laminate by the formation of the new cracks is given by

$$\Delta\Gamma = V[\Gamma(\omega_2) - \Gamma(\omega_1)] \qquad (33)$$

In Eqn. (33) the parameter $\Gamma(\omega)$ denotes the energy absorbed in unit volume of laminate during the formation of new crack surfaces in the 90° plies that have led to the damage state ω. The energy absorbed is taken as the area of crack surface formed multi-

plied by the fracture energy for transverse cracking in the 90° plies. The corresponding change of Gibbs free energy (equivalent to complementary energy which must be used when crack growth occurs under fixed applied loads) in the region V of the laminate is

$$\Delta G = \int_V [g(\omega_2) - g(\omega_1)]\mathrm{d}V \qquad (34)$$

It has been shown (McCartney 2000) that

$$\frac{1}{V}\int_V [g(\omega) - g]\mathrm{d}V = -\tfrac{1}{2}\Phi(\omega)[s - s_\mathrm{o}]^2 \qquad (35)$$

where s is the effective applied stress for multiaxial loading defined by

$$s = k'\sigma_\mathrm{t} + \sigma + k\sigma_\mathrm{T} \qquad (36)$$

and where $s_\mathrm{o} = -k_1\Delta T$ is the ply crack closure stress when the laminate is subject only to uniaxial loading in the axial direction normal to the ply cracks in the 90° plies.

The absorbed energy function $\Gamma(\omega)$, appearing in Eqn. (33), is calculated for length 2L of laminate using:

$$\Gamma(\omega) = \frac{h_1}{hL}\sum_{\mathrm{j}=1}^{m} \delta_\mathrm{j}\gamma_\mathrm{j} \qquad (37)$$

where $2h_1$ is the total thickness of all 90° plies in the laminate having total thickness $2h$, and where m is the number of potential cracking sites in 90° plies which are ordered in a regular way, e.g., from top to bottom in the plies which are taken in order from the center of the laminate to the outside, symmetry about the mid-plane of the laminate being assumed. The quantity $2\gamma_\mathrm{j}$ is the fracture energy for the growth of a ply crack in the jth potential cracking site of the 90° plies. The parameters δ_j describe the crack pattern in the laminate such that:

$$\delta_\mathrm{j} = \begin{cases} 0 & \text{if } \mathrm{j}^{\mathrm{th}} \text{ site of the } 90^\circ \text{ ply is uncracked,} \\ 1 & \text{if } \mathrm{j}^{\mathrm{th}} \text{ site of the } 90^\circ \text{ ply is cracked} \end{cases} \qquad (38)$$

It is of great practical interest to know the level of applied loading that is likely to cause the occurrence of ply cracking. Ply crack formation can lead to a loss of stiffness, an important issue for stiffness critical components, or to leakage in the case of liquid containers and pressure vessels. It follows from Eqn. (29) and Eqns. (32)–(35) that the formation of an initial set of ply cracks occurs when:

$$s > \sqrt{\left(\frac{2\Gamma(\omega)}{\dfrac{1}{E_\mathrm{A}(\omega)} - \dfrac{1}{E_\mathrm{A}}}\right) + s_\mathrm{o}} \qquad (39)$$

The result (Eqn. (39)) is consistent with fracture mechanics where the energy balance associated with a long ply crack propagating across the laminate is considered. It is also consistent with the results of Pagano *et al.* (1998) who applied the three dimensional J-integral to the tip region of a long ply crack in a cross-ply laminate.

It is useful to discuss progressive cracking in a length $2L$ of laminate where the damage parameter ω is defined by $\{L_1, L_2, \ldots L_n\}$ where n is the number of cracks in length $2L$ of the $90°$ plies and where L_i, $I = 1 \ldots n$ denote the distances between neighboring cracked planes. The criterion for progressive crack formation may be written in the form:

$$s > \sqrt{\left(\frac{2[\Gamma(\omega_2) - \Gamma(\omega_1)]}{\dfrac{1}{E_A(\omega_2)} - \dfrac{1}{E_A(\omega_1)}}\right) + s_o} \qquad (40)$$

It is emphasised that the exceedingly simple results (Eqns. (39) and (40)) are exact, and that they take full account of the effects of anisotropy, of multi-axial loading and of the effect of thermal residual stresses. The results involve only macroscopic properties defined at the laminate level even though they have been derived from a detailed consideration of the stress and deformation distributions in a cracked laminate at the ply level. The results are based on the single assumption of damage homogeneity where damage formation in the laminate is such that the stress/strain relationships (Eqns. (22)–(24)) are always satisfied.

When using Eqn. (40) to investigate progressive crack formation (where cracks form one at a time) the fracture energies $2\gamma_j$ are taken at random from a statistical distribution of fracture energies (assumed to be normal) and then allocated at random to the various potential fracture sites in the $90°$ plies. The value of the applied stresses are then regarded as slowly increasing until the condition (Eqn. (40)) can be met at just one potential fracture site in the laminate. This means that crack formation must be investigated at all sites in order to determine the location of the first crack to form. This procedure has to be repeated for every new crack that forms during loading. If the fracture energies at each site have the same value, then the criterion (Eqn. (40)) predicts that the crack densities are always uniform having values ρ_o, $2\rho_o$, $4\rho_o$, etc., where ρ_o is the initial crack density. Thus new crack formation for this case occurs as a progressive doubling of the crack density at discrete applied stress levels.

5. Thick Laminates

When the thickness of the laminate becomes of the same order as the laminate length and width, the laminate exhibits behavior that cannot adequately be represented by classical laminate theory. The reason for this behavior arises from edge effects in laminates which lead to stress transfer at ply interfaces near the edges of the laminate. Classical laminate theory is based on the assumption that each ply experiences the same in-plane strains and rotations leading to axial and in-plane transverse stress distributions that are discontinuous at ply interfaces. Such stress discontinuities cannot apply at stress-free edges so that stress transfer between plies through the action of interfacial shear tractions must occur in order to satisfy the stress-free condition at laminate edges.

While much literature has been devoted to the development of higher order deformation theories, a good approach is to attempt to model the stress transfer in the way that has already been achieved for stress transfer in cracked laminates (McCartney 2000). Edge effects can be modeled by predicting stress transfer at traction-free laminate edges using these ply crack models.

6. Strength Issues

For laminates, the strength is the maximum load that can be supported by the laminate before the occurrence of catastrophic failure where a test specimen separates into two pieces. While the accurate measurement of strength is often difficult, its prediction is even more challenging, as many damage modes occur before the catastrophic failure event, such as ply cracking, delamination and fiber fracture, and the associated fiber/matrix debonding. Experience has shown that the strength of the laminate is usually determined by the strength of the plies whose fibers are aligned in the direction of principal loading. This is particularly true for systems where fiber/matrix debonding and delamination occur. Indeed for ceramic matrix composites, where there are weak fiber/matrix interfaces, matrix cracking can occur to the extent that the matrix is virtually unloaded and the load is taken wholly by the fibers. Such a damaged composite is then behaving as a loose bundle of fibers. For strongly bonded composites this is not the case as fiber fractures lead to the growth of dominant cracks through neighboring matrix and fibers, resulting in much lower strengths.

For laminated polymer composites the situation is more complex. Monte Carlo modeling can be used to estimate the strength of unidirectional composites (see also: *Continuous Parallel Fiber Composites: Deformation and Strength**). Such modeling needs to be introduced into laminate calculations by applying the Monte Carlo model to the plies in which fibers are parallel to the principal loading direction. The effects of ply cracking can either be ignored (upper bound prediction of strength) or taken into account approximately by applying to the Monte Carlo model a larger stress that accounts for the stress transfer from the cracked plies to the plies where fibers are parallel
Figure 3

to the principal loading direction. Such developments are in progress for the case of cross-ply laminates.

7. Application of Models in Design

The models described in this article may be used to perform the following tasks that can be exploited at some stage during the design of composite structural elements:

Predict undamaged properties of general symmetric laminates from the properties and orientations of the individual plies.

Predict the conditions for the initial formation of fully developed ply cracks in a general symmetric laminate subject to general in-plane loading and thermal residual stresses. In components subject to fatigue loading, designers will want to avoid any form of microstructural damage.

Predict the progressive formation of ply cracks in a single orientation during the monotonic loading of a general symmetric laminate. Multi-axial non-linear stress–strain behavior is predicted (needed to understand strain softening due to microstructural damage), and the progressive degradation of the thermoelastic constants as a function of applied stress or strain. Such nonlinear behavior leads to load transfer in a structure from regions of stress concentration, where microstructural damage forms and degrades properties, to other regions in the structure. This phenomenon can lead to composite components performing beyond expectations using designs based on coupon data and the neglect of damage effects.

Predict the effects of varying the thickness of the plies in a laminate. Ply cracking is well known to become more difficult when the thickness of the plies is reduced. The energy based approach of this article can model this behavior, contrasting sharply with stress based approaches. Doubling the thickness and applied loads does lead to a different damage evolution that is not predicted by strength based methods.

Predict the effects of temperature changes on ply crack formation (can be used to investigate thermal cracking following manufacture, or during cryogenic cooling).

8. *Web Access to Laminate Models*

The ply cracking model for cross-ply and general symmetric laminates can be accessed over the internet using the address, http://materials.npl.co.uk. Following registration users of the demonstration models can predict progressive ply crack formation during loading and its effect on properties. Three-dimensional visualization software enables the user to examine the geometry of any laminate, observe damage formation during loading, and plot graphs of results. By double-clicking on Fig. 3 a video is shown that illustrating some of the features that can be operated over the internet.

Liquid Crystalline Polymers, Dispersed

Liquid crystal–polymer composites have been studied intensively for both fundamental aspects of science and practical applications. The main interest in the research and industrial development of "plastic" liquid crystal technology originated on the premise of *stabilizing* liquid crystals through their interaction with an underlying polymer matrix and for manufacturing a new generation of liquid crystal display devices. Although the concentration of one of the components in a composite may be small, the resultant effect on the characteristic electro-optic response is usually large. Based on their morphology, there are two main types of liquid crystal–polymer composites. The polymer dispersed liquid crystal (PDLC) represents one end of the spectrum, where a high concentration (greater than 20%) of polymer is used to create a macroscopically phase-separated system of continuous polymer phase with small liquid crystal droplets embedded in it. This results in the technology of large-area self-supporting flexible electro-optic displays. The addition of small amounts of polymer (less than 10%) to a liquid crystal host falls into the regime of polymer stabilized liquid crystal (PSLC). Here the phase-separating polymer forms a network of narrow strands in the continuous liquid crystal matrix, which are aligned along the director and thus anchor this orientation throughout the working cycle of the device. The principal technological advantage here is in reducing the characteristic length and the time scale of the electro-optic response.

The early milestones of the research in confined liquid crystals include studies of director orientation and response to external (electric) field in narrow capillary tubes and spherical droplets. Characteristic topological defects (linear disclinations, point-like monopoles and surface boojums, see Fig. 1) and their transformations have been observed, causing much excitement from theoretical physicists and applied mathematicians. Remarkably universal properties and conservation laws of topological defects have

led to significant advances in other areas, reaching as far as the mechanisms of galaxy formation at the early stages of expansion of the Universe (e.g., Zurek 1996) (see *Nematic Liquid Crystals: Defects*[#]). However, up to the mid-1980s, confined liquid crystals were only curious model systems from the basic science perspective.

The practical usefulness of spherical nematic droplets was appreciated when Fergason (1985) developed a system in which a nematic liquid crystal is dispersed in a water-borne polymer to form an emulsion. The liquid crystal becomes encapsulated by the polymer to form micrometre-size droplets. The emulsion is then sandwiched between two parallel plates and,
Figure 1
Nematic director alignment in spherical droplets. First shown is the droplet with planar director anchoring on its surface, leading to a pair of surface boojums on its poles. Radial anchoring results in a (+ 1) point defect in the middle, a "hedgehog". Applying a strong electric field aligns most of the bulk of the droplet, splitting the hedgehog into a ring of $(+\frac{1}{2})$ disclination.

depending on the final purpose of the product, the continuous polymer matrix could be dried or photo-cross-linked. In the literature this variation of a PDLC is called a "nematic curvilinearly aligned phase."

A more popularly used PDLC system was invented by Doane *et al.* (1986) at Kent State University in Ohio. In fabrication, a liquid crystal could be mixed with (i) a photopolymerizable reactive monomer, an example being the epoxy Epon 828 with an appropriate photocuring agent, (ii) a polymer melt, such as polymethylmethacrylate (PMMA) or polyvinylformal (PVF), or (iii) a mixture of polymer and solvent, compatible to the liquid crystal also, to form an initially homogeneous solution. The liquid crystal is then phase separated from the polymer matrix by one of the following methods: (i) polymerization-induced phase separation (PIPS); (ii) thermally induced phase separation (TIPS); or (iii) solvent-induced phase separation (SIPS). The advantage of this technology is that the phase-separation kinetics helps selection of a more uniform distribution of submicrometre droplet sizes.

A typical PDLC device, as shown in Fig. 2, is an electrically switchable composite film, consisting of a thin layer (10–30 μm) of micron-size dispersion of liquid crystal droplets in a solid polymer matrix, sandwiched between two transparent conductive glass or plastic supports. By matching the extraordinary refractive index of the liquid crystal in birefringent droplets, n_e, with that of the polymer binder, n_p, an
Figure 2
A scheme of PDLC device operation. Microdroplets are embedded in a polymer matrix, with transparent electrodes on both sides of the film. The refractive index of the polymer n_p is matched to the parallel (extraordinary) index n_e of the uniaxial birefringent droplets. In the OFF state all droplets are randomly oriented and strongly scatter the incident light I_o. In the ON state, the electric field aligns the director in each droplet, the refraction properties are matched with the matrix and the film becomes transparent to light.

electrically controllable light scattering medium transforms from a translucent, white appearance to a transparent appearance upon application of a voltage.

In the absence of fields (the OFF state), the PDLC film is highly scattering because the large variations of the refractive index ($\sim n_e$–n_o) occur on the scale of the wavelength of light: the material appears "opaque." On application of an electric field (the ON state), the liquid crystal molecules inside microdroplets are aligned with the field and PDLC film becomes "transparent" if the refractive indices are matched, $n_p = n_e$. The fast millisecond-scale switching response of director orientation inside droplets to the electric field causes a rapid interchange from "opacity" to "transparency" and is the basic operational principle of the PDLC device. Figure 3 shows a real-life device used, for instance, in architectural windows or privacy screens.

The physical principle of all liquid crystalline electro-optic devices is the effect of alignment of the nematic director (average direction of long molecular axes, the principal axis of birefringence) by the field. This dielectric coupling is local, with the characteristic energy determined by the uniaxial anisotropy of dielectric constant $\varepsilon_a = \varepsilon_\parallel - \varepsilon_\perp$, and in a droplet of radius R is of the order $\sim \frac{1}{2} \varepsilon_o \varepsilon_a E^2 R^3$. This is resisted either by the elastic energy stored in the director deformations, the Frank energy of liquid crystals, or by a viscous drag of rotating the bipolar director texture. The sketch in Fig. 2 shows both effects at play: the orientation of the boojum pair is along the applied field and the director profile inside each droplet is practically uniform.
Figure 3
The Switching Window—a glass screen coated with 20 μm PDLC film which is electrically switching between the opaque OFF state and transparent ON state (image courtesy of LCI, Kent, Ohio).

In practice, if the liquid crystal droplets are symmetric, spherical, then one finds that the boojum pair is rather indifferent to its orientation and the rotation of the droplet axis can be achieved without an energy barrier, by a low voltage $V = E/d$ in a film of thickness d. In this case the principal resistance is viscous and the PDLC film will have a long response time: $\tau_{ON} \approx \gamma_1 d^2 / \varepsilon_o \varepsilon_a V^2$ with γ_1 the nematic rotational viscosity, and an undetermined but very long recovery time τ_{OFF}. If, on the other hand, the droplets are asymmetric, i.e., deformed into an elliptical shape, there is a preferred orientation of the boojum pair. The electric field then has to work against the elastic resistance of the director field, which for spherical droplets of radius R is of the order of $\sim KR$. Thus, the electric field required for the switching of such a droplet has to exceed a threshold of the order of $E_s \approx (1/R)\sqrt{K/\varepsilon_o \varepsilon_a}$, or the applied voltage required to operate a PDLC film of thickness d is $V_s \geqslant (d/R)\sqrt{K/\varepsilon_o \varepsilon_a}$. This is $\sim (d/R)$ times higher than the characteristic Freedericks' voltage used to switch standard liquid crystal display cells; for a typical PDLC film of $d = 20\,\mu m$ thick and droplets of under $R = 1\,\mu m$, this may amount to a substantial increase and can be up to 200 volts. An interesting development by Drzaic (1988) and Wu *et al.* (1989) demonstrated the important role of asymmetry in the droplet shape in the relaxation dynamics. The recovery of the opaque OFF state proceeds with the relaxation time $\tau_{OFF} \approx \gamma_1 R^2 / K(l^2 - 1)$ with l the aspect ratio of the droplet ellipsoid. For even weakly deformed droplets, $l = 1.1$, this relaxation time is $\sim 10\,ms$, much faster than in conventional electro-optic nematic cells. By, for example, stretching the polymer film, one could produce a weakly elliptic shape of liquid crystal cavities consistently aligned along the stretching direction and thus remove the degeneracy in the position of the boojum pair on the droplet surface. This results in a recorded memory about the orientation in the OFF state and in a significant decrease in the device response times. Therefore, one finds an inevitable trade-off between the switching voltage and the relaxation times: decreasing one by altering the material parameters results in the undesirable increase of the other.

Another problem with the basic PDLC technology is that in the ON state, the material is transparent only for a light beam incident normally to the film and becomes hazy for obliquely incident light (where a difference between the matrix refractive index n_p and the ordinary index n_o of aligned droplets is being probed). An intriguing modification is possible if a liquid crystal polymer is used in PDLC instead of an isotropic binding matrix. The refractive indices n_{p1} and n_{p2} of the liquid crystal polymer could match those of the liquid crystal droplets. In the ON state, the liquid crystal polymer and the droplets are all aligned along the applied field; the refractive indices are matched for light incident at all angles and

therefore the material is transparent in all directions. However, a different problem arises: in order for the refractive indices of the liquid crystal polymer and the liquid crystal to be matched, the mesogenic moieties of the liquid crystal polymer must have a structure similar to that of the liquid crystal. For such a liquid crystal and polymer system, phase separation becomes difficult.

The potential of composite technology in high-contrast electro-optic light shutters revitalized the general interest in microconfined liquid crystals in curved geometries. In order to solve the problem of refractive index matching, a new concept of dispersing a small amount of polymer in liquid crystals to form a PSLC composite material has been developed by Yang *et al.* (1992). In preparation, the liquid crystal is mixed with a reactive monomer, which is then polymerized, usually by photo-initiation. During
Figure 4
SEM images of a polymer fibre network formed in the pre-aligned nematic PSLC: cross-section views from the side (along the nematic director) and from the top (looking down the birefringence axis) confirm that the polymer strands are well aligned by the orientational field of liquid crystal. The white bar ($= 5\,\mu m$) shows the length scales of polymer fibrils, their network and of polymer-free cavities (images courtesy of D.-K. Yang, LCI, Kent, OH).

polymerization, a surface alignment or external field can be used to control the orientation of the liquid crystal, and consequently the direction of the forming polymer network (see Fig. 4).

In this way, once established, the polymer fibrils will have an aligning effect on the surrounding liquid crystal. For best results for such a mutual alignment the reactive monomer is selected to be mesogenic, such as 4,4′-bisacryloyloxy-1,1′-biphenylene (BAB), consisting of a biphenylene rigid core and the diacrylate reactive groups on both sides. The rigidity of the resulting polymer network is tuned by using analogous monomers but with flexible spacers, which give conformational freedom to the chains and a more rubbery nature to the composite.

Because of the low concentration of polymer, the refractive index matching problem does not arise in the PSLC composite. Particularly when the polymer is a mesogenic network, the scattering caused by the small refractive index mismatch between the liquid crystal and the polymer network is negligible. After polymerization, the polymer network acts in turn to control the orientation of the liquid crystal in the surrounding cavities. Now the aligning anchoring of the polymer network is a bulk effect and much more efficient than a surface alignment layer. The characteristic length scale of such a system is the cavity radius ξ, of the order of $1–2\,\mu m$. Because the director is anchored on the polymer strands, the system effectively responds to the electric field $E = V/\xi$, rather than the voltage. Assuming the polymer network is mechanically rigid and the director anchoring is strong, as with the BAB materials, the field required to generate a significant optical change is $E \geqslant (1/\xi)\sqrt{K/\varepsilon_o \varepsilon_a} \sim 10^6\,Vm^{-1}$ or higher.

A number of display applications have been developed, based on the polymer-stabilized twisted and super-twisted nematic, cholesteric and ferroelectric smectic C* liquid crystals. When the pitch of a
Figure 5
A scheme of cholesteric PSLC operation. In the OFF state, the polymer network follows the planar cholesteric helix, and preserves its memory in later stages by anchoring the director in appropriate configuration. The helical birefringent texture selectively reflects light. In the ON state, the director attempts to align along the field but is held back by the bulk anchoring on the polymer network—the result is a scattering conical texture. At very strong field the director is fully aligned and the PSLC composite becomes transparent.

cholesteric liquid crystal is in the region of ultraviolet to near-infrared light, the most prominent application is the bistable reflective cholesteric display. In such a composite, in the OFF state, the stabilizing polymer network follows the planar helical twisting and the material selectively reflects light (Bragg reflection from the periodic modulation of the refractive index).

In the ON state, at moderate voltage, the electric field transforms the director texture into a relatively random focal-conic arrangement determined by the competition between the field-aligning effect and the director anchoring on the polymer network strands. The resulting material is strongly scattering and has an opaque appearance. At a substantially higher field $E \geqslant (1/P)\sqrt{K/\varepsilon_o \varepsilon_a}$ with $P \sim 0.5\,\mu\text{m}$, the cholesteric helical pitch, the director can be fully aligned and make the composite transparent. However, the memory about the initial planar cholesteric alignment is permanently fixed in the polymer network and on switching the field off the optical properties quickly return to their original state. Such a sequence of electrically controlled optical states leads to a design of a variety of multimode light valves.

The randomly inhomogeneous PSLC composite with a dilute rigid polymer network should be contrasted with the liquid crystalline gel network, a strongly diluted example of a new class of materials—liquid crystalline rubbers and gels. Terentjev *et al.* (1999) have shown that when the growing and crosslinking polymer chains do not phase separate from a liquid crystal majority phase, the latter acts as an anisotropic solvent in a homogeneous gel with a weak rubber-elastic polymer network. In such a system the electric field causes not only the optical axis rotation, but also the mechanical deformation of the gel network. The resulting length scale (which determines the field required for electro-optic response) is determined by the ratio of Frank constant of the nematic liquid to the rubber modulus of the gel, $\xi \approx \sqrt{K/\mu}$, and can vary in a broad range from 0.01 to 5–10 μm, leading to a variety of possible field effects.

Lumber: Laminated Veneer

Laminated veneer lumber (LVL), also known as parallel-laminated veneer, is one of the most suitable products for the dispersion of natural defects of wood (knots, etc.) by glue lamination of veneer. LVL can be produced with higher yields, in a greater range of dimensions and shapes, and with less time and labor than glued laminated timber or plywood. LVL is composed of mostly parallel grain laminations of veneer bonded to obtain lumber-size thickness. LVL has been approved as an engineering material with reliable strength and stiffness.

Most LVL is produced in flat shapes. When thin veneers are used as laminas, the manufacture of molded LVL with a small radius of curvature is possible. Curved (molded) LVL is used for door or window fittings and for furniture frameworks. Even cylindrical LVL with hollow or reinforced cores has been produced (Sasaki *et al.* 1996).

Development of LVL began with the production of high-strength wooden members in aircraft in the 1940s. In the following decades the machinability, natural appearance, and uniformity of mechanical properties of LVL were used to advantage in the production of curved furniture parts.

Since the supply of high-quality saw logs has diminished, LVL has become more important because of its higher yield potential, adaptability to engineering end-use designs, and the introduction of automatic production methods. Since the beginning of the 1970s LVL has also been used for structural members (e.g., tension chords of trusses or I-beams and outer

laminas of glued laminated beams) in place of lumber components because of its reliability in strength.

1. Processing

LVL is manufactured in a manner similar to plywood but contains mostly parallel laminas. Rotary-cut veneers are usually used. With the decrease in the diameter of available logs, more efficient lathes have been developed to get higher veneer yields. Rotary lathes with peripheral driving devices make it possible to peel logs down to very small (50mm) core diameters.

Veneers are sometimes treated with preservatives, fire retardants, or other chemicals before drying. These chemicals can also be mixed with adhesive. Normally, veneers are dried to about 5% moisture content in conventional hot air circulating, jet, or press dryers. Thin veneers can be dried more economically than thick veneers; however, the production of LVL with thinner veneer requires more adhesive. The balance of these factors, as well as the improved properties of LVL achieved with thinner veneer, must be considered in the choice of veneer thickness.

Phenolic-type or other equivalent adhesives (e.g., melamine, isocyanates) are used in the production of structural LVL, while urea resin is generally used for furniture or nonstructural materials.

Butt joints of veneer ends are significant defects in LVL. The joints must be staggered and distributed as evenly as possible. When the number of laminations is high, butt joints are acceptable because the decrease in the mechanical properties becomes less. Scarf joints in veneer ends are also employed in some cases. Although LVL with scarf-jointed veneer has better strength and appearance, the process is more complex than for butt joints. To obtain high tensile strength in a simpler process, crushed lap joints have been used in commercial LVL (Micro-Lam), where high processing pressure is applied to crush overlapping veneer ends.

Since LVL production started as an extension or variation of plywood production, most LVL is hot pressed in multiopening presses, where LVL is limited in length. Modern plants for the production of structural LVL tend to employ a continuous veneer assembly and hot pressing, in which the joints are well distributed. This makes LVL production less labor intensive than the production of plywood or glued laminated timber. A tractor-tread press with electrical heating units is employed to produce high-tensile-strength LVL (Micro-Lam). Another type of tractor-tread press uses radio frequency heating in which electrodes are set at the surfaces of the treads. Steel belt type presses use residual heat from veneer drying or hot platens set behind the belts. With these continuous presses, high yield and highly efficient production of continuous LVL is feasible. In the case of molded LVL, layers of thin veneer are pressed between male and female molds with radio frequency heating devices.

Cylindrical LVL is produced using a spiral winding method (Fig. 1) (Yamauchi *et al.* 1998). For instance, to manufacture an LVL cylinder with a 500 mm diameter, a continuous glued-veneer tape of 150 mm width (parallel to the fiber direction) and 2.5 mm thickness is wound spirally on a steel mandrel. A pressure of about 0.5 MPa is applied with an elastic belt. The steel mandrel, formed veneer cylinder, and pressure belt are then heated in an oven to cure the adhesive.

2. Mechanical Properties

Figure 2 shows how the variations of strength are reduced in LVL compared to solid lumber from the same logs. The reliability in strength increases with increasing number of laminas. The relative improvement in strength is higher when the quality of the logs is lower. Similar relationships exist between the stiffness of LVL and solid lumber.

The allowable design stress f_a can be estimated by the approximate form:

$$f_a = \frac{f_m - \eta\sigma}{2.1}$$

where f_m is the average strength, σ is the standard deviation, η is a coefficient depending on the shape of the strength distribution, and the factor 2.1 includes the effects of long-term loading, a safety factor, etc. In general, the 5% exclusion limit f_5 (the stress value below which the probability of failure occurring is 5%) is taken to be $(f_m - \eta\sigma)$. If the distribution is Gaussian, η is 1.645. A number of experiments with LVL have shown that η should be taken as 2.0, considering safety factors in use (Koch 1973, Bodig and Jayne 1982).

As can be seen in Fig. 2, the estimated allowable stress of LVL will be far greater than that of solid lumber. LVL manufactured commercially from 2.5–3.0 mm thick Douglas fir veneer (Micro-Lam) with 13 or more plies and crushed lap joints has been approved officially as a material having an allowable stress of 15.09 MN m^{-2} in tension and 19.21 MN m^{-2} in bending. The strength reduction due to butt joints in LVL decreases with increasing number of plies. The reduction is very small in 9-ply products and negligible for 12 or more plies. As derived from fracture mechanics theory, the tensile strength of LVL is inversely proportional to the square root of the thickness of the laminas. The distance between the butt joints in adjacent layers should be more than 16 times the lamina thickness to prevent strength reduction due to stress interaction (Laufenberg 1983).

The tensile strength of products produced by end-jointing short LVL, in general, is more than 90% of

Figure 1

Figure 2
Comparison of bending strength between solid lumber and LVL processed from the same logs. A: solid sawn, $2'' \times 4''$, Siberian larch; B: 8-ply LVL, same log as A; C: solid sawn, $2'' \times 4''$, southern pine; D: 6-ply LVL, same log as C.

the strength of unjointed LVL for scarf joints with a 1:9 slope, more than 70% for finger joints of 27.5mm in length, and more than 60% for minifinger joints of 10mm in length.

Low strength perpendicular to the long axis (i.e., cleavage and shear in the plane parallel to the fibers) is a drawback of LVL. This arises from lathe checks in veneers created during peeling. However, the average strength increases and the variation decreases with increasing number of plies, and thus the allowable stress perpendicular to the grain can be estimated to be the same value as for solid lumber.

3. Grading and Quality Control

One of the most promising characteristics of LVL is the capability of ensuring its structural performance by grading veneer according to quality and selecting the optimum combination or placement of the veneer. Visual grading of veneer which has been widely used in the plywood industry is not totally satisfactory for screening veneer used in stress-rated LVL. Mechanical methods of testing modulus of elasticity of veneer in tension are used in research, but the commercial application of this is not feasible. The stress-wave timing technique is one of the most promising nondestructive methods of estimating properties of each veneer piece before it is laminated into LVL in the industrial process (Jung 1982).

4. Applications

The furniture and fittings industries prefer LVL because of its ease of processing, uniform properties,

good adaptability to curved parts with small radius, stability, and better edge appearance. Arched door frames, staircases, chairs, beds, cabinets, counter tables, wardrobes, etc., are popular uses of this material.

The uniform mechanical properties of LVL, and especially its high allowable stress in tension compared to its weight, make this material useful for flanges of I-beams combined with plywood webs or steel pipe lattice webs. Such I-beams are widely used as joists in house construction. Open-web trusses combining LVL and steel pipe are used as roof trusses and second floor joists in large buildings such as factories and warehouses. These open-web trusses are also used for arched roofs of very large structures such as a 120m span football stadium and exhibition halls. The uses are extending to stringers and decks of highway bridges, stringers of trailer cars, cross-ties, scaffold planks, and to other engineered members in wood construction (Kunesh 1978). Cylindrical LVL can be used for columns in heavy wooden constructions and as arched frames with special functions such as ducting for ventilation, electrical wires, water pipes, etc. (Sasaki and Kawai 1998).

Magnets: Bonded Permanent Magnets

Bonded magnets are generally prepared by blending coercive powder with a binder followed by compacting or molding the material to the final shape. Because of the presence of the binder the energy product of bonded magnets is always lower than that of their sintered counterparts. However, two great advantages of bonded magnets are their superior mechanical properties and the fact that the magnets can be prepared under net shape conditions. Bonded and sintered magnets of ferrites have been known for many decades. Both types of magnets have very low energy products when compared to sintered rare earth-based magnets. The excellent properties of rare earth-based magnets are, however, accompanied by a high price.

The last decade of the twentieth century saw an increased use of actuators and small electromotors not only of low weight but also of low energy consumption, as in battery-driven motors in particular. There has also been an increased use of electronically controlled, electrically actuated systems in automobiles, especially for critical vehicle control functions. All this and the increased use of electromagnetic devices in the electronic and electric industry has led to an enhanced pressure to find improved or alternative permanent magnet materials lying between the low-cost low-performance ferrite magnets and the high-cost high-performance sintered NdFeB magnets. Bonded NdFeB magnets meet most of the criteria mentioned and their use is growing steadily. For this reason bonded types of rare earth permanent magnets will be discussed below in somewhat more detail.

1. Bonding Technologies

Bonded magnets are generally prepared by blending coercive powder with a binder or by encapsulating coercive powder in a binder, followed by compacting or molding the material to the final shape. The powder of the magnetic materials used in bonded magnets may be ferrites, alnico, samarium cobalt or neodymium–iron–boron. In some cases also hybrid powders are used.

Depending on the binder, the magnets produced may be flexible or rigid. Nitrile rubber or vinyl are commonly used for the former type whereas for the latter type nylon, teflon, polyester, or thermoset epoxies are employed.

There are four main manufacturing routes for bonded magnets: calendering, injection molding, extrusion, and compression bonding.

(i) Calendering involves processing the material between rollers and leads to continuous strips of adjustable thickness and length. This process is schematically shown in Fig. 1. The material used for calendering is usually a mixture of the magnetic powder and a thermoplastic binder. This mixture is processed between rollers forming a continuous strip that may be up to 100 m in length. Magnetic loading can be up to 70% by volume.

(ii) The injection molding process is schematically represented in Fig. 2. This process involves forcing the heated mixture of magnetic powder and thermoplastic binder via tubes into a mold where it is allowed to cool and harden. In this case too, magnetic loading can reach 70%, especially when using powder of spherical shape (Ma *et al.* 2002).

(iii) Extrusion makes use of an orifice through which the compounded material is squeezed, as illustrated in Fig. 3. During the extrusion process the orifice is heated and the profile is controlled as the compounded material cools. Depending on the binder, the cooled product can be firm, as for flexible end products, or rigid if a nonflexible end product is desired. The loading can reach slightly higher values (up to 75% by volume) than in the two previous cases.

(iv) Compression bonding uses magnetic powder blended with an epoxy that has been liquefied by dissolution in an organic solvent. The latter is evaporated during the blending process, leaving the magnetic particles in an epoxy-encapsulated state. After

drying, the coated powder is flowed into a conventional powder press (Fig. 4) and compacted into the desired shape. Finally, the compacted magnet is cured in an oven at temperatures of around 150–175 °C. This process can reach magnetic loadings up to 80%.

Because of the presence of the binder, the magnetic remanence is always lower than that of the fully dense magnetic material, as obtained, for instance, by sintering. The situation is even less favorable for the energy product, being roughly proportional to the remanence squared. There are, however, obvious advantages. The major advantage is that bonded magnets can be produced in net shape or near-net shape. Even fairly complicated shapes may be involved, as in injection molding. Another advantage is their superior mechanical properties. Bonded magnets are mainly manufactured from ferrite powder or coercive NdFeB-based powders. Bonded magnets based on NdFeB, owing to their superior intrinsic magnetic properties, offer substantial advantages in terms of size, weight, and performance over bonded ferrite magnets and even over sintered ferrite magnets.
Figure 4
Diagram showing the compression bonding process. The magnetic powder is blended with an epoxy that has been dissolved in an organic solvent. The latter is evaporated during the blending process, leaving the magnetic particles in an epoxy-encapsulated state. The coated powder is flowed into a conventional powder press and compacted into the desired shape. The compacted magnet is finally cured in an oven (after Ormerod and Constantinides 1997).

2. The Permanent Magnet Materials

The most common types of magnets used at present are hard ferrite magnets, rare earth-based magnets such as SmCo or NdFeB, and alnico-type magnets. Of these the alnico magnets have only a modest coercivity which leads to nonlinear demagnetization characteristics. For this reason their applicability is very limited compared with the other two types. The hard ferrites have higher coercivities than the alnico magnets and their demagnetizing characteristics are linear. However, the remanence and the concomitant maximum energy product are already low and are further decreased by bonding. Because of their low cost, ferrite magnets are still widely applied, although most of the corresponding magnetic devices are rather bulky and often give far from optimal performance. Ferrite permanent magnets currently dominate automotive and many other applications due to their low cost and proven long-term stability (see *Alnicos and Hexaferrites*[#]).

The rare earth based magnets have high values of coercivity which gives them linear demagnetization characteristics (see *Rare Earth Magnets: Materials*[#]). They have high remanences and typical values of the energy products reached in sintered magnets are 150 kJ m^{-3} for SmCo$_5$, and 300 kJ m^{-3} for Nd$_2$Fe$_{14}$B. The first types of magnets are frequently used in high-temperature applications, which possibility is lost in bonded magnets (see *Magnets: High-temperature*[#]). SmCo$_5$ type magnets are expensive owing to the high price of both samarium and cobalt.

The situation is more favorable for NdFeB magnets because neodymium is cheaper than samarium and iron is much cheaper than cobalt, the powder metallurgical processing arts being comparable with those of $SmCo_5$. Hence the performance/price ratio for $Nd_2Fe_{14}B$ is better than for $SmCo_5$. For this reason the market for sintered $Nd_2Fe_{14}B$ magnets has flourished and is still growing (see *Magnets: Sintered*[#]).

Although bonded magnets can be manufactured from all of the materials mentioned above, only bonded ferrite magnets and bonded $Nd_2Fe_{14}B$ magnets have penetrated into the market to an appreciable extent. The ferrites can be easily obtained in powder form (see *Alnicos and Hexaferrites*[#]). A somewhat special processing of the ferrite powders leads to hexagonal platelets that can be easily aligned mechanically during the formation process of flexible bonded magnets. The situation is more difficult in the case of $Nd_2Fe_{14}B$, because a simple powder metallurgical route from cast or annealed $Nd_2Fe_{14}B$ ingots does not generally lead to powders of sufficiently high coercivity for use in bonded magnets. Coercive NdFeB powders can be obtained though by melt spinning (see *Metallic Filaments*[*]). In this technique a fine stream of molten alloy is sprayed onto the outer surface of a rapidly spinning wheel, leading to thin rapidly quenched ribbons or flakes. During the melt spinning the material is protected from oxidation by performing this process in a protective atmosphere or in vacuum. The quenching rate is of the order of 10^5 K s^{-1} and can be varied by changing the rotational speed of the spinning wheel. Different quenching rates lead to different microstructures which in turn determine the magnetic properties of the melt spun material. Optimum melt spinning conditions lead to a nanocrystalline alloy consisting of fine grains (typically 30 nm) of the compound $Nd_2Fe_{14}B$, surrounded by a thin layer of a neodymium-rich eutectic phase. In practice, more reliable and reproducible results can be obtained by using a slightly higher quenching rate and subsequently annealing the melt spun material under carefully controlled conditions. The melt spun material is fairly brittle and can be ground to a fine powder suitable for manufacturing bonded magnets. Because the $Nd_2Fe_{14}B$ grains have a random orientation, these bonded magnets are isotropic. Powder particles of spherical shape flow better in the injection molding process, which allows a higher loading factor. Such powder can be prepared by an inert gas atomization process with typical values for the mean particle diameter of 45 mm. An additional advantage of the atomization process is the high production rate and low processing costs of the powders (Ma *et al.* 2002).

A different route leading to coercive NdFeB powders consists of the so-called HDDR process (see *Magnets: HDDR Processed*[#]). This process involves essentially four steps: **h**ydrogenation of $Nd_2Fe_{14}B$ at low temperatures, **d**ecomposition of $Nd_2Fe_{14}BH_x$

into $NdH_{2.7}$ + Fe + Fe_2B, **d**esorption of H_2 gas from $NdH_{2.7}$, and **r**ecombination of Nd + Fe + Fe_2B into $Nd_2Fe_{14}B$. This process profits from the fact that the formation of $Nd_2Fe_{14}B$ grains in the last step is a solid-state reaction and hence proceeds at a rate considerably lower than during solidification from the melt during a normal casting process. The average $Nd_2Fe_{14}B$ grain size remains in the nanometer range and gives rise to sufficiently large coercivities.

A further advantage is the fact that the HDDR process can be successfully used to obtain anisotropic particles. Takeshita and Nakayama (1992) discovered that additives of zirconium, hafnium, and gallium, in particular, are very effective in producing anisotropic HDDR powder. The amount of additive required is surprisingly small (for instance, $Nd_{12.5}Fe_{69.9}$-$Co_{11.5}B_6Zr_{0.1}$). Microscopic investigations described by Harris (1992) revealed that large facetted HDDR grains had formed within the original as-cast grain of the alloy. These facetted grains have a common orientation, which is probably the same as that of the original grain. The anisotropic nature of HDDR powders of alloys like $Nd_{12.5}Fe_{75.9}Co_{11.5}B_8Zr_{0.1}$ can thus be visualized by assuming that the HDDR grains have nucleated and grown within an original as-cast grain region from submicron grains, the latter having a common orientation (Harris 1992). Evidently the effect of the additive is to bring about nucleation centers for nucleation and growth of the HDDR grains, the latter grains having kept the orientation of the original cast grain.

Tomida *et al.* (1996) have used x-ray diffraction to establish a correlation between the anisotropic nature of the ultimate HDDR powder and the amount of $Nd_2Fe_{14}B$ phase remaining unreacted in the hydrogenation process. TEM studies made by Tomida *et al.* on powder hydrogenated under optimum energy product conditions showed that after hydrogenation the powder consists mainly of coarse-grained α-Fe and Fe_2B, with nanocrystalline particles embedded in between. These particles were identified by electron diffraction as NdH_2 particles. However, many of the particles were identified as $Nd_2Fe_{14}B$ particles having a crystallographical orientation almost the same as that of the original cast $Nd_2Fe_{14}B$ grains. Energy-dispersive spectra furthermore showed that these particles are of higher cobalt and gallium concentration than corresponding to the average concentration of the starting alloy. These results have led Tomida *et al.* to propose that this type of nanocrystalline $Nd_2Fe_{14}B$ particles serve as initiation centers in the recombination process and are the origin of the orientational memory effect in HDDR powders.

A different category of materials that appears to be promising is nanocrystalline rare earth-based composite magnets. Under special circumstances, two-phase composite materials can demonstrate a most interesting coercivity behavior. Such a behavior has

been described by Kneller and Hawig (1991), who investigated the combined effect of two finely dispersed and mutually exchange-coupled magnetic phases. One of these phases has a large uniaxial anisotropy constant and is able to generate a high coercivity. By contrast, the second phase is magnetically soft. It has a larger magnetic ordering temperature and concomitantly a larger average exchange energy than the hard phase. It is the comparatively high saturation magnetization of the soft phase that, when the latter is exchange coupled to the hard phase, provides a high remanence to the composite magnet. The possibility to prepare magnets showing remanence enhancement has triggered extensive research in this area (see *Magnets: Remanence-enhanced#*).

In most of the systems for which remanence enhancement has been reported, the magnetically soft phase is α-Fe or an iron-rich or cobalt-rich alloy. Examples of magnetically hard phases are $Nd_2Fe_{14}B$, $Sm_2Fe_{17}N_3$, Sm_2Co_{17}, and $Nd(Fe,Mo)_{12}N_x$. The microstructures of all these composite magnets have in common that they consist of a very fine distribution of the magnetic particles, falling into the nanometer range. In order to reach this fine distribution various techniques are employed, including melt spinning and mechanical alloying (see *Magnets: Mechanically Alloyed#*). This group of materials is referred to as lean rare earth permanent magnets. Their advantages compared with the standard alloys are their excellent corrosion resistance and the fact that they reach saturation in a comparatively low applied field. A disadvantage is their relatively low coercivity. The possibility of using these materials in resin-bonded magnets has been described by Croat (1997).

Another interesting group of materials are interstitially modified R_2Fe_{17} compounds. Although the low Curie temperatures and comparatively low magnetocrystalline anisotropies make the R_2Fe_{17} compounds less attractive for applications as permanent magnet materials, considerable improvements with respect to Curie temperature anisotropy and coercivity have been reached by forming interstitial solid solutions obtained by combining these materials with carbon or nitrogen. The composition of the corresponding ternary nitrides and carbides $R_2Fe_{17}C_x$ and $R_2Fe_{17}N_x$ is generally believed to be restricted to the range $0 \leq x \leq 3$. More details about the formation ranges and location of the interstitial atoms the lattice are described in the review of Fujii and Sun (1995).

Resin-bonded magnets from nitrogenited Sm_2Fe_{17} powders have been prepared with $BH_{max} = 136 \, kJ \, m^{-3}$, $B_r = 9.0T$, and $\mu_{oB}H_c = 6.5T$. In order to explore the favorably low temperature coefficient of the coercivity in magnet bodies suitable for high-temperature applications Rodewald *et al.* (1993) and Kuhrt *et al.* (1993) have investigated tin- and zinc-bonded magnets. In these cases, however, the obtained remanences were fairly low ($B_r < 0.7$ T).

3. Applications of Bonded Magnets

Bonded ferrite magnets are commercially available in isotropopic and anisotropic grades (see Table 1). The calendered material is commonly called sheet. Sheet magnets are mainly used by screenprinters for advertising specialties, novelties, and picture frames. Sign manufacturers use it for vehicle signs, but there are also medical applications such as needle counters. Extruded profile flexible magnets are called strip. They are used for a variety of gasket applications such as for refrigerator doors, shower doors, and removable storm windows. Other applications are in small motors and stereo speakers. Injection-molded ferrite magnets are mainly used in automotive applications, office automation, and in small motors. A great advantage of the ferrite magnets is that they are inexpensive and the raw materials are readily available.

Bonded SmCo-type magnets are used in applications where the temperature coefficients of remanence and coercivity have to be low and where a high corrosion resistance is required. Compared to bonded ferrite and NdFeB magnets their market share is low because of the high price of the raw materials.

Table 1
Maximum energy products ($kJ \, m^{-3}$) of commercially available bonded magnets (from Ormerod and Constantinides 1997).

Magnet powder	Manufacturing route	Magnetic isotropic	Magnetic anisotropic
Ferrite	Calendered	4.0–5.0	11.2–12.8
	Extruded	3.2–4.8	9.6–12.0
	Injection molded	4.0–6.4	12.0–13.6
SmCo	Injection molded		68–76
	Compression		104–136
NdFeB	Calendered	39–41	
	Injection molded	40–42	76–88
	Compression	64–88	112–128

The majority of bonded NdFeB magnets are used in personal computers but they are also used in a fairly wide range of automotive, consumer, and office products including VCRs, camcorders, and printers, and in smaller appliances such as watches, clocks, timer switches, and cameras. Most of the bonded NdFeB magnets go into various types of electric motors. The most prominent types of electric motors are spindle motors and stepper motors. Stepper motors have fairly small sizes and are characterized by their ability for precise incremental position or speed adjustment with electric pulses from digital controllers. In modern stepper motors, the stators consist of the coils system and the rotors are made of rare earth permanent magnets. The advantage of using rare earth permanent magnets is their high coercivity, which makes it possible to axially magnetize the rotor through the thickness with a large number of poles on the circumference. This allows fairly low step angles. The number of spindle motors produced is lower than the number of stepper motors. Spindle motors are much larger than stepper motors. This is the reason why they still consume a relatively large percentage of bonded NdFeB magnets. The largest application of electric motors is in computer peripherals, where they serve, for instance, as hard disk drive spindle motors, CD-ROM pick-up motors, CD-ROM spindle motors, floppy disk drive spindle motors, and floppy disk head actuators.

For a more detailed discussion of bonded magnet manufacturing, their performance, and their applications the reader is referred to the review articles of Croat (1997), Ormerod and Constantinides (1997), and Ma *et al.* (2002).

Materials Selection and Mechanical Design

1. Viability

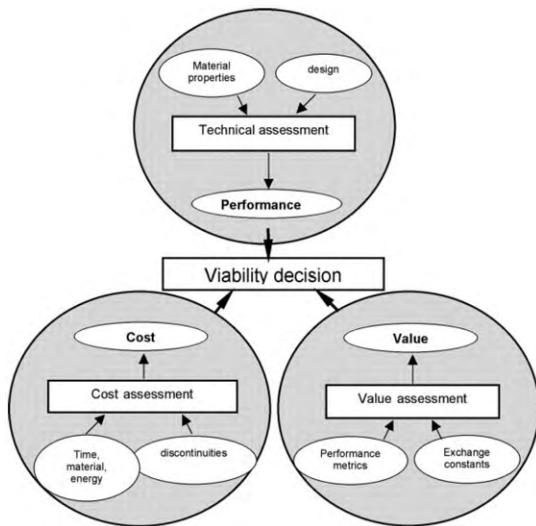
The viability of a new material in a given application depends on the balance between its performance and its cost. There are three steps in evaluating it. The first is the technical assessment (Fig. 1, upper circle). Performance metrics are identified and evaluated for competing solutions for the design. Each application can be modeled in this way in order to provide a basis for performance comparisons between new material solutions and existing solutions. The second step is the analysis of cost (Fig. 1, lower left-hand circle): how much does it cost to achieve a given performance metric? The quantity of material required to meet constraints on stiffness, on strength, on energy absorption, etc., is calculated from straightforward technical models. The cost, C, of producing this quantity of material in the desired shape is the output of the cost model, as described in Sect. 3. The final step is that of assessing value (Fig. 1, lower right-hand circle): is the change in performance worth the change in cost? Balancing performance against cost is an example of multiobjective optimization. It is discussed in Sect. 4.


Figure 1
Three parts of a viability study.

Figure 2
Schematic of a TCM.

2. Technical Assessment

The first step of a viability analysis is an application-specific performance comparison of the new material over the existing material by means of a technical model. This procedure should be applied to all promising applications. To construct a technical model, *performance metrics*, P_i, are identified and evaluated. A performance metric is a measure of the performance offered by the material in a particular application. In *minimum weight design* the performance metric is the mass: the lightest material that meets the specifications on stiffness, strength, etc., is the one with the greatest performance. In *design for energy mitigation*, in which it is desired that a protective packaging should crush, absorbing a specified energy, and occupy as little volume as possible, the performance metric is the volume. In *design to minimize heat loss*, the metric might be the heat flux per unit area of structure. In *design for the environment*, the metric is a measure of the environmental load associated with the manufacture, use, and disposal of the material.

Each performance metric defines an objective: an attribute of the structure that it is desired to maximize or minimize. Models are developed for the performance metrics following the methods detailed in Ashby (1999). The material that maximizes the chosen performance metric has the highest technical merit. But for this to be a viable choice, the performance must be balanced against the cost.

3. Technical Cost Modeling

The second step of a viability analysis is to establish the manufacturing cost differential between a component made with a novel process or material vs. existing processes and materials. If a predictive cost model has been created for manufacturing with a new material, then the model can be quickly used to compare the manufacturing cost of any part made with the new material with the known cost of the existing material part. *Technical cost modeling* (Field and de Neufville 1988, Clark *et al.* 1997) exploits the understanding of the way in which the control variables of the process influence production rate and product properties. It also uses information on the way the capital cost of equipment and tooling scale with output volume. These and other dependencies can be captured in theoretical and empirical formulas or look-up tables that are built into the cost model, giving greater resolution. In addition, informed sensitivity analysis and scenario building are enabled through the capturing of the linkages between the technical limitations of the process, intermediate variables such as cycle time, and cost line items.
A schematic of the structure of a technical cost model (TCM) is shown in Fig. 2. Each of the empty boxes represents the calculation of intermediate variables that capture the technical limitations of the process under varying input product specifications, process choices, and selected production volumes. The final output consists of both a range of unit cost numbers and the identification of cost drivers. As an example, we consider TCMs for two established processes for making *metal foams*. They are described briefly below.

3.1 Liquid-state Foaming of Aluminum

Consider a cost model for the production of panels of a SiC-stabilized aluminum-based metallic foam by the following four-step liquid-state process:
 (i) melting of the premixed alloy;
 (ii) holding, providing a reservoir;
 (iii) foaming, using compressed gas and a bank of rotating blades; and
 (iv) delivery of a continuous sheet of foam or of cut panels, via a moving belt.
 The output of one step forms the input to the next, so the steps must match, dictating the size of the equipment or the number of parallel lines in each

step. Data characterizing the dependence of desired material density and of production rate on the gas flow rate and the stirring rate have been incorporated in the model and links into the intermediate variables of limiting production rate, used hours per year, person-hours per year, fraction of capacity used, and number of parallel lines of equipment. Through these intermediate variables, the influences of how scale-up and varying product requirements affect the cost line items of equipment, direct labor, and power. Fixed costs are treated in the standard economics fashion, through the use of a cost-of-capital factor and by including the opportunity cost of capital associated with the working capital. A default range of product, process, and business variables can be overridden by the user, providing flexibility and the potential for extensive scenario and sensitivity analysis.

The outputs of the model (Figs. 3 and 4) show the way in which the cost of the manufactured component depends on production volume and also identify cost drivers. Significantly, the model indicates the production volume that would be necessary to reach the plateau level of cost at which, in the best case shown here, the material cost falls to roughly twice that of the input materials.

3.2 Titanium Hydride Expansion of Aluminum via Powder Metallurgical Processing

In comparison, consider a cost model for the production of panels of an aluminum-based metallic foam by either the batch or quasicontinuous processes for the powder metallurgical (PM) processing of aluminum foam. For the batch process, there are six steps:

(i) mixing of the aluminum powder with the powdered foaming agent ($<1\%$ TiH$_2$);

(ii) cold isostatic compression of the powder into an intermediate billet;

(iii) sintering of the billet (optional);

(iv) extrusion of the foamable precursor;

(v) placement of precursor in mold; and

(vi) batch foaming of precursor in mold.

For higher production volumes, automation of steps (ii), (iii), and (iv) and of steps (v) and (vi) have been proposed as follows:

(i) mixing of the aluminum powder with the powdered foaming agent ($<1\%$ TiH$_2$);

(ii) conversion of powder into precursor strip using the continuous CONFORM process; and

(iii) quasicontinuous foaming of precursor in the mold, meaning that the molds on a continuous belt are filled robotically, passed through the furnace, opened and, emptied.

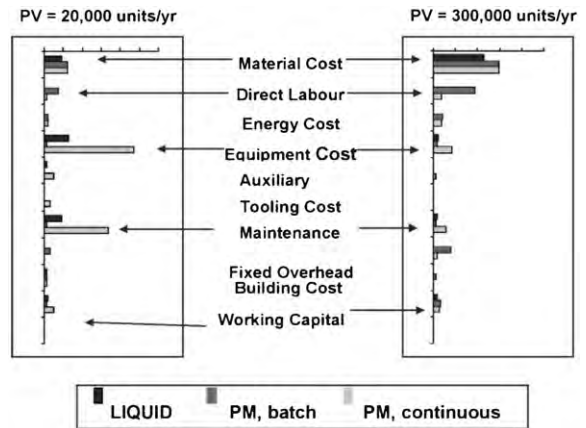
The rate-limiting step for the low production volume process is the batch foaming step. The cycle time of this step is heat-transfer limited. The time required to heat the mold then increases with increased part
Figure 3
Manufacturing cost for varying production volumes: processing of aluminum foam by three methods.


Figure 4
Line item cost for crossover annual production volume of 20 000 and 70 000 units: processing of aluminum foam by three methods.

dimensions and the time required to transfer heat into the precursor strips increases both with increasing part dimensions and with part curvature.

An important cost driver in this process is the substantial amount of scrap generated in the foaming stage in order to ensure mold filling, shape definition, and to avoid weak zones along the interfaces of the precursor strips where they meet during foaming. The cost of processing the material lost during the foaming stage is reflected in the material cost line item of the batch foaming and continuous foaming stages. It is assumed that the scrap material can be sold as prompt scrap.

By running comparison scenarios with this model, it has been determined that the CONFORM process is not a viable alternative to the manual steps of billet pressing, billet heating, and extrusion of the precursor strips. However, a quasicontinuous foaming process to automate the rate-limiting batch process appears viable from this analysis. A comparison has

been run for a simple flat panel of aluminum foam made by the three options of liquid-state processing, batch powder metallurgical processing, and the proposed quasicontinuous powder metallurgical process without the uneconomical CONFORM step. This simple flat panel comparison inherently favors the liquid-state process of Sect. 3.1, which is set up for the continuous production of flat panels. Figure 3 depicts the relative cost per unit of each of the different options over a range of annual production volumes. For annual production volumes of up to 20 000 parts, the batch powder metallurgical process is the most economical option. From examining Fig. 4, which shows a snapshot of the line item costs for each process at 20 000 and 300 000 parts per year, we can see that it is fixed costs, in particular equipment costs, that drive the low-volume cost of both continuous PM processing and liquid-state processing higher than that of batch PM processing. In this way, the TCM can be used to aid the decision about the suitability of converting to a continuous process.

By comparing the cheapest aluminum foam component (at the required production volume) with an existing material for any given application, the cost differential between a new and an existing material solution can be established. This provides input into the value assessment of the material.

4. Value Assessment

4.1 Multiobjective Optimization and Trade-off Surfaces

The viability of a foam in a given application depends on the balance between its performance and its cost. There may be several performance metrics that are important for the substitution decision, and the combination of these metrics and cost can be compared with those of the existing ones through the use of multiobjective optimization techniques.

When a design has two or more objectives, solutions rarely exist that optimize all objectives simultaneously. The objectives are normally noncommensurate, meaning that they are measured in different units, and in conflict, meaning that any improvement in one is at the loss of another. However, some solutions can be rejected quickly because they are dominated by other solutions: other solutions exist that have better values of both (or all) the performance metrics. The solutions that cannot be rejected in this manner lie on a line called the *nondominated* or *optimum* trade-off surface (Hansen and Druckstein 1982, Sawaragi and Nakayama 1985). The values of the performance metrics corresponding to the nondominated set of solutions are called the Pareto set (Fig. 5).

The trade-off surface identifies the subset of solutions that offer the best compromise between
Figure 5
Dominated and nondominated solutions, and the optimum trade-off surface.

the objectives, but it does not distinguish between them. Three strategies are available to deal with this:

(i) The trade-off surface is established and studied, using intuition to select between nondominated solutions.

(ii) All but one of the objectives are reformulated as constraints by setting lower and upper limits for them, thereby allowing the solution that minimizes the remaining objective to be read off.

(iii) A composite objective function or *value function*, V, is formulated; the solution with the minimum value of V is the overall optimum. This method allows true multiobjective optimization, but requires more information than the other two. It is explored below.

4.2 Value Functions

One strategy for optimizing over multiple objectives is through the use of a value function, V, defined below. For substitution to occur, the gain in value, ΔV, must be large enough to provide sufficient financial or strategic incentive to justify investment in the new technology, and also, if necessary, in the manufacturing facilities.

Value functions are used to compare and rank competing solutions to multiobjective optimization problems. The locally linear value function is defined as

$$V = \alpha_1 P_1 + \alpha_2 P_2 + \ \dots \ + \alpha_i P_i \ \dots \tag{1}$$

where V is proportional to each performance metric P. The coefficients α are *exchange constants*: they relate the performance metrics P_1, P_2 … to V, which is measured in units of currency (\$, £, DM, etc). The

exchange constants are defined by

$$\alpha_1 = \left(\frac{\partial V}{\partial P_1}\right)_{P_2, \ldots P_i} \tag{2}$$

$$\alpha_2 = \left(\frac{\partial V}{\partial P_2}\right)_{P_1, \ldots P_i} \tag{3}$$

that is, they measure the change in V for a unit change in a given performance metric, all others held constant. If the performance metric P_1 is mass m (to be minimized), α_1 is the change in value V associated with unit increase in m. If the performance metric P_2 is heat transfer q per unit area, α_2 is the change in value V associated with unit increase in q. The best solution is the one with the smallest value of V, which, with properly chosen values of α_1 and α_2, now correctly balances the conflicting objectives.

With given values of V and exchange constants α_i, Eqn. (1) defines a relationship between the performance metrics P_i. In two dimensions, this would plot as a family of parallel lines, overlaid on Fig. 5. The slope of the lines is fixed by the ratio of the exchange constants, α_1/α_2. The best solution is that at the point along a value line that is tangent to the trade-off surface, because this is the one with the smallest value of V. The method can be used to optimize the choice of material to fill a multifunctional role, provided that the exchange constants, α_i, for each performance metric are known.

(*a*) *Minimizing cost as an objective*. Frequently one of the objectives is that of minimizing cost, C, so that $P_1 = C$. Since we have chosen to measure value in units of currency, unit change in C gives unit change in V, with the result that

$$\alpha_1 = \left(\frac{\partial V}{\partial P_1}\right)_{P_2, \ldots P_i} = 1 \tag{4}$$

and Eqn. (1) becomes

$$V = C + \alpha_1 P_2 + \ldots + \alpha_i P_i \tag{5}$$

As a simple example, consider the substitution of a metal foam, M, for an existing (nonfoamed) material, M_0, based on cost C and one other performance metric, P. The value of P in the application is α. Substitution is potentially possible if the value V of M is less than that, V_0, of M_0. Thus substitution becomes a possibility when

$$V - V_0 = (C - C_0) + \alpha(P - P_0) \leqslant 0 \tag{6}$$

or

$$\Delta V = \Delta C + \alpha \Delta P \leqslant 0$$

from which

$$\frac{\Delta P}{\Delta C} \geqslant -\frac{1}{\alpha} \tag{7}$$

defining a set of potential applications for which M is a better choice than M_0.

To visualize this, think of a plot of the performance metric, P, against cost, C (Fig. 6). M_0 is centered at $\{P_0, C_0\}$; the potential substitute at $\{P, C\}$. The line through M_0 has the slope defined by Eqn. (7), using the equality sign. Any material that lies on this line, such as M_A, has the same value V as M_0; for this material, ΔV is zero. Materials above this line, such as M_B, despite having a lower (and thus better) value of P than M_0, have a higher value of V. Materials below the line, such as M_C, have a lower value of V (even though they cost more), a necessary condition for substitution. Remember, however, that while negative ΔV is a necessary condition for substitution, it may not be a sufficient one; sufficiency requires that the difference in ΔV be large enough to justify the investment in new technology.

As an example of the use of trade-off surfaces and value analysis, consider the performance–cost trade-off of aluminum foams vs. all other materials for a panel of specified stiffness. (This example is relevant in many automotive, aerospace, and infrastructure applications.) A cost metric is plotted along the vertical axis and a weight-adjusted stiffness performance metric along the horizontal axis. The Pareto set (shown by the trade-off line in Fig. 7) lies on a curved line owing to the logarithmic scale chosen to capture a wide range of materials. The three aluminum foams that lie on this trade-off surface are shown in black. The next step is to plot the value curves for different applications with different exchange constants onto this graph (as in Fig. 6), or evaluate them numerically. Table 1 illustrates the numerical method. Here
Figure 6
Trade-off between performance and cost.
Figure 7
Performance–cost trade-off example of a light, stiff panel.

Table 1
The selection of panel materials: stiffness constraint.

Material	ρ (Mg m^{-3})	E (GPa)	C_m (£ kg^{-1})	P_1	P_2	V ($\alpha_1 = $ £0.5 kg^{-1})	V ($\alpha_1 = $ £500 kg^{-1})
Cast iron, nodular	7.30	175	0.25	1.31	0.33	0.99	655
Low-alloy steel (4340)	7.85	210	0.45	1.32	0.59	1.25	660
Al 6061-T6	2.85	70	0.95	0.69	0.66	1.01	345
Al-6061-20% SiC, PM	2.77	102	25	0.59	14.8	15.1	309
Ti-6-4 B265 grade 5	4.43	115	20	0.91	18.2	18.7	473
Beryllium SR-200	1.84	305	250	0.27	67.5	67.7	202
Alporas[a]	0.25	1.0	40	0.23	10.0	10.1	125
Alulight[a]	0.30	0.8	16	0.3	5.2	5.4	155
Alcan[a]	0.25	0.4	5.8	0.34	2.0	2.2	172

[a] All three types of metal foam are made in a range of densities, with a corresponding range of properties. These three examples are taken from the middle of the ranges. The costs are estimates only, broadly typical of current prices, but certain to change in the future. It is anticipated that large-scale production could lead to substantially lower costs.

P_1 is the weight-adjusted stiffness metric shown as the horizontal axis of Fig. 7, and P_2 is the cost metric shown as the vertical axis. For an exchange constant of $\alpha_1 = $ £0.5 kg^{-1}, cast iron has the lowest value of V and is the best choice; but for a larger exchange constant of $\alpha_1 = $ £500 kg^{-1}, the Alporas foam panel is a better choice than any other material.

4.3 The Exchange Constants, α

An exchange constant is a measure of the value of performance. Its magnitude and sign depend on the application. Thus the value of weight saving in a family car is small, though significant: in aerospace applications it is much larger. The use of heat transfer

in a heat exchanger is positive; in applications requiring thermal insulation it is negative. The value of performance can be cost based, meaning that it measures an actual saving of cost, energy, materials, time, or information. But value can, sometimes, be perceived, meaning that the consumer, influenced by forces such as scarcity, advertising, fashion, aesthetics, convenience, etc., will pay more than the cost-based value of these metrics.

In many engineering applications the exchange constants can be derived approximately from technical models. Thus the value of weight saving in transport systems is derived from the fuel saving or the increased payload that this allows. The value of heat transfer can be derived from the price of the energy transmitted or conserved by unit change in this metric. Approximate exchange constants can sometimes be derived from historical pricing data; thus the value of weight saving in a bicycle can be approximated by plotting the price, P, of bikes against their mass, m, using the slope dP/dm as an estimate of α. Finally, exchange constants can be determined through interviewing techniques (Field and de Neufville 1988) that elicit the value to the consumer of a change in one performance metric, all others held constant.

5. Conclusions

Cost estimation is an important part of a material development strategy. A new material is viable in an application only if its value, so used, exceeds that of competing materials. Value is a function of both performance and cost and of one or more exchange constants that measure the use of performance. The value function that combines these allows optimized selection of material and process to meet a given design specification.

Mechanical Alloying

Mechanical alloying (MA) is a powder metallurgical process which was developed in the mid-1960s by the International Nickel Company (INCO) as a practical solid-state route for introducing and retaining fine refractory oxide particles in high-temperature alloys (Benjamin 1970, 1989). INCO established that it was possible to obtain the desired oxide distribution by using dry, high-energy ball milling of mixtures of raw material powders: mechanical alloying was born. It was quickly found that this solid-state powder processing route enabled intimately mixed, fine-scale composite powders to be produced from a wide range of elemental and master alloy starting powders. The principal aspects of powder processing and handling together with subsequent consolidation and thermo-mechanical processing which it was important to control in order to ensure reproducible end properties in high-temperature, creep-resistant nickel- (e.g., MA 754) and iron-based (e.g., MA 956) ODS alloys were also determined. Much of this processing knowledge has proved of generic relevance and is as applicable to the control of MA in the many other alloy systems that have subsequently been developed and explored as it was to the early MA ODS alloys.

An enormous amount of research has been performed on the MA technique and the materials systems that it has proved possible to synthesize using it. The broad categories for the latter include intermetallics, ceramics, composites (cermets and metal matrix composites (MMCs)), nanocrystalline materials, amorphous alloys, and self-propagating high-temperature synthesis (SHS) systems. The list is not exhaustive but at least illustrates the range of applicability and versatility of MA. Most of these applications of MA remain at the research stage.

1. Mechanisms and Processing

MA in high-energy ball milling equipment is accomplished by processing an initial powder charge usually comprising a mixture of elemental, ceramic (e.g., yttria for ODS alloys), and master alloy powders, all

supplied in strictly controlled size ranges. Master alloy powders are used in order to reduce *in situ* oxidation of highly reactive species, such as aluminum or titanium alloy additions during processing. The milling medium normally used in commercial systems is a charge of hardened steel balls, typically 2 cm in diameter. The ball-to-powder weight ratio is chosen carefully for each mill and powder charge combination, but is typically around 10:1 for commercial systems. Given the enormous surface area, both of the initial powders and the fresh powder surfaces generated during MA processing, control of the milling atmosphere and its purity is essential to avoid undue alloy contamination. The principal protective atmospheres employed during commercial milling of MA powders are usually either argon or hydrogen and this protection generally extends both to pre- and post-MA powder handling. Both the purity of these gas atmospheres and the integrity of gas seals on the milling equipment are essential to control contamination, particularly when processing reactive species. For example, levels of oxide contamination in Ni_3Al can double with just a few hours of milling in impure argon. Occasionally, however, deliberate doping of the milling environment has been used to facilitate alloying additions during processing.

The central event during MA is the ball–powder–ball collision within the milling medium during processing. It is repetition of these high-energy collisions which leads eventually to MA of the powder charge. Intimate mixing and eventual MA of the powder charge occurs in a series of identifiable, more or less discrete stages during processing (e.g., Gilman and Benjamin 1983). For ductile–ductile or ductile–brittle combinations of starting powders, MA initially proceeds by the flattening and work hardening of ductile powders and fragmenting of brittle constituents, which is followed by extensive cold welding between powder particles, formation of lamellar structures, and coarsening of the powder particle size distribution. Brittle powder fragments are trapped at cold weld interfaces between the evolving lamellas of the ductile constituents and thus, while continuing to comminute, become dispersed. With continued milling a balance, which is dependent on processing parameters and the composition of the constituents, is established between further cold welding and powder particle fracture, leading to relatively stable powder particle sizes.

This balance between welding and fracture is accompanied both by further decreases in lamella spacings and by folding and mixing-in of lamella fragments to produce microstructures typical of MA (Fig. 1). For ODS alloys, powder constituents are milled to the stage where light microscopy examination reveals that lamella spacings have decreased to below the resolution limit ($\sim 1\,\mu m$). For typical levels of oxide addition (e.g., $\sim 0.5\,wt.\%$ yttria) this criterion ensures average dispersoid interparticle spacings
Figure 1

of $< 0.5\,\mu m$ (Fig. 2). In other systems, milling can progress until true alloying occurs. Surprisingly, MA can also be achieved between essentially brittle powder constituents. The mechanisms by which this occurs are less well understood than in systems incorporating at least one ductile powder component. Nevertheless, granular as opposed to interlamellar mixtures of brittle powder constituents do evolve, typically with smaller, harder fragments progressively incorporated to a very fine scale within the less hard constituents, e.g., alumina–nickel oxide. Moreover, MA of these brittle constituents can progress to true alloying, as has been demonstrated using lattice parameter measurements on Si–28 at.% Ge progressively milled from constituent powders (Davis and Koch 1987).

Milling of very ductile metals such as aluminum and tin has to be carefully controlled to avoid complete agglomeration of the ductile phase rather than the balance between cold welding and fracture that leads to MA. This is normally achieved by adding precise amounts of organic compounds termed process control agents (PCAs) to the milling environment. Typically waxes or solvents, these compounds that interfere with cold welding progressively break down during milling to become incorporated within the final MA powders (e.g., in aluminum alloys) as fine-scale distributions of carbides or oxides. Similar restrictions to the proclivity for cold welding in ductile powders can be achieved without use of PCAs by milling at low temperatures, e.g., below $-100\,°C$ for aluminum.

The processing equipment used to effect MA by high-energy ball milling of powders originated in mining and conventional powder metallurgy industries.
Figure 2

The range of high-energy ball milling equipment divides, approximately, into two categories: small, high-energy laboratory devices, and larger facilities capable of milling commercial quantities of powder. The former category includes SPEX shaker mills and planetary ball mills. Both devices are capable of rapidly effecting MA, but in quantities of powders up to no more than a few tens of grams. SPEX mills vibrate at up to 1200 rpm in three orthogonal directions to achieve ball velocities approaching $\sim 5\,\text{ms}^{-1}$. Planetary mills incorporate a rotating base plate upon which are mounted counter-rotating, smaller-radius vials containing the ball/powder charge. The kinetic energy imparted to the ball charge in the planetary mill depends on the base plate and vial radii and angular velocities. Attritor or Szigvari ball mills, depending on their size, can be used either for laboratory or commercial ball milling applications and incorporate a rotating vertical shaft with attached horizontal impellors which stirs a container housing the ball and powder charge. These devices can process batches of up to several kilograms or more of powder through

the significant differential movement the impellors generate between the ball and powder charge. Balls can either cascade or tumble when leaving the mill wall during attritor processing, depending on the ball charge and impellor velocity.

The largest commercial devices applied to MA are horizontal ball mills. When these devices exceed several meters in diameter they impart sufficient kinetic energy through ball impacts to effect MA and can process over 1000 kg of powder per batch in larger units. Balls either cascade or tumble during processing in these mills depending on rotational speed (see Fig. 3). The time taken to achieve MA scales approximately inversely to the size of the milling equipment used. Hence, milling which might take minutes to accomplish in a SPEX mill could take hours in an attritor or days in a horizontal ball mill. All of these processing routes, however, have very low energy conversion efficiency, in that only a small fraction of the milling energy expended effects microstructural change contributing to the MA process.
Figure 3
Configuration of a horizontal ball mill, showing the release of the powder and ball charge (at angular position φ) from the inner wall of the mill rotating with angular velocity ω (after Lu *et al*. 1995).

It is worth noting that during MA, powder particles also coat (condition) the ball milling medium, which means that, to avoid cross-contamination of commercial alloys, the repeat use of ball charges is restricted to compositionally similar batches of raw materials.

2. Modeling

The approaches taken to modeling the mechanical and dynamical aspects of MA fall into two broad categories: local and global modeling (Courtney 1994, Soni 2000). Local modeling considers the likely fundamental nature of single-collision events, the energy transfer to trapped powder particles, and the way particle welding and fracture events may lead to temporal evolution of key powder parameters such as hardness, particle shape, and size distribution. In order to effect the computations necessary to follow iteratively the evolution of powder particle changes during MA, local modeling requires input of mill-specific parameters such as ball velocity and collision frequencies determined from global modeling approaches. Analytical approaches to local modeling have been based on assumptions of Hertzian collisions between balls leading to transfer of energy to trapped powder particles that deform in a manner that can be estimated from constitutive equations for plastic deformation. These models predict strain rates in the deforming powders of $\sim 10^3$–$10^4\,\text{s}^{-1}$ with accumulated strain per collision ranging from a few tenths of 1% (attritor mill) to 1% (SPEX mill).

Calculations of temperature change in MA powders during milling, assuming either adiabatic heating or temperature rise owing to Hertzian pressure, predict modest rises (several hundred kelvin in a SPEX mill) in line with observation. These local models of MA have been extended to consider particle cold welding and particle fracture. The latter events are modeled by assuming a mechanism similar to that of a forging fracture, where this can be taken to originate at the collision impact point and spread radially across the flattened powder under the appropriate conditions of crack initiation and propagation (*J*-integral approach). Using mill parameters estimated from global modeling, local analytical models have been incorporated in computational programs and run to predict the time-based evolution of powder size, hardness, and microstructural refinement occurring during MA.

Comparisons with experimental data obtained from elemental chromium and iron powders processed in a SPEX mill, reveal that the model is capable of predicting the correct shape of curve for the evolution of the average particle size with milling time but underestimates the time to achieve peak average particle size and overestimates its value. Other predictions are for lower hardness and less microstructural refinement than are observed experimentally. Similar predictions for aluminum milled in a SPEX unit again underestimate particle hardness but achieve closer agreement with evolving particle sizes. It is generally accepted that uncertainties in the values of key parameters used both in these and in more phenomenological, local models of MA mean they must be considered qualitative in nature. However, they enable reasonable predictions of trends when either powders or processes are changed systematically.

The requirement for global modeling of MA reflects the inherent complexity of the high-energy ball milling process, added to which are device-specific characteristics such as positional milling and powder inhomogeneities. For predictive purposes global models of MA seek to define ball impact frequencies, angles, and velocities together with estimates of the effective fraction (that leading to energy transfer likely to be of significance in terms of MA) of milling impact events. Much of this work has been underpinned by experimental validation of patterns of local milling behavior and specific effects of mill design using techniques such as high-speed photography. These models have revealed, for example, that <1% of ball impacts in a SPEX mill involve the near head-on collisions most effective for ball–powder energy transfer; and that increasing the ball charge increases the impact frequency, while simultaneously decreasing both ball collision velocity

(lower mean free path) and the final hardness of milled powders. Similar results have been obtained for analysis of planetary ball mill action, although here it has been established that two different milling regimes (energies) exist, depending on the dimensions and respective angular velocities of support plate and vial. These are ball rolling on the vial inner surface, and ball escape and impact on the vial opposite wall. By independently varying plate and vial angular velocity and thus ball energy, Gaffet (1991) demonstrated that it was possible to transform a powder charge with an average composition of $Ni_{10}Zr_7$ to end states ranging between fully crystalline and fully amorphous, thus underlining the link between process and outcome, or MA and microstructure.

One disadvantage of local/global modeling of the dynamics and mechanics of MA is that these models are not linked to fundamental transformation mechanisms, particularly important for understanding the formation of metastable phases during MA. However, atomistic models of metastable phase formation based, for example, on molecular dynamics are unconnected to the deformation parameters of MA (Khina and Froes 1996). Both phenomenological thermodynamic (e.g., based on heat of mixing) and kinetic (based on multiple layer diffusion couples) models have been used to interpret this metastable phase formation, but further developments of these models are needed to link plastic strain and defect levels directly to the kinetics as well as nucleation and growth mechanisms of metastable phases formed during MA.

3. Applications

Despite the fact that MA ODS alloys have been used successfully since high-strength, corrosion-resistant, nickel-based INCO alloy MA 754 bar was used by GEC in the nozzle guide vane assembly of the F404-400 military fighter aircraft engine in 1977, the high cost of these alloys has determined that they remain niche materials. Essentially, the only MA materials that have successfully penetrated commercial markets so far are ODS alloys, principally the nickel- and iron-based variants. Total worldwide production of these materials remains at a level of around several hundred tons per year. Several aluminum-based ODS alloys were developed by INCO from the late 1970s through the 1980s culminating in the commissioning of a production facility in 1988 that was closed in 1992 when INCO withdrew MA ODS aluminum alloys from the market. Potential aerospace end users of INCO high-strength, as-forged, lightweight, stress corrosion-resistant Al–Mg–Li ODS alloy, designated Al-905XL, had to wait seven years for a viable replacement to emerge (designated alloy 5091), produced by Aerospace Metal Composites Ltd.

Nickel-based ODS alloys range from the solid solution-strengthened ODS Ni–20 wt.% Cr alloy MA 754 to alloy MA 758, which is essentially similar but contains 30 wt.% chromium (for corrosion resistance in components used for manufacturing fiberglass from the melt), to the γ' and solid solution (tungsten, molybdenum) strengthened, creep, oxidation, and sulfidation (chromium, aluminum, titanium, tantalum, and tungsten) resistant ODS alloys MA 6000 and MA 760. These higher strength nickel-based ODS alloy variants have found applications as small, highly stressed first- and second-stage turbine blades (MA 6000) and for industrial gas turbine vanes and blades (MA 760). These latter alloys are supplied for service in a very coarse-grained, high grain aspect ratio condition generated by dynamic zone annealing that imparts excellent high-temperature creep resistance. The nickel-based ODS alloys are more difficult to form than their iron-based ODS alloy counterparts and are available in a more limited range of mill forms (e.g., bar, wire-rod, plate, sheet, and precision forgings).

Iron-based ODS alloys (MA 956, PM 2000, and the higher chromium, aluminum variant MA 956HT) which are, essentially, dispersion-strengthened, highly oxidation-resistant variants of FeCrAl alloys, have found a greater variety of specialist applications in a broader range of market sectors than their nickel-based ODS alloy counterparts. As with nickel-based ODS alloys, MA 956 and PM 2000 achieve maximum creep and oxidation resistance when used in service in the high aspect ratio, coarse-grained secondary recrystallized, preoxidized release condition, achieved for iron-based ODS alloys without resort to zone annealing. In contrast, the iron-based MA ODS alloy MA 957, which was developed for use as a low void swelling nuclear fuel cladding tube in fast breeder reactors and is intended for service in liquid sodium at $\sim 700\,^{\circ}C$, is supplied with a specified $\sim 30\,\mu m$ grain size. The excellent fabricability of iron-based ODS alloys ensures they are amenable to a wide range of metal processing techniques.

Other niche applications, for MA aluminum alloys, include race pistons for motorbikes forged from Al–12 wt.% Si, DISPAL-1, produced by reaction-milling techniques, and thin-walled tube for road racing bicycle frames extruded from hot isostatically pressed (HIP) billets of 2124-T4-17.8 wt.% SiC_p alloy, manufactured by MA. For both these alloys as well as for the low-density 5091 aerospace alloy, service applications are at ambient, hence the material is supplied in a very fine-grained condition (e.g., $< 1\,\mu m$ grain size for 5091 alloy).

Elsewhere, essentially small amounts of special composition MA materials have been tested in niche applications, such as the aluminum alloy DISPAL-2 used in electrodes for NaS batteries or for low-distortion aerospace interferometer parts, and the magnesium-based "supercorroding" alloy exhibiting

controlled corrosion rates for application as bolting to release deep-sea equipment or as controlled heating/hydrogen sources. In the area of nonstructural applications, a number of specialist coatings have been produced using MA powders. These include Ti–Al powders for RF plasma spraying, Ti–Al–SiC powders for wear-resistant coatings, and sieved, as-MA powders of the standard commercial ODS alloys such as MA 754 and PM 2000 for plasma spraying. A promising emerging MA ODS alloy is the intermetallic composition, yttria-strengthened alloy Fe_3Al, intended for application in components for use in fossil fuel power plants operating above 1100 °C, where the high aluminum content in the alloy is intended to confer enhanced oxidation resistance in aggressive environments.

Future commercial opportunities for MA alloys include the possible use of amorphous Al–Cu–Mg alloys as aerospace structural materials, intermetallics such as Ti_3Al, TiAl, and Cr_3Si for either airframe or high-temperature engine applications, and MA magnesium-containing combinations of Fe/Ni/Co/Ti as potential hydrogen storage materials (Lu and Lai 1998, Soni 2000).

Mechanical Testing Methods of Fibers and Composites

Commonly employed techniques to determine the mechanical properties of fibers and fiber-reinforced metal- and polymer-matrix composites (MMCs and PMCs, respectively) are briefly described in this article, some of which are also applicable to ceramic-matrix composites (CMCs). Wide coverage of these test methods is given in ASTM standards (ASTM Standards 1998) and in sections of this encyclopedia on composite materials (see *Composite Materials: Overview*[#]).

1. Fibers

The properties of interest at low temperatures are the elastic modulus and the fracture strength whereas for high temperature applications and long-term property modeling, creep properties such as the creep–rupture strength, time- and strain-to-failure are necessary. Most fiber properties are probabilistic in nature, hence, many fibers have to be tested and the data generated should be statistically analyzed. It is recommended that the fiber properties be measured on a material that represents composite behavior. For example, fibers extracted from as-processed or fatigued composite specimens should be tested to obtain properties after processing or fatigue testing, respectively.

The standard method for determining room temperature properties is the single-filament tensile test (ASTM D3379). In this method, a random selection of fibers is made from the material to be tested. The fibers are centerline-mounted on special slotted tabs (Fig. 1). The tabs are clamped so that the test specimen is aligned axially in the grips of a test machine and then loaded to failure at a constant displacement rate. It is important to measure the cross-sectional area carefully. The axial strain is measured using a noncontact- type extensometer.
Figure 1
Fiber testing method.

For carbon and graphite yarns, strands, rovings, and tows, the resin impregnated tow tensile test (ASTM D4018) is recommended. The purpose of the impregnating resin is to provide the tow with sufficient mechanical strength to produce a rigid test specimen capable of sustaining uniform loading of the individual filaments. Care should be taken to align the fibers prior to impregnation. A resin compatible with the fibers and in minimum required quantity to produce the tensile specimen should be used. The failure strain of the resin should be significantly higher than that of the fibers. End tabs (cast or mounted) may be necessary in some instances for alignment purposes and to prevent slippage at high loads.

Creep testing of fibers is carried out using dead load tests at constant temperatures (either in air or in a suitable environment). A length of fiber is gripped vertically in cold grips and a resistance furnace is used to maintain constant temperature over a specified gauge length (typically 25 mm) of the fiber. Elongation and fracture strain are measured using any of the noncontacting displacement devices. Bend stress relaxation is used for measuring the creep behavior, particularly for small diameter fibers. This method consists of tying the fiber into a loop and exposing it to the appropriate temperature for a specific time. Afterwards, the diameter of the loop is measured before breaking it. The residual loop radius is used to estimate the creep behavior.

2. Composites

2.1 Tension

Straight-sided dog-bone type loaded specimens with rectangular cross-section are commonly used for measuring the in-plane tensile properties of unidirectional, as well as cross-ply, composite laminates (ASTM D3039 for PMCs and D3552 for MMCs). Specimens can be end-tabbed if necessary to distribute the load from the grips (either wedge or hydraulic) into the specimen with a minimum stress concentration. Test specimens with round or tubular cross-sections can also be used. An important factor for obtaining highly accurate test results is minimization of the specimen misalignment with the load train and the resultant bending stresses. Likewise, good alignment between the desired fiber orientation and the specimen axis is a must.

The following alternative methods are also available.

(i) The sandwich beam test (ASTM C393) for evaluating the flexural properties of flat sandwich constructions in which the test laminate is bonded to either side of a suitable honeycomb core and the sandwich is subsequently tested in a four-point flexure configuration. To minimize thermal expansion mismatch problems, the thickness of the laminate on the compression side should generally be twice that of the tensile side. This test is also useful for tensile testing, particularly for the 90° properties of unidirectional composites.

(ii) Split-disc ring tensile test for apparent tensile strength of ring or tubular composites (ASTM D2290) in which a hoop-wound narrow ring is loaded using a split-disc loading fixture that applies a hoop stress to the test ring.

The out-of-plane tensile properties of composites can be evaluated by direct out-of-plane loading using a laminated specimen bonded between two fixture blocks (square or circular cross-sections) that are pulled in tension. Alternatively, curved composite beams, which take advantage of the out-of-plane tensile loading induced in the elbow of a curved laminate beam subjected to an opening moment, can be used for indirect measurements.

2.2 Compression

Compressive testing of composites is relatively more difficult than tensile testing. The mode of failure involves some type of buckling, ranging from classical column buckling of the entire specimen to local micro buckling of the individual fibers. The test fixture should be appropriate to avoid buckling. Many axial compression test methods in current use are some variation of the Celanese compression test (ASTM D3410). In this method, a thin, straight-sided specimen with a small gauge length (~ 13 mm) is loaded in the tabbed region using inverted cone wedge grips. The IITRI method (ASTM D3410), which is a minor modification, incorporates flat wedge surfaces rather than conical surfaces for greater stability. An untabbed, thick, straight-sided composite specimen can also be used, end-loaded in compression and side-supported to control lateral buckling (ASTM D695). The end-loading might induce deformation and minor crushing at the ends, however these are not of much concern if strain gauge or extensometers are used to monitor strains rather than cross-head displacement. This method has the advantage of requiring a simpler test specimen and test fixture than the Celanese configuration. The compression specimen geometry and method of load introduction should be relevant to the actual application for which the data is being generated.

2.3 Shear

The in-plane shear response of the composites can be obtained by tensile testing of a $\pm 45°$ laminate (ASTM D3518). This test is simple and requires little fixturing. The Iosipescu shear test (ASTM D5379) utilizes a V-notched beam wherein a material coupon in the form of a rectangular flat strip with symmetrical centrally located V-notches is loaded using a special test fixture with the notches located along the line of action of loading (Fig. 2). Two strain gauges,
Figure 2
The Iosipescu shear test.

oriented at $\pm 45°$ to the loading axis and located in the middle of the specimens and along the loading axis, are used for measuring the shear response. By changing the material coordinate system with respect to the loading axis, both in-plane and out-of-plane shear properties can be evaluated using this technique. Additional methods such as the rail shear test (ASTM D4255-83), the ten-degree off-axis shear test, and the tube-torsion test (ASTM D5448) are also available. The out-of-plane shear properties can be evaluated by using the short-beam strength test (ASTM D2344) or the Iosipescu test.

2.4 Fracture Toughness

The double cantilever beam (DCB) test (ASTM D5528) is the most widely used test method for measuring Mode I fracture toughness of unidirectional composites. The specimens are ~ 125 mm long, 20–25 mm wide, and 3–5 mm thick. One side of the specimen is notched (~ 25 mm deep) and the cracked faces pulled apart with the aid of either piano hinges or loading blocks attached to the specimen on the cracked end. Load–displacement data are recorded and used for computation of the energy release rates. For Mode II toughness, the end notched flexure test, which uses a specimen similar to that of the DCB test but loaded in three-point bending configuration, can be used.

2.5 Fatigue

Fatigue in composites is application dependent, hence the laminates should represent the application and testing should account for the loading spectra and environment experienced during service. Unnotched fatigue tests on specimens similar to those used for tension tests can be conducted, either under load or strain control and either triangular or sinusoidal waveforms (ASTM standard D3479 for PMC

and E466 for MMC). High loading frequency (>10 Hz) may lead to frictional heating at the fiber/matrix interface due to relative sliding. Fatigue crack growth tests are conducted using either center-notched or single edge-notched specimens, preferably with fixed far-field stress amplitude. Compact-tension (CT) geometry can also be used if the composite laminates have sufficient thickness. The data are typically presented as crack extension versus the number of fatigue cycles. By use of suitable fiber bridging models, the data can also be converted into crack growth rates against the effective stress intensity factor range.

3. Interfacial Properties

Fiber/matrix interface properties such as the debonding strength and sliding resistance play a predominant role in determining the properties of the composites. Fiber push-out testing is a commonly employed technique for measuring these properties. In this test, an indenter (punch) is used to apply axial compressive loading to a selected fiber in order to debond the fiber and force it to slide relative to the matrix. The specimen, a thin slice of the composite (typically 0.6–1.3 mm thick) with the fibers oriented axially within $\pm 1°$, is mounted on a support plate that has grooves to facilitate the fiber once it has been pushed out from the opposite face of the sample. A detector can be used to monitor acoustic emissions associated with the debonding events. Composites that have high interfacial strengths are not amenable to this technique. For composites that exhibit single or multiple matrix cracking, alternative techniques include single fiber pull-out and hysteresis measurements.

Membrane-based Polymer–Ceramic Nanocomposites

Membrane-based polymer–ceramic nanocomposites are a category of organic–inorganic hybrid materials. As their name indicates, these materials have a polymer membrane as the organic phase and a ceramic as the inorganic phase. To be clearer, the polymer membrane serves as a matrix, and ceramic materials are introduced into it as described below.

Significant progress has been made in research on membrane-based polymer–ceramic nanocomposites. Preparation methods have been developed for the fabrication of nanocomposites (Shao *et al.* 1995, Wen and Mark 1995a, 1995b, Apichatachutapan *et al.* 1996, Gummaraju *et al.* 1996, Deng *et al.* 1998a, 1998b). Also, the properties of nanocomposites have been investigated by different characterization techniques (Wen and Mark 1995a, 1995b, Deng *et al.* 1998a, 1998b, Young and Mauritz 1998, Start and Mauritz 1998, Siuzdak and Mauritz 1999). Applications for nanocomposites in a variety of areas have been explored as well. Presented here are the synthetic approaches, properties, and possible applications of membrane-based polymerceramic nanocomposites. The outlook for future research is also discussed.

1. Synthetic Methods

Great synthetic challenges arise in preparing organic–inorganic hybrid nanocomposites. Owing to the strong tendency of nanoparticles to agglomerate, organic–inorganic hybrid nanocomposites are not usually obtained by mechanical methods, and chemical routes have been developed instead. Techniques used to introduce, assemble, or organize the individual nanoparticle entities into polymers have included dispersion into polymers, direct synthesis in micellar polymers, and absorption into polymer layers (Hadjipanayis and Siegel 1993, Kunz *et al.* 1993, Roecher and Moller 1995, Spatz *et al.* 1996, Lerner and Oriakhi 1997). These techniques typically involve solution phase processes, with strategies of either (i) the nucleation or formation of an inorganic structure in a solution containing or embedded in the desired polymer or (ii) monomer insertion and subsequent *in situ* polymerization within an inorganic host framework. For membrane-based polymer–ceramic nanocomposites the first strategy, specifically, an *in situ* sol–gel approach (Fig. 1), is currently the most widely utilized.

To implement this sol–gel approach the following steps are required:

the polymer film is preprocessed to remove low molecular weight fractions or other unwanted materials;

the polymer film is swollen in a solvent (alcohol, toluene, mixed solvents, etc.) to make it able to or easier to accommodate precursors;

the polymer film is placed into a precursor solution to let the precursor penetrate, and the sol–gel reaction is initiated and implemented;

the nanocomposite film is postprocessed (dried, placed under vacuum, etc.).

1.1 Materials for the Ceramic Phase

Many ceramic materials are good candidates for membrane-based polymer–ceramic nanocomposites. Owing to the difficulties encountered in some synthetic
Figure 1
The currently employed synthetic approach for the preparation of membrane-based polymer–ceramic nanocomposites.

Table 1
Some membrane-based polymer–ceramic nanocomposite systems

Polymer membrane	Ceramic phase	Synthetic method	References
Poly(ethylene-co-methacrylic acid) (Surlyn)	Silicon oxide	Sol–gelreaction	Start and Mauritz (1998)
Perfluorosulfonate (Nafion)	Titanium oxide/silicon oxide, Aluminum oxide/silicon oxide, Organically modified silicate (ORMOSIL)	Sol–gelreaction	Shao *et al.* (1995), Young and Mauritz (1998) Deng *et al.* (1998a)
Poly(styrene-*b*-isobutylene-*b*-styrene)	Silicon oxide	Sol–gel reaction	Mountz *et al.* (1998)
Silicone	Silica, alumina, titania, zirconia, and mixed oxides	Sol–gel reaction	Wen and Mark (1995)

approaches, currently the most widely researched materials are oxides, organically modified oxides, and mixtures of oxides. Examples are silicon oxide, aluminum oxide, titanium oxide, and zirconium oxide. Consequently, the materials used in precursor are generally an alkoxide or a mixture of alkoxides.

1.2 Materials for the Polymer Phase

The polymer phase serves as a matrix to host the ceramic particles. In the sol–gel synthetic method the polymer membrane needs to be swollen by certain solvents, so it must be able to tolerate the solvents and precursor solutions. It will be ideal if the polymer is cross-linked. Also, it is desirable that the polymer phase has good compatibility with the ceramic phase to facilitate good ceramic uptake. Examples of polymer membranes are silicones, Nafion,

biopolymers, and many others, some of which are listed in Table 1.

2. Characterization Methods

Many traditional characterization methods can be used to investigate the general properties of membrane-based polymer–ceramic nanocomposites, and some special analytical techniques are available for specific properties. These include the stress–strain test and dynamic mechanical analysis for mechanical properties, thermogravimetric analysis, differential scanning calorimetry for thermal properties, infrared spectroscopy, and nuclear magnetic resonance for chemical structure and bonding, transmission electron microscopy for the imaging of inorganic particles, and environmental scanning electron microscopy for the exploring of element concentration profiles across the film cross-section.

3. General Properties

3.1 Percentage Uptake of Ceramics in a Composite

The percentage uptake of ceramics in a membrane-based nanocomposite depends on many factors: the thickness of the polymer membrane, the time allowed for swelling in the solvent, the length of time when soaking in the precursor solution, the compatibility between the polymer film and the precursor and ceramic materials, and so on. Research shows that most of the uptake of ceramic materials in nanocomposites occurs during a short initial period of time, longer times only increasing the uptake slightly.

3.2 Distribution Profiles of Ceramics across the Polymer Membrane Cross-section

The sol–gel process of generating ceramic nanoparticles within a polymer membrane requires the precursor solution to penetrate into the membrane. Due to the thickness of the membrane and the possible molecular incompatibility between the membrane and the precursor solution, even when a sufficiently long period of time has been allowed for the swelling process, the ceramic nanoparticles will not be evenly distributed across the cross-section of the polymer membrane. Research shows that the concentration of ceramic materials is the highest at and near the surface and drops sharply over the thickness. Figure 2 illustrates such a typical profile.

3.3 Mechanical Properties

The loading of ceramic materials into polymer films has a marked impact on the mechanical properties of the resultant membrane-based polymer–ceramic nanocomposites, in comparison with the properties of conventional composites (Mark *et al.* 1995). Generally
Figure 2
Typical distribution profile of ceramics across the polymer membrane cross-section.

speaking, compared with its corresponding original polymer membrane, the polymer–ceramic composite has improved mechanical strength, but lower elongation to break. Yet nanocomposites have their own advantages. Owing to their nanometer-scale size, the ceramic particles in these materials have larger surface areas, and therefore better binding or adhering interactions with a polymeric matrix than those in composites prepared from blending or from micrometer-sized particles. These interactions help reduce the mobility of the polymer chains and improve toughness and other mechanical properties.

3.4 Thermal Properties

The thermal properties of membrane-based polymer–ceramic nanocomposites benefit from the *in situ* sol–gel synthetic process. On one hand, nanocomposites have good thermal stability because the ceramic phase can be generated at low or even room temperature rather than at the elevated temperatures required in the production of conventional ceramic materials (Brinker and Scherer 1990, Hench and West 1990). On the other hand, nanocomposites have higher glass transition temperatures (T_g) than the corresponding polymeric membranes.

3.5 Other Functional Properties

The polymer phase in membrane-based polymer–ceramic nanocomposites generally does not possess the desired functional properties (electrical, dielectric, electronic, magnetic, optical, etc.). However, the introduction of a ceramic phase enhances the functional properties of nanocomposites.

4. Possible Applications

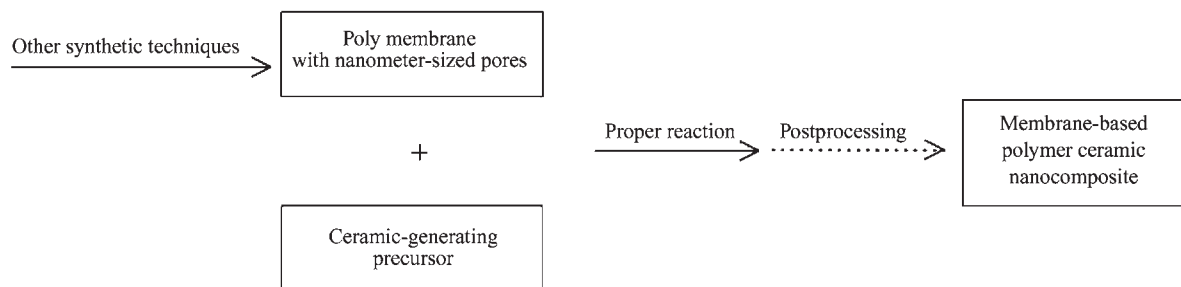
Even though membrane-based polymer–ceramic nanocomposites are still at an early stage of development, they may have great potential in many different applications because they possess properties of both the polymer membrane and the nanometer-sized ceramics. Some interesting areas are catalysis, gas separation, and filtration. Consider gas separation, for example. Traditionally gas separation and filtration take advantage of the permeability of membranes and the pore size of particles. By introducing ceramic nanoparticles into a polymer membrane, special functionality may be added to the resulting nanocomposite. For example, if the ceramic phase is a magnetic material such as γ-Fe_2O_3 or an oxide of another iron group metal, such as cobalt and nickel, a magnetic nanocomposite could be prepared. Such a nanocomposite may strongly bind gas molecules and can be used in gas separation or filtration for, as example, environmental protection.


Figure 3
Proposed alternative synthetic strategy for the preparation of membrane-based polymer–ceramic nanocomposites.

Functional materials constitute an unlimited and ever-expanding list. They include nanocomposites with good flame-retardant performance, even though the polymer is flammable (Dagani 1999), nanocomposites with high biodegradability, nanocomposites for lithography (nanolithography) (Whitesides 1997), and nanocomposites for electronics (nanoelectronics) (Murray *et al.* 1993).

5. Future Directions

Significant advances have been made in research on membrane-based polymer–ceramic nanocomposites, but there are technical difficulties remaining to be overcome and many new fields to be explored. Some brief discussions are presented for the reader's interest.

Of the remaining technical difficulties, one is the uneven distribution of nanoparticles across the polymer membrane cross-section—the distribution profile discussed above. The profile may have negative effects on the physical properties of composites. It is likely that an uneven distribution causes internal strain, which, in turn, results in inferior mechanical properties. It will be interesting and beneficial to disperse the ceramic particles evenly in the bulk of nanocomposites. This could be achieved by the use of very thin membranes, increasing the compatibility between the ceramic precursor and the polymer membrane, or taking a non-sol–gel synthetic approach.

Another technical difficulty is the limited number of ceramic materials available for the preparation of membrane-based polymer–ceramic nanocomposites through the *in situ* sol–gel reaction. Oxides of aluminum, silicon, titanium, and zirconium have been the most widely researched ceramic materials because the alkoxides of these elements are readily available. These ceramic materials may provide enormous opportunities in nanocomposites, but they may not be able to play a satisfactory role when demands on magnetic, electronic, dielectric, optic, or other functionalities arise. New synthetic techniques need to be developed to make membrane-based polymer–ceramic nanocomposites more attractive.

Regarding new fields to be explored, one is the development of new methods of preparing membrane-based polymer–ceramic nanocomposites. Figure 3 presents such a strategy. Unlike conventional methods, this strategy, although not yet researched, first creates polymer membranes with nanometer-sized pores, then introduces a ceramic precursor into the pores. It uses these pores as reaction vessels and forces ceramic materials to be generated inside the pores. In this way, it can be guaranteed that the ceramic particles will be nanometer sized. The best part of this strategy is that it can take advantage of many reaction methods, not solely the *in situ* sol–gel reaction. This strategy appears more promising with the advances in research on making polymer membranes with nanometer-sized pores (Martin 1996, Nguyen *et al.* 1999).

Another potential field may be membrane-based polymer–ceramic nanocomposites with a biopolymer as the organic phase. Biopolymers typically have low mechanical strength, and their reinforcement by the traditional powder technique is not suitable in many situations. It is anticipated that biopolymer–ceramic nanocomposites will be very promising in a variety of medical applications.

Of course, there are many other challenges remaining for membrane-based polymer–ceramic nanocomposites. In addition to developing better and more efficient synthetic methods and exploring new fields, searching for powerful characterization techniques and the ability to tailor the nanocomposites to application requirements will certainly be required.

Mesoporous Molecular Sieves

In 1992 Mobil scientists discovered that ionic surfactants could be used as templates for the synthesis of a family of mesoporous siliceous materials which are now commonly referred to as M41S (Kresge *et al.* 1992). These have pore sizes in the range 25–100 Å, and a narrow pore size distribution. The ordered structure precipitates out of the synthesis mixture into a composite silica/organic structured phase, which is then calcined to remove the organic material. The resulting M41S materials contain regular arrays of uniform channels, the dimensions of which can be tailored through the choice of surfactants, auxiliary chemicals, and reaction conditions. The syntheses of mesoporous materials are generally thought to be controlled via a supramolecular templating mechanism and for their formation the so-called liquid crystal templating (LCT) mechanism is postulated, which proceeds via co-precipitation of the organic template with the silica species (see Fig. 1).

A number of excellent reviews have already been written about LCT of mesoporous materials and related areas of research (Corma 1997).

Mesoporous materials have potential catalytic/separation technology applications in the fine chemicals and pharmaceutical industries. Because of their larger pore size, these materials are not restricted to the catalysis of reactions involving small molecules, which is the case for zeolites.

The most studied of the mesoporous materials is MCM-41, which possesses a hexagonal array of uniform mesopores. The calcined mesoporous products have surface areas often greater than $1000 \, \mathrm{m^2 \, g^{-1}}$, and exceptionally high sorption capacities.

Comprehensive accounts describing the synthesis and characterization of MCM-41 using various chain length alkyl trimethyl ammonium surfactants as templates are readily available in the literature. Characterization has been carried out by a variety of X-ray and neutron scattering experiments, high resolution and cryogenic transmission electron microscopy (TEM), electron diffraction, scanning electron microscopy (SEM), atomic force microscopy (AFM), sorption measurements, and solid-state NMR.

Studies on monitoring the effects of altering surfactant-silica ratios in M41S synthesis gels have led to the isolation of other structures with cubic and lamellar geometries. The lamellar product, MCM-50, was found to be unstable to calcination. The cubic M41S material was named MCM-48 and had Ia3d symmetry (by X-ray diffraction and TEM).

Ko *et al.* (1996) describe an interesting means of confirming the connectivity of the pores within mesoporous materials, by incorporating platinum wires into the mesopores as contrast agents.
Figure 1
Possible mechanistic pathways for the formation of MCM-41: (1) liquid crystal phase initiated and (2) silicate anion initiated.

One main characteristic of all M41S materials is that they are thermodynamically metastable. The metastability of the MCM-41 silica walls is highlighted by work conducted by Kloetstra *et al.* (1997) who, on recrystallizing MCM-41 and MCM-48, produced mesoporous materials containing small amounts of framework ZSM-5, or other higher stability silicate species.

M41S materials have been synthesized in both basic and acidic media, and all the variables (such as pH, gel composition, and temperature) in the process have been thoroughly investigated by various research groups. Complete phase diagrams for the M41S synthesis gels are now available in the literature.

Control of the rate of silicate polymerization by using different pH conditions and controlling the aluminosilicate reactivity in the synthesis gels produces materials with thicker pore walls and improved thermal and hydrothermal stabilities. The effect of gel aging time, temperature, stirring, source of silica, and alkyltrimethylammonium template (CTAB or CTACl), and overall concentration of the reactants on the quality of the MCM-41 product was studied by Cheng *et al.* (1997). It was found that highly basic gels, or gels containing low silicate concentrations, favored lamellar products.

Further work was carried out by Sayari *et al.* (1997) where hydrothermal restructuring of MCM-41 was used to produce large pore MCM-41 products. It was shown that the pore size enlargement was accompanied by a significant improvement of pore size uniformity, a gradual decrease of the specific surface area, and the pore wall thickening. It was suggested that the post synthetic hydrothermal restructuring is a convenient synthesis route for MCM-41 silicates with a bimodal pore size distribution with controllable amounts of microporosity.

Figure 2
Synthesis pathways using different combinations of surfactant and soluble inorganic species. S is the surfactant, X is a halide ion, M is a metal ion, and I is the inorganic ionic precursor (Huo *et al.* 1994).

Small particles of MCM-41 are obtained if reaction times are kept short. Cutting the reaction times short can, however, jeopardize the silica condensation process leading to poorly polymerized products.

material
Figure 3
Scheme showing the mechanism of formation of hexagonal mesoporous FSM-16 from kanemite.

Microwave heating overcomes this problem by speeding up the condensation step.

Large headgroup cationic surfactants such as $C_{16}H_{33}N(C_2H_5)_3Br$ with acid or base synthesis conditions lead to three-dimensionally structured silica products containing cage-like voids, with dimensions somewhat larger than the channel diameters measured for the M41S materials. SBA-1 is a cubic cage mesostructure with Pm$\bar{3}$n space group symmetry, and SBA-2 is a three-dimensional hexagonal cage structure with P6$_3$/mmc symmetry (Huo *et al.* 1994).

1. Neutral Templating Routes

A dilute regime method for the synthesis of mesoporous solids was reported where the template was a nonionic surfactant (a primary amine or polyethylene oxide) and the silica precursors were alkoxides such as tetraethoxysilane (TEOS) (Tanev and Pinnavaia 1995, Bagshaw *et al.* 1995). The mesoporous products resemble M41S materials, but have slightly less long-range order and have thicker silicate walls, smaller crystallite size, and improved textural mesoporosity (improved access to framework pores). The neutral synthesis system has the added advantage that the surfactant could be removed by neutral solvent extraction, avoiding the calcination step.

A neutral alkoxide/polyoxyethylene templating route can also be used to produce mesoporous products with the pores arranged in random worm-like motifs, with no distinguishable hexagonal or cubic long range ordering. The products, named MSU-X, are formed by firstly obtaining a homogeneous alkoxide/surfactant solution by aging at room temperature, and secondly initiating the mesophase assembly by adding fluoride ions. Fluoride ions had previously been shown to catalyze alkoxide hydrolysis and mesostructure cross-linking.

Similar types of material called TUD-1 can be made using triethanolamine as a template. This route offers great versatility and is easily up-scalable (Maschmeyer *et al.* 2000).

2. Gemini Surfactants as Templates

Dual chain dialkyldimethylammonium salts (gemini surfactants) can also be used as the templating agents. For gemini surfactants with the generalized molecular formula $C_{16}H_{33}(CH_3)_2[(CH_2)_nCH_3]N^+$, where $n = 1$–12, a range of structures can be produced. For odd n (1, 3, 5, 7), hexagonal MCM-41 was produced. For even n (2, 4, 6, 8) and any n greater than 7, the product was a lamellar phase.

Huo *et al.* used somewhat different gemini surfactants as templates for a whole range of mesoporous structures: MCM-41 (2D hexagonal, p6mm); MCM-48 (cubic, Ia3d); MCM-50 (lamellar); SBA-1 (cubic, Pm3n), SBA-2 (3D hexagonal, P6$_3$/mmc) and SBA-3 (2D hexagonal, p6mm). A new mesoporous supercage structure, SBA-2, which was analogous to a zeolite cage structure was also synthesized.

Virtually at the same time as M41S mesoporous silicas were first being synthesized, Inagaki *et al.* (1993) reported the synthesis of hexagonally packed channels from layered polysilicate kanemite. The mesoporous product was named FSM-16.

Kanemite consists of flexible, poorly polymerized silicate layers which buckle around the intercalated surfactant molecules. The kanemite-derived materials are more highly condensed, and exhibit thicker silicate walls than the M41S materials. Chen *et al.* (1995) suggest that the thermal and hydrothermal stability of FSM-16 is somewhat better than for MCM-41. Full characterizations of the kanemite-derived mesoporous silica product are described by Inagaki *et al.* (1996).

3. True Liquid Crystal Templating (TLCT) of Mesoporous Materials

Attard *et al.* successfully synthesized mesoporous silica from synthesis gels containing nonionic polyoxyethylene (POE) surfactants at concentrations required to form liquid crystal phases at room temperature (Attard *et al.* 1995). Hexagonal, cubic, and lamellar products were obtained, and the former two were stable to calcination.

BET nitrogen adsorption measurements showed that the hexagonal $C_{12}EO_8$-templated calcined product has a specific surface area greater than $1000 \, m^2 \, g^{-1}$, and a very narrow pore size distribution at $20 \, Å$ diameter. These values compared well with the large surface areas obtained for MCM-41, the LCT analogue.

Striking similarities were observed by polarizing microscopy between the birefringent patterns obtained for the hexagonal POE/water liquid crystal, the synthesis gel (after removal of the methanol hydrolysis product), the as-synthesized product and the calcined product. These observations strongly supported the TLCT theory, in which it is postulated that the surfactant forms a liquid crystal phase before the condensation of the silica, and remains in the same phase throughout the synthesis.

One main advantage of TLCT over the dilute regime M41S synthesis is that by using a preformed liquid crystal phase as the templating medium, the structure of the product is known *a priori* from the binary phase diagram of the surfactant/water system.

4. Macroscopic Morphology Control

The alkaline M41S synthesis procedure generally produces very fine particles of mesoporous material, which are suitable for catalysis applications but not for some specialized applications. Acidic conditions have become widely used for mesoporous silica synthesis because of the greater control which can be imposed on the macroscopic morphology of the product. The lack of ionic bonds at the silica/organic interfaces for acidic preparations allows more fluidity in the self-organizing system with respect to basic preparations. This effectively makes macroscopic morphology control possible in acidic systems.

For an acidic mesoporous M41S silica synthesis under aqueous conditions Yang *et al.* (1997) reported the formation of a remarkable array of macroscopic shapes, surface patterns and channel arrangements. The reaction conditions favored curved morphology (toroidal, disk-like, spiral, and spheroidal particles). Powder X-ray diffraction showed that the underlying mesostructure for all the morphologies was ordinary hexagonal MCM-41. The proposed initial step for the morphogenesis of these shapes was the formation of a silicate liquid-crystal embryo with hexagonal cross-section. This grew over time and depending on the various reaction conditions, was subject to different degrees of curvature (Yang *et al.* 1997). Many other examples exist where monolithic silica, films, and spheres are produced (Yang *et al.* 1996, Zhao *et al.* 1998).

5. Functionalization for Catalytic Applications

Much work has been directed towards the introduction of transition metals into mesoporous materials.

Transition metal oxides have variable oxidation states, and can therefore be used in tailoring catalytic, electronic and magnetic properties of materials, comprehensive reviews are available covering this subject (Corma 1997).

Siliceous solids can be functionalized for catalysis applications by framework substitutions, or activated by post-synthetic surface derivatizations. The four possible methods of derivatization are:

(i) Primary modifications: direct grafting of active sites onto the surface silanol groups of calcined or solvent extracted materials;

(ii) Second and higher order modifications: grafting onto previously functionalized surfaces;

(iii) One-pot synthesis of functionalized mesoporous silica; or

(iv) Transformation of materials prepared under conditions (i)–(iii) by further treatment such as heating, evacuation, calcination and/or reduction.

Transition metals incorporated into the MCM-41 framework, or grafted to the MCM-41 surface include titanium (Maschmeyer *et al.* 1995), platinum, vanadium, manganese, boron, aluminium, zinc, zirconium, binary lanthanum oxides (Na/La, K/La, Rb/La, Cs/La), cobalt (Maschmeyer *et al.* 1997), ruthenium, nickel–molybdenum clusters, and tin–molybdenum clusters.

A novel means of introducing metal ions into mesoporous structures is to use surfactant templates with organometallic complex head groups. Kevan and co-workers used a surfactant with Cu^{II} ions coordinated to a macrocyclic cage headgroup to template the formation of MCM-41. Also surfactant templates with ruthenium complex headgroups for the TLCT of mesoporous silica have been used.

Other approaches to functionalizing mesoporous silica include the incorporation of heteropolyacids such as $H_3PW_{12}O_{40}$, into the mesopores of MCM-41 materials. Burkett *et al.* (1996) discovered that the co-condensation of TEOS with organosilanes in the presence of a surfactant template led to the synthesis of organically functionalized mesoporous silicas.

For TLCT systems one-pot synthesis of functionalized silica is in theory quite straightforward. The key criterion which determines whether a particular synthesis gel will successfully produce a mesoporous structured catalyst is simply that the addition of the functional moiety does not disturb the liquid crystal template.

6. Further Applications

Advanced separation/purification, electronic, optical and electron transfer applications have been suggested for MCM-41-type materials, generally relying on the special characteristics of species encapsulated in the material mesopores. Potential applications

other than catalysis include:

    (i) stationary phases for chromatography,

    (ii) environmental remediation,

    (iii) minireactors for electron transfer reactions,

    (iv) mesoporous hosts for quantum confinement,

    (v) mesoporous supports for molecular wires (Wu and Bein 1994),

    (vi) shape-selective polymerization, and

    (vii) protein synthesis.

Metal Matrix Composites with Roughly Equiaxed Reinforcements: Microstructure and Mechanical Behavior

The early developmental work on metal matrix composites concentrated on continuous fiber reinforcement because this potentially gives the maximum improvement in elastic modulus and strength (see *Composites, Physical Properties of* *). However, this enhancement in mechanical properties was obtained at considerable cost, resulting from the high price of strong, continuous fibers, and the difficulty in fabricating such composites on a commercial scale. These limitations led to the development of discontinuously reinforced metal matrix composites containing roughly equiaxed reinforcing particles, and while these composites do not attain the very highest mechanical property enhancement of continuous fiber-reinforced metals, they still provide sufficient improvement to make them commercially attractive in some applications. Discontinuously reinforced composites can be made by a variety of methods, many of which are modifications of normal metal processing methods, resulting in much lower processing costs than for continuously reinforced composites (see *Metal Matrix Composites: Matrices and Processing**). In addition, the discontinuous reinforcement is readily available in the form of low-cost ceramic powders, such as the silicon carbide (SiC) and alumina (Al_2O_3) grits used in the grinding and polishing industry. Since the major applications take advantage of composites with low weight, high stiffness, and high strength, the major developments have involved low-density metals, particularly aluminum and magnesium, as the matrix of the composite.

1. The Reinforcement

Since the object of the reinforcement is to provide increased stiffness and strength to the unreinforced matrix, ceramic particles with their large elastic modulus and high strength are ideal as the reinforcing particles. In principle, many ceramic powders meet these requirements, but there are other restrictions that influence the choice of the reinforcement for a particular composite. Many of the ceramic particles of interest are thermodynamically unstable when they are in contact with pure metals, and will react to form reaction compounds at the interface between the particles and the surrounding matrix. Reaction compound layers at the matrix–reinforcement interface can degrade the interfacial strength of the composite, resulting in deterioration in the mechanical properties (Metcalfe 1974, Lloyd *et al.* 1990). The kinetics of the interfacial reaction will increase with increasing temperature, so the temperature history of the composite, either during processing or during service, has to be considered in choosing the appropriate matrix–reinforcement combination. When aluminum is the matrix, there are very few ceramics that are stable. SiC will react with molten aluminum to form aluminum carbide, Al_4C_3:

$$4Al + 3SiC \leftrightarrow Al_4C_3 + 3Si \qquad (1)$$
Aluminum carbide is very brittle, and very reactive in moist environments, so its formation degrades both the mechanical and corrosion properties of the composite. The reaction is accompanied by an increase in silicon level of the surrounding matrix, which can result in a change in the properties of the matrix alloy. Fortunately, SiC is stable in most aluminum alloys in the solid state, so reactivity is not a consideration when these composites are made without exposure to liquid aluminum. This is not the case with other reinforcements, and aluminum oxide, Al_2O_3, particles are an interesting example in this respect. Al_2O_3 is thermodynamically stable in pure aluminum, but commercial alloys often contain elemental additions that can react with Al_2O_3, in particular, magnesium. The reaction equations in this case are

$$3Mg + Al_2O_3 \leftrightarrow 3MgO + 2Al \qquad (2)$$

and

$$3Mg + 4Al_2O_3 \leftrightarrow 3MgAl_2O_4 + 2Al \qquad (3)$$

The first reaction (Eqn. (2)) to form MgO predominates when there is more than about 1 wt.% magnesium in the alloy, while spinel, $MgAl_2O_4$, will form in alloys containing lower magnesium contents, and can form in the solid state. It is obvious from Eqns. (2) and (3) that aluminum oxide is not a good reinforcement for magnesium alloys, but ceramic carbide particles are a good choice because magnesium does not have a stable carbide. Reaction stability is one of the most important factors in choosing the appropriate reinforcement, and in some cases attempts have been made to provide protective coatings on the surface of the reinforcement to avoid interface reaction (see *Composites: Interfaces**).

There are other factors that come into consideration, in addition to reaction stability, when choosing an appropriate reinforcement. Ceramic powders come in a wide range of sizes, but most composites use particles in the 5–25 µm size range. The larger the ceramic particle the lower is its fracture strength. This is because ceramic particles are brittle solids, where fracture is initiated by critical sized flaws present in the particles, and the probability of a particle containing a critical flaw increases with increasing particle size. Premature failure of the reinforcing particles will degrade the composite properties. The method of composite manufacture (see *Metal Matrix Composites: Matrices and Processing**) can also influences the size of reinforcing particles. If the composite is made by blending a mixture of solid powers, as in powder metallurgy manufacturing methods, the ratio of the metal powder size to that of the reinforcing particle is important if a uniform distribution of the reinforcement is to be achieved. In general, the more similar the size ranges of the metal and ceramic particles, the more uniform the reinforcement distribution. The situation is somewhat different if a molten metal mixing route is used for incorporating the particles into the matrix. In this case the ceramic particles are stirred into a liquid melt, and the viscosity of the resulting composite melt is important. If the ceramic particles are too fine, the viscosity of the melt increases to a level where it can no longer be poured from the mixing container. For molten metal mixing processes the reinforcing particles need to be in the 10–20 µm size range. Finally, the cost of the ceramic particles is important, since they are a major component of the cost of the final composite.

Considering all these factors, SiC and Al_2O_3 have emerged as the major reinforcements for particle-reinforced composites.

2. Composite Production and Fabrication

There are a variety of methods for producing composites (see *Metal Matrix Composites: Matrices and Processing**; Lloyd 1997), but they are of two generic types: powder metallurgy and molten metal processing. The powder process is essentially a solid-state processing route, involving relatively low temperatures, so reactivity problems between the matrix and reinforcement are significantly reduced. Since the process involves blending of the alloy matrix and ceramic powders, there is little limitation on the volume fraction of reinforcement that can be produced,

which is important if very high mechanical properties, such as elastic modulus, are required. However, to obtain optimum properties a good interfacial bond has to be developed between the particles, both metal–metal and metal–ceramic. This requires extensive secondary deformation after the initial consolidation of the blended powders, and this is usually obtained by extrusion of the initial, compacted billet. The initial billet has relatively low mechanical properties because the compaction of the powder to a billet with about 90–95% density does not introduce sufficient deformation to break up the oxide skin on the surface of the metal powders, which is required to obtain a good metal-to-metal bond. The initial billet has to be reduced in section by a ratio of about 20:1 to achieve optimum interparticle bonding and good mechanical properties. The molten metal processing routes do not have this limitation, and they can produce directly a composite with good mechanical properties. For composites made by molten metal mixing, the liquid composite can be cast directly to final shape (Cox *et al*. 1993), provided the viscosity of the melt is not too high to inhibit mold filling. The viscosity of the melt increases with increasing volume fraction of reinforcing particles, so this processing route is limited to reinforcement levels of about 20–25 vol.%. Other molten metal processing routes, such as melt infiltration into a ceramic powder bed, and some spray deposition methods are not limited by viscosity considerations. However, since they all involve molten metal in contact with a ceramic powder, the reactivity issues discussed above have to be taken into consideration.

One of the major attributes of particle-reinforced metal matrix composites is that they can be fabricated by conventional shaping processes, such as extrusion and rolling, into a variety of final forms, including sheet, bar, and hollow sections (Dixon and Lloyd 1996). In addition to developing the final form, the extrusion or rolling has an important effect on the distribution of the reinforcing particles. Prior to the shaping process the particles tend to be quite inhomogeneously distributed. In the molten processing methods, the particles are located in a network surrounding the dendrites formed during solidification. As the melt solidifies the dendrites grow and push the particles ahead of them, so that when solidification is complete the particles are inhomogeneously distributed in the interdendritic regions (Fig. 1(a)). The deformation accompanying the subsequent extrusion or rolling redistributes the particles more homogeneously within the metal matrix, although on a local scale the particles are still clustered to some extent (Fig. 1(b)). A similar situation occurs with the solid-state processing routes, but in this case the initial reinforcing particle distribution reflects the efficiency of the blending process and the relative size difference between the metal and ceramic powders. Some care has to be taken during the shaping process because
Figure 1
Dendritic microstructure (a) at solidification and (b) after processing.

the deformation involved is quite extensive, and high stresses can develop within the brittle ceramic particles, causing them to crack and become damaged. To minimize this effect the forming is usually carried out at elevated temperatures to minimize the stresses involved.

When aluminum is used commercially in the unreinforced form, it contains other elemental additions in a range of alloys that provide different combinations of physical and mechanical properties. In

addition, some of these alloys can be given different heat treatments to further extend the strength beyond that obtained by composition alone. Of particular importance are the Al–Mg–Si, Al–Cu, and Al–Mg–Zn alloys that can be heat treated to provide additional strength through precipitation hardening, often referred to as age hardening. Any of the commercially available alloys can be used for the composite matrix, provided the appropriate combination of reinforcement and processing route is used to minimize interfacial reaction.

3. Mechanical Properties

When the complete range of alloy compositions and heat treatments (or tempers) in aluminum alloys is considered, the strength range extends from about 20 MPa to over 600 MPa (Hatch 1984). This is one of the main reasons why aluminum alloys are used in such a wide range of products, from household foil to aircraft structures. However, while the strength range is very large, the elastic modulus is much more limited, extending from around 69 GPa to 72 GPa in the commercially available alloys. It is with regard to improving the elastic modulus that composites make their major impact on the properties of metals in general, and aluminum and magnesium alloys in particular. Other mechanical properties are also affected by the addition of reinforcing particles, and not always in a positive fashion. Unlike continuous fiber-reinforced composites, particle-reinforced materials have quite isotropic mechanical properties.

3.1 Elastic Properties

The elastic modulus is a global property that is largely independent of the distribution of reinforcing particles, but it is dependent on the quality of the particle–matrix interface, which has to have adequate strength to transfer loading in the matrix to loading the particle. The measured values in the literature show a wide degree of scatter, which reflects different methods of measurement—dynamic measuring methods tend to give larger values than static measurements—and the quality of the composite. The quality of the composite will involve factors such as the interfacial strength, porosity, which is often associated with "unwet" particle clusters, and damaged particles. As noted above, particles can be cracked during fabrication, reducing their ability to carry stress, which will reduce the elastic modulus (measurement of the elastic modulus has been used to monitor particle fracture with progressive deformation (Lloyd (1991)). The elastic modulus can also be affected by the presence of residual stresses in the composite, which are often generated during fabrication as a result of the coefficient of expansion mismatch between the alloy matrix and the reinforcing particles.

The simplest approach to representing the elastic modulus is the upper (K_U) and lower (K_L) bounds for the bulk modulus:

$$K_L = K_M + \frac{V_P}{1/(K_P - K_M) + 3(1 - V_P)(3K_M + 4G_M)} \quad (4a)$$

and

$$K_U = K_P + \frac{1 - V_P}{1/(K_M - K_P) + 3V_P/(3K_P + 4G_P)} \quad (4b)$$

where the subscripts M and P refer to matrix and particle properties, respectively, V_P is the volume fraction of reinforcing particles, and G is the shear modulus (see *Composites, Physical Properties of**). Young's modulus, E, can then be obtained using the standard relationship $K = E/3(1 - 2v)$, where v is Poisson's ratio. These bounds are quite broad, taking no account of particle shape, and Halpin (1984) used a micromechanics approach to take account of the particle aspect ratio:

$$E_C = \frac{E_M(1 + 2sqV_P)}{1 - qV_P} \quad (5)$$

where

$$q = \frac{(E_P/E_M - 1)}{(E_P/E_M + 2s)} \quad (6)$$

E_C is the Young's modulus of the composite, and s is the particle aspect ratio, defined as the ratio of largest to smallest perpendicular particle cross-sectional radii.

An alternative approach, which also takes account of the particle shape, is to use the Eshelby equivalent inclusion method (Clyne and Withers 1993).

Figure 2 shows some experimental upper and lower bounds for the Young's modulus of aluminum reinforced with silicon carbide particles. The results fall within the range predicted by Eqn. (4), and give reasonable agreement with Eqn. (5) and the Eshelby approach for $s \cong 1.5$, which is reasonable for the reinforcements involved.

A point regarding the modulus which is often overlooked, but which is commercially important, is that the modulus improvement given by composites is maintained, to essentially the same extent, at elevated temperatures. So the decrease in elastic modulus with increasing temperature reflects the decrease in the modulus of the matrix (Lloyd *et al.* 1994).

3.2 Yield Strength

Despite many reports to the contrary in the literature, the addition of particle reinforcement produces very little real increase in the yield strength over that of the matrix alloy. The confusion in the literature arises because of the usual method of measuring the yield strength in unreinforced material, and the nature of
Figure 2
Young's modulus of SiC particle-reinforced aluminum composites. Filled circles are experimental values; lines correspond to different models.
Figure 3

the elastic-to-plastic transition in composites. The yield strength in unreinforced material is defined as the stress at which a plastic strain of 0.2% is achieved. In unreinforced metals the transition from elastic to plastic behavior is relatively abrupt, and the rate of work hardening decreases quite rapidly. In composites the elastic-to-plastic transition is much more gradual, and the work hardening rate is much higher at low strains. Figure 3 shows this difference in
Figure 4
Stress–strain curves of composites of Al–Si–Mg casting alloy A356 reinforced with 20% SiC particles in the as-quenched condition (T4) as a function of particle size (600 grit size and 400 grit size correspond to roughly 9 μm and 17 μm average particle diameter, respectively).

behavior, and it results in an apparent increase in the yield stress. At larger strains the increased initial work hardening rate gives a composite stress–strain curve above that of the matrix alloy, and a higher ultimate strength. The higher work hardening rate is a result of several factors. (i) There is locally a high dislocation density associated with reinforcing particles that results from the misfit in the coefficient of thermal expansion. This causes a higher flow stress overall, as well as a higher rate of dislocation accumulation with continued straining, resulting from an increased density in dislocation sources. (ii) The influence of the constraints the elastic reinforcing particles have on the plastic deformation of the matrix, owing to elastic misfit between the particle and the matrix; this can be modeled using the Eshelby approach or using finite element models. (iii) The way dislocations rearrange themselves with increasing strain, which lowers the total energy of the deformed state and reduces the resulting work hardening rate, can be impeded in the presence of elastic particles. All of these factors have been considered in the literature (Withers *et al.* 1989, Taya *et al.* 1991, Clyne and Withers 1993), but the models are dependent on a range of microstructural features, such as particle shape, size, and distribution, which makes analysis difficult. Experimentally, refinement of particle size, for reinforcement volume fractions up to about 25 vol.%, also results in an increased work hardening rate, and an apparent increase in strength, as shown in Fig. 4.

When a heat-treatable alloy is used for the matrix, the composite can be aged at elevated temperature to increase the strength of the matrix, and hence the strength of the composite. In some cases the

composite may age harden somewhat more quickly than the unreinforced alloy, so the optimum heat treatment to obtain the appropriate temper properties may differ from that of the unreinforced alloy. Differences in aging kinetics are attributed to the presence of lattice defects generated in processing the composite (Prangnell and Stobbs 1991).

The yield strength of the composites decreases with increasing test temperature, which mainly reflects the temperature dependence of the matrix flow stress.

3.3 Tensile Elongation

The increase in elastic modulus and ultimate strength in particle-reinforced composites is accompanied by a decrease in the tensile elongation, or ductility, which is a major limitation to the use of these materials. Many factors can influence the ductility of the composite, but the major ones are the matrix strength–ductility dependence, the reinforcing particle distribution, and the particle–matrix interfacial strength (Lloyd 1995). The importance of matrix ductility is because of the fact that any global plastic strain to the composite results in much higher local matrix strain since the ceramic particles can only deform elastically. Particle distribution is very important because in regions where the particles are closely spaced, as in particle clusters, they constrain the plastic flow of the adjacent matrix, resulting in locally high complex stresses that result in premature failure. This failure may occur in the matrix regions between the particles if the matrix fracture stress is exceeded, or at the particle–matrix interface if the interfacial strength is exceeded. A high interfacial strength is obviously a requirement for optimum mechanical properties with such composites. Other factors, such as reinforcement size, where very large particles show particle cracking, and particle shape, where irregular shaped particles can give rise to local stress concentrations, can have an impact on the composite ductility. However, these tend to be second-order effects in good-quality composites.

3.4 Fracture Toughness

The fracture toughness to some extent mirrors the tensile ductility, decreasing with increasing volume fraction of reinforcement. However, the toughness decreases most rapidly with the first addition of reinforcing particles, and decreases only slightly for reinforcement loading beyond about 10 vol.% (Mortensen 1990, Davidson 1991). The toughness is much less sensitive to the degree of aging (i.e., the matrix strength) than to the tensile elongation, and there are some data suggesting that coarse particles are beneficial compared with smaller ones. Typical toughness values are in the 15–20 MNm$^{-3/2}$ range, but there are some difficulties in carrying out valid

fracture toughness tests because it is often difficult to generate correct starting and propagating crack profiles (Roebuck and Lord 1990). If the toughness is considered in terms of high strain rate impact, the impact energy absorbed is quite low, reflecting the susceptibility of low-ductility materials to unstable crack propagation under impact conditions.

3.5 Creep and Fatigue

Elevated-temperature creep behavior is usually considered in terms of the minimum steady-state creep rate that a material will sustain at a particular stress and temperature (see *Creep and Creep-Fatigue of Metal-Matrix Composites**). Generally, the creep resistance of particle-reinforced composites is better than that of the equivalent unreinforced material. Since the particles are elastic also at creep temperatures, creep of the matrix alloy must be the dominant process, yet there are often large discrepancies between matrix and composite for the activation energies for creep, and the stress exponent of the creep. These could indicate that very different creep mechanisms are involved, but this is probably not the case. Many of the composites have limited ductility under the creep conditions being tested, which often results in a poorly defined or nonexistent steady-state creep region. Also, it is now generally accepted that the reinforcing particles result in an increased threshold stress, below which the creep rate is essentially zero, and this accounting for the threshold stress often allows the creep behavior of the composite and the unreinforced matrix to be rationalized. It is still not clear what controls the threshold stress in particle-reinforced composites. Thermal cycling in the absence of stress does not produce a significant shape change, which is different to the situation in continuous fiber-reinforced composites. In particle-reinforced composites the residual stresses are quite low (especially at elevated temperature) and the mechanical and physical properties are isotropic, so there is no significant driving force for a shape change with thermal cycling.

An improvement in fatigue behavior is often suggested as an advantage of particle-reinforced composites, but this is an over simplistic generalization (see *Fatigue of Particle Reinforced Materials**). Stress-controlled fatigue behavior, as typified by the stress–fatigue (*S–N*) plot, usually indicates an improvement in fatigue life, particularly at low stresses and long lives. This reflects the higher elastic modulus of composites, but at higher stresses the fatigue lives tend to converge in response to the reduced composite ductility. Fatigue crack growth curves also show an improvement at lower stress intensity levels because the threshold stress intensity for crack growth is higher in composites. However, if fatigue behavior is examined in strain control, where the fatigue life is

measured for a particular strain amplitude, composites show inferior fatigue life, particularly as the strain amplitude increases. This mainly reflects the higher modulus and work hardening rate in composites.

4. Concluding Remarks

Particle-reinforced metal matrix composites offer a useful improvement in some of the mechanical properties of metals, particularly the elastic modulus, without incurring the fabrication difficulties and cost penalties associated with continuous fiber-reinforced composites. There are often modest gains in some physical properties, such as a reduction in the coefficient of thermal expansion (see *Composites, Physical Properties of**), and improvements in frictional and wear behavior with some systems (see *Polymer Composites, Friction and Wear of**). Their major disadvantage, as with most composites, is their reduced ductility and toughness when compared with unreinforced metals. Nevertheless, particle-reinforced metal matrix composites are now finding commercial niche markets that take advantage of the property improvements they provide (see *Metal Matrix Composites: Applications**).

Metal Matrix Composites, Recycling of

Recycling of a material is defined as submitting the material to secondary processing steps that produce the same material with the same properties as the original primary product. Recycling can in some instances be conducted several times, the material undergoing, after primary processing, several cycles of secondary processing, service, and recovery without significant degradation. This is, for instance, the case for conventional aluminum alloys (Krüger 2000, ASM 1999), which can be remelted and processed with full restoration of the primary microstructure, resulting in identical material properties. Recycling can be done within the production line without any service exposure of the material, or after re-collection of components already out of service. In the latter case some degradation of the material is expected, which would have to be repaired by the recycling process. Alternatively, a material can be processed by reclamation, in which case it is processed to a different form or microstructure to produce a different, but still useful, material.

Primary processing of metal matrix composites is essentially the bonding of the composite ingredient materials, metallic matrix and reinforcement, so as to form a percolating metallic matrix containing the reinforcement as an embedded second constituent. The main issues in primary processing of metal matrix composites are to achieve bonding between the two

usually nonwetting ingredient materials and to avoid deleterious interface reactions after contact between these constituent materials is established. Frequently, primary metal matrix composite processing yields near-net-shape products, at times by the very nature of the process, and also often because these composites are very difficult to machine. Depending on the composite and the component at hand, the material can be recycled, or alternatively more profitably reused in another form after reclamation.

Recycling of metal matrix composites takes advantage of the already achieved bonding between matrix and reinforcement. Recycling of metal matrix composites is attractive, given that it provides the commercial benefit of avoiding the frequently costly primary processing, and on some occasions saves expensive reinforcements. There are, however, some specific issues that must be taken into account in the recycling of these materials. Namely, it is important to avoid excessive thermal exposure in the recycling process if the constituents are mutually prone to chemical interaction. Also, because metal matrix composites are prone to accumulation of internal damage during deformation, their recycling or reuse will often require severe nondestructive testing to verify that the microstructural integrity has been preserved. Another concern that is specific to the recycling of metal matrix composites is that the reinforcement of metals is frequently only used for partial, localized, reinforcement of metal-based components. With such components, an additional effort is necessary to separate the composite from the unreinforced section, in order to allow recycling of both materials separately.

Reclamation of the composite ingredient materials requires work to separate the two constituents of the metal matrix composite. Although the interface free energy of the reinforcement in the composite often exceeds its surface free energy in air, matrix/reinforcement separation does not occur spontaneously because the complementary free surface energy of the matrix has to be formed anew in the process. This results in a positive total free energy barrier, which must be overcome in the reclamation process. This barrier can be overcome by several methods, one being the use of insoluble flux materials having a smaller surface energy with the reinforcement than the matrix. Other processes for metal matrix composite reclamation rely on gravity for separation of the composite constituents. These can be aided by blowing bubbles of an appropriate gas through the molten composite, so as to separate the reinforcement by attachment and flotation with gas bubbles (this process is akin to froth flotation processes used in ore preparation). An additional issue in reclamation of expensive reinforcements like fibers is that their properties are often degraded in the process. In some cases, when the reinforcement is far more costly than the matrix, reclamation of the reinforcement alone

can be envisaged; this is achieved with relative ease by dissolving the matrix chemically.

Given the relatively wide variety of metal matrix composites and components made therefrom, recycling and reclamation of these materials raises issues that depend on the materials class. Issues specific to the two principal metal matrix composite classes are therefore more specifically addressed in what follows, together with questions specific to reclamation of composite ingredients.

1. Particle Reinforced Metals

Cast primary metal matrix composite products containing relatively low volume fractions of discontinuous reinforcements, like foundry ingots, extrusion billets, or rolling slabs, can be recycled with comparative ease. If the recovered metal matrix composite cannot be used for the same component and application at equal performance quality, reuse can be envisaged for different applications allowing a certain degree of downgrading of the performance of the material. In the case of components selectively reinforced by particulates, remelting results in dilution of the reinforcement, yielding a different composite; here again, the resulting material could be reused in a different application.

With particulate reinforcements at volume fractions less than 30%, recycling of the composite can be achieved by remelting if the constituents are not overly reactive. The foundry composite alloy Al-Si9Mg/SiC/10-20p (Lloyd 1989) provides an example where in-house return rates in the production line may amount to up to 50% without property degradation (Klimowicz 1994). Some specific measures are recommended for the recycling procedure: dry preheated scrap and tools, no overheating of the melt above 750 °C, impellers to produce convection beneath the dross without formation of a vortex, and moderate fluxing with argon or SF_6 (Provencher *et al.* 1992, Chamberlain and Bruski 1998). Careful sorting and cleaning is required before the recycling of used particle reinforced metal components in a similar remelting process not yet established industrially.

Aluminum alloys of the 2xxx, 6xxx, and 7xxx series reinforced with alumina particles react at the interface even close to the solidus temperature. Therefore, any remelting process can potentially alter the composite constituent phases and properties. In the case of AA6061/Al_2O_3/10-20p it is reported (Schuster *et al.* 1993) that the amount of interface spinel formation stabilizes without significant influence on the mechanical properties of the composite. Recycling of Duralcan wrought alloys is so far only executed on a large scale by the producer (Klimowicz 1994). Composite systems such as Mg–SiC, Al–SiC with little silicon content, Al–B_4C, and Cu–SiC, are too reactive to allow remelting without severe interface reactions.

Iron-base alloys with Ti(C,N) reinforcement stabilize at the solubility limit, which depends on the concentration of other carbide-forming alloying elements.

It has been proposed to reuse particle reinforced aluminum alloys for the production of aluminum foam (Gergely *et al.* 2000). Indeed, several closed-cell aluminum foam production processes rely on the presence of ceramic particles within the melt for stabilization of the foam structure during the process (Jin *et al.* 1992, Ruch and Kirkevag 1991, Gergely and Clyne 1999). One advantage of this recycling route is that property requirements placed on composites to be used for the production of metallic foams may not be as stringent as for bulk composites.

Particle reinforced metals also have the attribute that they can be disintegrated into smaller fragments without disintegration of their microstructure. Machining chips of these materials can thus be reused to fabricate MMC components by solid state compaction methods. This solid state process has the added advantage of minimizing interfacial reactions between matrix and reinforcements.

2. Melt-infiltrated Preforms

Metal matrix composites with short or continuous fibrous reinforcements are usually produced by infiltration of preforms, in a process that also defines the final shape of the metal matrix composite, and which can also produce fully or partially reinforced components. Recycling of such composites would thus require preservation of the shape of the component. For example, the alumina short fiber preform ring reinforcing the crown of an aluminum alloy piston can be recuperated during remelting. Although the matrix is molten, such MMCs are mechanically stable up to about 850°C (Burkhard 1995) and can be handled. The integrity of such MMC rings can be confirmed by nondestructive testing and inserted again into the casting of a piston, which has only to achieve bonding between the composite and the matrix, as the primary casting process had already infiltrated the preform. Recycling of MMC sections of defined shape can be envisaged for alumina fiber reinforced aluminum (or magnesium alloys, provided that recuperation of the composite from the melt is rapid enough to restrict interface reactions), SiC reinforced aluminum–silicon alloys, carbon fiber reinforced magnesium, and, with some reservations, for monofilament reinforced titanium alloys.

Particle reinforced metals with particulate volume fractions greater than 40% are also frequently prepared by melt infiltration of powder preforms. It may be envisaged to reshape simple geometries of these composites to some extent by forming processes; if remelted, the volume fraction of reinforcement might be increased if some of the matrix is squeezed out during secondary pressure casting (Burkhard 1995).

Alternatively, these composites could be used as a basis for the production of lower volume fraction composites by remelting and dilution by a matrix melt (Klier *et al.* 1991).

3. Reclamation of Ingredients

Isolated ceramic particulates or fibers can be removed from aluminum or magnesium melts by conventional salt addition or fluxing techniques as executed to remove oxide films (Provencher *et al.* 1992). By gravity settling, the fluxed ceramic ingredients float to the dross at the top of the aluminum melt, or accumulate as sediment at the bottom of a magnesium alloy. Rotary salt furnace technology is an established reclamation process to recover aluminum from various mixtures, including particle reinforced metals; however, this requires 20–50 wt.% salt (Duralcan 1990). Both wrought and foundry alloys can be recovered using this technique, even machining-chips of fiber reinforced MMC. Typically, about 80% recovery of the available aluminum can be achieved (Klimowicz 1994).

The efficiency of particle removal by fluxing is related to the probability of contact between the ceramic constituent and the flux. Duralcan, as a supplier of particulate reinforced aluminum, proposes to incorporate the salt into the melt, agitated by injecting gas (Duralcan 1996). Thus dewetting is achieved by much smaller salt additions (less than 1 wt.% for alumina and about 1.5 wt.% for SiC) and the combination with adsorption of gas to the reinforcement also accelerates particle separation by floating. This gas injection technique can also be applied to melts incorporating fiber reinforced components (Kainer 1996). Gas bubbles are adsorbed sufficiently to the fiber preforms to make these float to the surface of an aluminum melt; however, this process proves more difficult with magnesium melts. With these, dewetting can be achieved by stirring in a suitable salt; here, the preform with the incorporated salt will then sediment to the bottom of the crucible instead of floating (Kiehn *et al.* 1996). Nishida *et al.* (1999) reported on different flux systems for 10–20 vol.% alumina reinforcement in pure aluminum and in AlSiCuMg alloys (AA6061); these allow reclamation of up to 50% of the matrix. Only 20% of the AA6061 matrix could, however, be reclaimed from a 25 vol.% SiC-whisker reinforcement, presumably due to severe interface carbide formation. The preforms are partly infiltrated by the flux, causing these to float on the aluminum melt where they can be skimmed off.

Burkhard (1995) reports on centrifugal filtering of aluminum alloys reinforced by particulates, and also by short or continuous alumina fibers. Using medium-grade graphite filters in a centrifugal plasma torch furnace at accelerations above $2000 \, \text{m s}^{-2}$, more than 50% of the matrix melt can be separated from ceramic

reinforcements. Further reuse can also be imagined for the highly enriched filter cakes containing up to 40 vol.% particulates or short fibers.

A melt extraction technique was reported (Lotze *et al.* 1996) to recover the aluminum melt by producing rapidly solidified needles thereof. In this method, remelted particulate or short fiber reinforced aluminum are held above the liquidus for times sufficient to segregate the heavier reinforcements to the bottom. A cooled copper disk with grooves is then dipped into the melt to extract flakes or metallic needles by fast rotation; these can then be submitted to powder compaction techniques. Again the sediment is enriched in discontinuous reinforcement and could be reused.

The reclamation of the reinforcement free of metal matrix can be achieved by dissolving the matrix chemically. The necessary effort will increase with the volume fraction of the inert reinforcement, because convection is progressively hindered. Such leached reinforcement, especially fibers, could be chopped for reuse as discontinuous reinforcements. Klimowicz (1994) mentions that from the segregates of discontinuously reinforced metals resulting from the gas injection method or from of the plasma furnace, a ceramic powder may also be recovered.

Metal Matrix Composites: Applications

Metal matrix composites (MMCs) comprise a relatively wide range of materials defined by the metal matrix, reinforcement type, and reinforcement geometry (see *Metal Matrix Composites: Matrices and Processing**). As regards the matrix, most metallic systems have been explored for use in MMCs, including aluminum, beryllium, magnesium, titanium, iron, nickel, cobalt, copper, zinc, and silver. By far the largest usage is in aluminum matrix composites.

As for the reinforcement, the materials used are typically ceramics since they provide a very desirable combination of stiffness, strength, and relatively low density. Candidate reinforcement materials include SiC, Al_2O_3, B_4C, TiC, TiB_2, graphite, and a number of other ceramics. In addition, there has been work on metallic materials as reinforcements, notably tungsten and steel fibers.

The morphology of the reinforcement material is another variable of importance in MMCs. The three major classes of reinforcement morphology are continuous fiber, chopped fiber or whisker, and particulate. Typically, the selection of the reinforcement morphology is determined by the desired property/cost combination. Generally, continuous-fiber-reinforced MMCs provide the highest properties in the direction of the fiber orientation but are the most

expensive. Chopped-fiber- and whisker-reinforced materials can produce significant property improvements in the plane or direction of their orientation, at somewhat lower cost. Particulates provide a comparatively more moderate but isotropic increase in properties and are typically available at the lowest cost.

By adding to the three variables of metallic matrix, reinforcement material, and reinforcement morphology the further parameters of reinforcement volume fraction, orientation, and matrix alloy composition and heat treatment, it is apparent that there is a very wide range of available material combinations and resultant properties. The specifics of MMC systems, their manufacturing processes, and properties are covered elsewhere; this article discusses how MMCs have been, and are being, used in engineering, with a focus on principal application areas.

In the vast majority of these applications, MMC materials have been implemented after displacing other materials, such as unreinforced metals and alloys or polymer matrix composites. Reasons for this substitution vary widely, and include increases in modulus, strength, wear resistance or damping capacity, as well as reductions in thermal expansivity or density, and the cost competitiveness of MMCs.

1. Applications

Applications of MMCs can be conveniently grouped by market area, since each area requires sets of properties and costs that result in particular subsets of MMC materials being of primary interest. The primary markets for MMCs are divided into aerospace, automotive, commercial and industrial products, and electronic packaging and thermal management; all these represent the areas of greatest interest. In each of the sections that follow, a summary of applications either in production or in an advanced prototype stage will be covered to provide a realistic perspective on the status and potential of these materials in the selected market areas. Further information can be obtained in the specific references in each section as well as reviews on the subject (Zweben 1992, Koczak *et al.* 1993, Harrigan 1994, Eliasson and Sandstrom 1995, Peel 1995, Kevorkijan 1998, Maruyama 1999, Froes 1999).

1.1 Aerospace

Aerospace applications were the original driving force for MMC development. This was due to the quest for weight reduction for improved performance and payload capability combined with the high value placed on weight savings.

(*a*) *Aircraft structure*. A significant portion of aircraft structure is designed by stiffness, so as a result

many of the aircraft structure applications for MMCs seek to capitalize on the increased specific stiffness that these materials provide. Aircraft structural applications actually require a combination of properties, including adequate strength, damage tolerance (including ductility, fracture toughness, and fatigue resistance), and corrosion resistance. MMCs typically have lower damage tolerance properties than their unreinforced matrix metal counterparts, and hence the extent of structural application in primary structures has been limited. More extensive application depends on the development of cost-effective large-scale MMC production processes that result in materials with improved combinations of properties over currently available materials. There have been selected aircraft structure applications that have been realized. These are exclusively aluminum-based MMCs, and will be discussed briefly below.

SiC particulate-reinforced aluminum MMCs are used in the Lockheed F-16 fighter aircraft. One application is in the ventral fins of the aircraft, which provide lateral stability during high angle of attack maneuvers. A 6092/SiC/17.5p MMC sheet material replaced the unreinforced aluminum skins in the honeycomb structure of the fin and, due to the increased specific stiffness of the MMC material, increased the service life significantly. The same material is used in the fuel access door covers for the F-16. Unreinforced aluminum access covers were experiencing cracking due to overload, and again the increased specific stiffness property of the MMC allowed this material to be used successfully (Maruyama 1999).

The Eurocopter rotor sleeve is another application that has been reported (Hurley 1995). A forged SiC particulate-reinforced 2009 alloy having good stiffness and damage tolerance has been used. It is a replacement for a titanium part with a reduction in weight and production cost.

Replacement of a carbon-fiber-reinforced polymer tube by a SiC particulate-reinforced aluminum extruded tube for a floor support strut in Airbus aircraft has also been reported (Hurley 1995, Peel 1995). The driving force is improved damage tolerance and reduced cost.

(*b*) *Aeroengines*. Gas turbine engines also have substantial needs for lightweight, high-performance materials. This application area has a rich history of innovative materials developments, and the expectation that MMCs would be an important materials class in aeroengines is not surprising. In the case of this application, both specific stiffness and specific strength, especially at elevated temperature, are the critical properties. But similarly to the case for aircraft structure, other properties, including fatigue, creep, and oxidation resistance, are also very important.
Figure 1
Fan exit guide vane for Pratt and Whitney PW4000 engine made from extruded 6092/SiC/17.5p material.

Aluminum MMCs are being applied in aeroengines, specifically in the area of the fan exit guide vanes for the Pratt and Whitney PW4000 series engines that power many of the Boeing 777 commercial aircraft (Fig. 1). In this application, a 6092/SiC/17.5p-T6 extruded material replaced a graphite/epoxy material in order to achieve improved resistance to foreign object damage and erosion. Significant acquisition and lifecycle cost savings have been reported (Maruyama 1999).

Titanium MMCs have also been explored for replacement of nickel-based alloys (Wei 1992). While there was extensive development effort in this area, actual application has not been realized.

(*c*) *Space structures.* The premium for weight savings in structures that will be launched into space is very high. Typically, space structures can be viewed as platforms for electronic components, and hence specific stiffness and, to a lesser degree, specific strength are important. In addition, the physical properties of the materials, particularly coefficient of thermal expansion and thermal conductivity, are important due to the thermal excursions that occur in orbit and the need to maintain dimensional accuracy.

An early application for MMCs was in the Space Shuttle. In this case, continuous boron-fiber-reinforced aluminum is used in struts comprising the fuselage frame (Kinner 1980).

On the Hubble Space Telescope, a high-gain antenna boom constructed of continuous graphite-fiber-reinforced aluminum is used. The primary driving force for this material was the dimensional stability that can be engineered into the composite through the addition of graphite fibers with a negative coefficient of expansion in the fiber direction at an appropriate volume fraction to balance the positive coefficient of expansion of the aluminum matrix. This structure replaced an aluminum waveguide and

graphite/epoxy tube assembly with a single part with a weight saving of 30% (Harrigan 1994).

(*d*) *Other aerospace applications.* SiC particulate-reinforced aluminum was used in the form of extruded sections for electronic racks. Specifically, a 6061/SiC/25p material replaced unreinforced aluminum racks in a military aircraft with a 30% weight saving (Harrigan 1994).

In addition, the ability to tailor the coefficient of thermal expansion of MMCs has been useful in replacing materials in structures requiring thermal stability. General Electric Co. designed an advanced composite optical system gimbal, using 6061/SiC/40p MMC in selected areas requiring low expansion and high wear resistance (Harrigan 1994).

Another application using the ability to match coefficient of thermal expansion with mating materials was the use of 6061/SiC/40p MMC in the covers for an inertial guidance unit. In this application, the MMC replaced beryllium that had to be machined from a solid block. The MMC material could be forged to near-net shape, with final machining only required. In addition, the machining of the MMC could be done in conventional machine shops, since it does not have the toxicity concerns of beryllium machining (Harrigan 1994).

1.2 Automotive

In the automotive market, properties of interest to the automotive engineer include the increased specific stiffness, wear resistance, and improved high-cycle fatigue resistance (Allison and Cole 1993). While weight savings are also important in automotive applications, the need for achieving performance improvements with much lower cost premiums than tolerated by aerospace applications drives attention

toward low-cost materials and processes. There has seen successful application of MMCs in selected automotive applications in which the combination of properties and cost satisfied particular needs.

(*a*) *Engine*. Replacement for steel and cast iron in engine applications relies on the increased specific stiffness, improved wear resistance, and, in some cases, on the increased high-cycle fatigue resistance provided by MMCs.

A watershed application for aluminum MMCs was the Toyota piston for diesel engines (Donomoto, *et al*. 1983). The part consists of selective reinforcement of the aluminum alloy by a chopped fiber preform in the ring-groove area in order to provide improved wear and thermal fatigue resistance. These pistons have been in commercial production in Japan since the early 1980s.

Other piston applications have included the use of SiC particulate-reinforced aluminum forgings in racing applications. Due to the lower coefficient of thermal expansion of the MMC, reduced clearances between the piston and cylinder wall are possible. Based on trials of MMC pistons in drag-racing bikes, improved performance compared to conventional hypereutectic Al–Si alloys results (Harrigan 1994).

Another application in which selective reinforcement is employed is in the Honda Prelude 2.3-liter engine (Hamajima *et al*. 1990). In this case hybrid preforms consisting of carbon and alumina fibers were infiltrated by molten aluminum to form the cylinder liners during the medium pressure squeeze casting process for the engine block.

Other drivetrain components, particularly connecting rods, have been a focus of development (Harrigan 1994). By reducing the mass of the connecting rod/ piston assembly, the objectionable secondary shaking forces that can develop, particularly in smaller engines, can be reduced. In addition, lower reciprocating loads should lead to lower loads on the crankshaft, lower friction losses, and increased fuel economy or performance can be realized (Allison and Cole 1993). No commercial applications of connecting rods in high-volume vehicles have been achieved, largely because of the difficulty in obtaining a material with the necessary high-cycle fatigue performance and low cost combination. While prototype connecting rods from hot forged aluminum MMC have been prototyped and tested, further cost reduction is required.

(*b*) *Brake system*. Aluminum-based MMCs offer a very useful combination of properties for brake system applications to replace cast iron. Specifically, the wear resistance and high thermal conductivity of aluminum MMCs enable substitution in disk brake rotors and brake drums with attendant weight savings of the order of 50–60%. Since the weight reduction is
Figure 2
Brake rotor and brake drum components from cast SiC particulate-reinforced aluminum MMC.

in unsprung weight, it also reduces inertial forces and provides additional benefit. In addition, lightweight MMC rotors provide increased acceleration and reduced braking distance. It is reported that, based on brake dynamometer testing, MMC rotors reduce brake noise, do not wear as much, and have more uniform friction over the entire testing sequence compared to cast iron rotors (Allison and Cole 1993). Commercial applications of aluminum MMC in brake rotors and drums have been achieved; these include the rear drums on the GM EV-1 as well as the rotors on the Plymouth Prowler and Lotus Elise. Examples of these components are shown in Fig. 2.

Application of aluminum MMCs in automotive racing applications, where higher priced material is acceptable for improved performance, has also been reported. Brake calipers for Formula 1 racing cars produced from a 2124/SiC/25p MMC provide less displacement, more leverage, and quicker stops due to the increased material stiffness (Hurley 1995).

(*c*) *Driveshaft*. Use of aluminum MMCs in the driveshaft takes advantage of the increased specific stiffness of these materials. Conventional driveshafts, whether aluminum or steel, are constrained by the speed at which the shaft becomes dynamically unstable. The critical speed of the driveshaft is a function of the length, inner and outer radius, and specific stiffness. In vehicles with packaging constraints, that do not allow increased driveshaft diameter, MMCs offer a desirable solution. Use of MMCs enables longer driveshaft lengths at a given diameter or smaller diameter shafts at a given length. As a result of these benefits, driveshafts comprised of 6061/ Al_2O_3 materials produced by stir casting and subsequent extrusion into tubes have been applied in the GM S-T truck and Chevrolet Corvette.

(*d*) *Other automotive applications*. MMCs, specifically those based on aluminum matrices, are candidates for use in brake calipers, pump housings, gears, valves, brackets, pulleys, turbocharger and supercharger compressors, and suspension components (Allison and Cole 1993). In addition, they have been cited for use in clutch parts, suspension pushrods and rockers, as well as other gearbox and engine parts (Hurley 1995).

An engine cradle for the General Motors EV-1 has been prototyped in B_4C-reinforced aluminum produced by die casting (Froes 1999).

Snow tire studs have been manufactured from 6061/Al_2O_3 drawn wire. In Finland, where steel tire stud jackets have been outlawed and unreinforced aluminum has insufficient wear resistance, MMC tire stud jackets have been successfully applied (Nussbaum 1997).

1.3 Electronics Industry

The ability to tailor the coefficient of thermal expansion of MMCs through additions of ceramic reinforcement, while maintaining the thermal conductivity of the metallic base alloy, has opened up an entirely new area of application, namely in thermal management and electronic packaging applications (Zweben 1992). MMCs produced by both powder metallurgy and liquid metal infiltration methods have been employed in thermal management applications, and are commonly known in the market as "AlSiC" materials; Fig. 3 shows an example of an electronic substrate produced from SiC particle-reinforced aluminum.

An emerging application in which MMCs would appear to offer advantages is in substrates for hard disk drives. These substrates are predominantly made from aluminum, with some selected applications using glass or ceramic materials. As the disk drive developers seek to spin the hard disks at higher speeds for faster data transfer, the upper speed is limited by the occurrence of disk flutter, which is determined by material modulus. Increasing the elastic modulus of the substrate could allow higher speeds without flutter, and aluminum MMCs have been prototyped for this application (Froes 1999).

1.4 Other Commercial and Industrial Products

In the recreational products market, improved performance (real or perceived) is highly valued. As a result, many of the materials that gain favor in the aerospace market are also applied in recreational products. The primary property of MMCs that is of interest for this market area is the increased specific stiffness.

A range of materials has been targeted at the golf equipment market. Both shafts and club heads for both woods and irons are of interest, taking advantage of the high specific stiffness and strength properties of MMCs (Hurley 1995, Froes' 1999).

Applications in the bicycle market have included frames, front forks, handlebars, and seat posts (Hurley 1995, Peel 1995). In this market the stiffness and durability of MMCs are desired, and for one 6061/Al_2O_3 extruded tube product, it has been reported that over 50 000 aluminum MMC frames per year were sold by one bicycle company (Nussbaum 1997).

One application of SiC particle-reinforced aluminum that was developed but never applied was a mast for the America's Cup racing yacht *Stars and Stripes '88*. The mast was made from a 6061/SiC/20p MMC that was to replace a thicker walled unreinforced aluminum mast with the attendant weight savings (Harrigan 1994).

B_4C-reinforced aluminum has promise in nuclear shielding applications. The B-10 isotope present in B_4C naturally absorbs neutron radiation, and as a result this type of MMC is being considered for use in storage casks that will contain spent fuel rods from nuclear reactors (Froes 1999).

Use of aluminum MMCs in an industrial application requiring a lower weight material for improved precision has been reported. Specifically, a 6 m long MMC needle was used in a carpet-weaving machine to replace a steel needle (Hurley 1995).

2. Concluding Remarks

MMCs have found selected applications in areas that can cost-effectively capitalize on improvements in specific stiffness, specific strength, fatigue resistance, wear resistance, and coefficient of thermal expansion. New inroads will depend not only on further
Figure 3
Electronic package manufactured from AlSiC MMC.

enhancement of the properties of these materials but also on further reductions in raw materials as well as part-manufacturing costs.

Metal Matrix Composites: Matrices and Processing

The term metal matrix composite (MMC) covers various types of system, and also a wide range of scales and microstructures. Common to them all is a metallic matrix, which is normally contiguous. The reinforcing constituent is in most cases a ceramic, although there are exceptions to this and MMCs can be taken to include materials "reinforced" with relatively soft and/or compliant phases, such as graphitic flakes, lead particles, or even gases. It is also possible to use refractory metals, intermetallics, or semiconductors rather than true ceramics. MMC types are commonly subdivided according to whether the reinforcement is in the form of (i) particles, which are at least approximately equiaxed; (ii) short fibers (with or without a degree of alignment); or (iii) long aligned fibers. Choice of matrix and reinforcement,

specification of the way in which the composite material is to be synthesized, and the manner in which a stock item or component is to be fabricated from this material are key interwoven issues for technologists interested in product development. In this article, a brief overview is given of the state of the art in these areas.

1. MMC Systems and Issues for their Processing

A flow chart of the routes used for MMC processing is given in Fig. 1. The individual composite production operations are briefly described in Sect. 2. A summary is given of the different types of MMC, the matrices and reinforcements primarily involved, and associated issues related to processing—particularly the specifics of chemical compatibility.

1.1 Particulate MMCs

Particulate MMCs are being used or developed for a range of industrial applications. While these are often focused on aluminum alloy matrices, titanium-, iron-, and magnesium-based systems are also of interest. The particulate is most commonly SiC or Al_2O_3, but others (TiB_2, B_4C, SiO_2, TiC, WC, BN, ZrO_2, tungsten, etc.) have been investigated. Chemical reaction during processing can occur in some cases. Silicon carbide can be particularly problematic in aluminum- and titanium-based MMCs. The reaction between SiC and aluminum melts has been investigated in detail and SiC reacts with titanium even during solid-state consolidation. Alumina is less reactive than SiC in aluminum alloys, but it does react quite strongly with titanium.

Magnesium is rather different from aluminum and titanium, in that it does not readily form a stable carbide. However, its affinity for oxygen is very strong. The greater stability of Al_2O_3, compared with SiC, in aluminum is therefore reversed for magnesium matrices. In general, while coatings or other surface treatments may be worth considering for fibers (particularly monofilaments), economic and practical considerations mean that particulate reinforcement is normally introduced into MMCs in the virgin state. This may, however, be such that a surface oxide layer is present and deliberate thickening of this layer, for example by heat treatment in air, has in some instances been found to have a beneficial effect on interfacial bonding or other characteristics.

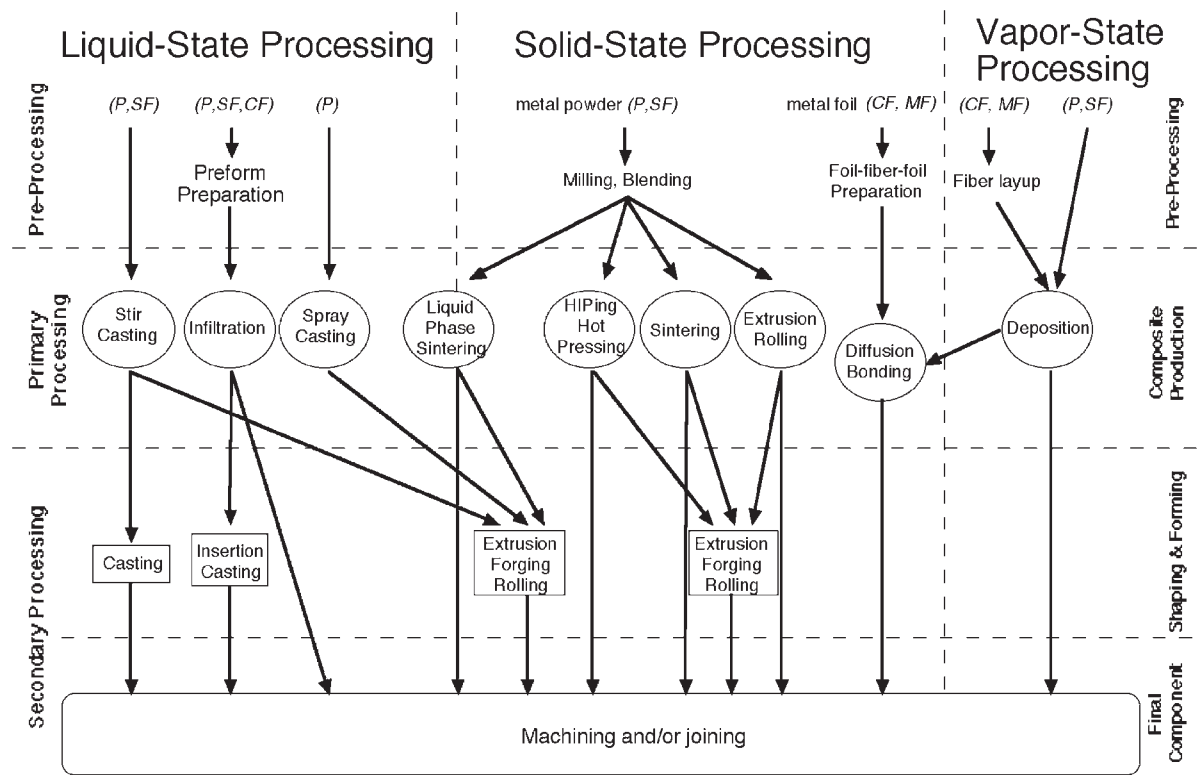
Particulate MMCs are most commonly manufactured either by a melt incorporation and casting technique or by powder blending and consolidation. Other routes include reactive processing or spray codeposition. Quality control objectives include the elimination of excessive interfacial reaction during processing, particularly for melt routes, and also the avoidance of microstructural defects such as poor


Figure 1
Overview flow chart of MMC processing routes (courtesy of A. Mortensen, C. San Marchi, and H. P. Degischer).

interfacial bonding, internal voids, and clustering of the reinforcement. Typically, for structural applications reinforcement particles are about 10–20 µm in diameter and constitute about 10–30% by volume of the material, although MMCs in which the values concerned lie outside of these ranges have been studied and are available commercially (particularly finer particles and higher particle contents). For electronic substrate applications, far higher particle contents, around 70% by volume, are commonly employed. These are obtained using multimodal particle size blends.

1.2 Short Fiber MMCs

Short fiber MMCs first attracted widespread attention in the mid-1980s, with the development of aluminum diesel engine pistons selectively reinforced with short alumina (e.g., ICI's "Saffil") fibers. Other rather similar (alumino-silicate) fibers have also been employed for applications of this type. These fibers have a fine-grained polycrystalline microstructure. Typical fiber diameters are a few micrometers and

they are initially produced in lengths of several hundred micrometers. Components are commonly produced by melt infiltration. Interfacial characteristics are partly dependent on the degree of reaction during processing, which is in turn affected by the surface chemistry of the fibers. For example, Saffil fibers have a thin silica-rich surface layer that tends to react with an aluminum melt during processing, particularly if magnesium is present. Some secondary processing, such as forging and extrusion, can be carried out under appropriate conditions. However, their formability is in general markedly inferior to that of particulate MMCs. Certain property advantages over particulate MMCs are common, however, particularly in terms of resistance to creep and, to a lesser extent, wear.

Superior mechanical properties are obtained if the fine-grained structure can be replaced by that of a single crystal. The so-called "whiskers" that result when fine, slender fibers are produced as monocrystals created considerable interest as early as the 1960s. Whiskers are usually ~1 µm in diameter, with aspect ratios of up to several hundred. Their tensile strengths are often very high. While they were

504

originally expensive to manufacture, relatively cheap methods for the production of SiC whiskers have been developed. However, while excellent properties have been reported for whisker-reinforced MMCs, work in this area decreased in the early 1990s and there has been little commercial exploitation. This is largely a consequence of handling difficulties. These commonly arise with very fine fibers, which tend to form tenacious ball-like structures and are difficult to orient in a controlled way. However, the most significant problem of this type concerns perceived health hazards. Whiskers and whisker fragments in the slightly submicrometer size range can become airborne very readily and are likely to reach and damage the lungs.

1.3   Long Fiber MMCs

Several long fiber MMCs systems have been investigated and some have been used in certain applications. However, as a consequence of processing difficulties and of constraints on ductility and toughness, this usage has in general remained limited. The term "multifilament" refers to relatively small-diameter (~ 5–$30\,\mu m$) fibers, which are flexible enough to be handled as tows or bundles. These can be woven, braided, filament wound, etc. The materials concerned include carbon, SiC, and various oxides. Other multifilaments are in common use, but most are either unable to survive the elevated temperatures involved in MMC production (e.g., polymeric and organic fibers) or are of limited interest for MMCs because of relatively poor mechanical properties such as stiffness or creep resistance (e.g., glass fibers). Multifilament MMCs can be produced by melt infiltration, although problems can arise with unidirectionally aligned fibers if applied melt pressure transverse to the fiber axis brings them into close contact so that the melt is unable to penetrate. This problem can be reduced by introducing particulate or transverse fibers.

Carbon fibers are not popular as MMC reinforcement, primarily due to interfacial reactions and galvanic corrosion effects. Chemical reaction problems are severe for aluminum, titanium and iron alloys. With aluminum, the interfacial reaction product (Al_3C_4) is hygroscopic, so that graphite fiber-reinforced aluminum tends to undergo rapid corrosion in aqueous environments. Attempts have been made to protect carbon fibers with a surface coating, such as titanium nitride, but in general this is difficult and expensive for multifilaments. Magnesium does not form a carbide so magnesium-based carbon multifilament MMCs have received some attention. There has also been interest in carbon fiber-reinforced zinc alloys, another system in which interfacial reaction is limited. While SiC has been successful in particulate MMCs, multifilament SiC fibers suitable for incorporation into metallic matrices are not commercially available. Products on the market, under trade names such as Nicalon, tend to have high levels of free carbon and silica, leading to excessive reaction with most metallic matrices during processing. There are, however, oxide multifilaments that are fairly resistant to attack by molten metals. Notable among these are polycrystalline alumina fibers, usually composed primarily of the stable α phase, which have been studied for use in aluminum and, to a lesser extent, titanium matrices. Industrial interest in all such systems has remained low, although there has been some activity concerning reinforcement of intermetallic matrices with oxide multifilaments.

Monofilaments are large-diameter (~ 100–$150\,\mu m$) fibers, usually produced by chemical vapor deposition (CVD) of either SiC or boron onto a core of carbon fiber or tungsten wire. Monofilaments are much less flexible than multifilaments, so they are handled as single fibers, rather than bundles, and precautions are necessary to avoid causing damage by the imposition of sharp curvature during handling. Interfacial reaction, however, is less of a concern, since the proportion of the fiber consumed is much less than for multifilaments. There is also greater scope for tailoring the surface chemistry and introducing surface coatings, which can be done as part of the fiber production process. For example, coatings have been developed for SiC monofilaments to be incorporated into titanium matrices. Thick graphitic coatings (which are progressively consumed but prevent defects from forming on the fiber itself) have been popular and there has also been work on various duplex layers, such as TiB_2/C and Y/Y_2O_3, which are designed to slow interfacial reaction rates down to very low levels.

1.4   Cermets

Cermets, which have microstructures comprising an assembly of ceramic particles bonded together by a small proportion of a metallic phase, can be regarded as a special type of MMC. A key to the success of cermets in industrial applications concerns their ease of processing. They are commonly produced by blending of ceramic and metallic powders followed by liquid-phase sintering. Typically, the ceramic particles are 1–$10\,\mu m$ in diameter. Blending involves a milling operation, which tends to coat the ceramic particles with metal. This is usually followed by cold isostatic pressing or injection molding to give the required shape, and then holding at a suitable temperature under vacuum, inert gas, or hydrogen. During liquid-phase sintering, particle rearrangement occurs, driven by capillarity forces. These may effect densification, depending on the degree of wetting. In some cases, notably for the oxide-based cermets, it is often necessary to impose unixial or hydrostatic pressure in

order to eliminate porosity. This is reminiscent of melt infiltration processes used to form MMCs, but the very high ceramic content and fine scale of the structure means that in the absence of wetting very high pressure might be necessary to ensure that liquid flows into all the cavities.

One approach to the problem of inadequate wetting is to deliberately promote selected chemical reactions during sintering. For example, cermets such as TiAl–TiB$_2$ can be produced via the ''XD'' process by reacting powder blends such as aluminum, titanium, and boron. More details of reactive processing techniques are given in Sect.2.1(d). However, pronounced chemical reaction can cause difficulties in the form of uncontrolled volume changes, heat release, and undesirable phase formation. Fortunately, the carbides and nitrides concerned (e.g., WC, TiC, etc.) are in general more stable than the carbides or nitrides of the binder metals (e.g., cobalt), so there are few problems of pronounced chemical attack during sintering.

Some metal ion exchange may occur, and in certain cases there is a degree of dissolution of the ceramic in the metal and reprecipitation on solidification. Such processes probably have the effect of raising the bond strength, but for most systems there is little danger of thick, brittle interfacial reaction zones forming during sintering. Of course, this is largely because cermet systems have been chosen partly with this chemical compatibility in mind, since there are not the same constraints of economics and matrix mechanical properties that operate when choosing the constituents for MMCs. The aluminum-, titanium-, and magnesium-based matrices commonly used for MMCs are attractive in these terms, but are very reactive in the liquid state, which often leads to problems during this type of processing.

1.5 Metallic Foams

Metallic foams have attracted considerable interest—partly because processing advances have led to material becoming available at competitive cost and partly because attractive property combinations can be obtained, particularly in terms of specific stiffness and specific energy absorption. Several approaches are available for the production of metallic foams. Some of these, particularly those generating closed-cell structures, involve processing the metal in the liquid or semisolid state. A problem then arises from the low viscosity of liquid metals. Depending on the processing methodology employed, it is often necessary to stabilize the foam against cell coarsening and collapse while the metal is in a liquid or semiliquid state. This is commonly achieved by introducing a dispersion of ceramic into the melt, either as oxide films or as ceramic particles, which increases its viscosity. MMC feedstock can thus be used for melt route production of metallic foams (see Sect. 2.1(d)).

2. Processing Routes

As depicted in Fig. 1, processes can be classified according to whether the matrix is in the liquid, solid, or vapor phase while it is being combined with the reinforcement. The individual composite production operations are briefly outlined below under these groupings.

2.1 Liquid-state Processing

(a) *Stir casting*. This involves stirring the melt with solid ceramic particles and then allowing the mixture to solidify. This can usually be done using fairly conventional processing equipment and can be carried out on a continuous or semicontinuous basis. A concern is to ensure that good particle *wetting* occurs. Difficulties can arise from the increase in viscosity on adding particles or, especially, fibers to a melt. However, this increase is typically only by a factor of two or so with up to about 20 vol.% particulate, provided the particles remain well dispersed. This viscosity is sufficiently low to allow casting operations to be carried out. Microstructural inhomogeneities can arise, notably particle agglomeration and sedimentation in the melt. Redistribution as a result of *particle pushing* by an advancing solidification front can also be a problem. This is reduced when solidification is rapid, both as a result of a refinement in the scale of the structure and because there is a critical growth velocity, above which solid particles should be enveloped rather than pushed.

Stir casting usually involves prolonged liquid–ceramic contact, which can cause substantial interfacial reaction. This has been studied in detail for Al–SiC, in which the formation of Al$_4$C$_3$ and silicon can be extensive. This both degrades the final properties of the composite and raises the viscosity of the slurry, making subsequent casting difficult. The rate of reaction is reduced, and can become zero, if the melt is silicon rich, either by prior alloying or as a result of the reaction. The reaction kinetics and silicon levels needed to eliminate it are such that it has been concluded that casting of Al–SiC$_p$ involving prolonged melt holding operations is suited to conventional (high-silicon) casting alloys, but not to most wrought alloys.

(b) *Squeeze infiltration*. Liquid metal is injected into the interstices of an assembly of short fibers, usually called a *preform*. Commonly, the preform is designed with a specific shape to form an integral part of a finished product in the as-cast form. Preforms are commonly fabricated by sedimentation of short fibers from liquid suspension. The process can also be adapted for production of particulate MMCs. In order for the preform to retain its integrity and shape, it is often necessary for a *binder* to be used. Various

silica- and alumina-based mixtures are popular as high-temperature binders. The binding agent is normally introduced via the suspension liquid, so that it deposits or precipitates out on the fibers, often forming preferentially at fiber contact points, where it serves to lock the fiber array into a strong network.

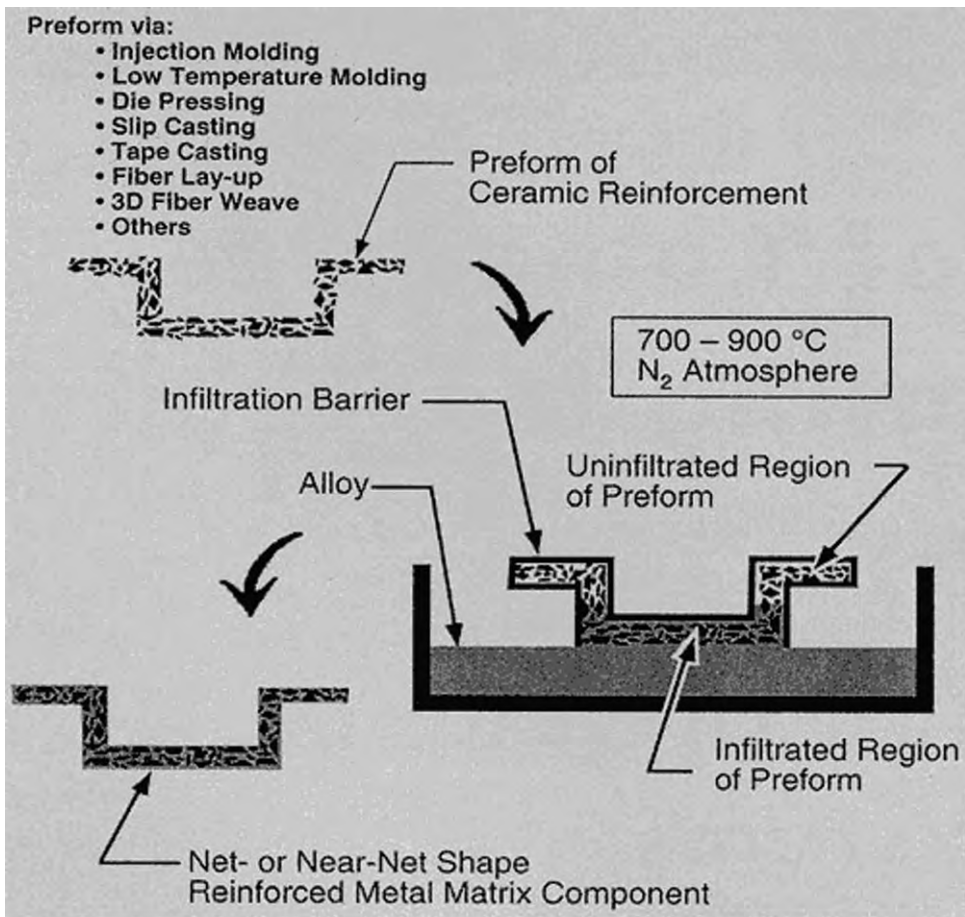
The pressure required for infiltration can readily be calculated on the basis of the necessary meniscus curvature and corrections can be made for melt/fiber wetting. In practice, substantial pressures in the megapascal region are likely to be needed. In most cases, fibers do not act as preferential crystal nucleation sites during melt solidification. One consequence of this is that the last liquid to freeze, which is normally solute-enriched, tends to be located around the fibers. Such prolonged fiber/melt contact, often under high hydrostatic pressure and with solute enrichment, tends to favor formation of a strong interfacial bond. Other forms of defect are, however, common in squeeze infiltrated composites. These include porosity and local variations in fiber content and in average alloy composition.

(c) Spray deposition. Spray deposition techniques fall into two distinct classes, depending on whether the droplet stream is produced from a molten bath or by continuous feeding of cold metal into a zone of rapid heat injection. The process was developed for building up bulk metallic material by directing an atomized stream of droplets onto a substrate. Adaptation to particulate MMC production by injection of ceramic powder into the spray has been extensively explored, although with limited commercial success. Droplet velocities typically average about 20–40 m s^{-1}. A thin layer of liquid, or semisolid, is often present on the top of the ingot as it forms. MMC material produced in this way often exhibits inhomogeneous distributions of ceramic particles. Ceramic-rich layers approximately normal to the overall growth direction are often seen. This may be the result of hydrodynamic instabilities in the powder injection and flight patterns or possibly to the repeated pushing of particles by the advancing solidification front in the liquid or semisolid layer, until the ceramic content is too high for this to continue. Porosity in the as-sprayed state is typically about 5–10%.

Thermal spraying differs in several respects from melt atomization processes. Deposition rates (usually ~1 g s^{-1}) are slower, but particle velocities (~50–400 m s^{-1}) are higher. Quenching rates for each individual splat can be very high (~10^6 K s^{-1}). Porosity levels are typically at least a few percent. Thermal spraying onto arrays of fibers to form MMCs has received some attention. An attraction here is the possibility of producing composite material in an operation involving only very brief exposure to high temperatures. Provided the void content and distribution are such that full consolidation can

be effected with little further heat treatment, this would allow problems of excessive fiber/matrix chemical reaction during processing to be avoided—a particularly important objective for titanium-based MMCs. Unfortunately, it has proved very difficult to spray onto fiber arrays so as to produce MMCs with acceptably low void contents and there are also problems in maintaining a uniform fiber distribution.

(d) Reactive processing. Several processes have been developed in which constituents are brought together under conditions such that a chemical reaction occurs while the mixture consolidates. In some such processes, liquid metal is introduced and progressively oxidizes. For example, the *directional oxidation* of aluminum is exploited in several processes patented under the "Dimox" trade name. Other processes consist of blending several elemental powders, and reacting these by heating with transient formation of a liquid phase; one important class of such processes are the "XD" processes. An example of such a process is to blend powders of aluminum, titanium, and boron to produce Al–TiB$_2$ composites.

By making a suitable powder compact, into which liquid metal is infiltrated as it reacts with the preform, near net shape forming is possible. The product often contains residual unreacted metal, so that it is effectively an MMC. Such materials often bear a marked resemblance to cermets (see Sect. 1.4), but a distinction can be drawn in terms of certain differences in processing conditions and in the materials used. The work originated in attempts to facilitate melt infiltration, particularly with aluminum-based melts, by reducing the pressure required for infiltration. Ideally, "wetting" and/or chemical reactions occurring at the infiltration front would be such as to promote spontaneous infiltration without the need for external application of pressure. While it has proved difficult to promote rapid infiltration under these conditions, MMC products can be made in this way with good near net shape characteristics, particularly when the ceramic content is high. For example, wetting in aluminum melts can be promoted by the introduction of magnesium into the melt and nitrogen into the surrounding atmosphere (preferably in the absence of oxygen). While the thermodynamic and kinetic details are complex, reactions take place so as to promote spontaneous penetration of an aluminum-based melt into an array of ceramic particles or fibers. A schematic depiction of the process is shown in Fig. 2(a). Terms such as the "PRIMEX" process have been applied to this and related procedures. Note the bimodal size distribution of the SiC particles shown in Fig. 2(b), which facilitates the generation of high ceramic contents in the initial powder compact; this type of microstructure is typical of composites intended for applications as electronic substrates, as mentioned in Sect. 1.1.


(a)
(b)

PRIMEX process, showing (a) a schematic representation and (b) an optical micrograph of an Al–70 vol.% SiC MMC (Clyne 2000).

A special type of reactive processing is that in which a gaseous product is released, generating a metallic foam. These are often made from MMC stock material, since foam production requires raising the melt viscosity sufficiently to ensure that bubbles created by gas evolution do not collapse prematurely. Ceramic particles have this effect, which is illustrated by the foam structures shown in Figs. 3(a) and (b). However, the presence of (relatively coarse) ceramic particles within the cell walls can promote cell wall rupture (see Fig. 3(c)), leading to coarsening.

2.2 Solid-state Processing

(*a*) *Powder blending and consolidation*. Blending of metallic powder with ceramic fibers or particulates is a versatile technique for MMC production. This is usually followed by cold compaction, canning, evacuation, degassing, and a high-temperature consolidation stage such as hot isostatic pressing (HIPing) or extrusion. Achieving a homogeneous mixture can be difficult, particularly with fibers. A feature of much powder route material is the presence of fine oxide particles, usually present in aluminum MMCs in the form of plate-like particles a few tens of nanometers thick, constituting about 0.05–0.5 vol.%, depending on powder history and processing conditions. This fine oxide tends to act as a dispersion-strengthening agent and often has a strong influence on the matrix properties, particularly at high temperature.

MMCs produced by powder blending are commonly *extruded*. This can generate alignment of fibers parallel to the extrusion axis, but often at the expense of progressive *fiber fragmentation*. The degree of fiber fracture decreases with increasing temperature and decreasing local strain rate. Other microstructural features of extruded MMCs include the formation of ceramic-enriched *bands* parallel to the extrusion axis. The mechanism of band formation is still unclear, but it appears to involve the concentration of shear strain in regions where ceramic particles or fibers accumulate. However, extrusion of consolidated MMCs, such as castings, can *reduce* the level of clustering and inhomogeneities in the material. In general, the microstructural changes occurring in MMCs during forming processes are explicable in terms of local temperatures, stresses, and strain rates. Processes such as *rolling* and *forging* involve high deviatoric strains being imposed quickly, and hence can cause damage such as cavitation, particle fracture, and macroscopic cracking, particularly at low temperature. Very high temperatures, and the possibility of matrix liquation, however, can cause macroscopic defects such as *hot tearing* or *hot shortness*. In contrast to these forming processes, HIPing generates no (volume-averaged) deviatoric stresses and so

is unlikely to give rise to either microstructural or macroscopic defects. It is an attractive method for removing residual porosity, which can include surface-connected porosity as long as some form of encapsulation is provided. It has been quite widely applied to MMCs. However, it can be very difficult to remove residual porosity in regions of very high ceramic content, such as within particle clusters, and the absence of any macroscopic shear stresses means that such clusters are not readily dispersed during HIPing. Furthermore, the oxide skins that normally coat powder particles of aluminum or magnesium are usually left intact by HIPing, leading to poor interparticle bonding.

(*b*) *Diffusion bonding of foils*. Monofilament-reinforced MMCs are mainly produced by the foil–fiber–foil (diffusion bonding) route or by the evaporation of relatively thick layers of matrix material onto the surface of the fiber (see Sect.2.3(a)). Work in this area is very much oriented towards titanium and titanium-based matrices. Fortunately, titanium diffusion bonds to itself very readily, mainly because it dissolves its own surface oxide layer at elevated temperatures in controlled atmospheres. Titanium reinforced with long fibers is commercially produced by the placement of arrays of fibers between thin metallic foils, often involving a *filament winding* operation, followed by *hot pressing*. One of the main problems lies in avoiding excessive chemical reaction at the fiber/metal interface. Additions of aluminum, molybdenum, or vanadium slow the kinetics of interfacial reaction, but also tend to make the rolling of thin foils more difficult. There is interest in *fiber coatings* designed to reduce these problems of interfacial attack (see Sect. 1.3). In general, the foil–fiber–foil route is cumbersome and obtaining high fiber volume fractions and homogeneous fiber distributions is difficult unless special techniques are used. Also, the process becomes difficult when the objective is to produce parts of complex shape. Diffusion bonding has also been used to fabricate laminates composed of alternate layers of metal and ceramic.

2.3 Vapor-state Processing

(*a*) *Physical vapor deposition* (*PVD*). All PVD processes are relatively slow, but the fastest is *evaporation*—involving *thermal vaporization* of the target species in a vacuum. An evaporation process used for fabrication of monofilament-reinforced titanium involves passing the fiber through a region having a high vapor pressure of the metal to be deposited, where condensation takes place so as to produce a thick surface coating. The vapor is produced by directing a high-power (~ 10 kW) electron beam onto the end of a solid bar feedstock. Alloy composition can be tailored, since differences in evaporation
Figure 3
Structures of metallic foams produced by a melt route. Two cell structures are shown, corresponding to the same production conditions except that the SiC particulate content is (a) 10 wt.% and (b) 20 wt.%. (c) Microstructure of a cell wall for a 20 wt.% SiC_p case (Gergely *et al.* 2000).

rate between different solutes become compensated for by changes in composition of the molten pool formed on the end of the bar, until a steady state is reached in which the alloy content of the deposit is the same as that of the feedstock. A further point worth noting is that there is little or no mechanical disturbance of the interfacial region; this may be of significance when the fibers have a diffusion barrier

layer, or a tailored surface chemistry. Typical deposition rates are $\sim 5\text{--}10\,\mu\text{m}\,\text{min}^{-1}$. Composite fabrication is usually completed by assembling the coated fibers into a bundle and consolidating this in a hot pressing or HIPing operation. A very uniform distribution of fibers is produced in this way, with fiber contents of up to about 80%. A typical coated fiber and consolidated titanium composite are shown in Fig. 4. The fiber volume fraction can be accurately controlled via the thickness of the deposited coatings and the fiber distribution is always very homogeneous.

3. Summary

MMCs represent a wide range of materials, which includes cermets and metallic foams, as well as more conventional particle- and fiber-reinforced metals. Techniques employed for production of MMC material and components depend on the types of matrix and reinforcement concerned; these are classified according to whether the matrix is in the liquid, solid, or gaseous state when it is combined with the reinforcement. Each of these processing routes has advantages and disadvantages. In particular, some
Figure 4
(a) SiC monofilament with a 35 μm vapor-deposited layer of Ti–5Al–5V and (b) Ti–5Al–5V/80 vol.% SiC composite produced by HIPing of a bundle of monofilaments with 8 μm thick coatings (Ward-Close and Partridge 1990).

are far more expensive than others. The lowest cost routes are generally those in which particle-reinforced aluminum is produced using liquid metal handling—particularly stir casting. Material produced in this way represents a substantial proportion of the MMCs in commercial use. Other materials and processes have, however, also gained in importance. For example, melt infiltration techniques are used to produce components for automotive engine and electronic substrate applications and powder processes are employed for aerospace applications. It is likely that, as MMC applications continue to expand, the range of materials and processes employed will remain relatively wide.

Metallic Filaments

Thin wires or "filaments" of metal, by definition of diameter below about half a millimeter, have been used for many years in a variety of applications. Besides many well-established applications, such as tungsten filaments in the production of electric lightbulbs or thin wires used in electronics, thin metallic wires or filaments also represent a particular class of continuous high-strength fibers that can be used as reinforcements in composite materials. This article gives a short overview on the production methods, the particular properties, and some typical applications of thin wires and metallic filaments.

1. Drawn Wires and Filaments

Metallic filaments of submillimetric dimensions are produced by various techniques. The most frequently used method is the classical wire drawing technique (Mielnik 1991), in which wires are successively pulled through thinner and thinner dies (Fig. 1). Clearly this technique works best with ductile metals such as copper. Less ductile metals have to be drawn at elevated temperature. Metals with a high work
Figure 1
Drawing in a multiple-die machine. The drawing speeds *v* increase after each diameter reduction and must be closely controlled or slippage must be allowed to guarantee continuity. Drawing speeds of up to several meters per second are common.

hardening rate need more frequent annealing steps in this multistage process.

Wires are typically drawn with a drawing force that corresponds to 60% of their ultimate tensile strength. This force equals the sum of the plastic deformation force and the force needed to overcome friction in the die. For a given diameter reduction, the friction is larger than the deformation force in dies with low opening angles, whereas in dies of larger opening angles the deformation force becomes dominant. The minimum drawing force, which also depends on the metal to be drawn, its state of work hardening, and the lubricant used, occurs when the total opening angle 2α of the die is in the range $10-20°$. With an appropriately designed die such forces allow a reduction of the cross-section of 20–40% per die for ductile metals and 10–20% for less ductile ones. Bonding wires for applications in electronics, made of pure gold, copper, and aluminum, with diameters from 20 to 50 μm, are typically produced from a wire of 1 mm initial diameter. Consequently they need about 30–40 steps before they reach their final dimensions. For less ductile metals this number easily doubles. Further reductions of the diameter down to a few microns is still possible with this technique but practical and fundamental limits of this process rapidly become important. Due to the relative increase of the wire surface area, friction becomes more and more important with respect to the drawing force and, consequently, imposes smaller diameter reductions per step. Finally, towards the smallest diameters, safely manipulating wires of the thickness of spider silk and having a breaking load of less than 1 g becomes the dominant problem.

Since diamond has the highest resistance to abrasion, dies of natural monocrystalline or synthetic polycrystalline diamonds are the preferred tools for the production of fine and ultrafine wires. In order to limit the consumption of diamonds, used dies are reshaped and reinserted in a preceding step. Dies made of tungsten carbide and other hard metals are mainly used for wires and rods of larger diameters.

Practically all steels can be drawn to thin wires. For applications where high tensile strength is demanded, plain carbon steels with 0.5–0.9% carbon are well suited. The strength of steel wires is mainly controlled by the steel carbon content and its microstructure, which in turn can be modified by heat treatments and the work hardening that occurs during the drawing process. Typically hot rolled rods are cooled by forced air at a much lower cooling rate $(5-30\,°Cs^{-1})$ than by quenching in water. This gives grains of intermediate sizes which give sufficient ductility to allow cold drawing down to the desired diameters. The extreme cold work gives rise to a considerable strain hardening, which raises the tensile strength well beyond the level that could be achieved by quenching. The strongest carbon steel wires (0.9% C), also known as piano wires (used as piano cords), achieve a tensile strength of over 3 GPa by this treatment. Major applications of such steel wires are the reinforcement of tires, and fabrication of stranded cables for flexible force transmission, cable cars, and suspension bridges. In order to get improved corrosion resistance, stainless steel wires are used. They often have a low carbon content, which results in a lower tensile strength but higher ductility. Since work hardening is as effective in stainless steels as in carbon steels, appreciable tensile strengths can also be achieved. In some high alloy steels the ultimate tensile strength can be further increased after drawing by precipitation hardening. Stainless steel wires with diameters as low as 10 μm are commercially available. A major application of thin stainless steel wires is in the fabrication of sieves.

Bonding wires are typically made from high-purity gold. More recently pure copper and aluminum–1% silicon have become also competitive substitutes. Very small amounts of other metals may be added to modify their mechanical performance. These wires are used to electrically connect integrated circuits on silicon chips to the metallic pins and are selected according to the bond strength that results following thermal compression or ultrasonic compression bonding on the metallized silicon surface and the pins.

Bonding wires, as well as wires made from other ductile metals, which are submitted to substantial reductions of their cross-section without intermediate recrystallization annealings, often develop extremely strong textures. Drawn gold and copper wires that have undergone a diameter reduction from 2 mm to 50 μm without intermediate and final heat treatment, for instance, develop an almost perfect (100)-texture (100) axis parallel to the drawing direction. In this state their Young's modulus along the wire axis approaches the modulus measured along the (100)-direction in a single crystal. For copper this gives an observed modulus of the textured wire of 65 GPa whereas the modulus $E(100)$ for a single crystal is 60 GPa and the isotropic modulus in a polycrystal amounts to 120 GPa.

The use of fine tungsten filaments in incandescent lamps is an application that dates back to the nineteenth century. Tungsten has important advantages over filaments made of carbon or other metals. It not only has the highest melting point, but also the lowest vapor pressure of all metals. Moreover its mechanical strength even at high temperatures remains satisfactory and its emissivity in the visible part of the spectrum is particularly favorable. Tungsten wires are produced from sintered ingots of tungsten powder containing grain growth inhibitors. These ingots are first swaged and then drawn to the desired diameter. The diameter and length of the filaments operating at a given temperature depends on the electrical tension and the desired power of the lamp. For a standard

lamp (220 V and 100 W) filaments of about 50 μm diameter and 1 m length are needed. In order to accommodate this length in a bulb of usual size the filaments are doubly coiled, first on small mandrel (0.1 mm) and then on bigger one (0.5 mm). Over the years many metallurgical studies have contributed to improve the lifetime of tungsten lamps. The major problems are grain growth in the hot filaments, which may lead to the so-called bamboo structure and evaporation. Since tungsten filaments are operated near or above 2000 °C and the recrystallization temperature is only about 1200 °C, grain growth, which makes the filaments extremely brittle, must be prevented. By adding 1–2% of a very fine powder of ThO_2 or by doping with small amounts (few ppm) of alumina or potassium silicate, followed by intense deformation, it is possible to produce a tungsten in which the small and elongated grains typical of drawn wires remain stable. The problem of evaporation has no metallurgical solution. It is tackled by filling the bulb with argon (about 0.8 atm) or, as in halogen lamps, by employing a regenerative chemical cycle inside the glass that redeposits the evaporated tungsten on the filament.

2. The Wollastone Technique

This method is particularly useful to draw wires of a few microns diameter or to draw brittle metals. The metal to be drawn is tightly packed in a tube made of a ductile metal. Both metals are then drawn by the conventional drawing technique until the desired reduction is achieved. To get the fine wire the surrounding metal is removed chemically. In several important cases, however, this separation is not necessary since the resulting composite forms the desired end-product. In particular, this is the standard method to produce superconducting wires as well as thermocouples and heating wires with metallic sleeves. For example, most of the technically interesting superconducting alloys, e.g., NbTi and Nb_3Sn, are extremely brittle and cannot be drawn directly to form very thin wires, whereas when packed in a copper or brass rod drawing becomes possible. For reasons related to the stability of the superconducting state such conductors are usually formed by hundreds or thousands of individual filaments embedded in the matrix, rather than by one single wire.

Coaxial thermocouples and heating wires are produced by the same technique. In order to isolate electrically the external sleeve from the inner wires, very fine powders of oxides (e.g., MgO) are packed in the initial rod before drawing. Compared to an electrical insulation made from sintered ceramic capillaries and tubes the coaxial wires and couples have the advantage of remaining flexible.

3. The Taylor Method

This drawing technique takes advantage of the ease of production of glass fibers by drawing from the molten end of a solid glass bar. The Taylor technique (Nixdorf 1970) uses the same method on glass tubes containing a core of the molten metal to be formed. By selecting a glass with a softening temperature in the vicinity of the melting temperature of the metal to be formed in a filament, the enclosed liquid metal will follow with practically no friction to the imposed cross-section reduction of the continuously deforming glass tube. Clearly, there must be good chemical compatibility between the glass and the metal. Finally, the capillary sheet surrounding the metallic filament has to be removed; this can be achieved using HF for noble metals and stainless steel, or alternatively molten alkaline salts, which also dissolve glasses of any composition and show little reaction with many metals. The Taylor method can be used to produce wires of many common metals and alloys down to 1 μm.

4. Metallic Filaments Directly Produced from the Melt

It is quite easy to produce a cylindrical jet of liquid metals. Unfortunately, the combination of high surface tension and low viscosity in liquid metals leads to a rapid disintegration into small droplets (Rayleigh instability). To produce thin wires directly from the melt, the liquid metal therefore has to be cooled and solidified within a very short distance (< 1 cm) from the orifice. This is the principle used in the melt spinning method (cooling on a solid substrate) and the in-rotating-water spinning technique (liquid quenching medium).

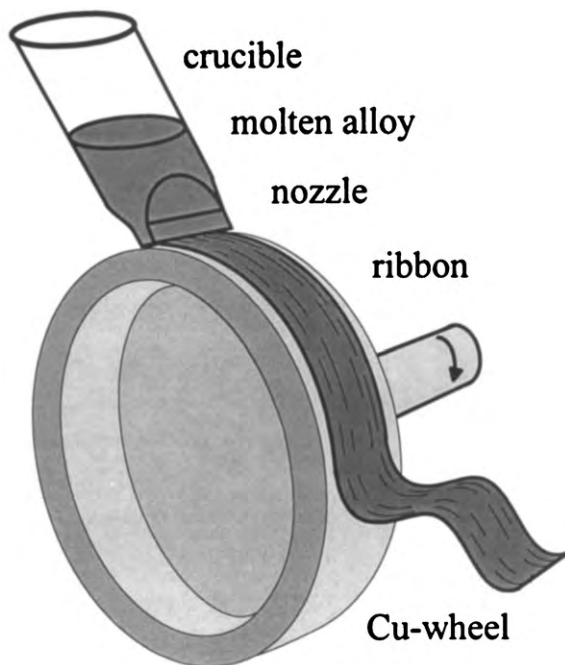
The meltspinning technique (Cahn 1983) is mainly used to produce 20–60 μm thick ribbons of glassy metals. A typical melt spinning apparatus consists of a rotating wheel, an induction heater and a crucible with a round or rectangular nozzle at its bottom (Fig. 2). The width of the nozzle essentially defines the width of the ribbon to be produced. The distance between the nozzle and the wheel surface is often adjusted in such a manner that a sessile drop forms between the moving wheel and the orifice. After the metal is molten, the wheel is set into rotation to a surface velocity of about 30 m s^{-1} (110 km h^{-1}) and the liquid metal is ejected through the orifice by slightly raising the pressure inside the crucible. The liquid puddle that forms on the wheel surface immediately starts to cool and a solidification front moves into the droplet. Since the solidified metal, which forms the ribbon, moves with the wheel this front remains spatially stationary. The ribbon then remains in contact with the wheel until it detaches after about 10 cm. This method has been used to produce ribbons


Figure 2
Melt spinning apparatus.

and fibers of amorphous alloys of many different compositions (e.g., $Fe_{80}B_{20}$, $Pd_{80}Si_{20}$, $Fe_{40}Ni_{40}B_{20}$).

Several amorphous alloys are nowadays industrially produced by this method for magnetic and mechanical applications. By machining equally spaced transversal grooves of about 1 mm depth on the wheel, fibers of a fixed length can also be produced. Some fibers made from iron-based alloys may have a tensile strength of over 3 GPa; these have been used to reinforce concrete. Ribbons and fibers produced by this technique unfortunately often have serrated edges and mold-like impressions, which stem from air turbulence and air inclusions between the wheel surface and the liquid metal. Such surface defects reduce the intrinsically high tensile strength of the amorphous metals, which is why melt spinning is often practiced in a vacuum to reduce or eliminate these defects.

Improved surface quality and circular wire cross-sections can be achieved by quenching the jet of molten metal into a liquid medium. The "in rotating water technique" uses water that is kept within a groove on the inner surface of a hollow rotating wheel Hagiwara *et al.* (1982). Contrary to melt spinning, the major problem with this technique is that it is very intolerant to even small variations of many casting parameters such as angle of jet incidence, or absolute and relative velocities of the rotating water and jet.

5. Quantum Wires

The progressive miniaturization of electronic devices also calls for thinner and thinner conductors. Submicron filaments can be produced by optical, x-ray, and electronic lithography. Such filaments, however, cannot be handled without the substrate on which they have been produced. The production of even smaller filaments, the so-called quantum wires, is presently a field of intense research. Their name stems from the fact that due to their small diameter, quantum mechanical effects in the electronic transport properties become important. In order to reach this limit their lateral dimension should be no greater than a few atomic diameters (<50). Presently such filaments have been produced by field evaporation of silver from the tip of a scanning tunneling microscope.

6. Conclusion

Drawing of wires and rods is an ancient technology. Its origin dates back to 3000 BC in the Middle East (Blake-Coleman 1992). Continuous drawing machines came along with the Industrial Revolution and were subsequently developed to near perfection. Nowadays the drawing of wires is clearly the most important manufacturing process for metallic filaments. The Wollastone technique allows the production of composite wires that could hardly be made by other techniques. The Taylor method has so far gained little or no industrial importance. The use of the melt spinning technique for the production of amorphous metallic filaments is more recent but has reached industrial scale. Due to their excellent mechanical properties, metallic filaments have a good potential for use as reinforcement fibers in composites for applications in which the relatively high density of metals carries little, or no, penalty.

Mineral-filled Polymers

Particulate-filled polymers are widely used in many fields of application. With the exception of poly(vinyl chloride) (PVC) it is mostly technological reasons that justify the introduction of fillers, since a separate compounding step increases considerably the price of the composite. The combination of a filler with a polymer results in a new material with changed properties. Some of these changes are advantageous (improved stiffness, higher heat deflection temperature, better heat conductivity) while others are less favorable (decreased deformability and impact toughness, wear of the processing equipment). In this article a brief account is given of the most important fillers used in plastics, the method of incorporation, and the factors influencing the properties of the composites; finally, some areas are mentioned where mineral filled polymers are used in considerable quantities.

1. Fillers

The most important particulate fillers are described below; more detailed information can be found in Katz and Milewski (1978), Wypych (1999), and Rothon (1995).

1.1 Calcium Carbonate

The application of $CaCO_3$ in polymers is 10-fold greater than the use of any other filler. This mineral exists in three crystalline modifications—calcite, aragonite, and vaterite—but only calcite has practical importance. It can be found in large quantities all over the world, but minerals mined at different locations differ considerably in purity, size of the crystals, and origin, which all influence their use as fillers. Calcium carbonate is also prepared via synthetic routes; however, the price of precipitated $CaCO_3$ is considerably higher than that of the ground mineral, and thus it can be used only in special applications.

1.2 Talc

The chemical composition of pure talc is $Mg_3(Si_4O_{10})(OH)_2$; it is a secondary metamorphic mineral. The filler consists of platelets in which the layers of the particles are bonded only by secondary van der Waals forces. Cleavage takes place very easily under the conditions of usual thermoplastic processing technologies. Talc is the softest mineral with a Mohs hardness of 1. Its surface is rather hydrophobic; active hydroxy groups can be found only on broken edges and surfaces, thus the surface treatment of the filler is difficult. It reinforces polymers due to its platelet-like geometry and has a strong nucleation effect in some crystalline polymers, further increasing its stiffening effect.

1.3 Glass Fiber

Short glass fibers represent a transition between anisotropic mineral fillers and long fiber reinforcements. They are introduced mostly into engineering thermoplastics, but considerable quantities are used also in polypropylene (PP) and in sheet molding compounds. Short carbon-fiber reinforced composites have also appeared on the market. The proper surface treatment of the fiber is crucial in all fiber-reinforced composites.

1.4 Other Fillers

Kaolin is used in various forms in polymers (china clay, calcined clay). The anisotropic particle geometry of wollastonite and mica reinforces the polymer. Barite-filled polymers, mostly PP, have excellent vibration-damping properties due to the high density of this filler. Wood flour and natural fibers (flax, hemp, jute, sisal, etc.) are applied in increasing quantities, mostly in composites for the automotive industry. The water absorption of these fillers creates problems in processing and application. Increasing interest is being shown in layered silicates, mostly in montmorillonite. The nanocomposites prepared from these minerals possess unique properties at reduced filler content. The main characteristics of some mineral fillers are listed in Table 1 (see also *Clay-based Polymer Nanocomposites**).

2. Compounding

The polymer and the filler must be homogenized prior to the manufacture of a product, since insufficient homogenization leads to aggregation. Aggregates cause surface blemishes and affect adversely all the properties, especially impact strength, because they initiate cracks under external loading (see *Polymer Melt Mixing: Agglemarate Dispersion**).

Compounding is mostly done in twin screw extruders in a continuous operation, with high productivity and flexibility. The machine configuration and processing conditions can be adjusted according to the properties of the processed material. High shear must be used for the homogenization of particulate-filled polymers to avoid aggregation, but low shear and intensive mixing is preferred in the case of shear-sensitive polymers (e.g., PVC) and fillers (e.g., starch), as well as glass fibers. The attrition of fibers leads to the loss of their reinforcing effect and generally to the deterioration of composite properties.

3. Factors Influencing the Properties of Filled Polymers

The properties of mineral-filled polymers are determined by the characteristics of the components,

Table 1
Composition and properties of particulate fillers.

Filler	Composition	Density $(g\,cm^{-3})$	Mohs hardness	Shape
Calcium carbonate	$CaCO_3$	2.7	3	sphere
Talc	$Mg_3(Si_4O_{10})(OH)_2$	2.8	1	plate
Kaolin	$Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$	2.6	2.5–3.0	plate
Wollastonite	$CaSiO_3$	2.9	4.5	needle
Mica	$KM(AlSi_3O_{10})(OH)_2$	2.8	2.0–2.5	plate
Barite	$BaSO_4$	4.5	3.5	plate

composition, interfacial interactions, and structure. All four factors can vary in a wide range, thus allowing the preparation of tailor-made composites.

3.1 Component Properties

Important properties of the matrix polymer are its chemical composition and melt viscosity. The first determines the strength of interaction with a non-treated filler, while the second influences the shear stresses developing during homogenization. The extent of aggregation, as well as the smallest particle size that can be used in a polymer, are determined by the relative magnitude of adhesion and shear forces acting in the melt during homogenization (Pukánszky and Fekete 1999). The mechanical properties of the matrix polymer strongly influence the micromechanical deformation processes taking place under the effect of external load. Large stresses develop in a stiff matrix, and the dominating deformation mechanism is usually debonding. In such cases yield stress and strength decrease with increasing filler content (Fig. 1). In a softer polymer (e.g., low-density polyethylene (LDPE)) the introduction of the same filler results in true reinforcement, with yield stress and strength increasing with increasing amount of filler.

Numerous filler characteristics influence the properties of the composites. Chemical composition and purity affect color and stability. However, mechanical properties and performance are determined mainly by particle size, particle size distribution, specific surface area, and shape. An optimum particle size exists for each polymer and processing technique. Large particles debond easily from the matrix under loading, while small particles tend to aggregate; both processes weaken the composite properties significantly. The specific surface area determines the contact surface between the filler and the polymer and thus the amount of interphase formed. The surface free energy (surface tension), hardness, and thermal properties of the filler also influence the production or application of mineral-filled polymer composite parts.
Figure 1
Effect of matrix properties on the reinforcing effect of a particulate filler ($CaCO_3$, 3.6 μm): ○ LDPE; △ PP; □ PVC.

3.2 Composition

The stiffness of the composite increases, while its price often decreases, with increasing filler content; therefore, significant effort is concentrated on the introduction of the highest possible filler loadings into the polymer. Since other properties deteriorate at the same time, a composition must be found where the combination of all properties is optimized.

It is generally held that tensile yield stress and tensile strength decrease with increasing filler content when fillers of nearly spherical shape are used. The composition dependence of these properties is also strongly influenced by particle characteristics. As Fig. 1 shows, true reinforcement can be achieved with fillers in a soft polymer, and if the particle size is sufficiently reduced the same effect is observed in PP (see Fig. 2) and also in PVC (Pukánszky 1995). The effect of anisotropic fillers depends on the orientation of the particles. Deformability, yield strain,
Figure 2
Effect of particle size on the tensile yield stress of PP composites. Particle diameter: ○ 0.01 μm; △ 0.08 μm; □ 3.3 μm; ▽ 58 μm.

and elongation-at-break always decrease with increasing filler content. Impact toughness often exhibits a maximum at a certain filler content, which depends on the characteristics of the filler and on interfacial interactions (Pukánszky and Maurer 1995). The maximum is a consequence of several competitive effects; the debonding of the filler during deformation leads to energy consumption, while increasing filler loading leads to increased stiffness and decreased impact toughness. Most other properties (heat conductivity, heat deflection temperature, hardness) are more or less proportional to the filler content of the composite.

3.3 Interfacial Interaction

This factor strongly influences the properties of polymer composites. Although it is mostly weak van der Waals forces that act between the polymer and the filler in thermoplastics, they are sufficiently strong to bond the two components. The adsorption of the polymer on to the filler surface leads to the formation of an interphase region in which molecules have decreased mobility. The effect of interaction depends on the size of the contact surfaces (specific surface area of the filler) and the strength of the interaction. Smaller particles have a larger surface area leading to increased yield stress (Fig. 2).

To modify interfacial interactions four types of methods are frequently used. *Nonreactive treatment* (surfactants) leads to a decrease in particle–particle and matrix–filler interaction. The latter results in decreased strength and increased deformability, and occasionally to increased impact resistance, while the

former leads to improved processability, homogeneity, and appearance. *Reactive treatment* (coupling), which assumes covalent coupling of both components, is difficult in most thermoplastics due to the lack of reactive groups on the polymer. Reactive coupling is easier in thermoset matrices. The introduction of *functionalized polymers* into the composite was shown to improve adhesion and increase yield stress as well as tensile strength in the case of various fillers, from CaCO$_3$ through wood flour and magnesium hydroxide to glass fibers (Fig. 3) (Felix and Gatenholm 1993). This technology is used mostly in polyolefins, and especially in PP, but occasionally also in other polymers. The fourth method of modification involves multicomponent polymer systems containing a filler and two polymers. In these systems a special morphology may form in which one of the polymer components encapsulates the filler. Such a structure is accompanied by significantly modified interaction and properties (Pukánszky 1995).

3.4 Structure

Particulate-filled polymers are believed to have a simple structure consisting of uniformly dispersed particles in a homogeneous matrix. Two important structural phenomena must always be kept in mind when filled polymers are prepared and applied. Small particles tend to form aggregates which weaken the properties. Above a certain specific surface area the aggregation tendency of spherical nontreated fillers

becomes significant. This critical surface area depends on several factors including the viscosity of the polymer, characteristics of the filler, processing technology, etc. The orientation of the anisotropic particles determines their reinforcing effect.

4. Application

Large amounts of $CaCO_3$ are used in PVC, both in plasticized (cable, flooring) and rigid (pipes, fittings, profiles) products. Although at a much lower level, $CaCO_3$ and also talc are often introduced into PP. Such composites are used in the automotive industry as bumpers, air-filter covers, or heater boxes, and as household articles. Artificial paper and breathable films are prepared from HDPE containing considerable amounts of $CaCO_3$. Sheet and bulk molding compounds represent the most important application in thermosets, and products prepared from them are used in construction, automotives, etc. The new class of mineral-filled polymers, nanocomposites, may be used mainly in structural applications. These composites possess improved mechanical properties, decreased gas permeation, and flame-retardation and the enhanced properties are accompanied by considerable weight savings.

5. Summary

The use of mineral fillers increases continuously. The incorporation of the filler into the polymer results in new materials. The properties of these composites are determined by the characteristics of the components, composition, interfacial interaction, and structure. The last factor is often neglected during the development of mineral-filled polymers, although both aggregation and orientation of anisotropic filler particles affect strongly the composite properties.

Mineral-filled polymers are used in a wide range of applications, mostly in fields where increased stiffness and heat resistance are required. Although $CaCO_3$, talc, and glass fibers are used in the largest quantities, new fillers (natural fibers) and novel composites (nanocomposites) are also gaining increasing importance in this field.

Nanoscale Ceramic Composites

A new class of structural ceramic materials with superior mechanical properties is currently being developed. These materials are known as "ceramic nanocomposites" and are produced by combining a structural ceramic matrix, such as Al_2O_3, ZrO_2, or Si_3N_4 with a nano-sized second phase. The second phases typically used are "nanoparticles" which are 300 nm or less in size and added in quantities between 1 vol.% and 30 vol.% (Todd 1995). Ceramic nanocomposites have been reported to possess both room- and high-temperature properties which are greatly superior to those of the monolithic matrix in a variety of material systems, indicating that a "structural synergism" occurs between the matrix and second phase in these systems (Niihara and Nakahira 1988, Ding et al. 1993, Pezzotti and Sakai 1994). In this article, the development of the most widely studied ceramic nanocomposite, Al_2O_3–SiC, will be discussed. In particular, the processing steps required to fabricate Al_2O_3–SiC nanocomposites and a review of their microstructures will be given. Most importantly, the improvements in mechanical properties over monolithic Al_2O_3 will be presented, and the possible mechanisms responsible for these improvements will be discussed.

1. Processing and Microstructure of Al_2O_3–SiC Nanocomposites

Al_2O_3–SiC nanocomposites are produced using standard ceramic processing techniques. Matrix and second-phase powders are typically comilled in an organic medium to achieve a uniform dispersion of second phase throughout the matrix. After milling, the nanocomposite powder is dried and then densified using pressureless sintering or hot pressing. Relative to that of monolithic Al_2O_3, densification in the nanocomposite is strongly inhibited by the presence of particles on grain boundaries, which reduce the rate of grain-boundary diffusion. As a result, the sintering conditions necessary to achieve full densification are strongly dependent on the amount of second phase, with the sintering temperature increasing significantly with the second-phase volume fraction. While monolithic Al_2O_3 can be pressureless sintered to near-theoretical density at 1400 °C, a temperature of 1775 °C is necessary for full densification in a nanocomposite of Al_2O_3 containing 5 vol.% SiC (Stearns et al. 1992). In fact, no study has shown that full density can be achieved using pressureless sintering in a nanocomposite containing more than 5 vol.% SiC. The difficulties of densification in the nanocomposite can be alleviated by hot pressing. During hot pressing, an applied pressure increases the driving force for densification, allowing dense nanocomposites to be manufactured at lower temperatures (e.g., 1500 °C for 5 vol.% SiC) and with higher volume fractions of second phase (e.g., 20 vol.% SiC at a temperature of 1675 °C) (Stearns and Harmer 1996).

The processing steps used to produce nanocomposites have a significant effect on their microstructures and properties. It is well known that the properties of the nanocomposite are strongly dependent on the second-phase dispersion (Stearns et al. 1992). Specifically, a uniform dispersion of second phase is critical to obtaining superior properties in the nanocomposite relative to the monolith. Unfortunately, the spatial distribution of the second phase has been shown to be very sensitive to the processing conditions used, indicating that small changes in processing can lead to significant differences in the properties of the nanocomposite.

The microstructures of nanocomposites produced using the above technique are also strongly dependent on the amount of second phase present. In nanocomposites with a high volume fraction of second phase (> 5 vol.%), matrix grains are equiaxed with a narrow size distribution, and second-phase particles are uniformly distributed among the matrix grains. An example of this type of microstructure (5 vol.% SiC in Al_2O_3) can be seen in Fig. 1. On the contrary, in samples with a low volume fraction of second phase, the grain-size distribution of matrix grains may be significantly wider and in extreme cases, abnormal grains may be present.
Figure 1
Scanning-electron-microscope image of the microstructure of a Al_2O_3–5 vol.% SiC nanocomposite showing the presence of both intergranular and intragranular particles.
Figure 2
Scanning-electron-microscope image of SiC particles
(5 vol.%) inhibiting grain growth by pinning migrating
Al_2O_3 grain boundaries.

As shown in Fig. 1, second-phase particles in the
nanocomposite are either located on grain bounda-
ries (intergranular) or inside grains (intragranular).
As will be discussed later, the location of particles
with respect to grain boundaries plays the paramount
role in the improvement of the properties of the
nanocomposite over the monolith (Xu *et al.* 1997). In
particular, intragranular particles are believed to
be responsible for the superior room-temperature
properties of the nanocomposite, while the intergran-
ular particles are believed to be responsible for its
superior high-temperature properties. Intergranular
particles also significantly increase the microstruc-
tural stability of the nanocomposite. The interaction
of particles with grain boundaries strongly inhibits
matrix grain growth which would normally take
place at high temperatures. Figure 2 shows SiC
particles inhibiting grain growth in the nanocompos-
ite by pinning migrating grain boundaries. The
relative proportions of intra- and intergranular par-
ticles is strongly related to the matrix grain size in the
Al_2O_3–SiC system, with the percentage of intergran-
ular particles decreasing significantly with the grain
size. For example, approximately 70% of particles
are expected to be intergranular for a grain size of
$1\,\mu m$, whereas 25% of particles are expected to be
intergranular for a grain size of $5\,\mu m$ (Stearns and
Harmer 1996).

2. Room-temperature Properties of Al_2O_3–SiC Nanocomposites

The superior mechanical properties of Al_2O_3–SiC
nanocomposites at room temperature were first

shown by Niihara, who found that the addition of
5 vol.% of 300 nm SiC particles to Al_2O_3 increased
the strength from 380 MPa to 1100 MPa (Niihara
and Nakahira 1988). Furthermore, it was shown that
a simple annealing treatment at 1300 °C for 1 hour
in argon gas subsequently increased the strength of
the nanocomposites to over 1500 MPa. Niihara re-
ported that the addition of the SiC particles also re-
sulted in a significant increase in the fracture
toughness, from $3.8\,MPam^{1/2}$ to $4.7\,MPam^{1/2}$. The
superior properties of Al_2O_3–SiC nanocomposites
over monolithic Al_2O_3 have been confirmed by a
number of researchers, although none of these im-
provements have been as dramatic as those reported
by Niihara (Zhao *et al.* 1993, Borsa *et al.* 1995, Jang
et al. 1996).

While the superior properties of the nanocompos-
ite are well documented, the mechanisms responsible
for the improvement in properties are still unclear.
Proposed strengthening and toughening mechanisms
for the unannealed nanocomposite include the re-
duction in critical flaw size due to the development of
intragranular particle-induced subgrain boundaries,
the attraction of intergranular cracks into matrix
grains by residual tensile hoop stresses which arise
due to the large thermal-expansion mismatch be-
tween Al_2O_3 and SiC, and the formation of a surface
layer of compressive stresses during machining. The
subsequent increase in strength and toughness after
annealing has been attributed to the healing of sur-
face flaws and the retainment of machining-induced
compressive surface stresses, both the result of a
slower stress relaxation behavior in the nanocom-
posite (Thompson *et al.* 1995).

In addition to having improved strength and
toughness relative to monolithic Al_2O_3, Al_2O_3–SiC
nanocomposites also have superior wear properties.
The improved wear properties are the result of
a change in fracture mode which occurs when the
concentration of the SiC second phase is greater
than $\sim 4\,vol.\%$. While monolithic Al_2O_3 exhibits
predominantly intergranular fracture, the large ther-
mal-expansion mismatch between Al_2O_3 and SiC re-
sults in an apparent strengthening of Al_2O_3 grain
boundaries, causing the nanocomposite to fracture
transgranularly. As a result, grains in Al_2O_3–SiC
nanocomposites are worn away slowly, in contrast to
monolithic Al_2O_3 where wear typically involves the
removal of entire grains due to the relatively weak
interface at grain boundaries. The effect of the
change in fracture mode on the wear properties of
the nanocomposite is dramatic. In one study, the wet
erosive wear rate of a 5 vol.% SiC nanocomposite
was measured to be one-third that of monolithic
Al_2O_3 with the same grain size (Walker *et al.* 1994).
Furthermore, the lack of grain pullout in the nano-
composite allows a higher-quality surface finish to be
prepared (and retained during wear) than is possible
with monolithic Al_2O_3.

3. High-temperature Properties of Al_2O_3–SiC Nanocomposites

In addition to its superior room-temperature properties, Al_2O_3–SiC nanocomposite also possesses superior high-temperature properties. The superior strength and toughness of the nanocomposite at room temperature are retained as high as 1000 °C (Niihara and Nakahira 1988). Furthermore, studies have shown that at higher temperatures, the creep resistance of Al_2O_3 is increased significantly by the presence of SiC particles (Ohji *et al.* 1995, Thompson *et al.* 1997). As shown in Fig. 3, the creep rate of Al_2O_3 containing 5 vol.% SiC (150 nm) is 2–3 orders of magnitude lower than that of monolithic Al_2O_3 at temperatures as high as 1300 °C. In addition, the creep life of the nanocomposite is more than an order of magnitude longer than in the monolith. Unfortunately, the failure strain of the nanocomposite is lower than that of Al_2O_3 due to the nucleation of cavities at intergranular particles. The improved creep resistance of Al_2O_3–SiC has been attributed to a number of mechanisms. These mechanisms include a reduction in the rate of grain-boundary diffusion due to the presence of intergranular particles; an inhibition of shape-accommodation processes necessary for creep to occur, such as grain-boundary sliding and migration; and a reduction of the intrinsic grain-boundary diffusivity of Al_2O_3 by silicon cation contamination. The dominant mechanism responsible for the improved creep behavior of the nanocomposite is unknown.
Figure 3
Plot of creep strain rate as a function of temperature for monolithic Al_2O_3 and Al_2O_3–5 vol.% SiC nanocomposites (after Thompson *et al.* 1997).

4. Concluding Remarks

Ceramic nanocomposites are relatively new materials which appear to have promise. In particular, Al_2O_3 containing nano-sized SiC second-phase particles has been shown to possess both room- and high-temperature properties which are superior to monolithic Al_2O_3. These properties, which include higher strength and toughness, increased wear resistance, lower creep rates at elevated temperatures, and excellent microstructural stability, make nanocomposites an attractive alternative to monolithic ceramics for many structural applications.

Natural Cellulose Fibers and Membranes: Biosynthesis

Cellulose is the most abundant organic material in nature. It forms the supporting framework in the cell walls of all plants, it occurs in the tissue of certain animals, and it is deposited extracellularly by some bacteria. Cellulose is a linear homopolymer with l,4-β-glycosidic units in the chains with no known branching or irregularity but of various chain lengths. The biosynthesis of most natural cellulose comprises three steps: synthesis of the cellulose chains, formation of "mini sheets" of parallel chains by hydrophobic bonding, and assembly of the sheets to microfibrils. In some cases the cellulose biosynthesis is incomplete: only sheets or chains are formed and no microfibrils.

1. Crystal Structure and Morphology of Natural Cellulose

The natural cellulose deposited in plant cell walls is predominantly in the form of thin microfibrils (5–10 nm wide) containing parallel chains crystallized in a lattice called Cellulose I (Meyer and Mark 1929). The most stable lattice thermodynamically is Cellulose II, which forms when cellulose is precipitated from solution or recovered after swelling in strong alkali or acid (Rånby 1952). The parallel chain orientation in the Cellulose I microfibrils has been proven by several independent methods (Kuga and Brown 1987). All chains in a microfibril have the same direction.

A minor part of the cellulose in plant cell walls, e.g., in cotton fibers, is found to have Cellulose II lattice with antiparallel chains and occurring together with Cellulose I. Large amounts of Cellulose II is synthesized by mutated bacterial cells of Acetobacter in aberrant cultures and is shown to have folded chains (Kuga *et al.* 1993).

It was discovered by Atalla and Vanderhart (1984), using solid state NMR, that Cellulose I has two allomorphs, 1α and 1β, of which the 1β form is more stable than the 1α form. The two allomorphs occur together in the Cellulose I microfibrils in native plant cellulose. The animal cellulose in Tunicates (mantle animals) is synthesized in almost pure 1β form (Kimura and Itoh 1996).

The cell walls of certain algae, e.g., *Halicystis* spp., contain cellulose in the form of membranes without microfibrillar structure and with the thermodynamically stable Cellulose II lattice. These findings led to the tentative conclusion that the formation of cellulose microfibrils with the metastable Cellulose I lattice is an enzymatic process and not a crystallization of free cellulose chains (Rånby 1952).

The biosynthesis of cellulose is not a simple and straightforward process. It is a complex process with several different enzyme systems involved. A recent review describes the main steps and the known enzymes involved (Brown 1999).

2. Synthesis of Cellulose Chains

The monomeric glucose is formed from carbon dioxide and water by photosynthesis in green plants. By complex enzyme reactions, according to Leloir (1964) (Fig. 1), glucose-1-phosphate (1) is formed. It reacts with uridine triphosphate (2) to uridine diphosphate glucose (UDP-D-glucose) (3) and pyrophosphate (4). The UDP-D-glucose is polymerized by enzymes to cellulose chains, presumably by a stepwise reaction with release of UDP. There is a set of enzymes in plant cells simultaneously giving (1,3) glycosidic chains (callose) and (1,4)-β-chains (cellulose). Kudlicka and Brown (1997) have isolated and identified 12 polypeptides from mung beans (*Vigna radiate*) which are related to the formation of (l,4)-β-glucan chains in the cell walls. With these polypeptides present and separated from five other polypeptides forming (1,3)-glucans, pure (l,4)-β-glucan chains were formed and identified. With Acetobacter cells, corresponding enzymatic synthesis of cellulose chains has been verified.

There is evidence of a different pathway to UDP-D-glucose: sucrose and a sucrose synthase (SuSy) in plant cells react and form UDP-D-glucose (and then cellulose) and fructose according to Amor *et al.* (1995). This direct reaction would explain the fast and efficient cellulose synthesis in the heavy secondary wall of plant fibers.

3. Assembly to Cellulose Microfibrils

The discovery of the enzyme system for cellulose microfibril synthesis is a long story; Preston reported in
Figure 1
Enzymatic formation of the cellulose monomer uridine diphosphate glucose (UDP-D-glucose) (3) from a-D-glucopyranosyl-1-phosphate (1) and uridine triphosphate (2) under simultaneous release of pyrophosphate (4) according to Leloir (1964).

1964 that the cellulose microfibrils in wood fibers are associated with protein particles called "ordered granules" occurring together at the microfibril ends on the cell membrane and assumed to be the enzymes for cellulose synthesis.

In a study by Brown and Montezinos (1976) of the terminal complex (TC) particles, electron microscopic evidence was reported that the TC particles in the *Oocytis* algae were ordered-protein complexes of a linear type. They contain multiparticle protein subunits, associated with the tip of the growing microfibrils. In other organisms studied (mosses, ferns, and green algae) TC particles of both linear and rosette-like structure have been found to be associated with the growing cellulose microfibrils on the surface of the cell membrane (Fig. 2). Isolated intact rosette-like TCs in contact with UDP-glucose are shown to synthesize cellulose microfibrils *in vitro* (Kudlicka and Brown 1997), which strongly supports the view that the TC particles are the cellulose-forming enzymes which assemble microfibrils.

The dimensions of the microfibrils are related to the structure of the rosette-like TCs and their number of subunits. Valonia algae have large TSs with about 10 catalytic sites (=subunits per particle), which synthesize microfibrils with a thickness of about 30 cellulose chains, i.e., about 10 nm. *Vaucheria* algae have only one catalytic site per TC, which produces very thin microfibrils.

For cellulose chains synthesized enzymatically, Cousins and Brown (1995), have reported a second step where the parallel chains form "mini sheets" by hydrophobic bonding. The hydroxyl groups of the cellulose chains are on the sheet surfaces (Fig. 3). The parallel chains are held together in sheets by hydrophobic van der Waals forces. In a third step, the sheets are stacked together by hydrogen bonds and form elementary microfibrils with the Cellulose I lattice (Fig. 4). The specific stacking reaction appears to occur when the cellulose sheets (monomolecular layers) react with a connected complex enzyme system on the cytoplasmic membrane and form elementary cellulose microfibrils. This mechanism has been supported by the observation that the assembly of cellulose chains to microfibrils is prevented by the addition of a hydrogen-bonding compound, Tinopal,
Figure 2

Figure 3
Cellulose chain (a) and monomolecular sheets of chains (mini sheets) held together with van der Waals forces (b) (Brown 1996).

LPW, which absorbs onto the cellulose chains and the "mini sheets" (Cousins and Brown 1997).

It was reported that plant cells of a mutant of Arabidopsis with incomplete rosette-like TC particles on the cell membrane produced single glucan chains, which fold and form Cellulose II lattices (Arioli *et al.* 1998).

4. Sequencing and Cloning of Cellulose-forming Enzymes

The first enzyme in the Cellulose synthase to be identified, sequenced, and cloned to a gene was a polypeptide (83 kDa) from *Acetobacter* (Saxena *et al.* 1990; Saxena *et al.* 1991). The active polypeptide had been purified before and applied for synthesis of 1,4-β-glucans (Lin *et al.* 1990). In later work, the enzymes and genes responsible for the biosynthesis of cellulose in *Acetobacter* and several eukaryotic organisms have been thoroughly studied (Saxena *et al.* 1994; Saxena and Brown 1995; Saxena *et al.* 1995).

Acetobacter forms cellulose microfibrils deposited by extracellular extrusion (Figs. 5 and 6). The active genes have been cloned. Corresponding genes have been found in cotton and rice (Delmer and Amor 1995) and defined as a Cel A homolog for cellulose synthase.

A tentative picture by Saxena (Fig. 5) of a cellulose-synthesizing enzyme complex in *Acetobacter xylinum* gives the main steps in microfibrillar formation (Brown 1996). The monomer UDP-D-glucose is synthesized by ACS AB gene products (= enzymes), the 1,4-β glucan chains by the sites indicated, "mini sheets" of the cellulose chain by the ACS D gene products and the stacking of the sheets to Cellulose I microfibrils by the ACS C gene products. For a mutated *Acetobacter* cell membrane (Fig. 6), with the ACS D gene inactive, the result is separate cellulose chains which are free to fold and give the observed stable Cellulose II lattice (Saxena *et al.* 1994). There is good evidence that the biosynthesis of cellulose in higher plant fibers, which occurs inside the cell wall,
Figure 4
Cellulose microfibril formed by stacking mini sheets of cellulose chains to Cellulose I α lattice (Brown 1996).

is due to the same enzyme system as in *Acetobacter*. Cellulose and various polysaccharides are formed simultaneously in these fibers.

5. *Chemical* in vitro *Synthesis of Cellulose*

Cellulose chains and cellulose microfibrils with Cellulose I lattice have been synthesized *in vitro* by cellulose enzymes. Kobayashi *et al.* (1991) used β-cellobiosyl fluoride and an extracellular cellulose enzyme in a 5:1 acrylonitrile/acetate buffer and obtained cellulose chains which crystallized in the stable Cellulose II lattice (Fig. 7).

In later experiments, Kobayashi *et al.* (1994), in cooperation with Malcolm Brown, used more crude cellulose enzymes in a 2:1 acrylonitrile/acetate buffer

and obtained microfibrillar cellulose with the metastable Cellulose I lattice. These are the first successful attempts of extracellular *in vitro* cellulose synthesis reported. The key is to use the enzymes under optimal conditions.

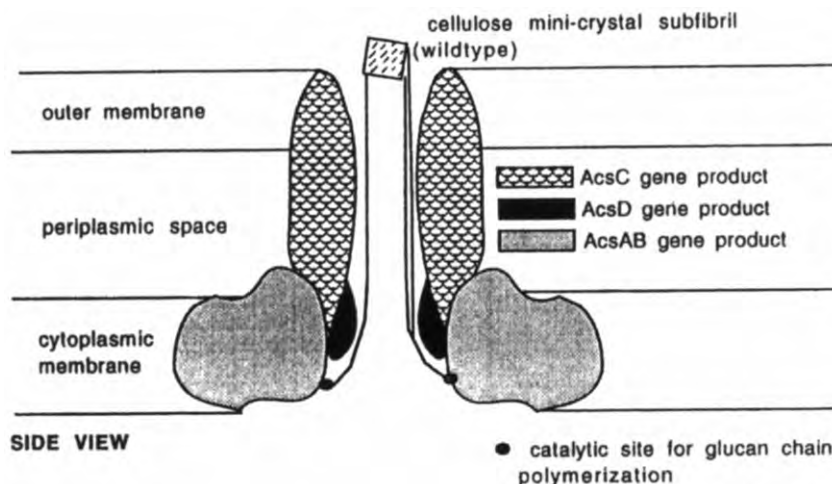
The first successful enzyme-free synthesis of cellulose chains has been reported by (Nakatsubo *et al.* 1996). They used a cationic ring-opening reaction, e.g., of glucose 2-orthopivaoyl 3,6-di-O-benzyl ether dissolved in the N,N′ carbonyldiimidazol of benzene under reflux, followed by treatment in Ph_3CBF_4/CH_2Cl_2 at room temperature. This synthesis has nothing to do with the biosynthesis but it shows an example of interesting possibilities for synthesizing specific polysaccharides and their derivatives using cationic ring-opening reactions.


Figure 5
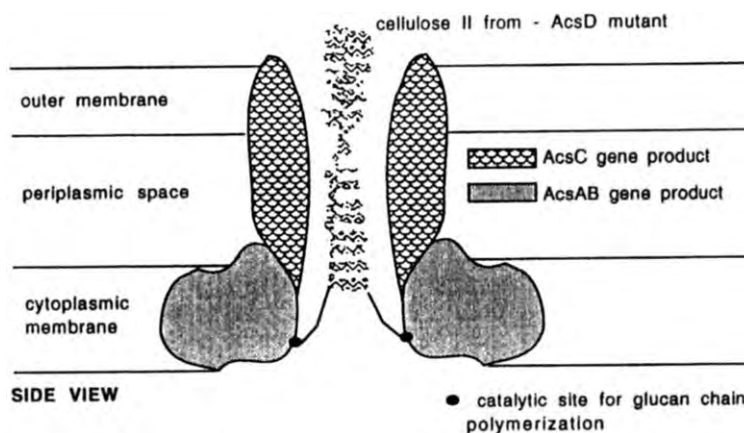
Schematic drawing of extracellular formation of a cellulose microfibril (Cellulose I) by the synthesizing complex of *Acetobacter*.


Figure 6
Corresponding synthesizing complex of a mutant which does not produce the ACS C gene product. The cellulose chains do not form mini sheets and are, therefore, free to fold and crystallize in Cellulose II lattice with antiparallel chains (Brown 1996).
Figure 7
Synthesis of cellulose chains *in vitro* using cellulose enzymes (Kobayashi *et al.* 1996).

6. Conclusions

The crystal structure and the morphology are outlined, describing the predominant microfibrils with Cellulose I lattice and the cellulose membranes crystallizing with the thermodynamically more stable Cellulose II lattice. The biosynthesis of cellulose is described as a three-step process: the synthesis of cellulose chains from the monomer uridine diphosphate glucose (UDP-D-glucose), the formation of monomolecular "mini sheets," and the stacking of the mini sheets to cellulose microfibrils with Cellulose I lattice. The corresponding enzymes are isolated and cloned to genes, which form the cellulose synthase

system in plants, ferns, and mosses, and a few bacteria and primitive animals. The enzyme system forms terminal complex (TC) particles from which the cellulose microfibrils are extruded. Certain algae, e.g., *Halicystis,* and mutated *Acetobacter*, have an incomplete cellulose synthase system and form cellulose chains that are folded and crystallize in the more stable Cellulose II lattice.

Natural Cellulose Fibers: Properties

Cellulose is the main component of the plant cell wall, with a share of 60–90%. At the same time, it is the main strengthening element of this natural composite material. The mechanical properties are quite remarkable: a cellulose filament of 1 mm diameter can hold more than 60 kg in weight—it has 80% of the strength of steel. Mechanical properties for a number of different fibers are given in Table 1.

The cellulose is incorporated into the cell wall in form of thin fibrils, so called *microfibrils* or *elementary fibrils*, with an elaborate substructure (Fig. 1). Their diameter measures 35 Å. The native cellulose is an unbranched polymer of β-1-4-linked glucose residues arranged in linear, antiparallel chains, where every other glucose residue is rotated at approximately 180°. As a result, cellobiose is the structural

Overview over the various levels of organization within plant cell walls (after Niklas 1984).

repeating unit of the glucan chains in cellulose. This is in contrast to other glucan polymers such as starch where glucose is the repeating unit. In the native cellulose microfibril crystalline regions alternate with unordered, amorphous regions. From x-ray diffraction and negative staining with subsequent electron microscopic observation the length of the crystalline regions has been calculated to be 60 nm. Crystalline cellulose can take on two different polymeric structures—the extended-chain configuration (cellulose I) and the folded-chain configuration (cellulose II, Fig. 2). While the former is found in native cellulose and is the thermodynamically more stable form, the latter arises by crystallization from solution, where it is unlikely that the random-coil molecules will extend fully to fit into an extended-chain crystal. The folded-chain configuration can thus be viewed as an energetic compromise. In the plant cell wall cellulose I can form because here the synthesis and crystallite formation take place simultaneously and there is no solution phase (see *Natural Cellulose Fibers and Membranes: Biosynthesis**). Regenerated, technical cellulose such as rayon always has the folded-chain configuration with lower values of modulus and tensile strength than native cellulose. Interestingly, cellulose II forms fibrils of the same diameter as cellulose I. This first led to the conclusion that they would be identical. This caused a lot of confusion as regards the crystal structure of native cellulose.

It is not possible to measure the mechanical properties of native cellulose directly. In the plant cell it is always found together with different matrix substances and upon isolating it loses its native conformation. Thus, theoretical approaches were made to calculate these properties from the molecular structure and the interatomic forces. The resulting values range from 60 GPa (Treloar 1960) to 320 GPa (Gillis 1969). Experimental measurements have been made on cells consisting almost exclusively of cellulose, e.g., ramie fibers. More sophisticated studies have derived the modulus of cellulose from x-ray measurements on strained ramie fiber, where the specific strain of the cellulose fibrils was calculated from changes in the x-ray diffraction angles (Sakurada *et al.* 1962). The experimental values for bast fibers go up to 110 GPa (Meyer and Lotmar 1936). The theoretical values should be higher, since they do not take into account the amorphous regions of the microfibril but only the much stiffer crystallites.
For theoretical calculations different models have been used concerning the accuracy of the employed molecular model and the interatomic forces taken into account. A very comprehensive model has been published by Gillis (1969) and is based on the real 3D anisotropic crystal lattice of cellulose in its native state. The molecular processes occurring upon straining are mainly interchain hydrogen bond deformations and alterations in the valence angle at the bridging oxygen atoms between the monomers. The necessity of these two processes can be derived from the schematic representation of a unit cell depicted in Fig. 3. Straining will align the individual molecular strands and necessarily deform the hydrogen bonds in angle and length together with a change in the valence angle of the bridging oxygen atom. In tension, deformation of the bridging oxygen bond plays the most important role, accounting for about 50% of the deformation. These oxygen bridges also constitute the limiting factor with regards to strength: the multiple interchain hydrogen bonding is so strong that the failure of cellulose fibrils is not due to slipping of adjacent chains but to chain scission.

In the plant cell wall the cellulose microfibrils are embedded in an aqueous medium, which affects their mechanical properties. The water penetrates the amorphous regions and competes for potential hydrogen bonding sites, loosening the interactions between

Figure 2
Polymer configurations: (a) extended-chain (b) folded-chain.
Figure 3
Crystalline unit cell of inextensible glucose residues linked in the chain direction by oxygen atoms and cross-linked by hydrogen bonds (after Gillis 1969).

adjacent crystalline regions. This effects an increase in both extensibility and strength of the fibrils, while the modulus of elasticity is decreased. A counteracting effect to the hydration is exerted by deposition of hydrophobic lignin in the cell wall, which waterproofs it. This opens the possibility of a specific adjustment of the mechanical properties. For bast fibers the difference between wet and dry in the modulus of elasticity amounts roughly to a factor of 3.5. In wood, which is heavily lignified, the factor is about half. A further modification of the cell walls' overall mechanical properties is made on the structural level through orientation of the microfibrils. In cells subjected mainly to tension, such as fiber cells, the fibrils are predominately oriented parallel to the longitudinal axis. Some cells, such as wood cells, also have to cope with tension, with bending, with negative pressure for water transport and with damping of vibration. Here the fiber axes are tilted for a trade-off between these different demands (Booker and Sell 1998).

Natural Protein Fibers

Many of Nature's functional materials are produced as fibers. This geometry allows the covalent bonds in polymer backbones to be aligned optimally along directions where reinforcement is needed. A fibrous morphology is also compatible with the short transport distances needed to expedite the self-assembly of materials from an aqueous environment. Larger cross-sections are self-assembled efficiently by lateral association of adjacent fibers, rather than depending on the growth of a thick monofilament.

Water plays a pivotal role in the biological self-assembly of fibers. It promotes liquid crystallinity and thus supramolecular self-assembly. It can help to maintain the structural and functional integrity of the assembled fibers (e.g., muscle, cytoskeleton, and virus spikes), and it provides a medium in which the biological mechanisms of assembly and self-repair can be effected.

Natural protein fibers include collagen, keratin, silk, mussel byssus, viral spikes, tubulin, and actin. All exhibit hierarchical molecular order. Their properties therefore depend on structure over a range of length scales as well as on the composition of the individual molecules. Hierarchical molecular order promotes both damage resistance and damage tolerance. It also enables a material to be multifunctional because different structural features, at different length scales, can be tailored to optimize different properties. The optimized properties need not all relate to load-bearing ability; they may include responsiveness to electrical stimuli (muscle fibers), to chemical information (insect antennae), or to ambient water (capture threads in spider webs).

1. Background

1.1 Technological Interest in Natural Protein Fibers

Fibrous proteins have been exploited directly for hundreds—in some cases thousands—of years. Examples include silk and wool harvested for textile applications, the use of intestinal collagen to stitch wounds or to "string" instruments of music and sport, and hair serving as the moisture sensor in hygrometers. However, it was late in the twentieth century before materials characterization technology became sufficiently advanced to reveal detailed links between structure and function in these complex materials.

Studies of natural fibers promise a number of potentially useful lessons for materials chemistry and processing. Nature's range of functional materials represents the success stories of up to four billion years of research and development. Nature has optimized supramolecular self-assembly mechanisms, hierarchical microstructures, property combinations, and in-service durability. Nature's fibrous materials are not only damage-tolerant but often self-repairing. They offer the attractions of biosynthesis (they are produced from renewable resources), benign processing conditions (they are assembled and shaped in an aqueous environment and at mild temperatures), and biodegradability (they break down into harmless components when exposed to some specific natural environments).

The techniques of molecular biology can be used to genetically engineer host cells or even multicellular organisms that are capable of synthesizing economic quantities of protein for possible processing into fiber. Proteins that already exist in Nature, as well as entirely new materials, can be produced in this way.

1.2 Technological Limitations of Proteins in Fiber Engineering

Many materials that are indispensable in technology have no counterpart in Nature because natural selection has exerted no pressure to evolve such materials. Thus, natural proteins cannot compete with carbon fiber in regard to high temperature applications, or with conjugated polymers in regard to electrical conductivity.

Natural mechanisms of materials production are usually complex and/or slow in comparison to conventional artificial methods. Spiders produce fiber more rapidly than any other organism, but the maximum rates are around $10 \, cm \, s^{-1}$ and are not maintained continuously. This maximum is two to three orders of magnitude slower than typical rates for industrial dry solution spinning. The need to achieve economical fiber production rates while applying Nature's lessons for ''green'' materials processing and microstructure–property optimization represents a formidable challenge.

Proteinaceous materials are sensitive to both moisture and temperature. In some cases, water may be essential for a protein fiber to exhibit optimum properties, e.g., the energy-dissipating ability of capture thread in a spider's web, or the compressive strength of viral coat protein spikes. Such fibers would be of little use under dry conditions.

There are many factors that limit the viability of genetically altered organisms as a source of functional polymers: the stability of the altered gene (to mutation as well as to repair), toxic effects of the foreign protein on the host organism, intracellular degradation of the foreign protein by the host's enzymes, and the extent to which the desired protein can be recovered in useful amounts and in a processable form.

1.3 Fiber Self-assembly

Successful fiber self-assembly requires molecules that can serve as appropriate building blocks, a source of structural anisotropy, an environment that promotes self-assembly, and intermolecular interactions (bonds) that stabilize the assembled fiber.

(*a*) *Proteins as versatile fiber-forming materials.* The natural monomers of proteins are α-amino acids – $(CO–CHR–NH)_n–$. Following protein synthesis, some of the R-groups (Fig. 1) may undergo derivatization, effectively increasing the diversity of monomer types in the polymer. The unique properties of a given protein depend on which amino acids are present, the relative amounts of those amino acids, the specific sequence in which they are arranged, and the overall length of the molecule. The variety of possible proteins is therefore extremely large, limited only by the practicalities (i.e., kinetic considerations)

of getting long molecules to fold into a conformation that ensures the desired properties.

Two characteristics of protein molecules underlie their versatile fiber-forming ability:

(i) The backbones are intrinsically flexible, so proteins have the potential to fold into a large variety of possible conformations.

(ii) The R-groups (Fig. 1) confer a locally hydrophilic (acidic, basic, or neutral) or hydrophobic character to the molecules. In aqueous environments, the charge distribution along the molecules will therefore be sensitive to the presence of other charged species, and so will depend on pH and dissolved ions. The flexible protein chains will tend to fold in a way that allows hydrophobic segments to be screened from the water by the more hydrophilic segments, while also tending to maximize the extent to which charged sites participate in hydrogen bonding.

It follows that the three-dimensional structure of a protein depends on the nature and sequence of the amino acid side groups along the molecule, the related backbone flexibility, the characteristics of the aqueous environment, and the characteristics of neighboring protein molecules.

(*b*) *Proteins as a source of structural anisotropy.* The intrinsic flexibility of proteins allows them to form geometrically anisotropic structures such as helices or β-sheet crystals (Fig. 2). This occurs in water, and can be promoted by hydrogen bonding and hydrophobic interactions. Structural stability is sensitive to the amino acid sequence of the protein, and to the pattern of intramolecular and intermolecular bonding favored by interactions between the protein and its environment. Polymer–water interactions are particularly significant. Some fibrous proteins, such as those found in the byssal threads of mussels, exhibit a hybrid structure which incorporates collagen-like (helix-forming) and silk-like (sheet-forming) sequences to achieve a gradient in mechanical properties along the fiber.

Protein molecules which instead have a globular conformation can form anisotropic structures by aggregating (Fig. 2). This process can be promoted by an asymmetric charge distribution (dipoles) on the interacting macromolecules, and by specificity of sites that take part in intermolecular hydrogen and hydrophobic bonds. Ions may also play a role in binding.

The nucleation of anisotropic supramolecular aggregates from helices, β-sheets or globular molecules can be promoted by molecular templates. Examples include the extension peptides which aid the assembly of collagen triple helices, templates for the hollow triangular prisms (consisting of three cross-β-sheet crystals) that constitute viral spikes, and the microtubule organizing centers (MTOCs) that assist the formation of microtubules in the cytoskeleton and flagellae.

Figure 1
The side groups that distinguish the 21 α-amino acids from which all known natural proteins are synthesized. Conventional three-letter and one-letter abbreviations for each amino acid are shown, along with the characteristics of the side groups in aqueous environments.
Figure 2
Four commonly occurring anisotropic structures formed by protein molecules.

Liquid crystalline order can also promote the aggregation of globular molecules into anisotropic structures. In F-actin (muscles), in microtubules, and in silk secretions prior to spinning, synergism develops between alignment-enhanced assembly and shape-enhanced alignment.

(*c*) *Propagation of structural anisotropy: self-assembly at greater length scales.* In an aqueous environment, helices can form superhelices (coiled coils) stabilized by hydrophobic bonding across the area of helix-helix contact. Superhelix formation may alternatively be promoted by electrostatic interactions. Liquid

crystalline order can directly control the higher level pattern into which rod-like structures become organized. There are many distinguishable schemes according to which rods can pack in a liquid crystalline fluid, and all the major classes have been detected in protein fibers.

2. Examples of Natural Fibrous Materials Based on Helices

2.1 Keratins

The characteristic α-helical conformation of keratins, first described by Pauling and Corey in 1951, is one of

the simplest regular conformations that a sequence of amino acids in a protein can adopt. When it occurs in fiber-forming proteins, it tends to account for all the secondary structure, i.e., the entire molecule is α-helical. The structure of keratin is described in detail in *Keratin*[#].

2.2 Collagens

(*a*) *Collagen helices*. The individual linear unbranched polymer chains in collagen are called *procollagen*. Their general formula is (Gly-X–Y)$_n$, where many of the amino acid residues X and Y are proline. The inflexibility of the backbone nitrogen–carbon (N–C) bond within proline (Fig. 1) ensures the formation of helical conformations that are more stretched out than the α-helix in keratins. Many of the proline residues—and also some lysine residues—undergo modification (hydroxylation), after which they are able to form hydrogen bonds and covalent cross-links that stabilize the supramolecular structure of collagen.

The left-handed procollagen helices self-assemble into right-handed triple-helical supercoils. Assembly and stability are favored by several factors:

(i) The sequence of amino acid residues at one end of the procollagen molecule includes cysteine. The molecule is therefore capable of forming disulfide bonds with the corresponding sequence on an adjacent procollagen. (The cysteine-containing sequences are known as *extension peptides*, because they are discarded at a later stage of collagen synthesis.)

(ii) Intramolecular and intermolecular hydrogen bonding is extensive.

(iii) The amino acid sequence and the helical conformation of procollagen together generate a hydrophobic stripe of glycine residues along one side of the helix. Glycine has a small side group (hydrogen), so there is room to accommodate the glycine residues in the space between three parallel close-packed helices.

Attempts to produce artificial analogs of such a structure must therefore recognize that there are several superimposed contributions to stability in the natural material. Some of the polymer–polymer interactions involve the localization of water molecules to participate in hydrogen bonding, while other interactions specifically involve the local exclusion of water.

(*b*) *Tropocollagen and collagen*. Subsequent stages in the hierarchical assembly of collagen occur outside the cell. The extension peptides are cleaved off by enzymes, leaving *tropocollagen* triple helices. Tropocollagen then self-organizes into a wide variety of structures, many of which exhibit features typical of liquid crystalline order.

(*c*) *Properties*. Molecular and supercoil twists in tropocollagen occur in opposite directions. This rope-like structure ensures that tropocollagen is stiff and strong in tension. At coarser length scales there can be additional levels of "rope-within-rope" structural hierarchy, as well as pleated structures (e.g., in tendon) that enhance extensibility without sacrificing ultimate tensile strength. The hierarchical microstructure of collagen confers outstanding damage tolerance and toughness. The bulk properties of collagen depend on the orientation of fibers relative to the loading geometry, the degree and nature of cross-linking within fibers (which increases with age), moisture content, temperature, the relative amounts of fiber and any matrix phase, and the rheology of the matrix.

More than a quarter of the protein in mammals is collagen, much of it existing as fibers in tendons, ligaments, cartilage, bones, and teeth. The breaking strength of rat tail tendon is approximately 60 MPa, while the tensile modulus depends on the age of the rat. Collagen is remarkably resilient: a human lifetime of 70 years and a heart rate of 70 beats per minute equate to 2.6×10^9 heartbeats, each of which requires a reliable elastic response from the collagen-reinforced arterial walls (see *Collagen Derived Materials*[#]).

3. Examples of Natural Fibrous Materials Based on β-sheets

3.1 Silks

(*a*) *β-strands, β-sheets, and β-sheet crystals*. The β-strand is another simple, regular conformation that can be adopted by amino acid sequences in a protein. Individual protein chains with this conformation exhibit the following characteristics:

(i) The chains are almost fully extended, following a zigzag trajectory. If there is a twist, it is right-handed and gradual, ranging from an effectively infinite pitch in spider drag line silk to several hundred angstroms in many other protein crystals.

(ii) Stability of the conformation is maintained by hydrogen bonds with neighboring strands.

A planar arrangement of juxtaposed hydrogen-bonded β-strands looks like a pleated sheet, and is usually referred to as a β-sheet. Such sheets can stack into three-dimensional β-sheet crystals (Fig. 3), in which the separation of the β-sheets is dictated by the size of the side groups that must be accommodated within that space. The repeat distances in the covalent bond and hydrogen bond directions are independent of the amino acid sequence in the constituent protein.

(*b*) *Non-periodic lattice* (*NPL*) *crystals*. In some spider silks, the complicated amino acid sequence and the non-equilibrium conditions of fiber spinning make it unlikely that good matches will develop between adjacent sheets in the largest crystals. While the

chains, the β-sheet crystals confer axial strength and stiffness. Segments of the same polymer chains that build β-sheet crystals also make up the intercrystalline amorphous phase, so there is no discrete interface between these phases. The fiber can therefore extend significantly once the yield strength imparted by the crystalline phase is exceeded.

Hydrogen bonding and water are important to silk in several respects. Individual secreted protein molecules are folded into a globular (isotropic) conformation; this shape is stabilized by intramolecular hydrogen bonds which are balanced by the favorable interactions between water molecules and hydrophilic residues at the surface of the globules. At higher protein concentrations, the coils assemble into anisotropic structures. The driving force for this process has not been quantified, but may be due to the greater entropy achieved when bound water is released from the surface of coils and replaced with coil–coil interactions. The aqueous solution of linear aggregates forms a processable liquid crystalline phase from which spiders and silkworms spin water-insoluble fiber. As the solution is spun, the intramolecular hydrogen bonding pattern is disrupted, chains are extended, and hydrophobic residues are exposed to water; β-sheet crystals develop from the more regular amino acid sequences. Their hydrophobic side group content, dense molecular packing, and extensive hydrogen bonding between backbones makes the crystals insoluble in water.

Water also affects the macroscopic properties of silks. Spider drag line undergoes large, non-volumetric dimensional changes that depend on moisture content, allowing spiders to achieve the correct tension in the web framework as it is spun. The energy dissipation mechanisms available to capture thread are partly the result of its microstructure, and partly depend on the presence of water.

3.2 Viral Spike Protein

The structural characteristics of virus coats (capsids) are highly relevant to virus propagation, and are therefore the subject of intensive study. The coat must contain and protect the nucleic acid (genetic) contents, be resilient against impact, be capable of broaching the outer wall of a target cell, and provide a secure pathway for conducting nucleic acid into the target. Hollow spikes on the capsid fulfill the latter two roles, from which it has been deduced that they must have unusually high strength and stiffness in axial compression. Because compressive strength and stiffness have been a long-term but elusive goal of polymer science, the hierarchical structure of spike proteins deserves careful attention.

(*a*) *Cross-β-sheets.* Viral spike protein contains several repeats of relatively short β-strand-forming

Figure 3
Structure and principal features of a β-sheet crystal.

molecular backbones tend to pack on a three-dimensional lattice, this periodicity is frustrated by the complex sequence of amino acid side groups along each molecule, and the consequently necessary fluctuations of the inter-sheet spaces in which the side groups are accommodated.

The term "non-periodic lattice crystal" therefore succinctly describes the distinguishing features of this phase. Because NPL crystals involve statistical rather than perfect matches, they can reliably confer reinforcement to the solidified microstructure regardless of the exact processing conditions (spinning rate, temperature, humidity).

(*c*) *Properties.* Silks exhibit a wide range of optimized tensile properties, for example stiffness of the radial threads and frames of spider webs, compliance of the capture spiral in webs, and toughness of egg cocoons. Due to the extended conformation of their constituent

amino acid sequences. The chain folds back and forth to assemble a β-sheet, stabilized by intramolecular hydrogen bonds (Fig. 2). Because the long axis of the sheet is transverse rather than parallel to the molecular backbone, the structure in this case is known as a cross-β-sheet. Some silks, e.g., the egg stalks of green lacewing flies, are also reinforced by cross-β-sheet crystals.

(*b*) *Higher-order structure*. The structure varies significantly between different virus types. For both rotavirus and human adenovirus, there is evidence that three cross-β-sheets interact to form a hollow trimeric box beam that resists buckling in compression. Structural characterization is hampered by the small size of individual spikes (length $\leqslant 30$ nm and width $\leqslant 5$ nm). Hydrophobic bonding is presumed to be important in stabilizing their structure, since 70% of the amino acid residues are hydrophobic in representative cases.

Genetically engineered model polymers, based on multiple consecutive copies of the principal repeated sequence in native adenovirus spike protein, can self-assemble into a liquid crystalline phase in solution. However, trimeric box beams have not been found in the hierarchical microstructure of fibers spun from this phase. The spun fibers are formed under significantly off-equilibrium conditions, and should not be expected to have the same internal structure as the native spikes.

(*c*) *Properties*. In tensile tests conducted on dry fiber, the breaking strength is ~ 0.3 GPa, the stiffness ~ 4 GPa, and the elongation to failure $\sim 30\%$. Given the evidence that the native spikes rely on hydrophobic bonding to maintain their structure, the properties of analog fibers as measured in air are likely to be inferior compared to results obtained in water—even if the detailed microstructure of the native material could be reproduced. In other words, the natural material is designed to work in an aqueous medium, and attempts to mimic its properties must take this reality into account.

4. Examples of Natural Fibrous Materials Based on Aggregation of Globular Molecules

4.1 Actin

(*a*) *Structure*. Actin is a principal constituent of muscle, and plays an important role in cell motility. Individual protein chains fold into a non-spherical globular conformation that can fit into a space approximately $5.5 \times 5.5 \times 3.5$ nm (Fig. 4). These globular molecules are conventionally called G-actin. They self-assemble into a right-handed, double-helical, elongated aggregate that is known as F-actin in recognition of its fibrous structure. The rate at which

F-actin forms is limited by nucleation: non-covalent association between just two G-actin molecules is much weaker than the interactions binding G-actin in a larger aggregate, because there are more nearest-neighbor interactions per G-actin molecule in the latter case. Self-assembly of F-actin is driven by several interlinked factors:

(i) There are entropic considerations. G-actins that have become aggregated are able to bind significantly fewer water molecules compared to the same number of independent G-actins. Although G-actin aggregation is synonymous with an increase in G-actin order, the accompanying increase in the disorder of water is more than enough to compensate.

(ii) The F-actin rods can become locally oriented, forming liquid crystalline domains. Axial growth of the rods is favored within such domains, and longer rods are in turn more successful at stabilizing orientational order.

(iii) Actin-bundling proteins help to reduce the chemical activity of G-actin in solution, allowing a greater concentration to accumulate in a particular location and thus enhancing the chances of contact and aggregation.

(iv) Aggregation is promoted by an increased concentration of cationic solutes, because cation-phosphate complexing helps to reduce the activity of phosphate released by the aggregation reaction.

(v) The presence of globular proteins that are not attracted to actin can promote liquid crystalline phase separation, because the mixing of rods and flexible coils is entropically unfavorable.

(*b*) *Properties*. F-actin is rigid in tension, so that muscle and cytoskeletal fibers can slide past neighboring fibers without stretching. At the same time, actin fibers are flexible in torsion, allowing cells to change shape; this flexibility is provided by the hinged structure of the individual G-actin molecules (Fig. 4).

The ability of cohesive, durable fibrous structures to assemble via non-covalent aggregation of globular molecules has significant implications for commercial polymers. Traditional polymer science and engineering holds that fluid polymer can be processed into useful fibers only if there is a greater-than-critical level of chain entanglement. Watching a weightlifter in action, one cannot dispute the cohesivity of fibers made from non-covalently associated, non-interpenetrating G-actin coils. However, a route has yet to be found for making analogous fibers that function in a dry environment.

4.2 Tubulin

Microtubules in flagella and actin filaments in muscle exhibit similar features of hierarchical structure. The most striking difference is that the tubulin-based structures are hollow.
Figure 4
Molecular and supramolecular features of actin filaments and tubulin microtubules.

(*a*) *Dimers, protofilaments and microtubules*. Microtubules consist of two distinct types of globular protein, α-tubulin and β-tubulin (Fig. 4). The first stage of microtubule assembly involves α-tubulin/β-tubulin dimerization. A circular pattern of a third, related protein, γ-tubulin, occurs at the surface of MTOCs, providing a template to which the dimers are attracted and on which the microtubules are therefore nucleated.

A head-to-tail sequence of dimers forms a *protofilament*. The number of protofilaments in a microtubule can be as little as seven or as many as 16, depending on the *in vivo* or *in vitro* environment in which the microtubule is formed. There are usually 13 protofilaments in natural microtubules. Longitudinal bonds between tubulin molecules are stronger than latitudinal ones, leading to the view that microtubules grow by the simultaneous, longitudinal growth of all the constituent protofilaments. Whether or not the protofilaments are parallel to the microtubule axis depends on how many protofilaments there are. Parallelism is obtained with 13 protofilaments.

As was the case with actin, several factors combine to drive self-assembly. The number of protofilaments in the microtubule is dictated by the distribution of γ-tubulin in MTOCs. Each α/β-tubulin dimer exhibits a charge dipole, which helps it to assume the correct orientation to dock with a growing protofilament. There is evidence that liquid crystalline domains are formed in which axial growth and sustained alignment of rods are favored. The release of bound water from the aggregating tubulins can lead to a net increase of entropy in the solution.

(*b*) *Properties*. Like actin filaments, microtubules fulfill diverse roles. They are found in cytoskeletal fibers, flagella, cilia, and mitotic spindles, and are therefore integral to maintaining cell structure, to cell motility, and to cell reproduction. The fibers must be strongly cohesive to maintain rigidity under tension, despite the fact that they consist of non-covalently aggregated globular chains. The non-covalent bonds are sufficiently numerous, and collectively

strong enough, for the globular actin molecules to maintain their shape under load and to remain connected to their neighbors in the aggregates. The tensile modulus of microtubules is approximately 1.2 GPa, similar to that of rigid plastics such as poly-methylmethacrylate (PMMA) where significant molecular entanglements do occur. The flexural rigidity of microtubules is about 300 times greater than that of actin filaments. Microtubules are therefore rigid over cellular dimensions and can offer support to actin filaments in the cytoskeleton. Their rigidity is mainly due to their larger cross-section, achieved without unnecessary material expense because their cross-section is hollow.

5. The Future

Continuing studies of natural protein fibers will provide further insights into the principles of supra-molecular materials self-assembly. The lessons learned will help to direct the development of new polymer fibers and other materials. Eventually, these lessons will lead to a practical understanding of how subtle chemistry (especially at the level of genetic coding) can be used to control the hierarchical structure and thence the properties of self-assembled materials and devices. *Adaptation* of Nature's lessons will be more fruitful than attempts to *copy* the structure or production route of any one natural material.

Copying Nature is attended by the limitations of complex composition, slow growth, poor thermal stability, and sensitivity to the presence (or absence) of water.

Optical Properties of Functional Hybrid Organic–Inorganic Nanocomposites

Functional hybrids are nanocomposite materials lying at the interface of organic and inorganic realms, whose high versatility offers a wide range of possibilities to elaborate tailor-made materials in terms of chemical and physical properties. Because they present several advantages for designing materials for optical applications (versatile and relatively facile chemistry, easy shaping and patterning, materials having good mechanical integrity and excellent optical quality), numerous silica- or/and siloxane- based hybrid organic–inorganic materials have been developed in the past few years. Figure 1 illustrates the interest of using multifunctional hybrid sol–gel-derived hybrid organic–inorganic coatings developed by several glass packaging industries in Japan and in Europe.

The most striking examples of functional hybrids exhibiting emission properties (solid-state dye lasers, rare-earth-doped hybrids, electroluminescent devices), absorption properties (photochromic), nonlinear optical (NLO) properties (second-order NLO, photochemical hole burning (PHB), photorefractivity), and sensing properties have been extensively reviewed (Avnir *et al.* 1994, Boilot *et al.* 1996, Dalton *et al.* 1995, Dunn and Zink 1991, Levy 1997, Sanchez and Lebeau 1996, 2001, Sanchez *et al.* 2003). These properties are summarized in this article.

Figure 1

1. Hybrids with Emission Properties

There has long been an interest in fabricating solid-state gain media containing organic laser dyes, because it provides ease of use and replacement. Moreover, the encapsulation of the dye in solid matrices is favorable for decreasing health and environmental hazards.

Avnir *et al.* (1984) first synthesized luminescent dye-doped sol–gel matrices and demonstrated the possibility to use them as solid-state dye laser (see *Microchip Lasers*[#]). However, it is only a few years later that first laser emissions were reported in sol–gel materials (see *Sol–Gel Reactions: Theory*[#]). The main reasons of this delay are several drastic conditions required to elaborate efficient solid-state organic dye lasers. The laser material must exhibit an excellent transparency without scattering and a well-polished surface (roughness surface < few nanometers). Class II hybrid materials where organic and inorganic components are covalently linked were quickly found to be well appropriate for elaborating such solid-state dye lasers. Indeed, the organic component could improve matrix characteristics such as hydrophobicity to repel residual polar solvent and thus protect the organic dye from chemical degradation, density to decrease optical inhomogeneities, and mechanical resistance necessary to withstand surface polishing. Moreover, the covalent bonding of the dye allows a high dye loading to be achieved with minimized dye aggregation.

Performances of solid-state dye-laser materials are not only based on properties of the host matrix but also on the choice of the organic dye (see Fig. 2(a)). The dye must exhibit a good laser gain and must be chemically, photochemically, and thermally stable under the conditions of use of the laser.

The huge optimization potential of hybrid solid-state dye-laser materials is illustrated by the strong improvement of their performances over the past few years. Slope efficiency increased from a few percent to more than 80%. The maximum output energies reached simultaneously from a few μJ to a few mJ. At the same time, lifetimes progressed from about 10^4 pulses in the μJ range to more than 10^6 pulses in the mJ range.

Since the report of bright emission from thin layer molecular dye films, there is a growing interest in using organic electroluminescent devices in display applications because of their low operating voltage, large viewing angle, and high efficiency and brightness. Sol–gel processes provide the opportunity to design new hybrid light emitting diodes (LEDs) based on functionalized alkoxysilanes that are able to transport charges and emit light.
Figure 2
Molecular structures of laser-dye rhodamine 6G (a), silylated precursor with light emitting naphthalimide used to prepare electroluminescent devices emitting in the green (b), photochromic spirooxazine (SO) dye for fast optical switches (c), photochromic furylfulgide dye for optical data storage (d), silylated Red17 dye for nonlinear optics(e), and silylated fullerene C60 for optical limiters(f).

Hybrid organic–inorganic light emitting diodes (HLEDs) were elaborated for the first time by using new silylated precursors with hole transporting units prepared by modification of different active molecules (carbazole, oxadiazole, and tetraphenylphenylen-diamine derivatives) (see Fig. 2(b)).

All the first results on HLEDs are promising and further experiments are required to test these new materials as hole transporting layers in photorefractive and electroluminescent devices.

Due to their advantages, such as low-temperature processing and shaping, higher sample homogeneity and purity, and the opportunity to prepare noncrystalline solids, sol–gel matrices have been investigated for some years as potential matrices for lanthanide luminescence. Rare-earth ion (Nd^{3+}, Eu^{3+}, Er^{3+}, Tr^{3+}, Ce^{3+}, Eu^{2+},…) doped materials offer a wide range of optical applications such as tunable lasers, luminescent displays and amplifiers for optical communication.

In order to be able to achieve these objectives, the main strategies consist of the following: (i) Encapsulation of lanthanide ions within nanoparticles before embedding the doped nanoluminophore inside a hybrid matrix. (ii) One-pot sol–gel synthesis performed through a careful tuning of the sol–gel processing conditions (reactive hydrophobic precursors, hydrolysis ratio, catalysts, curing at moderate temperatures, etc.) to allow minimization of the hydroxyl content. (iii) Finally, the use of nonhydrolytic sol–gel processes permits it to generate hybrid matrices free from OH groups. Their main drawback is related to the difficulty to obtain from such processes transparent monolithic pieces or films (i.e., powders are usually obtained).

The sol–gel process provides also the unique opportunity to introduce in the same solid network both organic and inorganic chromophores. Moreover, the location of the organic dyes can *a priori* be tuned through dye–matrix interactions (covalent bonds,

hydrogen bonds, ionic and van der Waals bonds). Only a few studies have reported on the simultaneous incorporation of rare-earth ion and organic dye into sol–gel-derived hybrid hosts. Energy transfer between Nd^{3+} and rhodamine 6G dyes incorporated inside hybrid siloxane oxide coatings was demonstrated, opening a multitude of possibilities to make new optical devices.

2. Hybrid with Absorption Properties: Photochromic Hybrid Materials

Photochromic materials can be used for the design of optical switches, optical data storage devices, energy-conserving coatings, eye-protection glasses, and privacy shields. Photochromic materials and systems have several important uses depending on the rates of the optical transformations. For example, very slow transformations are useful for optical data storage media, whereas fast transformations are required for optical switches.

Photochromic compounds such as diarylethene (DE), dithienylethene (DT), and furylfulgide (FF) derivatives are thermally stable and resistant to photochemical side reactions, were mainly used in optical information storage (see Fig. 2(d)).

Photochromic molecules such as spirooxazines (SO) and spiropyrans (SP) have been embedded into sol–gel glasses to produce optical switches (Fig. 2(c)). The rates of both light-driven structural changes and those of the back reactions are sensitive to the environment in the matrix. Pioneering work in this field by Levy and co-workers (summarized in Levy 1997) showed the important role played by the dye–matrix interactions on the photochromic response of spiropyrans. For hybrid organic–inorganic matrices containing different chemical environments, a competition between direct and reverse photochromisms can be observed. Several authors introduced the hydrophobic/hydrophilic balance (HHB) of the hybrid matrix as an important factor, which controls the competition between direct and reverse photochromism.

New nonsiloxane photochromic hybrid matrices made with spyrooxaxine or cationic spyropyran dyes embedded in nonsiloxane-based hosts have been reported very recently.

3. Nonlinear Optics

Quadratic nonlinear optics is a domain of "sol–gel optics" where the optical response and its temporal stability are strongly dependent on the nature of the bonding between the organic dye and the matrix. The random orientation of organic dyes in sol–gel matrices rules out second harmonic generation (SHG). Second-order nonlinearities can only be observed after poling in order to orient the organic dyes within the sol–gel matrix. Sol–gel processed hybrid materials, being usually amorphous, do not fulfill easily the phase-matching conditions required for frequency doubling. As a consequence, the most targeted applications are related to the electro-optic effect (electro-optic modulator, photorefractive materials, etc.).

The achievement of these materials is related to the quadratic susceptibility of the dye and the thermal stability of the polymeric hybrid matrix. Therefore, hybrid materials built from many matrix–NLO chromophore couples started to be optimized in terms of intrinsic NLO response, matrix rigidity, and dye–matrix interactions.

The best results are generally obtained when NLO dyes are grafted to the oxide matrix via several covalent bonds (hybrids of class II) (Dalton *et al.* 1995, Lebeau *et al.* 1997, Sanchez *et al.* 2003) (see Fig. 2(e)). Moreover, class II hybrid organic–inorganic materials allow a better control of the film thickness, the film hydrophobicity, the matrix rigidity, densification, and NLO chromophore concentrations. It was also observed that dye grafting leads to higher surface quality films and corona poling can be optimized to preserve this quality.

However, as far as NLO devices are concerned, measurements of electro-optical efficiency, wave guiding properties, and the evaluation of the optical losses must complete these promising results.

The large potential of these NLO hybrid materials in the field of photorefractive materials was demonstrated by Darracq *et al.* (1997). Photorefractive effects have been reported in hybrid sol–gel materials containing a second-order nonlinear chromophore (Disperse Red 1 (DR1) or 4-[N,N-bis(β-hydroxy-ethyl)amino]4′ nitrostilben (DHS) derivatives) and a charge transporting molecule (carbazole unit: CB) which was used to form a charge transfer complex with the photosensitizer (Trinitrofluorenone: TNF) to facilitate photocarrier generation at the visible wavelengths.

PHB has been attracting attention in recent years because of its scientific interest and the possibility of the application to high-density optical storage. Furthermore, PHB is a useful method to estimate the local structure around the organic dyes. Among several requirements for practical application, high hole efficiencies and high-temperature ($T > 77 \, K$) persistent spectral hole burning with long-term stability are the most important. PHB was first achieved in various organically modified silica matrices doped with different porphyrins or quinizarin derivatives.

Efficient hole burning was observed in hybrid matrices in which protoporphyrin IX was grafted by two chemical bonds to the inorganic network (Veret-Lemarinier *et al.* 1995). These hybrids of class II look promising for high-temperature persistent hole-burning materials.

The interest of hybrid matrices to preserve optical properties of a molecule was also shown with dyes known to exhibit strong reverse saturable absorption

(RSA). Efficient solid-state reverse saturable absorbers were made by entrapment of phtalocyanines and fullerene C60 in hybrid matrices. Improved LO performances were obtained by the use of grafting of C60 to the matrix backbone. Fullerene C60 derivative has been functionalized with Si tri-alkoxyde groups to increase its concentration in the final matrix without any clustering effects.

4. Hybrid Optical Sensors

Due to their attractive optical properties, a particularly intensive activity has recently characterized the area of reactive organically doped sol–gel materials for sensor applications. The advantage of sol–gel materials of being easy-to-process, combined with several other inherent advantages such as tunability of physical properties, high photochemical and thermal stability, chemical inertness, and negligible swelling both in aqueous and organic solvents, have resulted in an abundance of sol–gel optical sensors.

In some cases, the cracking of the sol–gel bulk material is a problem. In order to overcome this problem, organic–inorganic hybrid materials have been used as host matrices. Organically modified sol–gels not only allow an easy incorporation of probes but also an easy tailoring of properties such as mechanical properties, hydrophobicity, and refractive index. In some applications, silanization of the dye provides the advantage of a more homogeneous and well-defined distribution of the dye in the glass film. Moreover, the covalent coupling of the dye to the substrate allows it to prevent any dye leaching and thus to improve the sensor performance. An immobilization by chemical bonding is more appropriate to small indicators and sterically hindered analyte molecules. On the contrary, the entrapment by steric hindrance is more adapted for large indicator molecules and small fast diffusing analytes.

The sol–gel method offers the advantages of tailor-made porosity that is of paramount importance in sensing chemicals, because it may control the analyte diffusion and the leachability of the optical probe.

In the optical sensor area, the sol–gel method has also the advantage of easy shape modeling. This process may be used to fabricate thin glass films that have well-defined optical and physical characteristics, such as thickness, porosity, and refractive index. Moreover, the sol–gel method has the advantage to be compatible with fiber optic techniques that allow to design remote sensing systems, which are suitable for analyses in toxic or corrosive environments.

5. Hierarchically Organized Hybrid Materials for Optical Applications

Since the recent development of organic templating growth of materials, the elaboration of new types of hybrid photonic materials is emerging whose structure and function are organized hierarchically. Ordered periodic micro-, meso-, and macroporous materials allow the construction of composites with many guest types, e.g., organic molecules, inorganic ions, semiconductor clusters, or polymers. These guest/host materials combine high stability of the inorganic host system, new structure-forming mechanisms due to the confinement of guests in well-defined pores, and a modular composition. This could lead to new optical materials in, for example, switches, nonlinear optics, and lasers. Exploiting the periodic arrangement of the pore systems of mesoporous solids such as MCM-41 type could generate new optical devices.

Already in the early studies several proposals were made to apply such mesoporous systems as optical materials and highly specific chemical sensors. The self-assembled host, especially, allows appreciable control of mesoscale dimensions, symmetry, and orientational ordering of guest–host structures.

These composites can be structured hierarchically, leading to optical materials that have the desired optical properties due to the electronic states and molecular arrangements, and that have the desired light propagation of these complex structures of mesoporous materials.

The first reports of the optical properties of hybrid material whose structure and function are organized hierarchically showed that these solids are promising candidates for optical applications, including lasers, light filters, sensors, solar cells, pigments, optical data storage, photocatalysis, and frequency doubling devices (Stein *et al*. 2000, Wirnsberger and Stucky 2001).

6. Conclusion

Optically active hybrid solids are the fruit of multi-disciplinary research in chemistry and physics. In particular, the progress in this field largely depends on the core competence of inorganic, polymer, and organic chemists, and illustrates the central role of chemistry in the development of advanced materials with unprecedented performances.

Photonic materials are perhaps the first systems to take advantage of the hybrid materials approach. Significant improvements in the properties of photonic materials may be attributed to three factors: (1) matrix improvements (mechanical integrity, transparency, thermal conductivity, reduced optical loss); (2) improvements in dye characteristics (chemical, thermal and photochemical stability, and high optical efficiencies); and (3) improved control of dye–matrix interactions.

There is no question that the development of hybrid photonic materials will continue in the years ahead because of both technological and scientific

factors. The applications for dye-doped systems are, to some degree, limited by photochemical stability and improvements are clearly necessary if these materials are to emerge beyond the demonstration level.

The basic knowledge of organic–inorganic interaction and interfaces will play a major role for designing hierarchically ordered hybrid structures. These advanced materials which are now just appearing satisfy the requirements for a variety of applications and, in particular, optical communications and chemical sensing.

Organic Aerogels

While inorganic aerogels have dominated the sol–gel literature since the 1950s, organic aerogels represent a relatively new class of nanoporous materials. During the 1990s organic aerogels having an ultrafine cell/pore size ($<100\,nm$), high surface area ($>400\,m^2\,g^{-1}$), and a solid matrix composed of interconnected colloidal-like particles, platelets, or fibers have been synthesized from resorcinol–formaldehyde, phenol–resorcinol–formaldehyde, phenol–furfural, melamine–formaldehyde, polyurethanes, polyisocyanurates, and polyureas. In certain cases these organic aerogels can be pyrolyzed in an inert atmosphere to give carbon aerogels in the form of monoliths, powders, microspheres, or thin-film composites. Ko (1998), Husing and Schubert (1998), and Fricke and Tillotson (1997) have all published review articles that contain sections on organic aerogels.

For information on related materials see *Inorganic and Inorganic–Organic Aerogels** and *Xerogels**.

1. Synthesis

The sol–gel polymerization of a multifunctional monomer (i.e., one that contains more than two reactive sites) in solution, leading to the formation of a cross-linked gel that can be transformed into an aerogel, extends beyond the traditional hydrolysis and condensation of silicon alkoxides. While many organic reactions can proceed through a sol–gel transition to form a cross-linked gel, only some can be converted into aerogels. For example, cross-linked, transparent acrylamide gels are commonly used for carrying out biological separations; however, these gels cannot be supercritically dried to form aerogels. The two major requirements for producing a gel that can be converted to an aerogel include:

(i) favorable polymer–solvent interactions during polymerization that prohibit macroscopic phase separation; and

(ii) a high degree of intra- and intermolecular cross-linking.

Pekala (1989) initially identified the aqueous polycondensation of resorcinol (1,3-dihydroxybenzene)

with formaldehyde as a synthetic route to organic aerogels. In this system resorcinol is the multifuctional monomer which contains three reactive sites. The formaldehyde adds to the resorcinol ring to form hydroxymethyl groups that then cross-link to form a three-dimensional gel in which water resides in the pore structure. After a solvent exchange step, the gels are dried from supercritical carbon dioxide to form aerogels. If this same polymerization is attempted with phenol as the trifunctional monomer, macroscopic phase separation takes place and a precipitate is formed. Thus, the second hydroxyl group present on the resorcinol ring appears to be important in allowing gelation to take place prior to any macroscopic phase separation. Interestingly, mixtures of phenol and resorcinol can be polymerized with formaldehyde to form homogeneous gels, but only in cases where the mole ratio of phenol to resorcinol is less than approximately 3.

Although resorcinol–formaldehyde aerogels transmit light, these materials are dark red as a result of oxidation products formed during the polymerization. To circumvent this problem, Pekala *et al.* (1990) showed that melamine–formaldehyde oligomers could be cross-linked in water under acid conditions to form colorless, transparent gels. These gels were then supercritically dried from carbon dioxide to form aerogels. The optical clarity of melamine–formaldehyde aerogels is similar to that of silica aerogels.

While the above reactions demonstrated the feasibility of organic aerogels, they each required a solvent-exchange step from water to acetone to carbon dioxide. Pekala *et al.* (1995) demonstrated that a phenolic–furfural reaction conducted in *n*-propanol could also lead to organic aerogels. De Vos and Biesmans (1996) patented organic aerogels prepared from polyisocyanate-based reactions in organic solvents. In both cases, the cross-linked gels were placed directly in a pressure vessel and dried with supercritical carbon dioxide to form aerogels.

2. Structure–Property Relationships

Aerogels have a unique morphology in that *both* the covalently bonded clusters of the solid phase and the interconnected pores of the gas phase have nanometer-sized dimensions. This nanostructure can be engineered through control of the initial sol–gel polymerization conditions. For example, Pekala *et al.* (1992) have shown that the [resorcinol]/[catalyst] (R/C) mole ratio of the starting solution dictates the particle size, specific surface area, and pore size of resorcinol–formaldehyde (RF) aerogels. High R/C ratios (R/C ~ 200) give larger particles and lower surface areas than aerogels produced at low R/C ratios (R/C ~ 50). Saliger *et al.* (1997) showed that RF gels produced at very high R/C ratios (R/C ~ 1500) could even be dried subcritically using acetone as the pore

fluid. The rather coarse gel structure is able to withstand the capillary pressures more efficiently than gels produced at low R/C ratios. Similar effects have been found in melamine–formaldehyde gels where the pH of the starting solution determines the surface area and transparency of the dried aerogel.

The structures and properties of organic aerogels are analogous to their inorganic counterparts (e.g., silica). These materials have continuous porosity, an ultrafine cell/pore size (< 100 nm), high surface area (400–$1100 \, m^2 \, g^{-1}$), and a solid matrix composed of spherical particles, platelets, or fibers with characteristic diameters of 10 nm. This nanostructure is responsible for the unique thermal, acoustic, optical, electrical, and mechanical properties of aerogels.

2.1 Thermal Properties

In monolithic organic aerogels the total thermal conductivity can be described by a simple addition of the gaseous thermal conductivity, λ_g, the solid thermal conductivity, λ_s, and the radiative thermal conductivity, λ_r:

$$\lambda_{total} = \lambda_g + \lambda_s + \lambda_r \tag{1}$$

In such systems coupling between the different heat transfer modes is negligible. Additionally, convection of the gas within the pores is completely suppressed.

The gaseous thermal conductivity in air-filled monolithic organic aerogels can be described by the Knudsen equation:

$$\lambda_g = \frac{\lambda_{g0} \Pi}{1 + \beta K_n} \tag{2}$$

where Π is the porosity and λ_{g0} is the thermal conductivity of free air. The parameter β takes into account the energy transfer between gas molecules and the limiting structure: for air, β is approximately 2. The Knudsen number

$$K_n = \frac{t_g}{\phi} \tag{3}$$

is a characteristic quantity for the gaseous thermal conductivity in a porous system, where t_g is the mean free path of the gas molecules and ϕ is the pore diameter.

Organic aerogels have pore sizes in the 1–100 nm range. The mean free path of the gas molecules in air at 1 bar is around 70 nm and thus is comparable to the average pore size in aerogels. Aerogels are such good thermal insulators because of this relative relationship. In the most simplistic model, there are only a few gas molecules trapped within an individual pore vs. many molecules which are transported from pore to pore as for example in Styrofoam. Thus, the gaseous conductivity, λ_g, is partially suppressed even at

atmospheric pressure. Typical λ_g values range from $0.005\,\mathrm{W m^{-1}\,K^{-1}}$ to $0.010\,\mathrm{W m^{-1}\,K^{-1}}$, depending on density.

The above equations show that pore size is the important factor in reducing the gaseous thermal conductivity. Small average pore sizes increase the Knudsen number and decrease the gaseous thermal conductivity. For RF aerogels, smaller pores are achieved at a given density by reducing the R/C ratio.

Organic aerogels are optically thick for thermal radiation in layers of more than 1 cm, which means that the mean free path of infrared photons is small compared with specimen size. In this case radiative heat transport is a local phenomenon and the radiative conductivity can be described by:

$$\lambda_r = \frac{(16/3)n^2\sigma T^3}{e(T)\rho} \qquad (4)$$

where σ is the Stefan-Boltzmann constant, n is the mean index of refraction of the specimen, T is the absolute temperature, $e(T)$ is the mass specific extinction coefficient and ρ is the density of the material. The extinction coefficient, $e(T)$, can be determined from infrared optical reflection and transmission experiments. Lu *et al.* (1995) found $e \approx 50\,\mathrm{m^2\,kg^{-1}}$ as being typical for RF aerogels. Because of the strong infrared absorption of all organic aerogel compositions, radiative heat transfer is more effectively reduced in these porous materials as compared with nonopaque silica aerogels.

The solid thermal conductivity of organic aerogels is drastically reduced with respect to the non-porous material. Furthermore, the solid conductivity depends upon the interconnectivity of the solid phase. Lu *et al.* (1995) found that the solid thermal conductivity scales with aerogel density as follows:

$$\lambda_s = C\rho^\alpha \qquad (5)$$

The prefactor C depends upon the particle interconnectivity and $\alpha \approx 1.5$ holds for RF and carbon aerogels.

Figures 1 and 2 show the impact of the RF aerogel nanostructure upon gaseous and solid thermal conductivity, respectively. At a fixed aerogel density, the gaseous thermal conductivity is lower for samples prepared at R/C = 50 as compared to those produced at R/C = 200 or 300. This trend is a result of the smaller average pore size in organic aerogels synthesized at lower R/C ratios. In the case of the solid thermal conductivity, the opposite trend is observed. Those RF aerogels prepared at R/C = 50 exhibit a higher solid thermal conductivity at a given density as compared to those aerogels prepared at R/C = 200 or 300. This reflects the fibrous structure and better interconnectivity of RF aerogels synthesized at R/C = 50 as compared to the weak interconnection of

larger particles with narrow necks for RF aerogels synthesized at R/C = 200 or 300.

The total thermal conductivity of organic aerogels can be further suppressed if specimens are evacuated. Figure 3 shows the thermal conductivity of RF, polyisocyanurate, and carbon aerogels as a function of

gas pressure. A drastic reduction in thermal conduc-
tivity is observed in all cases as the pressure is de-
creased below 100 m bar. This critical pressure defines
where a loss in insulation would occur for monolithic
aerogels used in vacuum insulation panels. Such pan-
els are being considered for applications in household
appliances such as refrigerators.

2.2 Mechanical Properties

Differences in the nanostructure of organic aerogels
are also reflected in their mechanical properties. As a
result of their high porosity, aerogels exhibit an elas-
tic modulus many orders of magnitude smaller than
their full-density analogs. Gross *et al.* (1997) and
Pekala *et al.* (1990) have made extensive studies on
the mechanical properties of RF and carbon aerogels.
Gross *et al.* used acoustic techniques and a beam-
bending method to evaluate the shear modulus,
Young's modulus, and Poisson ratio of RF gels both
before and after supercritical drying from carbon
dioxide. They found that the elastic modulus typi-
cally increased by a factor of 1–5 after supercritical
drying. This increase depended upon the initial gel
concentration with the largest increases observed
at the lowest gel concentrations. Thus, supercritical
drying influences lower density gels more than high-
density gels.
   In analyzing the elastic modulus of RF aerogels
over a density range of 40–1200 kg m^{-3}, Gross *et al.*
(1997) observed that a simple power-law fit could not
be applied. In principle, the elastic modulus of porous
materials scales with the second power of density,
provided that the dominant deformation mechanism
is bending of the beams or struts that make up the
skeleton. When they limited the analysis to the den-
sity range 200–500 kg m^{-3}, a scaling exponent of 3.5
was observed. This high exponent reflects the fact
that organic aerogels are structurally inefficient. In
other words, there are many "dead ends" within the
aerogel network that contribute to the mass but
not to the mechanical strength. Gross *et al.* (1997)
observed that the fraction of elastically effective mass
was as low as 17% for RF aerogels having a density
of $\sim$100 kg m^{-3} and as high as 70% for RF aerogels
having a density of $\sim$500 kg m^{-3}.
   Pekala *et al.* (1990) precision-machined RF and
carbon aerogels into 1 cm $\times$ 1 cm $\times$ 1 cm cubes and
tested their uniaxial stiffness (i.e., compressive mod-
ulus). These organic aerogels were synthesized at R/C
ratios of 50–300, and all carbon aerogels were pyro-
lyzed at 1050 °C. Figure 4 shows a log–log plot of
compressive modulus vs. density for these organic
aerogel families. A scaling exponent of 2.7 $\pm$ 0.2 was
observed for all formulations over the density range
studied. Although the scaling exponents were identi-
cal, the modulus reflects the matrix material and R/C
ratio used to produce the aerogels. At a fixed density,
aerogels produced at low R/C ratios are stiffer than
their high-R/C counterparts in either the RF or car-
bon families. These data reflect the smaller particle
size and improved interconnectivity of aerogels pro-
duced at low R/C ratios.
   A comparison of RF and carbon aerogels prepared
at identical R/C ratios shows that the latter materials
are an order of magnitude stiffer than their RF pre-
cursors. The improvement in stiffness increased with
the R/C ratio. At equivalent densities, carbon aero-
gels were $\sim$7 times stiffer than their RF counter-
parts at R/C = 50, $\sim$16 times stiffer at R/C = 200,
and $\sim$23 times stiffer at R/C = 300. These data reflect
a greater improvement in interparticle connectivity
upon carbonization of RF aerogels prepared at

R/C = 300, which contain larger particles (~ 20 nm) with small interconnecting necks, as compared to RF aerogels prepared at R/C = 50 which already contain well-fused small particles or fibers (3–5 nm).

3. Applications

Aerogels have been proposed for many applications that take advantage of their unique structure and properties. Organic aerogels that exceed the performance of conventional foam technology in freezers or refrigerators would make it possible to offer more storage space or improved efficiency. Various companies (Aerojet, BASF, Hoechst, Armstrong World Industries, ICI) have demonstrated the feasibility of organic aerogel technology at the pilot scale; however, there are no organic aerogel-based vacuum insulation panels being used commercially. In fact, Ocellus Inc. (Alameda, CA) is the only commercial producer of organic aerogels.

Carbon aerogels represent the first electrically conductive aerogels. This property in combination with high surface area, controllable pore size, and high purity is leading to new electrochemical applications. Carbon aerogels are being investigated commercially as electrodes for electrochemical double layer capacitors (EDLCs) and electrosorptive processes such as capacitive deionization. Lipinski *et al.* (1998) have also examined the use of carbon aerogels as fuel cell electrodes.

Mayer *et al.* (1993) recognized that the high capacitance density (25–50 F cm^{-3}) of carbon aerogels would make them attractive for EDLC applications. In these devices the carbon aerogels serve as both the positive and negative electrodes, with a porous separator in between. The void space in both the separator and carbon aerogels is filled with an organic or aqueous electrolyte, and energy is stored via separation of charge across the polarized electrode/electrolyte interface. Such devices deliver higher power than conventional batteries, and they are finding applications in microelectronics and telecommunications. PowerStor Corp. (Dublin, CA) is manufacturing EDLCs based on carbon aerogel technology.

Capacitive deionization (CDI) can be viewed as an electrosorption process that takes place in a "flow-through" double layer capacitor. As contaminated water is passed through the CDI unit, charged impurities are transported to the electrode surface and held within the electric double layer to produce an effluent of purified water. Farmer *et al.* (1996) have studied the absorption profiles on many different ions captured on CDI units using carbon aerogel electrodes. This technology is being pursued commercially at Far West Corp. (Tucson, AZ).

Organic Analogues to Zeolites and Mesoporous Sieves

A major goal in the design of new heterogeneous catalysts has been to develop organic analogues to inorganic zeolites and mesoporous sieves. Zeolites are crystalline, open-framework materials with uniform channel diameters (3–10 Å) that have been used extensively in a number of industrially important processes, such as heterogeneous catalysis and size selective separations (Thomas *et al.* 1997) Mesoporous sieves are a relatively new class of surfactant-templated

silicates pioneered by Mobil that contain adjustable pore sizes (2–10 nm) and architectures. They hold exceptional promise as new catalysts and separation media (Beck *et al.* 1992). The ultimate goal in developing organic analogues to these inorganic materials is to generate systems with the chemical tunability and processability of an organic material, and the high surface area, stability, and reactivity of a crystalline, supercage material. This article will provide an overview of methods for generating extended organic materials with open, nanometer-scale pore architectures mimicking those of the zeolites and mesoporous sieves.

1. Formation of Porous, Noncovalent Organic Networks

One of the most elegant approaches to the construction of nanoporous organic materials is the use of organic building blocks capable of forming specific noncovalent bonds. The resulting crystalline organic networks are capable of incorporating small molecules in the 5–12 Å periodic cavities formed upon their self-assembly from solution.

Several types of noncovalent bonding have been employed in forming such structures. One of the most prevalent is the hydrogen bond. Extended hydrogen-bond networks can be constructed by using molecules capable of forming multiple hydrogen bonds in specific directions. For example, Whitesides *et al.* (1995) formed a robust organic channeled structure by simply combining melamine and cyanuric acid to form the 1:1 adduct. Su *et al.* (1995) have used specially designed "molecular tecton" building blocks to form three-dimensional hydrogen-bond networks with adjustable porosity that can selectively include guest molecules.

A second type of noncovalent bonding motif that has been employed is ionic bonding in concert with hydrogen bonding. Swift *et al.* (1997) demonstrated that guanidinium organodisulfonates can be crystallized in the presence of organic guest molecules to produce bilayer structures in which the organodisulfonates serve as pillars that connect opposing two-dimensional hydrogen-bonded sheets of guanidinium and sulfate ions. The resulting one-dimensional pores in the material are occupied by the guest molecules. Pore dimensions can be tuned by the choice of organodisulfonate pillar and guest molecule.

These organic coordination networks provide excellent control over nanometer-scale pore structure; however, several major challenges still exist in their development as functional materials. The first is that many of these systems are not structurally robust toward collapse when the guest molecules are removed, due to the weak nature of the non-covalent interactions (Swift *et al.* 1997). However, structural integrity in the absence of guest molecules appears possible

when the constituents are held in place by a large number of hydrogen bonds (Brunet *et al.* 1997) (Fig. 1). The second challenge is that the introduction of ancillary functional groups necessary for reactivity or selectivity in these systems is difficult to achieve without significant disruption of the desired lattice architecture (Swift *et al.* 1997). Consequently, only one example of catalytic activity in these organic coordination networks has been reported (Endo *et al.* 1997).

2. Nanoporous Materials Via Phase-separated Block Copolymer Assemblies

A second approach for making nanoporous organic materials involves performing chemistry on phase-segregated block copolymers. Block copolymers are macromolecules produced by coupling two or more chemically and physically distinct polymer blocks. When the different blocks are sufficiently incompatible with one another, ordered phase-segregated architectures often spontaneously form. A variety of ordered nanometer-scale structures are possible from this self-organization process, including spheres, ordered cylinders, lamellae, and combinations thereof (Bates and Frederickson 1999).
Figure 2

Figure 3
Schematic representations of the inverted hexagonal and *Pn3m* bicontinuous cubic phase of surfactant LCs. (Partially reproduced by permission of Elsevier Science. Copyright 1991.)

Lui and Ding (1998) have taken advantage of this phenomenon to generate nanoporous organic networks by using a diblock copolymer containing cross-linkable groups in one block and hydrolyzable groups in the other block. This material forms an ordered cylindrical phase in which the hydrolyzable block makes up the cores of the cylinders. Photopolymerization locks in the overall structure, and subsequent hydrolysis exposes hydrophilic carboxylic acid groups in the ca. 17 nm diameter cylinders (Fig. 2).

The most impressive features of these materials are their facile processability prior to cross-linking, their structural robustness due to cross-linking with covalent bonds as opposed to noncovalent interactions, and their ability to present certain functional groups in the pores. Catalysis in these nanoporous polymers has not yet been demonstrated but transport phenomena such as pH-gated water flow has.

3. In Situ *Polymerization of Surfactant-based Liquid Crystal Assemblies*

A third approach to the construction of nanostructured, porous organic assemblies is the cross-linking of self-assembled structures based on surfactant liquid crystals (LCs). Lyotropic or surfactant LCs are organic molecules that contain a hydrophilic headgroup and hydrophobic organic tail section. Above a certain concentration in water, these amphiphilic molecules spontaneously assemble into phase-segregated structures with the hydrophilic head-groups surrounding the water domains and the hydrophobic

tails merging to form the hydrophilic domains. Depending on the shape of the surfactant LCs, the amount of water in the system, and the temperature, a range of nanostructured assemblies with periodic structures in the 1–10 nm range are possible, such as spherical micelles, hexagonal arrays of cylindrical micelles, lamellae, bicontinuous cubic phases, reverse micelles, and ordered arrays of rodlike reverse micelles (Tiddy 1980). By making polymerizable analogues of these surfactant LC phases, it is possible to lock in the structure of these assemblies by crosslinking with covalent bonds. Robust nanoporous polymer networks with water-filled pores are thus created in which hydrophilic functional groups are presented exclusively in the pore walls.

Early work by Menger and Tsuno (1990) in this area demonstrated the possibility of obtaining catalytically active, porous polystyrene networks by polymerizing a simple inverse micellar system consisting of cross-linker, water, and a polymerizable surfactant. In such an arrangement, the headgroups of the modified surfactant are localized at the inner surfaces of microscopic, spherical, "water pools." Anchoring of copper(II) ions to the headgroups in the cavities have enabled these porous networks to catalyze phosphate ester hydrolysis. Ruckenstein and Hong (1992) and Sundell *et al.* (1993) have used this "reactive microemulsion" approach to produce porous organic networks with anchored palladium centers to demonstrate catalytic vinylation and hydrogenation, respectively. Unfortunately, these materials do not possess the ordered pore system, high surface area, or uniform size pores characteristic of molecular sieves. These factors may limit their reactivity and selectivity.

Herz *et al.* (1963), Smith *et al.* (1997), and Srisiri *et al.* (1997) have independently succeeded in crosslinking the inverted hexagonal LC phase with retention of microstructure. In addition, Lee *et al.* (1995) have succeeded in cross-linking the *Pn3m* bicontinuous cubic LC phase with retention. The pore architectures in these systems (Fig. 3) are more similar to

those of inorganic zeolites and mesoporous sieves, with nearly monodisperse pore diameters in the 1–7 nm range. Later studies have shown that different metal cations can be incorporated into the cross-linked inverted hexagonal phases to introduce new properties or alter pore dimensions (Deng *et al*. 1998). Preliminary studies have also demonstrated that cross-linked inverted hexagonal phases containing weakly basic sodium carboxylate headgroups in the nanochannels exhibit enhanced basicity and act as efficient heterogeneous base catalysts for organic reactions, with performances surpassing those of basic forms of zeolites and mesoporous sieves (Miller *et al*. 1999). The relevant features of this class of nanoporous organic materials are (i) structural tunability on the nanometer scale, (ii) processability prior to cross-linking, (iii) excellent structural integrity of the final product, and (iv) the ability to direct a variety of functional groups exclusively into the nanopores.

Organic–Inorganic Composite Crystals

Organic–inorganic hybrids offer the possibility of integrating organic and inorganic characteristics within a single "molecular composite" (Day and Ledsham 1982). Organic materials are generally lightweight, mechanically flexible, chemically versatile (e.g., molecules of different length, width, conformation), and can provide useful optical and electrical properties. Inorganic materials offer mechanical robustness, good thermal stability, high electrical and thermal conductivity, and interesting magnetic or ferroelectric transitions. Nature provides many examples of organic–inorganic composites that exhibit superior properties compared with those of the constituent organic or inorganic components (e.g., seashell, bone, tooth enamel).

A number of useful noncrystalline composites have also been constructed using techniques such as molecular beam epitaxy (MBE) (Takada 1995) and sol–gel processing (see, for example, Sanchez *et al*. 1999). This article will focus on those organic–inorganic hybrids that self-assemble from solution or vapor phase into a *crystalline* form, with mixing and interaction of the organic and inorganic components on a molecular level. The ability to grow the materials as single crystals enables structural studies and therefore the consideration of structure–property correlation. In addition, the structural self-assembly enables simple thin-film processing techniques and creates the potential for low-cost technological applications.

1. Crystal Structures

One scheme for classifying crystalline organic–inorganic composites involves sorting the hybrids based on the interaction between the inorganic framework and the organic moieties. The weakest interaction occurs in intercalated compounds, which are formed by reversibly incorporating organic molecules (guest species) into the interlayer or interchain gallery of a pre-existing host structure. Intercalated compounds have largely been studied in layered silicates and transition metal oxides, chalcogenides, and phosphates (Whittingham and Jacobson 1982). The structure of the inorganic framework is little affected by the guest molecule, highlighting the small degree of interaction between the two components. The next group comprises composites with stronger hydrogen and/or ionic bonding between the two components and includes organic–inorganic perovskites and related metal halide-based hybrids (Mitzi 1999). In contrast to the previous group, these compounds have specific stoichiometries, with the organic ions occupying well-defined sites in a crystal lattice. Finally, there are hybrids with strong covalent bonding between the two components. While this category includes all organometallic compounds (which generally consist of isolated organometallic clusters interacting via weaker molecular forces), several particularly interesting examples consist of extended inorganic frameworks with covalently bonded organic sidegroups (e.g., $C_nH_{2n+1}BiI_2$, CH_3ReO_3, $Zr(HPO_4)$ $(C_6H_5OPO_3) \cdot 2H_2O$).

While each class of hybrids offers unique opportunities, the ionically bonded metal halide-based systems are particularly notable because of the high degree of ambient-temperature solubility of the inorganic framework in common solvents and the tendency of these compounds to crystallize or self-assemble from solution or the vapor phase. The organic–inorganic perovskites are one of the most extensively studied families of metal halide-based hybrids.

1.1 Perovskites

The basic motif of the organic–inorganic perovskite family is the AMX_3 structure shown in Fig. 1(a). This framework consists of a three-dimensional (3D) network of corner-sharing MX_6 octahedra, where the M atom is typically a divalent metal and X is a halide (Cl^-, Br^-, I^-). The A cations fill the large 12-fold coordinated sites between the octahedra and balance the charge of the MX_3^- network. One example of a 3D organic–inorganic perovskite is $CH_3NH_3SI_3$, where $CH_3NH_3^+$ comprises the simple organic structural component of the hybrid and SnI_3^- forms the 3D extended inorganic network.

Layered perovskites are conceptually formed by taking an n-layer-thick cut from the 3D perovskite

structure along one crystallographic direction (e.g., $\langle 100 \rangle$ or $\langle 110 \rangle$) and alternating these layers with an organic modulation layer (Fig. 1(b)). Changing the thickness of the perovskite sheets alters the effective dimensionality of the inorganic framework, with a more 3D structure for large n and a more two-dimensional (2D) structure for small n (Fig. 2). In the $\langle 110 \rangle$-oriented family, the $n = 1$ structure reduces to layers of one-dimensional (1D) chains. This enables a progression from 1D ($n = 1$) to 2D ($n \geqslant 2$) to 3D ($n = \infty$) inorganic networks, all within a single structural family. With an appropriate choice of organic and inorganic components, these compounds resemble multilayer quantum well structures (typically produced using MBE or organometallic chemical vapor deposition (OMCVD)), with semiconducting inorganic sheets or chains (wells) alternating with much wider bandgap organic layers (barriers). However, the perovskites self-assemble into single-crystal structures and the effect of interfacial roughness between the well and barrier layers is therefore avoided. Modifying the length and/or the degree of conjugation within the organic layer molecules can also influence the electronic or magnetic interaction between inorganic layers.

Many studies have focused on the single layer ($n = 1$) $\langle 100 \rangle$-oriented perovskites of the form $(RNH_3)_2MX_4$ or $(NH_3RNH_3)MX_4$, with $M = Cu$, Cr, Mn, Fe, Cd, Ge, Sn, Pb, or Eu; $X = Cl$, Br, I (Mitzi 1999). The monoammonium cations hydrogen bond to only one inorganic layer, leading to a bilayer of organic cations between the perovskite sheets and a van der Waals gap between the organic layers. For diammonium cations, the organic cations span the entire distance between and bond to two adjacent inorganic sheets. Generally, simple R groups have been incorporated, including alkane and single/double ring aromatic components. Functional dye molecules have also been included (e.g., Fig. 3(a)). In addition, unsaturated monomers, including diene and diyne derivatives, have been substituted and can, given the correct pairing of inorganic framework and organic monomer, undergo topochemical polymerization in the solid state upon ultraviolet (UV) light or γ-irradiation (e.g., Fig. 3(b)). The inorganic framework in these systems acts as a template to control the orientation and conformation of the organic molecules, thereby influencing the degree to which the organic layer polymerizes upon irradiation.

1.2 Other Systems

While the perovskites are among the most extensively studied organic–inorganic hybrid crystal structures, with their characteristic framework of corner-sharing metal halide octahedra, alternate inorganic frameworks can be built up from edge-sharing or face-sharing octahedra (e.g., Corradi *et al.* 1997). In some
Figure 1
(a) The basic AMX_3 perovskite structure and a schematic representation of how the structure extends in three dimensions. The dashed square corresponds to the unit cell on the left. (b) Two families of layered perovskites, which are formed by taking *n*-layer-thick slices along the $\langle 100 \rangle$ and $\langle 110 \rangle$ directions of the AMX_3 structure, respectively, and stacking these layers alternately with an organic bilayer. In each case, only the $n = 2$ structure is shown. Different organic cations are used to stabilize the $\langle 100 \rangle$- vs. the $\langle 110 \rangle$-oriented structures.

cases, the repeating motif is not an octahedron, but rather one of many other possible geometrical forms, including tetrahedra, trigonal bipyramids, or dumbbells. One interesting example (Fig. 4) involves 2-amino-5-nitropyridinium cations ionically bonded within a layered inorganic framework of hydrogen-bonded $H_2AsO_4^-$ tetrahedra (Pecaut *et al.* 1993). The inorganic framework acts to screen the dipolar interactions between organic cations in adjacent layers and enables the formation of a polar structure that might be useful for quadratic nonlinear optical applications. As for the metal halide perovskites, $C_5H_6N_3O_2 \cdot H_2AsO_4$ crystals and films can readily be formed.

2. Processing

The interactions in the hybrid perovskites that promote self-assembly include covalent/ionic interactions, which favor the formation of sheets of corner-sharing metal halide octahedra, ionic/hydrogen bonding interactions between the organic cation and the inorganic sheet halogens, and the tendency of the organic cations to align "tail-to-tail." Other composite crystals exhibit a similar range of interactions. In general, self-assembling materials can be made by simple techniques, such as the Langmuir–Blodgett process (Petty 1996), since the various forces acting between the components favor the final atomic and
Figure 2
Schematic representation of a $\langle 110 \rangle$-oriented organic–inorganic perovskite family. In this case the $\langle 110 \rangle$-oriented structure is stabilized with the iodoformamidinium cation, leading to the family $[NH_2C(I)\!=\!NH_2]_2(CH_3NH_3)_nM_nX_{3n+2}$, where M is a divalent metal and X is a halide (Cl^-, Br^-, I^-).
Figure 3
(a) Crystal structure of the dye-containing $n=1$ $\langle 100 \rangle$-oriented perovskite (AEQT)PbBr$_4$, where AEQT is the doubly protonated form of 5,5$'''$-bis(aminoethyl)-2,2$'$:5$'$,2$''$:5$''$,2$'''$-quaterthiophene (Mitzi *et al.* 1999a). Note that in this structure, the organic cation is a diammonium cation and therefore bonds to two adjacent inorganic sheets. (b) Crystal structure of the polymerized product formed by subjecting $(HO_2CCH\!=\!CHCH\!=\!CHCH_2NH_3)_2CdCl_4$ to UV or γ irradiation. Polymerization yields ordered 1,4-disubstituted *trans*-polybutadiene [–CH(CO$_2$H)CH$=$CHCH(CH$_2$NH$_2$)–]$^\infty$. Hydrogen bonding between CO$_2$H groups on adjacent layers is shown by dashed lines (Tieke and Chapuis 1986).

Crystal structure of $C_5H_6N_3O_2 \cdot H_2AsO_4$, viewed down the crystallographic c-axis. The dashed lines represent the orthorhombic (*Pna2₁*) unit cell outline (Pecaut *et al*. 1993).

molecular configuration. A number of convenient techniques can therefore be used to grow crystals and films of organic–inorganic composites—especially those based on a metal halide framework.

2.1 Crystal Growth

The relatively low decomposition temperature for most organic cations suggests that low-temperature solution crystal growth techniques are favored over higher-temperature techniques (e.g., growth from a melt). Solution crystal growth involves finding a suitable solvent for the component metal halide and organic salts. Several potential solvents include the relatively polar solvents, water, hydrohalic ($X = Cl$, Br, I) acids, various alcohols, acetonitrile, acetone, glacial acetic acid, ethylene glycol, and *N*-methyl-2-pyrrolidone. Generally, stoichiometric quantities of the organic salt and the metal halide are dissolved in the solvent and crystals are grown either through unseeded isothermal evaporation or through unseeded

or seeded cooling of saturated solutions (Arend *et al.* 1978). While for many metal halide frameworks and simple organic cations a range of solvents are appropriate, for large, rigid, and relatively complex organic cations the competing solubility requirements of the organic and inorganic components of the structure limit the choice of solvent. For certain hybrids, layered solution growth and gel growth techniques have also been employed. The various techniques used for growing organic–inorganic perovskite crystals have been discussed (Mitzi 1999). Other metal halide-based crystalline composites can be similarly prepared.

2.2 Thin-film Deposition

While single crystals are generally the most useful medium for examining structural and physical properties of the hybrids, many applications and some measurements (e.g., optical properties) require the ability to deposit thin films. Crystalline organic–inorganic hybrids based on metal halide inorganic frameworks are deposited using a number of simple solution and evaporation techniques.

(*a*) *Solution techniques*. Spin coating enables thin-film deposition of a number of soluble organic–inorganic crystalline composites on a variety of substrates including glass, quartz, sapphire, and silicon. The process involves finding a suitable solvent for the hybrid, preparing a solution with the desired concentration, and applying drops of the solution to a spinning substrate. As the solution spreads on the substrate, the solution dries and leaves a deposit (generally crystalline) of the hybrid. The relevant parameters for the deposition include the choice of substrate, the solvent, the concentration of the hybrid in the solvent, the substrate temperature, and the spin speed. Pretreating the substrate surface with an appropriate adhesion promoter may improve the wetting properties of the solution. Postdeposition, low-temperature annealing ($T < 250\,°C$) of the hybrid films is also sometimes employed to improve crystallinity and phase purity. In addition to spin coating, other solution techniques for depositing the organic–inorganic hybrids include inkjet printing, stamping, and spray coating. All of these techniques require a suitable solvent for the organic–inorganic hybrid.

(*b*) *Evaporation techniques*. In some cases, a solvent cannot be identified for solution deposition of hybrid films. This could be due either to a lack of solubility of the hybrid or to surface wetting considerations for the given substrate. In addition, some applications or studies require deposition under vacuum conditions (e.g., thermal evaporation). The problem with evaporating the hybrid materials is that the organic component of the structure will generally dissociate or decompose from the material at substantially lower temperatures, or in a shorter time interval, relative to the inorganic component. Therefore, if a source containing the hybrid is gradually heated up in a vacuum chamber, the deposited films will not, in general, consist of the same hybrid as the initial source. Two approaches have been employed to overcome this thermal or temporal incompatibility between the organic and inorganic components during evaporation.

In two-source thermal evaporation, the organic salt and the metal halide components of the hybrid are contained in separate evaporation sources and each is heated appropriately to enable a nominally controlled evolution. Assuming that the evaporation rate for the two components can be controlled and calibrated, a stoichiometric and often crystalline film of the organic–inorganic composite can be prepared. Experiments have demonstrated (Era *et al.* 1997) the technique for the organic–inorganic perovskite $(C_6H_5C_2H_4NH_3)_2PbI_4$.

While the two-source technique is suitable for some hybrids and is entirely vacuum-compatible, it has the disadvantage of requiring control over the deposition rate of the organic salt. Often, while the metal halide evaporates in a well-defined fashion, the organic salt deposition is difficult to control. For each new organic–inorganic hybrid, new heater parameters are required to balance the rates of the two components. In addition, given the relatively long times required for evaporation, high vacuum conditions are needed during deposition.

A single-source thermal ablation (SSTA) technique has also been described (Mitzi *et al.* 1999b) which employs a single evaporation source and very rapid heating. A deposit of the organic–inorganic hybrid is placed on a thin tantalum heater within a vacuum chamber. When a large current is passed through the heater, the hybrid ablates over a very short interval ($<1\,s$) and deposits on the substrates positioned above the heater. Since the ablation process is essentially instantaneous, both the organic and inorganic components evaporate from the heater at essentially the same time and, in general, without substantial decomposition of the organic component. Surprisingly, in many cases (especially with relatively simple organic cations) the as-deposited films are single phase and crystalline, indicating that the organic–inorganic hybrids can reassemble on the substrate at room temperature. For more complex organic cations, a short ($<20\,min$), low-temperature ($<200\,°C$) anneal is sometimes required to improve film crystallinity.

(*c*) *Dip processing*. Some organic components will not withstand heating—even the short burst of energy leading to ablation during SSTA. In these cases, or if a suitable solvent for the organic–inorganic hybrid cannot be found, other techniques are required

for thin-film deposition. A dip-processing technique (Liang *et al.* 1998) has been described in which a predeposited metal halide film is dipped into a solution containing the organic cation. The solvent for the dipping solution is chosen so that the organic salt is soluble, but the starting metal halide and the final organic–inorganic hybrid are not substantially soluble. The organic cations in solution react with the metal halide on the substrate and form a crystalline film of the desired hybrid. For the family $(RNH_3)_2(CH_3NH_3)_{n-1}M_nI_{3n+1}$ (R = butyl, phenethyl; M = Pb, Sn; $n = 1$, 2) toluene/2-propanol mixtures work well as the solvent for the organic salt and the dipping times are relatively short (several seconds to several minutes, depending on the system). Single-phase polycrystalline films of the desired product are achieved using the process, without the need for finding a solvent that can dissolve simultaneously both the organic and inorganic components of the hybrid.

3. Properties

Given the flexibility to tailor independently both the organic and inorganic components of the hybrid, a number of interesting properties have been realized or can be envisioned for crystalline organic–inorganic composites. The inorganic framework, for example, can be used to define a well-ordered polar structure for hyperpolarizable organic cations (see Sect. 1.2), therefore potentially leading to large second harmonic generation (SHG) efficiencies. Several other representative examples are given below.

3.1 Magnetism

The effective dimensionality of an inorganic framework has a fundamental influence upon the observed magnetic properties—especially with regard to the possibility of long-range magnetic ordering. Low-dimensional magnetic systems are approximated in real crystals when the magnetic atoms making up the structure most strongly interact with neighbors that are arranged into clusters (0D), chains (1D), or planes (2D). Given the ability to control the effective dimensionality of crystalline organic–inorganic hybrids by varying the thickness of the inorganic layers and the length of the interleaving organic cations, the hybrid materials offer an ideal opportunity to study low-dimensional magnetism.

Many of the reported magnetic organic–inorganic hybrids are metal halides containing first-row transition metals. The $Cu^{2+}(S = \frac{1}{2})$ cation is a typical example, with a single magnetic orbital (d_{x^2}–d_{y^2}) occupied and essentially an isotropic Heisenberg exchange coupling. For antiferrodistortive CuX_4^{2-} (X = Cl and Br) perovskite sheets (Willett *et al.* 1988), the relatively strong in-plane superexchange interaction is ferromagnetic. The generally weaker interlayer magnetic interaction can be either antiferromagnetic or ferromagnetic, with the magnitude of the interaction being controlled through the length and conformation of the organic cation. While at higher temperature the copper(II) halide perovskites can be considered nearly ideal $S = \frac{1}{2}$ 2D Heisenberg ferromagnets, the weak interlayer interactions lead to an overall 3D magnetic ordering at low temperature. The 3D ordering temperature is in the range 4–70 K for the copper halide structures. Hybrid perovskites containing other metal cations also exhibit cooperative magnetic phenomena, including the Cr^{2+} salts which have in-plane ferromagnetic interactions (like the Cu^{2+} compounds), and the Mn^{2+} and Fe^{2+} salts, with antiferromagnetic coupling between nearest neighbors. Magnetism in the layered perovskites and related low-dimensional systems has been extensively reviewed (see, for example, de Jongh 1990).

3.2 Electrical Conductivity

Electrical measurements on the perovskites $(CH_3(CH_2)_nNH_3)_2MX_4$ and $(NH_3(CH_2)_nNH_3) MX_4$ (M = Cu or Cd; X = Cl or Br) indicate that these materials, like most metal halides, are good electrical insulators at low temperature (Tigges *et al.* 1983). At room temperature, a finite but very small conductivity ($\sim 10^{-12}(\Omega\,cm)^{-1}$) originates most likely from ionic rather than electronic conduction. In contrast, several tin(II) halide-based perovskites exhibit substantial electronic conductivity associated with the extended inorganic framework (Mitzi *et al.* 1994). In $(C_4H_9NH_3)_2(CH_3NH_3)_{n-1}Sn_nI_{3n+1}$, for example, there is a semiconductor–metal transition as a function of increasing n (perovskite sheet thickness). The $n = 1$ compound, $(C_4H_9NH_3)_2SnI_4$, is a semiconductor, with a room-temperature resistivity (pressed pellet sample) of $\sim 10^5\,\Omega\,cm$. The $n \to \infty$ compound, $CH_3NH_3SnI_3$, is a low carrier density p-type metal with a carrier density of approximately 10^{19} holes cm^{-3}, a room-temperature resistivity of $10^{-2}\,\Omega\,cm$, and a Hall mobility of $\sim 50\,cm^2$ (V s)$^{-1}$. Consequently, the metal halide-based composites exhibit a range of electrical properties (from insulating to metallic) and can provide a framework with substantial electrical mobility.

3.3 Luminescence

Some crystalline composites exhibit strong luminescence that can arise either from the inorganic or the organic component of the structure. For hybrid perovskites containing optically inert organic cations (i.e., those that do not absorb or emit in the visible range), a strong absorption and photoluminescence (PL) peak in the spectra for germanium(II), tin(II), or lead(II) halide systems arises from the radiative decay of relatively mobile excitons associated with the

bandgap of the inorganic framework. The position of the PL peak can be tuned across the entire visible spectrum by making substitutions on the metal or halogen site of the perovskite or by changing the thickness of the perovskite sheets (Papavassiliou and Koutselas 1995). Low-temperature ($T < 200\,\mathrm{K}$) electroluminescence (EL) has also been observed in these systems (Hong *et al.* 1992). However, the EL is quenched at room temperature as a result of thermal ionization of the excitons. Photoluminescence from the inorganic framework also occurs in some transition-metal (e.g., Mn^{2+}) and rare-earth metal (e.g., Eu^{2+}) halide perovskites. In these systems, the relevant transitions arise from more localized *d* and *f* band transitions and are therefore more sensitive to the local coordination of the metal cation (e.g., through crystal field splitting) than to the global features of the inorganic framework (e.g., the thickness of the perovskite sheets). In the Mn^{2+} halides, for example, red luminescence arises in manganese(II) chloride-based perovskites with octahedral Mn^{2+} coordination, while strong green luminescence is observed for organic–inorganic hybrids with tetrahedral Mn^{2+} coordination.

Chromophores have also been substituted for the optically inert organic cations within the perovskite framework and have been shown to have an important impact on the optical properties of the hybrid. A series of $(RNH_3)_2PbCl_4$ perovskites (R = 2-phenylethyl, 2-methylnaphthyl, and 2-methylanthryl) has been synthesized, for example, with the goal of varying the energies of the organic molecule singlet and triplet states relative to the exciton band of the inorganic framework (Braun *et al.* 1999). For R = 2-phenylethyl, the organic singlet and triplet transitions are at a higher energy than the inorganic exciton band transition, leading to emission only from the exciton state. For R = 2-methylnaphthyl, the exciton band transition lies between the singlet, S_1, and triplet, T_1, transitions and phosphorescence from the organic triplet state is observed. Finally for R = 2-methylanthryl, the inorganic exciton transition is at a higher energy than both the singlet and triplet transitions in the chromophore, leading to singlet emission from the organic layer. These observations are explained in terms of energy transfer between the organic and inorganic components of the structure.

Similarly, in the perovskite system (AEQT) PbX_4 (AEQT = 5,5$'''$-bis(aminoethyl)-2,2$':5',2'':5'',2'''$-quaterthiophene; X = Cl, Br, and I) the absorption spectra for the hybrids exhibit both the exciton transition from the inorganic sheets and a broader absorption associated with the quaterthiophene chromophore (Mitzi *et al.* 1999a). In the PL spectrum, however, the exciton peak from the inorganic framework is quenched. While there is strong PL from the AEQT molecule for X = Cl, this luminescence is substantially diminished across the series from X = Br to X = I. The PL quenching is associated with a progressively smaller inorganic layer bandgap relative to the chromophore HOMO–LUMO gap and the subsequent energy and/or charge transfer between the two components. It is interesting to note that, as for dye-sensitized inorganic semiconducting surfaces (Sakata *et al.* 1990), charge transfer between the organic and inorganic layers of hybrid crystalline composites can be expected.

3.4 Potential Applications

The potentially useful properties and simple thin-film processing techniques described above suggest that organic–inorganic hybrids may prove to be valuable for various technological applications. For example, organic systems have generated substantial interest as semiconducting channels in field-effect transistors (FETs) because of the possibility of simple processing. Spin-coated organic FET channel layers have been demonstrated (Herwig and Müllen 1999) with mobilities as high as $0 \cdot 1\,\mathrm{cm}^2\,(\mathrm{V\,s})^{-1}$ (comparable to that of amorphous silicon). If larger mobilities were achievable, higher-speed devices and therefore a more extensive range of potential applications could be considered. For the organic–inorganic hybrids, similar thin-film processing techniques can be employed as for the organic materials, but higher electrical mobilities are possible because of the stronger ionic and covalent forces binding the inorganic framework. An FET containing a spin-coated film of $(C_6H_5(CH_2)_2NH_3)_2SnI_4$ has recently been demonstrated with a field effect mobility of $0 \cdot 6\,\mathrm{cm}^2\,(\mathrm{V/s})^{-1}$ (Kagan *et al.* 1999). These early organic–inorganic FETs currently have the highest reported mobility values for spin-coatable films and higher values can be envisioned as other inorganic frameworks are explored.

A second area of interest involves organic light-emitting devices (OLEDs). Organic materials have the advantages of high luminous efficiency, spectral versatility, and easy processing. However, the organic dye materials are generally insulating and less thermally stable than inorganic compounds. Joule heating during device operation, as well as the necessarily very thin profile of the organic films, leads to device degradation and short lifetimes. Organic–inorganic hybrids offer the possibility of combining the strong luminous efficiency of organic dye materials with the electrical and thermal/mechanical properties of inorganic compounds. A LED based on the organic–inorganic perovskite (AEQT)$PbCl_4$ has been demonstrated (Chondroudis and Mitzi 1999) which has a thick emission layer (3000 Å) and relatively efficient room-temperature EL. This is in contrast to previous work on devices containing organic–inorganic perovskites with optically inert organic cations, which only exhibited EL at low temperature (Era *et al.* 1994).

While the field of electronic devices based on self-assembling organic–inorganic composites is relatively new, the already demonstrated organic–inorganic FET and LED devices offer several interesting opportunities. Other possibilities include the use of the composites in nonlinear optical devices and solar cells. The fact that the devices can be processed using low-temperature techniques, such as spin coating, inkjet printing, and stamping, enables processing on flexible plastic sheets, rather than on heavier, brittle, more expensive inorganic (e.g., silicon or glass) substrates, which are necessary for higher-temperature processing. Hence, organic–inorganic electronics technologies may help to enable flexible, lightweight, low-cost electronic devices and displays.

4. Conclusion

Crystalline organic–inorganic hybrids combine, on a molecular level, an extended inorganic framework and a network of organic molecules. The organic component can interact with the inorganic framework through a range of interactions, including van der Waals, ionic, and covalent forces, and can be used to define the dimensionality of and the interactions between the components of the inorganic framework. Currently, more complex organic molecules are being designed to fit within the composites, with the goal of creating more functional organic layers. This effort includes designing molecules that are strongly luminescent, exhibit nonlinear optical properties, or are photosensitive or electrically conducting. The inorganic framework, which can consist of 0D–3D arrays of corner-sharing, edge-sharing, or face-sharing inorganic polyhedra, may also provide distinct functionality for the material. By controlling the inorganic framework bandgap relative to the organic energy levels, self-assembling multiquantum well structures can be formed and engineered. In addition, the use of the inorganic framework as a template for performing chemical reactions on the tethered organic molecules has begun to be explored and offers a number of interesting possibilities.

While organic–inorganic composites may contain a variety of inorganic frameworks, metal halide frameworks are particularly interesting because of their solubility in a wide range of common aqueous and organic solvents, as well as their relatively low volatilization temperature. These characteristics enable crystal growth and thin-film deposition using a number of simple techniques. In addition, metal halides (e.g., the hybrid perovskites) offer a range of interesting properties including magnetism, high electrical mobility, and strong luminescence. The ability to conveniently process the hybrids, coupled with the potentially useful properties, suggests that organic–inorganic hybrids may find opportunities within a range of electronic and optical applications.

Paper Products: Classification

Paper and board products are those produced in papermaking and generally involve some converting process. The unit processes of papermaking and their primary functions are as follows:

(i) Refining: fiber structure modification,
(ii) Forming: network formation and water removal,
(iii) Wet pressing: network consolidation and water removal,
(iv) Drying: shrinkage control and water removal,
(v) Size press: surface sizing and coating,
(vi) Calendering and supercalendering: caliper control and surface property modification.

In the papermaking process paper is formed from a uniformly dispersed aqueous suspension of fibers placed onto a screen or forming fabric. Therefore, rice paper (a misnomer—it is actually a veneer cut from the pith of the *Fatsia papyrifera* tree) and papyrus (a woven reed structure produced by ancient Egyptians from which the term paper is derived) do not fall into this category (Hunter 1978). However, specialty products formed as wet-laid nonwoven materials do fall into the category of papermaking. The wet-laid nonwoven process attempts to make textile-like structures. Following web formation the remainder of the process is one of network consolidation, compaction, and water removal through the unit processes of couching, wet pressing, and drying. There are many ways of forming paper and board from the batch process of handmade paper to the special continuous web formers used in the high-speed production of tissue paper. According to Hunter (1978), the first attempts to produce a continuous web of paper were motivated by the strong hold that French handmade paper unions had on paper production.

The raw materials of papermaking are many and varied. The principal components are wood fiber, including softwood and hardwood, fillers, nonwood fibers, and a variety of chemical additives that may be used to improve the efficiency of the papermaking process as well as to enhance the end-use performance of the product. Softwood and hardwood fibers are produced from wood chips by mechanical and/or chemical means. Mechanical pulps include stoneground wood (SG), thermomechanical pulp (TMP), and chemithermomechanical pulp (CTMP). Chemical pulps are mainly produced by the kraft process, although a few sulfite pulp mills are still in operation. Nonwood fibers might include plant and synthetic polymer fibers, as well as glass, ceramic, and metal fibers.

Many paper products require that the product be produced from bleached fibers. In the bleaching process the residual lignin is removed to minimize losses in fiber strength and other chemical components, e.g., hemicelluloses, while at the same time producing a clean, bright pulp. Pulp cleanliness is not only important to the optical properties of paper, but also for electrical-grade papers that are sensitive to impurities and the presence of metal ions. There are many different types of bleaching processes; however, the principal bleaching agent is chlorine, which has been the subject of much criticism because of environmental concerns. This has led to the development of both elemental chlorine-free (ECF) and total chlorine-free (TCF) bleaching systems. Unfortunately TCF-bleached pulps suffer some loss in pulp physical properties including fiber strength and brightness (Heimburger 1998).

Refining, or beating, a term used interchangeably with refining, is part of stock preparation that occurs prior to the sheet-forming process to develop the papermaking potential of the pulp. Balance is sought between the development of paper properties and productivity on the paper machine. Productivity is mainly limited by water removal of which refining has a negative impact. In terms of the paper product aesthetics, converting and end-use performance refining are critical process elements. Refining can modify the structure of the papermaking fiber in a number of different ways, i.e., internally and externally fibrillate, by producing fines, inducing or removing fiber curl and kink, and reducing fiber length (Page 2000). The fiber can be made more flexible and conformable, and its surface area can be increased to promote bonding between the fibers in the network. Fiber shape can also be modified by making the fiber straighter, i.e., removing kinks and curl, or by purposely curling and microcompressing it. The former treatment is designed to produce a paper that is denser, stronger, and stiffer, while the latter treatment could be used to produce a paper that is softer and more bulky. Refining is considered to be an inefficient mechanical process. As refining proceeds there is an increase in water uptake owing to fiber swelling, and the fines or cell wall debris produced adversely affect the drainage behavior of the pulp. Water retention value (WRV) expressed as mass of water per mass of cell wall material is a common measure of water uptake in the cell wall (Anonymous 1991). One common measure of the drainage behavior of a pulp is known as Canadian Standard Freeness (CSF) expressed volumetrically in milliliters of filtrate (Anonymous 1998). If used intelligently, CSF can provide useful information, such as indicating the level of pulp refining. An unrefined softwood pulp would have a CSF of about 740 mL, moderately refined of about 500 mL, and well refined of 100 mL

Table 1
General converting processes.

Converting process	Comment
Coating	Aqueous, nonaqueous
Calendering and supercalendering	Including soft-calendering
Printing	Impact and nonimpact processes
Forming and molding	Corrugating, egg and fruit cartons, paper plates and cups
Laminating	Combining different sheet materials, metal, plastics
Impregnation	Sizing, strength additives, Formica
Modification of deformation behavior	Sack kraft, nonwovens
Gluing, bonding, jointing	Tube making
Size reduction	Slitting and rewinding, sheeting, business forms

or less. The initial or unrefined CSF of a hardwood pulp would be ~ 600 mL.

Converting is one or more processes that convert the large roll of paper from the paper machine, i.e., the machine or Pope reel, into a useable product. Converting processes may involve size reduction and sheeting, the production of smaller well-wound rolls of paper, coating and supercalendering, molding, embossing, laminators, corrugating, and the manufacture of corrugated containers. Table 1 summarizes the main areas of converting. Although some of these processes are specific product related, such as corrugating, they nevertheless may be combined and used to produce less conventional products. For example, corrugating has been used in the production of single-face board (a single liner bonded to corrugating medium) to produce filter-type materials, where the single-face board is wound to form a porous cylinder. It should also be noted that the converting processes given in Table 1 are not exclusively used off the paper machine. Coating, impregnation, calendering, including soft-nip calendering, are examples of converting processes that can be performed on the paper machine.

Paper products are many and varied, and can be classified into one of two broad categories: commodity products (high-volume, relatively low-cost products) and specialty products (essentially the converse). Paper is always in competition with other materials, such as plastics and metals. However, paper can also be combined with other materials to create new products using the converting process of lamination. Predictions have also been made of a significant reduction in paper usage should the paperless society, a product of the information age, ever become a reality. Perhaps the use of paper will decline in some areas; however, it is also possible that this will be offset by growth in new and unforeseen uses. There are not many textbooks dedicated to a comprehensive overview of paper and board products, although there is much information in patents and paper-related journals. However, Paulapuro (2000) is highly recommended. Although written from a Scandinavian and European perspective, it adequately covers the North American scene.

1. Commodity Paper and Board Products

The major high-volume, low-cost products include tissue, newsprint, printing and writing papers, linerboard, medium, and construction grades. The categorization of paper and board is somewhat arbitrary with respect to basis weight (mass per unit area). We might expect paperboard to coincide with some level of basis weight for which there are many measures, some being product specific. Table 2 gives the range of production speeds (approximately maximum) and basis weights associated with a range of commodity products. Also given in Table 2 is the relative importance of a number of physical properties associated with converting and end-use performance.

1.1 Containerboard (Linerboard and Corrugating Medium)

The properties associated with paper and board products are many and varied. TAPPI and ASTM test methods total about 500. The properties of paper and board can be conveniently grouped into the categories given in Table 3.

1.2 Tissue

Tissue and toweling manufacture is a highly specialized and competitive branch of papermaking, and thus very proprietary. Tissue is one of the lowest basis weight products produced, typically in the range $10–20\,\mathrm{g\,m^{-2}}$. The furnish is produced from special market pulps, and some production facilities are

Table 2
Paper products–property matrix.

Product	Speed (m s^{-1})	Basis weight (g m^{-2})	Mechanical	Optical	Dimensional stability	Printing
Tissue	38	15	X	X		
Newsprint	27	45	XX	XXX	XX	XXX
Fine papers	20	70	X	XX	XXX	XXX
Corrugating medium	18	125	XX		X	
Linerboard	14	205	XX	X	X	XX

Table 3
Test methods for paper and board products.

Category	Examples of properties
Structure and composition	Basis weight, caliper, apparent density, fiber orientation, formation
Mechanical properties	Elastic properties, tensile, compressive and shear properties, burst and tear properties
Physical properties	Optical properties including color, thermal conductivity, electrical properties
Surface properties	Smoothness, friction, surface strength, linting
Porous nature of paper	Void volume, pore size distribution, wettability, surface energy
Paper durability	Fold endurance, natural and accelerated aging tests
Converting and end use	Printability, print quality, runnability
Aesthetics and subjective properties	Appearance and uniformity, printing performance, tissue quality, softness

based on 100% recycled fiber. The furnish is beaten to some intermediate level, e.g., 400 mL CSF. Generally tissue is made on a high-speed former at 25–30 m s^{-1}. The web is supported through the consolidation and wet pressing stages before being transferred to a Yankee dryer. The Yankee dryer consists of a large-diameter drying cylinder with a highly polished surface. The web adheres to the surface of the dryer, which may be enhanced by the use of additives and results in more efficient drying of the web. A creping doctor is used to separate the web from the surface of the dryer to which it is bonded. In addition to separation, the most important function of the doctor is to change the properties of the web dramatically. The softness of the tissue is derived substantially from doctoring. The bonds between the fibers are partially broken and the fibers are both curled and microcompressed by the doctor blade in the process of web detachment. Special converting machinery is used to produce toweling, which consists of many layers of tissue, as well as the ubiquitous toilet roll.

1.3 Newsprint

Newspapers are produced from rolls of newsprint having a basis weight of about 45 g m^{-2}. The basic newsprint furnish comprises mechanical pulp and chemical pulp. The high-yield mechanical pulp is important in controlling the optical (particularly opacity) and printing properties of the sheet. The chemical pulp, or reinforcing pulp to which it is often referred, is important for the runnability of the web both on and off the paper machine. Runnability refers to the ability to get the web through the paper machine or printing press with the minimum of web breaks, ideally none. Newsprint is produced using twin wire formers to maximize productivity and to minimize two-sidedness. In fact some publishers insist in their specifications that newspapers be printed on paper produced on a twin wire former.

1.4 Printing and Writing Papers

Printing and writing papers can be both commodity and specialty products. The basis weight range can vary considerably and includes both uncoated and coated papers. As shown in Table 2, mechanical, optical, dimensional stability, and printing properties are very important. These papers are produced in both roll and sheet form for roll- and sheet-fed printing processes. The printing process, end-use performance, and economics dictate composition, coating, and the finish required. Printing includes impact and

Table 4
Coated paper grades.

Grade	Brightness	Gloss
Matte—premium	92–94	15–20
Matte—standard	82–84	10–15
Dull no. 1	85–87	20–30
Velvet no. 2	84–86	20–30
Velvet no. 3	82–84	25–35
Velvet no. 4	80–82	25–35
Enamel no. 1	85–87	65–70
Enamel no. 2	84–86	62–65
Enamel no. 3	82–84	57–62
Enamel no. 4	80–82	50–55

nonimpact processes. The former includes gravure (intaglio), offset (planographic), and letterpress (relief). Letterpress is one of the earliest printing methods now being replaced by flexography where relief is created using polymeric rather than metallic plates. Common nonimpact printing processes are inkjet printing and electrophotography.

Printing and writing papers are generally specified with respect to composition, brightness, and gloss (Table 4). Paper is usually coated to achieve high levels of gloss through the use of supercalendering or soft-nip calendering. Paper grades are referred to as wood- free or merchant grades, i.e., those not containing mechanical pulps, while the term publication grade is used for those containing a combination of bleached chemical and mechanical pulp fibers. Printing and writing papers contain high levels of hardwood fiber to improve formation and surface characteristics. Mechanical pulp fibers used in publication grades serve to increase the sheet opacity.

In addition to optical properties, offset papers require high levels of surface strength to resist picking and surface disruption when high-tack printing inks are used. Dimensional stability (water resistance) is also important with respect to register when two or more colors are being printed. Gravure requires a very smooth paper surface to provide intimate contact with the gravure printing cylinder to facilitate ink transfer. In general all printing papers must have a balance between ink absorbency and ink hold out. This is especially dependent on the pore structure and wetting characteristics of the surface. In addition to enhancing optical properties, coating modifies the pore structure of the surface to control ink absorbency and hold out. Thus coating enhances print quality, a highly subjective characteristic.

The long-term survival of paper or its archival value is a major concern for libraries and others involved in information storage. For example, the US Library of Congress has about three million books in a tender or advanced state of degradation. Earlier, it was not realized that acid-based papermaking

(pH < 6) would greatly reduce the life of paper from acid hydrolysis. There is now a much greater use of alkaline- as opposed to acid-based papers in the production of books. Alkaline papermaking has many advantages with few drawbacks. A calcium carbonate filler can provide a reserve that preserves the alkaline nature of the paper.

It is interesting that early handmade papers such as those made in Europe from the thirteenth to seventeenth centuries had excellent longevity and some are still in nearly mint condition. However, the inadvertent use of alum to improve the effectiveness of gelatin sizing caused some of these papers to be in very poor condition from acid-papermaking conditions (Waterhouse and Barrett 1991).

1.5 Containerboard

Corrugated containers (cardboard boxes) are manufactured from linerboard and corrugating medium collectively referred to as containerboard. Corrugating is the major converting process in a box plant that produces corrugated board blanks. These are subsequently processed by "flexo-folder-gluers" to produce printed corrugated containers in the flat or "knocked down" condition. Corrugated containers are engineered structures that protect the contents during shipment and storage, and in some instances need to be converted into a point-of-sale display item to promote the sale of the contents with appealing graphics.

In addition to the printing requirements, strength is also important. This includes top to bottom or stacking strength, the ability to resist creep particularly in cyclic environments, and end-to-end loads that might be caused by forklift trucks. Containers are often tested to determine their ability to withstand impact loads as well as vibration. The stacking strength of a corrugated container is mainly dependent on the ability of the walls of the container to withstand compressive loads, their flexural stiffness, as well as container geometry. For US interstate shipping and commerce, strength specifications are contained in Rule 41 Item 222. These properties are specified for a given container geometry and size by the compressive strength of the combined board, or the burst strength of the combined board and basis weights of its linerboard facings. Examples for single-wall corrugated fiberboard boxes are given in Table 5.

The row of data in bold print in Table 5 relates to a common container for a maximum load of 290 N, and having a typical construction of two 42 linerboards with possibly a $127\,kg\,m^{-2}$ medium, with a burst strength of 1.4 MPa. An alternative specification (right-hand column of Table 5) gives a compressive strength, known as the edgewise compressive strength, of $5.6\,kNm^{-1}$ for the combined board. This alternative specification could be for a

Table 5
Single-wall corrugated fiberboard boxes.

Maximum mass of box (kg)	Maximum outside dimensions (L + W + H) (m)	Minimum burst test (MPa)	Minimum combined mass of facings (kg m^{-2})	Minimum edgewise compressive strength (k N m^{-1})
9	1	0.86	0.25	4.0
16	1.3	1.03	0.32	4.5
23	1.5	1.21	0.37	5.1
30	**1.9**	**1.38**	**0.41**	**5.6**
36	2.1	1.72	0.54	7.0
43	2.4	1.90	0.67	7.7
54	2.7	2.42	0.88	9.6

wall construction that is a lower basis weight than one based on burst strength, providing the manufacturer with an opportunity for raw material savings. Edgewise compressive strength of the combined board is dependent on the cross-machine direction compressive strength of its component linerboards and corrugating medium. Only about 60–85% of the compressive strength of the components is realized.

Linerboard is manufactured from virgin high-yield unbleached kraft pulps and recycled pulps including old corrugated containers (OCC) and box plant waste or clippings. Most linerboard is manufactured with a base sheet from a higher yield pulp than that used to produce the secondary or top layer of the sheet. The main purpose of the top layer is to provide a good printing surface. Therefore, more refining is used for the secondary furnish, 300 mL CSF as opposed to the base sheet of typically 650 mL CSF. Since CD compressive strength is of paramount importance the paper maker attempts to make as "square" a sheet as possible, MD/CD = 1.

Corrugating medium is manufactured from a variety of furnishes including neutral sulfite semi-chemical (NSSC) and OCC. In a common board construction of 205/127/205 g m^{-2} the medium represents approximately 30% of the total basis weight. The medium also contributes to the CD compressive strength and plays an important role in resisting crushing where MD compressive strength is important.

2. Specialty Papers

Paper products, particularly specialty papers, are many and varied. Listings of paper products and descriptions can be found elsewhere (Anonymous 1999, Paulapuro 2000, Gould 1976, Mosher and Davis 1968, Casey 1983, and Lavigne 1993). A general listing of paper products is given in Appendix 1. Space does not permit a detailed description of all of the products listed, including raw materials, papermaking process, and converting and end-use requirements, but nevertheless it illustrates the diversity of products in papermaking.

2.1 Playing Card Stock

Playing cards, used both for entertainment, games, and educational purposes, have a long history originating in China. The modern playing card has high demands on its manufacturing and end-use performance. It is a coated laminated board product with a high level of print quality. In addition to the need to be dimensionally stable and warp free, the board must maintain a high level of mechanical performance during its usage, referred to as "snap," the ability of the card to maintain its flexural and elastic stiffness during repeated shuffling and dealing.

2.2 Filters

There are many different types of filters with a multitude of end uses ranging from teabags and vacuum cleaner bags to automobile air cleaners. The general but conflicting requirements of a filter are high permeability but a small pore size. Wood, plant, and glass fibers have long been used in filter materials, and also synthetic fibers, particularly as nonwovens. Although synthetic fibers are more costly they have a geometric advantage in control of their cross-sectional shape. Fiber types include polyester, rayon, nylon, Nomex, and Kevlar. The overall efficiency of the filter in terms of particulate removal is inversely proportional to the square of the fiber diameter. Therefore, small-diameter fibers are highly desirable, commensurate with their ability to achieve the desired level of permeability.

2.3 Shoe Innersoles; Luggage

Many specialty products are basically polymer-impregnated fiber networks manufactured using both softwood and hardwood fibers, sometimes with synthetic fiber additions. There are three main methods of polymer addition: furnish or beater addition, wet web saturation, and dry web saturation. In these methods, the polymer may be added before web formation, to the wet web after initial consolidation, or to the dry web either on or off the paper machine, respectively. The polymers available for web impregnation (natural rubber, neoprene, acrylics, and styrene butadiene) have a range of glass transition temperatures. Polymer addition can significantly improve the properties of the fibrous network, including improvement of interfiber bonding, abrasion resistance, fold endurance, and tear and tensile strength.

Unknown to many, footwear has a foundation innersole made from a polymer-impregnated fiber network. The innersole or shoe board material is made on an inclined Fourdrinier paper machine that operates at less than $0.5\,\text{m s}^{-1}$. Wet web saturation is used for polymer addition (Casey 1983). A wide range of products is available to satisfy a variety of shoe, boot, and sneaker styles, and methods of fabrication. Shoe board is essentially a substitute for leather as are other substitutes such as in luggage. In luggage applications the board material would be precoated, coated, and embossed to produce a "leather-like" finish.

2.4 Electrical-grade Papers

Examples of electrical-grade papers include electrolytic- and electrostatic-grade capacitor papers, cable and wire insulation, transformer insulation, and battery separators. Electrical-grade papers can be manufactured from both unbleached and bleached grades of pulp; however, purity is a key factor, e.g., absence of metallic compounds and chlorides, in obtaining the required insulating and dielectric performance. Electrostatic-type capacitor-grade paper is manufactured using deionized water. The well-beaten stock produces a paper that is nearly glassine and must be free of pinholes.

Transformer board is in the high basis weight range of 500–$3000\,\text{g m}^{-2}$. Water and pulp quality are also important requirements for this product. The papermaking process is an intermittent/continuous one. The board is produced by winding a wet web onto a forming cylinder, and when the desired basis weight is obtained the multilayer wet web is released from the forming cylinder for subsequent consolidation, drying, and calendering processes. The apparent density of the final product can be in the intermediate to high range.

Separators for both primary and secondary batteries have long been produced in the papermaking process. In lead–acid batteries, a paper-based separator, which replaced the earlier use of wooden veneers, must physically separate the negative and positive plates. The separator should have, in conjunction with the electrolyte, a low ohmic resistance, important for battery performance at low temperatures. The filter functions of the separator require that pores are sufficiently small and tortuous to prevent dendritic bridging. Other requirements include longevity in the harsh environment of battery acid. In the earlier wood veneer separators, cellulose was protected from acid hydrolysis by lignin. For cellulose fiber separators, this protection was provided by phenolic resin that was added using the wet web saturation process. However, with the advent of the maintenance-free battery in the mid-1970s, the phenolic–cellulose separator was replaced by a noncellulose glass mat.

2.5 Decorative Laminates

It is not often realized that bathroom and kitchen counter tops are paper-based products of laminates that evolved in the early 1900s. Saturating kraft is the basis of this product with the paper made on a Fourdrinier-type paper machine from very free-draining unbleached softwood and hardwood kraft pulps. The critical structure of the paper is such that it will have sufficient void volume and be readily wettable by the resin. The saturating kraft paper is subsequently impregnated with phenolic and melamine formaldehyde resins. A number of plies or layers are used to make the required laminate and are bonded together using heat and pressure. A decorative printed layer is then bonded to the outer surface to provide the necessary aesthetics together with a protective or overlay sheet.

2.6 Currency Papers

Paper money has been around for a long time and is expected to continue despite the wide use of private and business electronic transactions. The end-use requirements of this product are particularly demanding. The ability to maintain its performance over a reasonably long period of time in circulation is highly desirable. The production of currency paper is a very specialized papermaking process. Currency paper is generally made from a well-beaten mixture of linen and cotton fibers. Wet strength, a major end-use requirement, requires addition of wet strength agents. Whereas untreated paper retains only about 4–5% of its dry strength when wet, currency paper requires a strength retention of 40–50%. Melamine–formaldehyde has been the wet strength resin of choice, but environmental concerns about formaldehyde has promoted the use of alternative resins.

It is well known that currency paper loses its crispness during circulation. There is also the necessity of

maintaining flexural stiffness so that automatic teller equipment can operate correctly. Therefore, with improvements in furnish selection and treatment, and resin addition, the useful life of paper currency can be extended.

2.7 Metallized Papers

Joining paper with other materials such as plastics and metals can take many different forms. Paper metallizing is one such important process, involving application of a thin layer of metal to the surface of paper. Labeling is one of the largest end uses for metallized paper including beer and beverage labels, gift-wrap, and wall decorations, using silver, titanium, stainless steel, and aluminum.

The two basic methods of metallizing are direct vacuum metallization and transfer metallization. The main method of metallizing employs a batch or semi-continuous operation where the metal is typically aluminum. Ceramic boat temperatures in the range 1400–1500 °C and a high vacuum of 0.13–1.3 torr are required. The thickness and uniformity of the aluminum layer is controlled by boat temperature, web speed, and the rate of aluminum feed. Operations of unwinding, vaporization, metallizing, and rewinding are all performed under vacuum. Prior to metallizing, the base paper is treated with a lacquer coating, which is vital to promote the adhesion of metal as well as providing curl control. After metallizing, the substrate is remoisturized and may be given a protective topcoat.

Indirect or transfer metallization consists of metallizing a plastic film, applying an adhesive to it, and after partial drying, laminating it to the base paper. After curing, the plastic film is stripped for reuse. In this process, the base paper can be rougher and more porous without affecting the reflective properties of the metal film and does not have to be dried and remoisturized.

2.8 Paper Tubes

There are many varieties of tubes ranging from transparent tape dispensers to paper tube molds for forming concrete columns. The two main methods of tube making are spiral and convolute winding. The spiral method is one of continuous tube production where tube length is determined by a cutoff saw. The paper tube mandrel or former is stationary, and the tube is formed by winding several layers of paper strips spread with adhesive. After cutting, the tubes are dried in an oven. Paper rolls for tubes are generally made from recycled paper.

For tubes for pouring concrete columns, the design specifications are quite challenging in that the tubes must not fail during both the pouring and curing processes. A main performance criterion is the ability of the tube to withstand a large hydrostatic pressure, with a minimum of paper to achieve the optimum strength to weight ratio. This permits the tube manufacturer an opportunity to be cost competitive. There also must be a reasonable level of wet strength performance and dimensional stability. Tube testing is important to validate performance such as burst strength; however, testing of very large tubes is difficult and the performance is often extrapolated from that of smaller tubes.

2.9 Vulcanized Board

Vulcanized board is an interesting specialty product in that the base paper undergoes significant chemical and structural alteration. The resulting board is extremely tough in both in- and out-of-plane properties. The basic process involves treating the base paper with zinc chloride or sulfuric acid, causing a partial surface conversion of cellulose I to cellulose II. As a consequence, the board is densified during consolidation of the structural multilayers, with an improvement in interfiber bonding. As a result of the partial conversion of the cellulose, the board becomes more hydrophilic. Changes in fiber structure such as curl reduction, fibril orientation, and enhanced interfiber bonding provide high tensile energy absorption and toughness.

2.10 Glassine

Glassine is used in a wide variety of applications including cereal and other food packaging. It is produced from a well-refined furnish where fibers undergo extreme hydration. Improvements in the process to allow some reduction in refining have been brought about by size press treatments. The furnish has traditionally included both high-yield softwood kraft pulps and hardwood sulfite pulps. Headbox temperatures are usually quite high, about 60 °C, to promote drainage of the low CSF stock. The density of glassine, depending on the specific product, is typically very high, achieved by supercalendering the moist sheet. Supercalendering, a process where the sheet is passed between a hard steel roll and a relatively soft roll that creates a small, extended nip, may consist of a series of up to 16 nips. The final sheet has an apparent density in excess of $1000\,\mathrm{kg\,m^{-3}}$ (cell wall density of cellulose is approximately $1550\,\mathrm{kg\,m^{-3}}$), and therefore has low air permeability as well as being grease resistant. A highly desirable attribute is the absence of pinholes, which are tested for using dye penetration.

2.11 Embossing Papers

Papers to be embossed need a high level of extensibility (elongation to breakage) to avoid rupture

during embossing. Controlled moisture and temperature can also ensure satisfactory embossing. In addition, the paper must have a level of permanent set to maintain the embossed pattern; fortunately, paper is viscoelastic–plastic and has this characteristic. The elongation or molding characteristics depend on the types of fiber, their treatment, and the drying restraints applied.

2.12 Carbonless Papers

Before the advent of high-speed office copiers, duplication was carried out using a ''carbon,'' paper to which a wax-based, carbon-containing film had been applied. In 1954 the National Cash Register Company began marketing the carbonless paper, which has undergone extensive development to improve and extend its application. Carbonless papers have categories of chemical and mechanical transfer, although chemical copy papers are preferred. The chemical mated system uses matching sheets to create an image in response to pressure. The back of the top sheet (CB) has a coating applied that contains microcapsules (produced by the process of microencapsulation) of a colorless organic dyestuff. This is matched to a second coating on the front of the bottom sheet (CF), acting as a receptor for the dye released from the microcapsules when they are ruptured by impact, such as typing or pressure from a ballpoint pen. The sheets between the CB and CF in multipart forms are coated on their front side with the receptive coating and on their backside with the color microcapsules. The microcapsules are formed by coacervation, interfacial polycondensation, and solvent-induced processes. Coacervation consists of emulsification of the liquid dye in a dispersion of the encapsulating material. The solvent characteristics are then changed to separate the dye from the wall material, which is subsequently polymerized. The resulting microcapsules are about 1–10 µm in diameter. Coating of the base paper with microcapsules is a critical operation and starch is typically used as a spacer particle to prevent damage during winding and other converting operations. The base paper must have excellent formation, and sizing agents may be used to achieve adequate strength and air and solvent resistance.

2.13 Ceramic Papers

The papermaking process can be used to produce papers with high levels of inorganic fiber, metals, and synthetic fibers. Ceramic papers made in this way are precursors to subsequent converting processes to form and mold the material as well as adding high-temperature bonding agents, if not already incorporated. In comparison with wood fibers, ceramic fibers are stiff, noncomformable, and devoid of any natural bonding agent. One approach to forming ceramic

papers in papermaking is to incorporate a small fraction of wood fiber with low-level refining and possibly polymeric bonding agents.

The ceramic green sheet, to which it is sometimes referred, has been proposed for use in catalytic converter applications and other high-temperature gas treatment processes. In the catalytic converter, the ceramic green sheet after corrugating can be rolled into a porous tube and fired to produce a true ceramic. Cellulose and other organic additives are pyrolyzed during this process. Following this operation a platinum film can be applied and fired.

2.14 Dissolving or Water-soluble Paper

Some specialties are produced in very limited quantities since their demand is quite low. Water-soluble paper was at one time produced in the USA, but is now manufactured in Japan. It is remarkable because it ''dissolves'' in a fraction of a second when immersed in water, although it is quite strong in the dry state. Dissolving is a misnomer since the cellulose does not go into solution, but swells at an extremely rapid rate, immediately breaking the bonds between the fibers in the network.

Applications have included in espionage, gardening, and novelty applications. The technology for producing such a paper closely parallels that used to produce superabsorbents, such as used in feminine hygiene products.

2.15 Xerographic Paper

Xerographic paper is important in both printing and copying. The development of high-speed color printers and copiers has placed even greater demands on runnability and printability. Fused toner particles, which have been deposited on the surface of the paper by electrostatic attraction, produce the printed image. The quality of the printed image is dependent on both the physical properties of the toner and paper as well as the mechanical condition of the printer or copier. The quality of the printed image is dependent on the optical, formation, and surface characteristics of the paper. Furthermore, the uniformity of charge on the surface of the paper is also likely to affect print uniformity. Dimensional stability, i.e., resistance to curl formation induced by heat and/or moisture changes, is probably one of the most demanding physical characteristics of xerographic-type papers.

3. Conclusions

This article attempts to provide a broad overview of paper products, including the raw materials, papermaking, and converting processed involved. The interactions of these basic elements are vital in

controlling the productivity, properties, and end-use performance of the product, and importantly its cost. Converting is considered to include nine basic processes each one of which may have many subcategories. Some of these can be performed on the paper machine, while others are off-machine processes. Paper products have been divided into two categories, namely commodity and specialty. The latter category is meant to include those products that are relatively low volume but have high added value. The wide range of specialty paper products discussed indicates the tremendous variety and novelty involved in papermaking.

Appendix 1: Alphabetical Listing of Paper and Board Products

Abrasive backing
Abrasive papers
Absorbent papers
Acoustical board and tile
Adding machine paper
Adding machine rolls
Album paper
Albums
Alkaline-based printing papers
Announcements: commercial, social, wedding
Antitarnish papers and board
Art papers
Asbestos paper and board
Aseptic (extended shelf life) paperboard and packaging
Asphalted paper and board
Bag papers: combination rope and kraft shipping sack, recycled bag and sack, unbleached kraft bag and sack, unbleached kraft shipping sack, other bag and sack
Bags (materials of construction): cellophane, glassine, laminated textile, parchment, waterproof, waxed, wet strength
Bags: multiwall shipping sacks, refuse sacks
Battery paper and board
Beaming paper
Bible paper
Binders board
Black paper
Blanks: coated, plain, mill
Blotting: plain, coated, embossed, enameled, tablet
Bond: chemical wood pulp, cotton (rag content), recycled content, No. 4 cut size (plain copier paper)
Book, alkaline based (acid free, neutral): coated, uncoated
Book coated: cast coated, machine coated, dull C2S, C1S, lightweight (lwc)

Book uncoated: antique, bulking, eggshell, English finish, machine finish, supercalendered
Book offset: coated, uncoated, web
Book end leaf papers
Boxboard folding and set up (14 grades)
Box cover papers (5 grades)
Box liner paper
Boxes, corrugated
Boxes, solid fiber
Boxes, folding (14 grades)
Boxes, set-up (rigid) (10 grades)
Braille paper
Bristols (10 grades)
Burlap lined paper
Business forms
Butchers papers
Button board
Calendar papers
Calendars
Can board stock
Cans (paper, composite)
Cap board
Caps and closures (4 grades)
Carbonizing papers
Carbonless copy base stock
Carbonless copy papers
Carbon paper (4 grades)
Cards, cut
Car liner
Catalog
Cellophane
Ceramic papers
Chart paper (electrosensitive)
Check paper
Chocolate dividers
Cigarette papers
Cloth-lined papers
Coasters
Coating base stock: groundwood papers, book papers
Computer printout paper
Concrete moulds
Condenser paper: electrolytic, electrostatic
Construction (colored school) paper
Copier papers: bond no. 4, inkjet, laser, reprographic
Core stock
Cores
Corrugating medium: semichemical, recycled
Cover papers (10 grades)
Covers and binders
Creped papers
Cup stock
Cups, baking
Cups, drinking (5 grades)
Currency bands and coin wrappers
Currency paper
Decorative laminates
Decorative papers
Dishboard
Disposable garments (14 products)

Doilies
Drawing papers
Dusting paper
Dynamite shell, blasting paper
Egg cases
Electrical transformer board
Electrical cable paper
Electrical insulation paper
Embossed boards and paper
Embossing papers
Envelope stock (4 grades); envelopes (23 types)
Extensible paper
Facsimile paper (bond no. 4 reprographic papers)
Felt, dry (roofing, saturating, organic glass mat)
Fiberboard
Fiber drums
File folder stock
Filter paper
Filters
Fish paper
Flameproof paper and board
Flexible packaging
Fluorescent papers
Food board
Friction board
Gaskets
Gift-wrapping
Glass papers
Glassine (plain, printed, coated, embossed, laminated, metallized, wet strength, waxed)
Greaseproof paper
Grease-resistant paper and board
Greeting card stock
Groundwood printing papers (coated, uncoated, supercalendered, LWC)
Gummed paper (gumming paper)
Gypsum board liner
Hanging paper (wallpaper)
Hardboard
Heat-sealing papers
Hygiene paper specialties (hospital, doctor, dental)
Illustration board
Impregnating paper (absorbent, dry felt, saturating)
Imitation parchment
Industrial packaging and converting papers and board?
Industrial wipes
Inkjet copier papers (bond no. 4 reprographic)
Insecticide papers
Insulating building papers
Insulation paper
Interleaving papers
Ion-exchange paper
Kraft converting paper
Label stock (uncoated and coated)
Laminating stock
Lampshade papers (fire- and flame-retardant, translucency)
Laser copier papers (bond no. 4)

Latex-treated paper and board
Layer board
Layer insulation paper
Ledger (coated, rag content, sulfite, recycled content)
Lens paper
Linen paper (linen finish, paper made from linen rags)
Linerboard (10 grades)
Liners
Lithograph (coated, uncoated)
Manila paper and board
Map paper
Marble papers
Masking papers
Mat board
Matchbook board
Masking tape
Matrix board
Mats (bath, automobile, place)
Metal fiber
Metallic papers and board
Mica papers
Micro paper
Milk carton stock
Mill boards
Mimeograph paper
Mulch paper (garden and agricultural)
Music paper
Napkins
Needle paper
Newsprint (11 types)
Nitrating paper
Noiseless paper
Novelties, toys, and games
OCR paper (optical character recognition)
Oiled papers and board
Onionskin
Opaque
Ovenable paperboard packaging (microwavable)
Overlay papers
Packing board
Packing and cushioning materials (dunnage)
Pallets
Panel board
Pan liners
Papeterie papers
Parchment papers (imitation, vegetable)
Partition stock
Pasted board
Pattern board
Pattern paper
Phenolic impregnated papers
Photographic base paper
Photomount stock
Placemat stock
Plates (molded pulp, pressed paper, baking, ice cream)
Playing card stock
Pleating paper

Polycoated paper and boards
Postcard
Poster board
Poster paper
Pressboard (genuine, imitation)
Pressure-sensitive paper
Proofing paper
Pyroxylin-coated papers
Railroad board (coated, uncoated)
Reinforced papers
Release papers
Reproduction base papers
Reproduction papers (blueprint, blackline, brownprint, diazo, whiteprint, thermal, xerographic, diffusion transfer)
Ribbon papers
Rope papers
Rotogravure papers
Rust inhibitor papers
Sanitary napkins
Saturating paper
School papers
Self-sealing papers
Sheathing (plain, waterproof)
Shelf paper
Shirt board
Shoe board
Shredded paper (cellophane, glassine, packing, parchment, tissue, waxed)
Slipsheets (corrugated, solid fiber)
Stencil board and papers
Straw paper (drinking)
Synthetic fiber papers
Tablet paper
Tabulating card stock
Tag board
Tag stock
Tape, gummed
Tape, pressure sensitive
Teabag paper
Technical specialty papers
Template board
Text papers
Ticket stock
Tissue facial
Tissue papers (9 types)
Tissue toilet (rolls, household, interfolded sheets, jumbo rolls)
Toweling
Tracing papers
Translucents
Transfer paper
Tube board
Tubes
Twisting paper
Tympan paper
Vaporproof paper and board
Vellum papers
Velour papers

Vulcanizing paper
Vulcanized fiber
Wallboard
Wallpaper
Watermarked papers
Waterproof boards
Waterproof building papers
Waterproof papers
Water-soluble paper
Waxed papers (wet-waxed, dry-waxed, wax-laminated, wax-sized)
Wet strength papers
Wrapping papers
Wrapping tissue
Wrappers (13 types)
Writing papers
Xerox copy papers

Paper: Creep

The tendency of paper to conform to its surroundings is of great utility in the conversion of paper to an end-use product. Unfortunately, the same behavior can be detrimental to the end-use performance. An excellent

example of this is the corrugated box. With the aid of steam and pressure, one can take a flat sheet and form the fluted medium that constitutes the middle layer of corrugated board. Then one can score and crease the combined board to produce a box, load it with goods, and store it in a warehouse at the bottom of a stack of similar boxes. Over time, the sides of the box will bulge, sometimes to the point where the stack collapses. All of these deformations are a consequence of the viscoelastic and plastic behavior of paper. The bulging of the box is a consequence of creep, which is defined as deformation accumulated over time and under constant load. The creep behavior of paper is of key importance to the paper and packaging industries.

1. Characteristic Creep Behavior of Paper

Paper, being a polymeric material, exhibits a creep response similar to that of many polymers. In addition, the creep behavior is affected by the fibers and chemicals used to make paper, environmental effects such as temperature and moisture, and the type and level of loading applied to the paper. The effect of moisture on creep is of special interest and the phenomenon known as "accelerated creep" is studied and discussed tirelessly in the paper industry. Brezinski (1956) completed a thorough scientific study of the creep behavior of paper, characterizing the creep behavior of paper in uniaxial tension as a function of applied load and moisture content of the sheet. All of his data exhibited the same characteristic behavior: when a sheet of paper is loaded, there is an immediate elastic response followed by creep, with a typical response as shown in Fig. 1. Note that the initial creep rate is rapid, but diminishes quickly with time. At some point, the creep rate can accelerate, leading to failure.

As shown in Fig. 2, Brezinski (1956) found that the creep compliance (creep strain divided by load) plotted against the logarithm of time for different load levels produced a family of curves that had log-linear regions of creep with equal slopes. Correctly shifting the curves in log time created a master creep curve that can be used to predict the creep strain at any load at any time. Brezinski (1956) also found a linear relationship between the shift in log time required to form a master creep curve and the applied load. The result is that paper exhibits a highly nonlinear relationship between creep rate and load.

A useful method for characterizing the creep behavior of paper is to form isochronous stress–strain curves, which are produced by plotting stress vs. strain at a specified time. The different points for the curve are obtained by varying the applied load and measuring the strain at the specified time. Isochronous curves are useful to discern the effect of varying a particular parameter. Such measurements
Figure 1
Typical creep response of paper.
Figure 2
Family of creep curves used to form master creep curve (from data of Brezinski 1956)

were utilized in both tension and compression by Haraldsson *et al*. (1993). In Fig. 3, isochronous curves are shown for 1 and 10^4 s for both machine direction (MD) and cross-machine direction (CD) of a commercial linerboard subjected to edgewise compressive loading. Note that the curves are initially linear and become nonlinear with increasing strain.

If the load is removed after some creep has accumulated, partial creep recovery is observed. Paper also exhibits creep hardening, where the creep rate is reduced for subsequent creep loading of paper. It can be inferred from the work of Padanyi (1993) that much of the hardening effect can be eliminated by subjecting paper to a cycle of changing moisture content between creep loadings.

The creep response outlined above is typical of paper products. Specific papers will have slightly different behaviors, depending on their composition and testing conditions.

574

2. Compression vs. Tension

Haraldsson *et al.* (1993) found that compressive and tensile creep were the same at low loads, but as the load increased the creep was greater under compression. While a tensile creep test is very simple to perform, compression creep testing is difficult because of the low buckling resistance of a sheet of paper. This has led to several compressive creep tests, using lateral support fingers (Haraldsson *et al.* 1993), vacuum pressure to hold the specimen flat (Setterholm and Gunderson 1983), or testing of paper cylinders (Setterholm and Gunderson 1983). Although these tests produce the same basic behavior, the magnitude of results will most likely differ.

3. Effect of Various Parameters

Increasing moisture content of paper causes higher creep rates in both tension and compression (Brezinski 1956, Söremark *et al.* 1993). Brezinski (1956) also found that increasing the density of the sheet by wet pressing and beating reduced the rate of creep in paper. At the same density, increased beating of the pulp also reduced the creep.

In general, increased restraint during drying creates a sheet that exhibits less creep (Schulz 1961, Söremark *et al.* 1993). As shown in Fig. 3, machine-made papers typically exhibit less creep at a given load in MD than CD. This creep anisotropy is from the combined effects of drying restraint and fiber orientation (Söremark *et al.* 1993).

Byrd (1984) reported compressive creep rates of paperboard made from different fiber sources, including virgin, recycled, and high yield pulps that were very similar when tested under a load equal to 25% of the compressive strength of the board. Bobu

et al. (1984) found that increasing calcium carbonate increased the creep rate of paper. Caulfield (1994) showed that use of cross-linking agents, such as formaldehyde, in the papermaking process greatly reduced creep rates.

4. Accelerated Creep

Much of the creep research for paper has focused on the acceleration of creep by cyclic humidity. Since the first observations of Byrd (1972), it has been well established that a cyclic humidity environment is more severe for creep of paper than constant exposure to high relative humidity, which is illustrated in Fig. 4. This coupling of a mechanical action (creep) with a moisture effect (hygroexpansion) is termed the mechano-sorptive effect.

Accelerated or mechano-sorptive creep is probably the critical factor that limits the lifetime of a box. The majority of warehouses do not have controlled humidity environments, and the humidity cycles on a daily basis. This increases the rate at which the box creeps in compression and accelerates the bulging and failure of the boxes. Although the actual rate of accelerated creep varies as a function of the cycle time (Urbanik and Lee 1995), the total amount of creep appears to be relatively constant as a function of the number of cycles (Gunderson and Tobey 1990). Below some optimum cycle time, the accelerated creep rate decreases. This is especially true if the cycle

Figure 3
Example of isochronous creep curves for paper subjected to edgewise-compressive loading (from data of Haraldsson *et al.* 1993)
Figure 4
Creep at constant high moisture and accelerated creep of paper exposed to tensile loading (from data of Habeger and Coffin 2000).

time is less than the time needed for the paper to reach moisture equilibrium.

Researchers in the paper industry have focused on explaining the mechanisms of accelerated creep, relying on special phenomena such as dependence of creep rate on moisture gradients, or hydrogen bonds breaking and reforming. Söremark and Fellers (1993) have proposed that stress gradients and the formation of local dislocations explain accelerated creep. Habeger and Coffin (2000) have shown from a pure mechanics standpoint that accelerated creep is a natural consequence of the stress gradients created by changing moisture combined with the creep properties.

5. Summary

Creep behavior of paper is important to many converting operations and end-uses. Beyond creep, other rheological characterizations, including stress relaxation, dynamic mechanical analysis, and constant strain-rate loading and unloading tests, have been done for paper. The viscoelastic and plastic behavior of paper is quite difficult to fully characterize, because of the complexities arising from paper structure, temperature and moisture effects, differences in tension and compression, and the coupling of all these effects. There is still no adequate mathematical model that fully explains creep behavior. There is also not a full explanation of the mechanisms of creep and the role of fibers and bonded regions. One must still characterize creep behavior experimentally, including the mechano-sorptive effects. This is especially true when evaluating commercial paper for potential end-use products.

Paper: Effects of Moisture and Temperature

Paper physicists, in attempts to understand mechanical and rheological properties of paper, have used two apparently competing approaches—molecular and structural. The molecular approach assumes that the important mechanical and rheological properties of paper stem ultimately from the cohesive molecular forces that hold the material together. The structural approach views the important mechanical and rheological properties of paper as being controlled ultimately by fiber and network structure on a supermolecular level. In the structural approach the rheological behavior of paper arises from the bending, stretching, and shearing of fiber segments between bond sites as well as the deformation of fibers at the actual bond sites (Page 1969). This approach has included the many network models and deals with the structure of paper on a microscopic, rather than a molecular level.

These two views are not necessarily contradictory, but represent complementary views of paper as seen

at different levels of magnification in its complicated hierarchy of structure. At an intermediate level of this hierarchy of structure is the macromolecular level, which provides an alternate view for explaining mechanical and rheological properties. Ultimately, although the mechanical properties must depend upon the intermolecular forces that hold any material together, there is a complicated interplay between forces and geometry or structure. Clearly the structure and morphology of paper provide the framework upon which molecules are arrayed and through which those intermolecular forces operate. Consequently, there are alternate explanations for the behavior of paper, dependent upon the level of the hierarchy of structure that is examined. However, in the important questions concerning the influence of temperature and moisture on paper properties, the defining level of structure is not arbitrary. How do temperature and moisture interact with paper? With what level of the hierarchy of the structure of paper does temperature or moisture interact? And is this interaction quantifiable? Clearly heating or cooling always involves a molecular process, and water interacts with cellulose or paper at a molecular level.

1. The Molecular Approach—Factoring Out Structure

The molecular approach attempts to describe the rheological behavior of paper in terms of the molecular forces. Macroscopic stress–strain behavior is assumed to arise from interatomic potentials and the straining of molecular bonds. A strong proponent of the molecular approach to explaining the rheology of paper has been Nissan (1977), who incorporated into his approach a number of simplifying assumptions to minimize mathematical formalism. The major simplification is that the only important interatomic potential is that associated with the hydrogen bond. Nissan's molecular approach emphasizing the importance of the hydrogen bond has been called the theory of hydrogen bond-dominated solids. (Nissan's many contributions to this theory span a period of almost 50 years.) A solid is generally considered hydrogen bond-dominated where stiffness and mechanical strength disappear when fully saturated with liquid water. Ice represents the pre-eminent hydrogen bond-dominated solid. Paper repulpability and recyclability offer evidence of being in this class of materials.

Nissan's hydrogen bond theory that deals primarily with the elastic modulus of paper (and to a lesser extent, the flow portion of the stress–strain curve) sees the hydrogen bond as the predominant average local molecular feature of the structure. It is distinct from structural models in that the elastic modulus of paper appears to be independent of its network structure. In its simplest form, assuming isotropy,

Nissan's theory states that the elastic modulus of paper is proportional to the cube root of the number of effective hydrogen bonds per unit volume:

$$E = k(n)^{1/3} \tag{1}$$

where E is the modulus of elasticity, n is the number of effective hydrogen bonds per cubic volume, and k is the spring constant of the hydrogen bond. This expression states that the density of hydrogen bonds, along with the force constant of the hydrogen bond, determines the modulus of the material. This idea that the elastic modulus of a material depends only on intermolecular interactions is not unusual to polymer science. Polymer scientists have long understood that the elastic modulus of most polymers in the glassy state is determined primarily by the strength of intermolecular forces and not by the strength and geometry of the covalent bonds along polymer chains (Nielsen 1974).

Intermolecular forces are generally characterized by polymer scientists in terms of the material's *cohesive energy density* (CED), a measure of the energy needed to separate and remove completely one molecular unit from its neighbors. For small molecules, CED is approximately equal to the heat of vaporization at constant volume, but for polymers it must be evaluated by indirect methods. CED generally correlates with the elastic modulus of polymers. Tobolsky (1960) pointed out a simple proportionality between the bulk modulus of polymers and their cohesive energy densities and Holliday and White (1971) noted a similar proportionality between elastic modulus and CED of polymers. These observations that modulus is determined largely by intermolecular forces expressed in terms of cohesive energy density are very similar in essence to Nissan's suggestion that the elastic modulus of paper depends only on the density of hydrogen bonds, the type of intermolecular force that dominates in hydrogen bonded materials. Two aspects of paper that the molecular or hydrogen bond approach can help explain in both qualitative and quantitative terms are the effects on elastic modulus that are caused by changes in either temperature or moisture.

2. Effect of Temperature on Modulus

Nissan (1977) has provided in some detail a derivation of the temperature dependence of elastic modulus (see also Dodson and Herdman (1982) for a concise summary.) Using statistical mechanics and the well founded Lippencott-Schroeder potential for the hydrogen bond, Nissan and Batten predicted a temperature dependence for the elastic modulus of cellulose to be approximately equal to

$$d(\ln E)/dT \sim -2.4 \times 10^{-3} \, {}^\circ C^{-1} \tag{2}$$

This relationship was rigorously derived without arbitrary parameters (Batten and Nissan 1987) and means that the elastic modulus should decrease about 0.24% for every 1 °C rise in temperature. Nissan (1977) compared the predicted value with measured values for a variety of cellulosics and found the theory reasonably predictive. Values for $d(\ln E)/dT$ obtained from the literature ranged from -1.8×10^{-3} to $-6.3 \times 10^{-3}\,°\text{C}^{-1}$ for various cellulosics including paper. Two additional sets of experimental data on paper also give values for the temperature dependence of modulus that support the theoretically derived value. Salmén and Back (1977) report that between $-25\,°\text{C}$ and $175\,°\text{C}$ the elastic modulus of paper decreases at a rate of about 0.3% per degree. From data obtained in torsional experiments, de Ruvo *et al.* (1976) report the relative change in rigidity of paper with temperature to be about $-2 \times 10^{-3}\,°\text{C}^{-1}$. No network theory of paper has been capable of predicting a temperature dependence of modulus.

3. Effect of Moisture Content on Elastic Modulus of Paper

The reduction of the elastic modulus with moisture is another property of paper that is well described by Nissan's theory of hydrogen bonded solids. This reduction in elastic modulus (E) is viewed as resulting simply from the reduction in the number density of effective hydrogen bonds by the disrupting, competitive action of water. Nissan concludes that the elastic modulus should show an exponential decline with moisture content, w, in two distinct regimes.

$$\text{Regime I for} (0 < w < w_{\text{crit}}) \quad d(\ln E)/dw = -1 \quad (3)$$

$$\text{Regime II for } w_{\text{crit}} < w \quad d(\ln E)/dw = -(\text{C.I.}) \quad (4)$$

In the region of low moisture contents, below monolayer coverage, w_{crit} (about 5% moisture content), the value of the slope when plotting in (modulus) versus moisture content is expected to be about minus unity. At moisture contents above w_{crit}, the negative slope is greater (equal to ~ 5 or 6), and is designated by the symbol C.I., signifying *Cooperative Index*. Nissan views the reduction of E with increasing moisture as resulting simply from a reduction of the number of effective network hydrogen bonds by the disrupting, competitive action of water.

In the region of low moisture contents, below about 5% moisture, the value of unity is predicted. At moisture contents above $\sim 5\%$ (and to saturation), the value of C.I. is considerably larger; predicted by Nissan to be about 6.7. This value was obtained by combining the ideas of hydrogen bond-dominated solids with the cluster integral concept of water in order to help explain how one molecule of water added to a cellulosic network seems to disrupt

several effective network bonds; i.e., a cooperative bond-breaking effect. A value of 6.7 for C.I. indicates that the decrease in elastic modulus is expected to be about 7% for every 1% increase in moisture content. Data at low moisture contents are sparse, but for moisture contents above 5%, Nissan (1977) has compared the experimental value of C.I. evaluated from results reported in the literature and, excluding values obtained from sonic measurements, finds values ranging from 5.7 to 8.2. Sonic and other dynamic methods of measurement (Caulfield and Weatherwax 1978, Htun *et al.* 1985) have shown exponential decrease of elastic modulus with increasing moisture content, but give smaller values for C.I., in the range of $\sim 3–5$.

3.1 Moisture Effect on Ultrasonic versus Static Modulus Measurements

For many years there have been these unresolved differences between measurements of elastic modulus. Typically the values for modulus obtained ultrasonically, E_u, have exceeded those measured on mechanical-type machines, E_s (the subscript s signifying static as opposed to the ultrasonic {u} method). At low moisture content, the elastic modulus measured sonically, E_u, exceeded the static modulus E_s, by about 10%. But this discrepancy between measured E_u and E_s appeared to worsen as the moisture content of the paper increased. Nordvall (1992) has confirmed these differences and has provided data comparing elastic modulus measured by both methods measured on 24 different papers in both machine and cross-machine directions as a function of moisture content. These results clearly quantify the nature of the differences, and have provided important data with which to test some aspects of the internal consistency of one of the predictions of the hydrogen bond theory.

One starts with the basic assumption that the elastic modulus depends on the cube root of the effective number density of hydrogen bonds (Eqn. (1)) and that the effective number density of hydrogen bonds is different. Depending on the method of measurement; that $(n)_u > (n)_s$, and that the observed moisture dependence of the measured modulus is given by the relationship shown in Eqn. (4), then it can be shown (Zauscher *et al.* 1996, 1997) that

$$(E_0)_u^3/(E_0)_s^3 = \{(\text{C.I.})_s + 1\}/\{(\text{C.I.})_u + 1\} > 1 \quad (5)$$

The cube of the modulus ratio (ultrasonic/static) at zero moisture content should be predictable from the ratio obtained from the slopes of plots of $\ln E$ versus moisture content in Regime II. Although a ratio larger than unity arises from the initial assumptions, the prediction that the cube of the modulus ratio should be derivable from the moisture dependence

of the modulus can only arise if the concepts of the hydrogen bond theory are valid.

The two ratios were obtained from the experimental measurements in both machine and cross-machine directions, and also for equivalent isotropic papers. For both ratios the values are greater than unity, closer to 1.3, but they are not statistically different. This equality of the ratios indicates an internal consistency with the hydrogen bond explanation of the phenomenon. The experimental results also indicate for typical papers as those examined, that in the dry state, sonically measured elastic modulus exceeds the statically determined modulus by about 10%, but that the difference becomes more pronounced, i.e., $> 30\%$, as moisture content increases. These differences arise from the existence of two different forms of energy storage and propagation in paper dependent on the method and time scale of modulus measurement.

3.2 Nonlinear and Viscoelastic Effects on Strength of Paper

When paper is deformed by external forces, part of the work done is dissipated as heat, but paper can also store and dissipate mechanical energy. If a solid is subjected to a sinusoidally oscillating stress, and the strain is intermediate between exactly in phase and $90°$ out of phase with the stress, then its behavior is called viscoelastic. Paper behavior is viscoelastic, which is evident in other rheological properties and stress–strain behavior. Paper exhibits nonlinear load–elongation curves. Paper creeps when subjected to a constant load; deformation of a paper strip is not instantaneous, but elongates with time. Analogously, paper also exhibits stress-relaxation. If paper is stressed and held at a fixed elongation, the internal stresses relax with time. Paper also exhibits marked rate of loading (ROL) and duration of load (DOL) effects (Caulfield 1985). The measured strength of a piece of paper increases with the rate of stressing. The failure strength in a linear-ramp ROL experiment increases with the logarithm of the rate of stressing. In DOL behavior, paper deadloaded to a level below its normal breaking stress will nevertheless fail if the stress is maintained for sufficient time. The logarithm of the time to failure under a constant deadload stress increases with decreasing stress levels.

The presence of moisture in paper accentuates all viscoelastic characteristics. In addition, moist paper and paper in changing humid environments exhibit a host of additional viscoelastic phenomena generally classified as mechanosorptive effects. Grossman (1976) has described a long list of these effects as they are manifested in wood, and many presentations in one of a series of symposia (Fellers and Laufenberg 1994) have been devoted to topics of mechanosorptive effects in paper.

3.3 Viscoelastic Properties

The elastic properties of the hydrogen bond-dominated solid are described as dependent on an average number density of effective hydrogen bonds. Little is said about its time dependence and how this average is obtained. In order to make explicit the viscoelastic properties of a hydrogen bond-dominated solid, the labile nature and time dependence of the hydrogen bond distributions must be considered. Molecular models show that the cellulose molecule is completely covered with hydroxyl groups. Within the fiber, the stiff cellulose molecules are connected in long chains by strong chemical covalent bonds. But these chains are held side-by-side by hydrogen bonds that are much weaker than the chemical bonds along the chains. Within the cellulose structure there is little chain entanglement and there are no chemical covalent bonds between fibers, also held together by only weak hydrogen bonds. The hydrogen bond is so much weaker than the covalent bond that its energy is of the same order of magnitude as the thermal kinetic energy associated with molecules at ordinary room temperature:

Covalent bond energy $340 \, \mathrm{kJ \, mol^{-1} \, K}$
Hydrogen bond energy $\sim 19 \, \mathrm{kJ \, mol^{-1} \, K}$
Thermal kinetic energy at room temperature $3.8 \, \mathrm{kJ \, mol^{-1} \, K}$

Only 1% of molecules at ordinary temperatures (estimated by Boltzmann statistics) have thermal energies greater than the energy associated with the hydrogen bond. This can only mean that hydrogen bonds are breaking and forming very quickly at room temperature, just as they are presumed to do in water. Therefore, paper is held together not by a locked array of hydrogen bonds, but rather a flickering array of bonds. At any one instant, a fraction of the hydrogen bonds is open. This flickering array is effective in providing the mechanical integrity and high modulus of paper since the array is densely spread over a large area, and because cellulose chains are stiff. Even if a number of bonds open cooperatively while a dry fiber assembly is stressed, the resultant strains can be small because the hydrogen bond array tends to reform quickly with the same atoms paired.

When paper is exposed to moisture or high humidity, cellulose absorbs water between fibers and within the cell wall (Chatterjee and Ramarao 1997). The water molecules compete for the hydrogen bonding sites, disrupting bonds between cellulose surfaces. The swelling action of water separates the cellulose chains from one another (and at the same time plasticizes them, making them more flexible by allowing more free volume.) Now if a stress is applied when water is present, the hydrogen bond array still flickers open and closed. But on closing, the array need not reform with its original partners paired. The details of how the flickering array responds must clearly depend upon the time duration over which the stress is

applied. In this respect, the number density of effective hydrogen bonds has an inherent time dependence. Two instances in which this time dependence is revealed are (i) the differences in elastic modulus when measured by ultrasonic or static methods (mentioned above), and (ii) creep and stress relaxation.

3.4 Bond-breakage Theories, Stress Relaxation and Creep of Paper

When a sheet of paper is subjected to a constant stress, it will deform and the strain will increase with time. Likewise, when a sheet of paper is strained and held at constant length, the initial stress relaxes with time. Rance (1950) was the first to suggest that the irreversible flow characteristics of the viscoelastic behavior arise from a continuous series of internal ruptures in the sheet, and ultimately lead to failure. However, the irreversible breakage of bonded area between fibers has been reported to play only a modest role, and then only in the final stages of the stress–strain curve near failure. Steenberg's (1947) idea of viscous elements was introduced to the bond-breaking theory when the bonds are weak and have the potential to reform after breaking. This concept led to the hydrogen bond explanation of elastic and viscoelastic behavior. Although hydrogen bonding alone may be the predominant structural entity during the early stages of deformation, and thereby easily related to tensile modulus, it is difficult to relate hydrogen bonding with rheological behavior further out on the stress–strain curve, where other features of fiber and network structure contribute. However, Nissan and co-workers have made attempts to relate the plastic or nonlinear region of the stress–strain curve to the form of the hydrogen bond potential (Nissan *et al*. 1985).

Stress relaxation, (or equivalently creep) has been described by Nissan (1977) in terms of the kinetics of hydrogen bond breaking and reforming. He viewed stressed hydrogen bonds as being less stable than unstressed, so that stressed bonds flicker open and re-close in different unstressed configurations. And because this stress relaxation is viewed in terms of chemical bond rearrangements, classical chemical kinetics can be applied. If the relaxation is assumed to result from the cooperative process in which bonds break simultaneously, Nissan suggested a basic kinetic equation (Nissan 1967):

$$-\mathrm{d}(n/n_0)/\mathrm{d}t = k(n/n_0)^a \qquad (6)$$

The left side of the equation represents the rate at which the fraction of the initially stressed bonds relax into an unstressed state; k represents the 'chemical' rate constant; and a, the order of the reaction, is the C.I. of the bonds breaking simultaneously. Analysis of the experimental data led Sternstein (1961) and

Nissan and Sternstein (1962, 1964) to conclude that there was more likely a spectrum of C.I. involved. For example, stress relaxation data for cellulose at 75% RH exhibits C.I. maxima at about $-70\,°\mathrm{C}$ and $-150\,°\mathrm{C}$, i.e., close to temperatures at which instrumental methods also indicate relaxation phenomena. This interpretation of stress relaxation, however, is based on the axiom that viscoelastic properties can be interpreted in terms of the hydrogen bond. From this viewpoint, viscous effects are the result of the time-dependent change in the number of effective hydrogen bonds, and not primarily due to the flow characteristics of a viscous element.

4. Factoring in Structural Considerations

4.1 Models for Viscoelasticity

The study of the viscoelastic behavior of materials may be approached on many levels. For much of its history, one approach to viscoelasticity has been in terms of models. Springs and dashpots coupled as Maxwell bodies and/or Voigt (Kelvin) bodies and, arranged in a multitude of arrays, have been used as helpful analogs for different viscoelastic materials (Alfrey 1948) including paper. Dashpots containing non-Newtonian fluids have often been found necessary to more accurately represent the behavior of the model to a real viscoelastic material (Andersson *et al*. 1949). In all cases, however, the use of spring/dashpot models, combining elastic and viscous elements, is essentially an empirical curve-fitting technique, and far removed from actual molecular behavior.

Aside from the thermodynamic approach to rheology discussed later, viscoelasticity may be described from a fundamental phenomenological approach using only mathematics and a continuum theory. To some purists, this is the only sound way that viscoelasticity can be understood. However justified that viewpoint may appear, the fact remains that matter (and paper certainly) is not a continuum but consists of molecules, and the differences in properties of different materials must be due essentially to the differences in their molecular structures and behavior.

4.2 Macromolecular Behavior

One molecular approach to describe rheological behavior of paper in terms of molecular structure applies concepts that have been successful in the field of macromolecules; glass/rubber transitions, free volume, and plasticization. The methods have been adopted from polymer physicists, where dynamic mechanical behavior, dielectric behavior, ultrasonic response behavior, dilatometry, and DSC properties have been used. In the dynamic response methods, behavior is monitored as frequency, temperature, and/or moisture are varied. To the polymer physicist

dealing with synthetic polymers, damping peaks in many macromolecules can be identified as belonging to certain specific atomic groups. For synthetic polymers, these results are presently the best examples of experimentally observed connections between rheological behavior and molecular dynamics.

As strains become larger, however, the role of other elements of structure necessarily increases. The function of cellulose chains can be looked upon as providing a framework, a geometric backbone, upon which the hydroxyl groups are arrayed. The morphology and structure of fibers determines how this framework is distributed through space and, thereby, how the hydrogen bonds are distributed. As strains increase, distortions arise not only from increases in interatomic separations, but also from movement of larger elements of the framework structure. Consideration of larger elements of structure also permits the treatment of anisotropy, whereas the molecular approach fits easily only with an idealized case of uniform distribution in three dimensions.

One way to factor in the role of polymeric and fiber structure has been through previously mentioned methods in polymer research, permitting combining molecular chain mobility and the effects of both temperature and moisture on mechanical behavior of paper.

To the paper physicist, the problem of relating rheological behavior to molecular structural dynamics has proven to be more difficult. Cellulose appears to be more complicated than common synthetic polymers; experimental results concerning various measured transitions are incomplete and, in certain respects, not reproducible (Klason *et al.* 1976). In cellulosics, there is general agreement that two relaxations are observed below room temperature at low frequencies (~ 1 Hz) at about 250 and 180 K. These have been suggested as arising from conformational changes involving methylol groups (Bradley and Carr 1976). Relaxations reported near 373 K are probably due to evaporation of water; and the weakly developed relaxations near room temperature have been attributed to transitions of adsorbed water or to other conformational transitions that were first suggested by Wahba (1965).

It is not until considerably higher temperatures are reached that transitions appear like true glass transition. Salmèn and Back (1977, 1980) in quantifying the effect of temperature on elastic modulus, found a marked decrease in modulus starting at 200 °C that resembled a glass transition. They found that for dry cellulose the glass transition is as high as 230 °C, while for hemicelluloses it lies between 165 °C and 225 °C. They describe the effect of water as plasticizer and interpret its effect on the mechanical properties of cellulose as a lowering at the effective glass transition of the polymer. Qualitatively this must be the case, but there is no indication as to what molecular chain segments might become mobile, and at what

moisture contents. Salmèn and Back admit that an interrelation must exist between apparent glass transition and a pronounced increase in hydrogen bond mobility. Goring (1966) has suggested a description in which water does not plasticize cellulose at a molecular level, but rather at a microfibrillar level.

Kubàt and co-workers (1969) and de Ruvo and co-workers (1976) have also related elastic modulus to volume effects that result from either thermal expansion or hygroexpansivity. Paper coefficient of thermal expansivity is of the order of $1 \times 10^{-5}\,°\mathrm{C}^{-1}$, and is approximately three times greater in CD than MD. Kubàt and co-workers (1969) found that the product of the elastic modulus and the thermal expansion coefficient is constant and independent of direction in which the measurements are made. De Ruvo and co-workers (1976) verified this observation and also found a similar approximate relationship for swelling. The product of hygroexpansivity and elastic modulus was also almost constant, independent of the direction of measurement. The swelling relationship appeared somewhat improved, however, if the geometric mean of the dimensional swelling was combined with the geometric mean of the elastic modulus in the MD and CD directions. From the similarity of behavior of paper sheets and individual fibers, de Ruvo *et al.* (1976) concluded that the network structure *per se* has little role in changes caused by temperature or moisture on elastic properties. Instead, response to changes in temperature and moisture are governed by properties and structures intrinsic to fibers and not a result of their network consolidation.

The addition of plasticizing water is qualitatively equivalent to an increase in temperature in that it provides an increase in the free volume available. Expansional strains, caused either thermally or by swelling, are inversely related to elastic modulus.

As the distance of separation between interacting groups is increased, either by thermal expansion or by swelling, the mean attractive force diminishes. This reduced attraction can be viewed as a type of bond weakening, and, in the limit, as a type of bond breaking. In this way, the concepts of glass transitions, plasticizers, and free volume afford a means of rationally connecting the mechanical properties of an anisotropic fiber structure to one whose elastic properties may also be described as hydrogen bond-dominated.

5. *Ultimate Strength Properties*

Paper strength properties as evaluated from tests to failure or rupture are more difficult to relate to the structural features of paper. Whereas elastic modulus reflects an intrinsic, average structural feature of a sheet, ultimate strength properties may be dominated by other less general features such as flaws and

defects. Nevertheless, strength properties show many of the same correlations with temperature and moisture as the elastic modulus. (The survey by Crook and Bennett (1962) remains the best overall source of general data on the effects of humidity and temperature on paper's ultimate strength properties.)

The effects of temperature on ultimate strength properties tend to be less important than the effects of moisture and are often masked by the small changes in RH or moisture that accompany changes in temperature. Wink (1961) has presented a graphical representation of the average effect of temperature on strength of paper while keeping moisture content of the paper constant (by adjusting RH). Over a range of about 30 °C, he shows that tensile strength drops about 20%, or at a rate comparable to the loss in tensile modulus. Stretch, on the other hand, shows an increase of about 30%. Tensile energy absorption, being effectively the integration of tensile stress over strain up to failure, shows only modest changes (<10%) in the same temperature range.

The generally held view is that paper strength varies with temperature and moisture content by affecting two basic factors. Page (1969) has developed a network theory of tensile strength that identifies and tries to separate the effects of these two factors, fiber-to-fiber bonding and individual fiber strength. Fiber bonding and fiber strength do not react similarly to moisture. Fiber bonding weakens as moisture is absorbed, while individual fibers become softer, more pliable, and stronger (Crook and Bennett 1962). Physical properties that are measures of strength tend to have maxima at low or moderate relative humidity (RH). Properties for which flexibility is of importance will generally increase in value as humidity rises. Tensile strength, for example, tends to have a maximum at RH between 30% and 50%. Above 50% RH, the tensile strength tends to show a moderate decrease to about 65% RH, where it drops sharply with further increase in RH. Extensibility or strain to failure, conversely, tends to increase continuously over the full range of increasing RH. Strain to failure may increase over four fold from 20% to 90% RH, an increase among the highest of any mechanical property. Burst strength is a complex property that is influenced by both tensile strength and extensibility; and a change in moisture affects the tensile strength and extensibility in opposite directions. Thus, of strength tests, burst shows the least effect of increasing humidity. A typical curve of burst value vs RH shows little curvature, with only a slight maximum between about 40 and 70% RH. Tear resistance generally shows a continuous increase of between 0.5 to 1% per +1% RH to about 80% RH. At very high humidities, tear resistance also decreases as very weakened fiber–fiber bonding allows fibers to slip apart more easily. Fold endurance is a measure of flexibility and tends to show an increase of between 1

and 5% per +1% RH to above 80% RH. At very high humidities the small tensile load applied to the fold specimen probably becomes limiting and fold endurance also drops off near saturation.

6. Time-dependent Effects

The most challenging unresolved problems in the rheology of paper are connected to time effects. Paper exhibits a wide range of time-related phenomena, and the introduction of time into the already complicated interrelationships of temperature, moisture, and paper structure increases the difficulty. Kolseth and de Ruvo (1983) have reviewed the time–temperature–moisture-dependent properties of paper, which is the most current and comprehensive in the field. There are three main areas of study in which time effects are significant: (i) creep and stress relaxation, (ii) duration lifetime/rate-of-loading phenomena, and (iii) dynamic mechanical measurements.

6.1 Duration-of-load/Rate-of-loading Phenomena

Paper exhibits two related time-dependent rupture phenomena that influence its load-bearing capacity. If paper is stressed to only a fraction of its short-term breaking stress and maintained at that stress over a long enough time, the paper will fail. It has been found empirically that for paper under constant stress, the logarithm of the time to failure varies inversely as the stress level (Guthrie and Fulmer 1969). A related time-dependent phenomenon is the rate-of-loading effect. The breaking stress of paper increases as one increases the rate at which it is stressed. If the applied stress is increased linearly with time, the breaking stress increases with the logarithm of the rate of stressing (Rance 1953). For this reason meaningful strength testing always requires a standardized rate of stressing (or straining).

Duration lifetime studies of materials can be aided by the use of a so-called *semi-empirical* equation that has been credited to Zhurkov (1965).

$$t = t_0 \exp[(l/kT)(U - \gamma\sigma)] \qquad (7)$$

where t is the time to failure, T the absolute temperature, k Boltzmann's constant, σ stress, U activation energy, and t_0 and γ are constants.

A form of Eqn. (7) was derived and used years earlier by Coleman (1956) to describe the duration-of-load and rate-of-loading phenomena exhibited by nylon. In Coleman's analysis, the equations describing the duration-of-load behavior and rate-of-loading behavior arise from the integration of an equation he derived for the rate-of-creep deformation. Coleman's fundamental equation, based on Eyring's rate theory, involves an explicit temperature dependence (for details see Coleman's classic paper, 1956). At fixed

stress, Coleman's equation indicates that increased temperature will decrease a loaded specimen's lifetime, and this behavior has been confirmed for viscose yarn as well as nylon.

De Ruvo and Lundberg (1972) have reported the moisture dependence of duration lifetime for chipboard at three RH. At a constant stress level, paper at a low RH will support a stress for a longer time before failing than at a high RH. Alternatively, paper at a high RH must be loaded to a smaller stress level in order to equal the duration lifetime of the same paper at low RH. One area of intense research involves the phenomenon of accelerated creep in cyclic humidity conditions (Fellers and Laufenberg 1994, de Ruvo and Lundberg 1972, Byrd 1972a, 1972b, Gunderson 1981, Back *et al.* 1983). Whereas paper may exhibit a creep rate at 90% RH that is several times the creep rate at 35% RH, if the same loaded paper sample is cycled between 35% and 90% RH, its creep rate can be over 10 times the creep rate shown at the constant 90% RH (Sternstein 1961).

In a phenomenon related to the case of accelerated creep in cyclic humidity, Byrd (1972a, 1972b) has reported the shortened lifetimes in both tension and compression of paper loaded in cyclic humidities. Similar findings were reported also by de Ruvo and Lundberg (1972). A better understanding of this phenomenon of accelerated creep-rupture is crucial in the design of packaging and in the structural performance of paper in long-term exposures to cyclic-humidity environments. The basic features of creep and stress relaxation of paper in tension and compression are similar. However, the effects appear to be more serious in the case of compression.

This phenomenon of creep-rupture in cyclic humidity probably arises because of the interference or coupling of two thermodynamically irreversible processes: sorption hysteresis and stress–strain hysteresis. The thermodynamic fundamentals of the coupling of deformation and sorption, the so-called *mechanosorptive* effect, was provided by Barkas (1953); but a complete description of the irreversible thermodynamics involved by the methods of either Prigogine and DeFay (1954) or Onsager (1931) is lacking. In mechanistic terms, the phenomenon is describable in terms consistent with the theory of hydrogen bond-dominated solids (Caulfield 1980). During each adsorption leg of a humidity cycle, a 'spreading pressure' pries apart two cellulose lamellas and intercalates a layer of water molecules, reducing the number of effective load-bearing elements. The subsequent reduction in humidity fails to reverse completely this process, because the restraining modulus is lower at the higher moisture content, and also stressed bonds have had time to re-form into stress-relaxed configurations. Failure can then be triggered, as in Coleman's creep–rupture theory, when the strain deformation exceeds a critical strain. A better creep–rupture explanation will probably involve

consideration of the accumulation of nonrecoverable work, and the formulation of fatigue lifetime in terms of energy dissipation rather than as a result of a critical strain (Caulfield 1994).

6.2 Dynamic Mechanical Behavior (Fatigue) of Paper

When paper is subjected to a periodic stress, its strain response exhibits a time-dependent behavior that arises from its viscoelastic nature. If a simple harmonic stress is applied to paper, its strain response is also periodic but lags behind the stress. This time lag can be measured in terms of a phase angle, δ, whose tangent is equal to the ratio of loss modulus to storage modulus. Tan δ is a measure of the energy lost due to the internal friction generated in the sample during its cyclic deformation. When examined as a function of frequency of oscillation, the internal friction or tan δ exhibits a maximum wherever the elastic modulus undergoes a rapid change. In polymers, the frequencies at which energy losses are maximized have been interpreted as caused by transitions from glassy to rubbery behavior. The wood polymers, lignin and hemicelluloses, have been recognized as essentially thermoplastic polymers whose glass–rubber transitions are both temperature- and moisture-dependent (Goring 1966). For example, whereas isolated dry lignin softens at a temperature near $200\,°C$, in water its transition is lowered to about $80–90\,°C$. Hemicelluloses are even more moisture sensitive; softening at about $55\,°C$ at a moisture content of only 23%. The work of Kubàt (1969), de Ruvo *et al.* (1976), and Htun *et al.* (1985) has verified that both increased temperature and moisture dampen the dynamic response of paper to cyclic stress.

An area of intense research interest has been the effect of changing moisture content on the dynamic loss property of paper (Htun *et al.* 1985). Kubàt and Lindbergson (1965) first reported that a sudden change in humidity causes a transient increase in mechanical damping and suggested that the damping was associated with the moisture diffusion process taking place during equilibration. An analysis by Salmèn and Back (1977) has discounted the importance of moisture gradients *per se* but emphasizes the temporal change of gradients with time. Htun *et al.* (1985) have studied the dynamic mechanical behavior of paper during drying and attribute transient damping as well as increased modulus to the loss of mobility of amorphous components of cell wall polymers. Understanding the dynamic behavior of paper in transient-humidity environments will certainly aid our understanding of how creep and failure are accelerated by cyclic humidity. Whereas dynamic behavior may be explained phenomenologically in terms of chain motions and second order transitions, there is good reason to believe that this

time-dependent phenomenon, too, is ultimately governed on the molecular level by the making and breaking of hydrogen bonds.

7.   *Thermodynamics Approach*

Finally, a thermodynamic approach formulated by Meixner (1960) shows that the introduction of an additional time-dependent internal variable is both necessary and sufficient to provide a complete description of viscoelastic behavior. A correspondence between Meixner's model-less method and the suggested time dependence of the number density of effective hydrogen bonds has been suggested (Caulfield and Zauscher 1997).

For a general presentation of viscoelasticity of paper in terms of irreversible thermodynamics, Meixner (1960) has done this rigorously, and Kestin (1978) has put Meixner's ideas into comprehensible terms. This treatment not only has a general validity, but also results in a form that seems directly applicable to the earlier analysis of the differences between ultrasonic and 'static' measures of elastic modulus.

Kestin (1978) starts with the argument (when considering creep and relaxation) that the usual number of variables needed to define the state of a material is insufficient. A stressed material maintained at a fixed elongation and temperature, for instance, does not exhibit a constant stress if observed over long times, but relaxes. At least one other degree of freedom is necessary to define its state. He calls that other variable, ξ; an internal degree of freedom or parameter of state. Prigogine and DeFay (1954) called such an additional variable a "degree of advancement" especially when the change involves a chemical change or chemical reaction in the material. Although we do not know what change the variable represents, it must exist from Meixner's thermodynamic analysis. For our purposes, it represents the degree of advancement of the 'chemical' change involving transitions of bonds from effective (load-bearing) to noneffective (nonload-bearing). However, we never know from thermodynamics what ξ might represent, because thermodynamics is independent of any putative model. Kestin establishes the case for viscoelasticity by defining the Helmholtz function, F, as a function of strain, ε, and that additional variable, ξ at constant temperature as a Taylor series expansion about equilibrium conditions:

$$F(\varepsilon, \ \xi) = \tfrac{1}{2} E_\infty \varepsilon^2 + b\varepsilon\xi + \tfrac{1}{2} c\zeta^2 \qquad (8)$$

where E_∞ is the elastic modulus at infinite strain rate (because ε does not have time to change) and b and c are constants characteristic of the material. Because

$$dF = \sigma d\varepsilon - A d\zeta \qquad (9)$$

then stress,

$$\sigma = (\partial F/\partial \varepsilon)_\xi = E_\infty \varepsilon + b\xi \qquad (10)$$

and the associated affinity,

$$-A = (\partial F/\partial \xi)\hat{\varepsilon} = b\varepsilon + c\xi \qquad (11)$$

One of the immediate results

$$\sigma = (E_\infty - b^2/c)\varepsilon = E\varepsilon \qquad (12)$$

where E is the elastic modulus at a lower rate of straining, and necessarily $E_\infty > E$. In this form the similarity of the relation between ultrasonic modulus and static modulus is apparent (compare Eqn. (5) where E_u is analogous to E_∞). Further research is needed to confirm these similarities and quantify the magnitudes of the material properties, b and c. Kestin also shows, using Meixner's arguments, that through the introduction of just this additional variable, ξ, a complete, consistent description of the phenomena of stress relaxation and creep is achieved.

The model-less thermodynamic approach of Meixner shows that a description of viscoelasticity arises from an additional internal variable that has a time-dependent character. By allowing a time dependence to the effective number density of hydrogen bonds, the hydrogen bond theory that accounts well for the elastic properties of paper can be extended to explain the viscoelastic properties of paper as well. Alternatively, to the polymer chemist, the explanation of relaxation phenomena involves molecular motions that result from the increased free volume that arises either from thermal expansion or the introduction of plasticizer molecules. For cellulose and paper, at usual temperatures and moisture contents, it is clear that significant hydrogen bond disruption must precede any free-volume increases associated with glass-like transitions. In papers with high noncellulosic components, at high moisture contents, the assumption that mechanical properties are controlled only by hydrogen bonds becomes less valid. But even in those cases, to the extent that increased molecular motion requires an increase in free volume, the basic concepts that apply to true 'hydrogen bond-dominated' solids must be valid. An advantage to the hydrogen bond explanation is its quantitative aspect of relating mechanical properties to intermolecular attractions, the ultimate source of all mechanical properties.

8.   *Concluding Remarks*

A number of materials science approaches have been employed to understand the mechanical and rheological behavior of paper. These have included both network theories and molecular theories and both have shown some measure of success. However for

understanding the important time–temperature–moisture relationships that affect elastic and viscoelastic behavior, the molecular approaches have been more successful because they examine the role of structure of paper at the appropriate level of interaction, where hydrogen bonds dominate interactions. A molecular approach called the theory of hydrogen bond-dominated solids has succeeded in describing in both qualitative and quantitative terms the effects of temperature and moisture on paper's elastic properties. Paper's viscoelastic properties are also adequately described qualitatively by this hydrogen bond approach. The importance of paper's macromolecular structure is emphasized by the materials science concepts of glass transitions, free volume and plasticization that help explain the roles of temperature and moisture in affecting paper's properties. The ultimate strength of paper, its inelastic deformation, creep, and rupture properties are greatly dependent on morphological and network characteristics. But how these properties are affected by temperature and moisture is through paper's macromolecular nature and largely through processes that involve the making and breaking of hydrogen bonds. Finally thermodynamic (model-less) approaches to rheology that make no materials science assumptions about the nature or structure of the material have displaced earlier empirical models, such as springs and dashpots.

Paper: Pulping and Bleaching

Wood pulping processes are broadly categorized as mechanical or chemical according to the relative importance of mechanical treatments compared to chemical modification, degradation, and/or solution of wood components.

The properties of wood pulps and papers made from such pulps are affected by the selection of wood species (see *Pulp and Paper: Wood Sources*[#]) and by the complex mechanical, chemical, and thermal processes occurring during pulping and bleaching. The physical characteristics of the fibers, their chemical composition, and the supramolecular properties of the constituent polymers can all change in these processes.

Reductions in air and water emissions from pulping and bleaching processes are being accomplished by process selection, increased process closure, effective recovery of chemicals, and/or end-of-pipe treatments.

1. Mechanical Pulping

Mechanical processes use attrition to separate wood into fibers and fiber fragments. The resulting pulp properties are highly dependent upon the applied energy and the nature of the physical interactions with the wood. Mechanical pulping processes use large quantities of electrical energy. Equipment design, chemical applications, and thermal energy are applied to reduce this energy requirement (Cannell 1999). Mechanical pulps are produced at high yields, often exceeding 90% of wood mass. The fibers tend to be stiff and produce bulky paper structures. Papers can also be made with good printing characteristics and opacity. Mechanical pulps are well suited for production of newsprint, publication papers, and some coated catalog and publication grades. Mechanical pulps are also used in tissue papers, cartons, and building boards.

1.1 Mechanical Pulping Processes

In groundwood (GW) mechanical pulping, wood logs or bolts are pressed against a revolving grinding

stone, and fibers and fiber fragments are separated by abrasion. Pulp characteristics are influenced by the stone surface characteristics, stone surface speed, energy consumption, temperature, and pulp consistency in the grinder. Higher strength, longer-fibered pulps can be made by operating the grinding process at elevated temperatures (130 °C) and pressures up to 0.5 MPa in the pressurized groundwood (PGW) process.

Production of pulp by abrasion of wood chips or sawdust in a refiner between rotating steel disks allows greater flexibility in raw material selection and provides options for producing pulps with a wider range of properties. Refiner mechanical pulps (RMP) are produced at atmospheric pressures. In thermomechanical pulping (TMP), the refining process is steam pressurized to allow temperatures up to 170 °C. The wood lignin is softened and the wood fracture location is controlled, by temperature, to inside the fiber wall at 130 °C or in the lignin-rich middle lamella region between fibers at higher temperatures. Refiner mechanical pulping processes can utilize two stages in series to achieve the desired pulp qualities.

Small amounts of chemicals, such as sodium hydroxide, carbonate, sulfite, bisulfite, or combinations thereof, are sometimes added to produce chemimechanical (CMP) or chemithermomechanical (CTMP) pulps. Wood components are chemically modified by the additives to be more hydrophilic and, in some cases, are partly dissolved. Swelling of the wood is increased and the response to the mechanical pulping process is altered dramatically. Chemical additions affect the location of the fracture in the fiber structure as well as the nature of the fiber surfaces formed. Both of these factors influence the capacity of the fibers to develop strong bonds in the final paper product. Typical yields in chemimechanical pulping are in the 80–95% range.

Semichemical pulps are produced at yields between 65% and 80% by adding larger amounts of chemicals and/or increasing the pretreatment time or temperature. As larger amounts of chemicals are used, recovery of the spent chemicals becomes an economic and environmental consideration.

1.2 Bleaching Mechanical Pulps

Production of high brightness mechanical pulps requires consideration of the entire process including: selection of the wood source, in-process storage of the wood, the pulping process, and pulp bleaching, as well as the intended use of the product. Light-colored woods without fungal discoloration or dark-colored resins are preferred. Wood lignin and resins are modified and partially removed in the preparation of mechanical or semichemical pulps. Remaining lignin, resins, extractives, and other minor components of the wood contribute to the color of these pulps.

Chemicals applied in pulping can reduce loss of brightness in the process and, in some cases, improve the color of the pulp. Mechanical pulp bleaching processes are designed to remove chromophoric structures and brighten the pulp with minimum losses of mass. Lignin-preserving bleaching is accomplished commercially primarily with hydrogen peroxide and/or sodium dithionate. Sequential bleaching stages with these chemicals are used to achieve high brightness. Chelating or complexing agents can be applied to control trace amounts of metal ions which can form colored complexes or adversely impact the bleaching process by decomposing hydrogen peroxide.

While reasonably high brightness can be developed with mechanical and chemimechanical pulps, it is difficult to prevent reversion or brightness loss over time. Exposure to heat and light accelerates brightness reversion. Brightness reversion often limits mechanical pulps to products with relatively short life cycles.

1.3 Environmental Emissions from Mechanical Pulping

Water-soluble wood components, pulping and bleaching chemicals, and wood substances dissolved in the mechanical pulping processes contribute biological oxygen demand (BOD), chemical oxygen demand (COD), and color to the aqueous effluent. Emissions of volatile organic compounds can occur in pulping and bleaching. Aqueous effluents are treated with primary and secondary treatment processes before discharge. "Zero effluent" production of bleached CTMP has been commercialized in Canada to avoid aqueous emissions (Meadows 1996).

2. Chemical Pulping Technology

Chemical pulping processes produce low brightness pulps in yields ranging from 40% to 65% by dissolving lignin, hemicellulose and cellulose carbohydrates, and extractives from the wood. At the lower yields, intact, individual fibers are readily separated from the wood structure. Chemical pulps made at the higher yield levels and containing larger amounts of the wood lignin require appreciable mechanical energy input from disk refining equipment to complement the chemical pulping process.

2.1 Alkaline Pulping

In the commercially dominant kraft (sulfate) process, sulfide and hydroxide ions are used to depolymerize and dissolve the wood extractives, lignin, and some hemicelluloses. The pulping reactions require one to three hours at temperatures up to 170 °C. Both batch and continuous pressurized digesters are used. Kraft

pulping has been improved by the use of additives, selective control of chemical concentrations, and optimization of temperature profiles. Modified kraft pulping processes apply four principles to improve the selectivity of lignin removal: leveled-out hydroxide concentration, high initial hydrosulfide concentration, low sodium ion and dissolved lignin concentrations in the final part of the cook, and avoidance of high temperature. These principles have been employed in various ways to achieve improved pulping and the ability to pulp to lower lignin contents (Teder *et al.* 1997).

Anthraquinone (AQ) addition to kraft pulping increases the rate of the delignification reaction and the yield of carbohydrates. Although AQ is used at very low levels, less than 0.1% on wood, it is a relatively expensive chemical and is often used on an as-needed basis to provide incremental production capability.

Polysulfide (PS) ions in kraft pulping stabilize the carbohydrates against the alkaline degradation reaction known as "peeling." With PS addition, the yield of kraft pulp can be increased by 1–3%. To maintain the sulfur balance in the pulping-recovery cycle, it is necessary to regenerate PS from the recovered pulping chemicals. Polysulfide and anthraquinone can be applied together in the PS-AQ process to get synergistic pulp yield benefits.

Soda pulping using sodium hydroxide avoids the odorous sulfur-containing gases associated with kraft pulping. However, pulp strength properties are adversely impacted by the high concentrations of hydroxide ion needed to achieve practical pulping rates. AQ can be added for improved pulping rates.

Alkaline sulfite pulping processes have shown promise for increased pulp yield and good pulp quality. AQ and/or methanol are additives in some alternatives. Commercial application has been limited by the lack of a cost-effective recovery option.

2.2 Sulfite and Solvent Pulping Processes

In sulfite pulping, usually conducted under acid or neutral conditions, sulfur dioxide and/or bisulfite ions react with lignin to produce water-soluble sulfonated lignins that are degraded by acid hydrolysis reactions. Sulfite pulping can be controlled to produce pulps over a wide range of lignin contents and pulp yields. The residual lignin in sulfite pulps is sulfonated and is relatively easy to remove in pulp bleaching processes. The conditions of sulfite pulping lead to extensive hydrolysis of the carbohydrates, and sulfite pulps typically have less strength potential than kraft pulps in papermaking applications. The recovery and regeneration of chemicals in the waste liquors from sulfite pulping are more difficult than for kraft liquors.

Solvent pulping processes have been extensively evaluated in laboratory and pilot tests, but have found only limited commercial application. Many organic solvents have been used including alcohols, acids, ketones, esters, and others. Often an inorganic acid is added to promote hydrolytic cleavage of lignin bonds. Solvent pulping offers possibilities for alternative chemical recovery processes with lower capital costs and by-product recovery. Very high solvent recovery must be achieved for economic and environmental reasons.

2.3 Recovery of Chemicals for Pulping

Efficient recovery and regeneration of pulping chemicals are essential for chemical pulping processes. Wood components dissolved in the pulping process are converted to useful by-products, such as tall oil soap and lignin, or to energy by combustion. The availability of a cost-effective chemical and energy recovery cycle for kraft pulping contributes to the dominance of this process. Kraft pulping operations are often energy self-sufficient.

In the kraft pulping/recovery cycle, pulp from the digester system is washed with water to separate a solution of spent pulping chemicals and dissolved wood components known as black liquor. This black liquor is concentrated by multiple effect evaporation to a high solids concentration ($>50\%$) and then burned in a heat recovery boiler. The inorganic compounds are removed from the furnace as a molten smelt and are dissolved in water to form green liquor. The active pulping liquor, a solution of sodium hydroxide and sodium sulfide called white liquor, is regenerated by causticizing the green liquor with lime. The lime is also regenerated in a separate cycle using a kiln to convert calcium carbonate to calcium oxide.

The recovery cycle operations for kraft pulping are capital intensive, and many alternatives have been evaluated. Gasification processes under development for burning the concentrated black liquor offer promise for improved energy recovery by application of combined cycle power generation.

2.4 Bleaching Chemical Pulps

Chemical pulps contain 2–5% lignin after the pulping process and are dark brown in color. For white products, these chromophoric residues are removed in multistage processes with oxidative chemicals such as oxygen, chlorine, hypochlorites, chlorine dioxide, and hydrogen peroxide. Alkaline extraction facilitates removal by solubilization of the oxidatively degraded materials.

An oxygen stage is often used as a transition between pulping and bleaching. Oxygen delignification removes 30–60% of the residual lignin. Oxygen stages operate at either medium ($\sim13\%$) or high ($\sim30\%$) consistency with 1–4% sodium hydroxide addition. Temperatures range from 80 to 120 °C with oxygen

pressures up to 10 atmospheres. Two oxygen stages in series are sometimes used. Oxygen stages are integrated with the washing of the unbleached pulp so that wood components dissolved in this stage can be processed in the chemical recovery cycle. This closure of the process is a major advantage of oxygen compared to many other bleaching chemicals where the effluent is not recovered and must be treated before discharge to the environment.

The chemistry of pulp bleaching has changed dramatically since the mid-1980s, when trace amounts of dioxin were found in bleached chemical pulps and effluents from bleaching processes using chlorine in the first oxidative bleaching stage at low pH. Dioxin formation was avoided by changing chlorination stage conditions or by bleaching without chlorine (elemental chlorine free, ECF). Bleaching technologies also were developed that avoid all chlorine bleaching chemicals (totally chlorine free, TCF) (Nelson 1998). ECF bleaching processes provide several pulp quality advantages relative to TCF. Comparative evaluations demonstrated that treated effluents from the two approaches are comparable. ECF bleaching sequences have been preferred by the industry for kraft pulp bleaching.

Hypochlorite bleaching uses chlorine at alkaline pH conditions with either sodium or calcium as the base. Hypochlorite reactions with lignin produce chloroform as a by-product. As a result, hypochlorite bleaching has been largely replaced by hydrogen peroxide or by increased use of chlorine dioxide.

Chlorine dioxide is a very effective pulp bleaching chemical. Initially, because of its high cost, chlorine dioxide was used mostly in the later stages of bleaching to remove the last traces of residual color in the pulp. In ECF bleaching, chlorine dioxide is used in the first stage as a delignifying chemical to replace chlorine. Chlorine dioxide is a very selective chemical that removes lignin residues with very little chemical attack on the carbohydrates in the fiber. The first dioxide stage of a bleaching sequence is usually followed by an alkaline extraction stage where oxidized fragments of lignin are solubilized and removed from the pulp. Alkaline extraction stages are sometimes used between two dioxide stages in the last stages of bleaching. Recycling of ECF bleaching effluents to recovery requires additional processing to remove sodium chloride that can accumulate in the pulping–recovery cycle liquors and cause corrosion problems.

Hydrogen peroxide has become more important in both ECF and TCF pulp bleaching processes. Hydrogen peroxide is most effectively used as a pulp brightening chemical. It is often used as an additive to alkaline extraction stages.

TCF bleaching applies combinations of oxygen, ozone, and peroxide bleaching stages. Trace metal ions present in the unbleached pulp can adversely affect the stability of peroxide resulting in wasteful loss of the chemical as well as radical species that can attack the pulp carbohydrates. The effects of trace metals can be reduced by removal of the metals with an acid or chelant treatment.

Ozone was developed as a commercial bleaching chemical in the late 1980s in response to the need for more effective chlorine-free bleaching chemicals. Ozone stages can be operated at medium or high consistency. Ozone is a very reactive chemical, and undesired reactions with the pulp carbohydrates must be controlled. Efficient mixing of the ozone gas with the pulp is a major challenge. Developments in the technology for generation of ozone have resulted in ozone becoming a cost-competitive option for the industry. Effluents from ozone stages early in the process can be recycled back to the chemical recovery cycle.

Achieving very high brightness levels has been a challenge with TCF bleaching processes. To facilitate these processes, it is common to extend delignification of unbleached pulp to lower lignin contents and to operate the oxygen stage at higher delignification levels. These steps, as well as the alkaline conditions and high temperatures used in TCF peroxide stages, raise concerns about the loss of additional carbohydrates and thus pulp yield.

The most significant effects of bleaching on the properties of chemical pulps are related to the extent of oxidative chemical attack by the bleaching chemicals on the cellulose and hemicellulose polymers. Some hemicelluloses can be dissolved during bleaching; if significant amounts are intentionally removed, as in the production of high-purity α-cellulose pulps, the properties of the pulp can be strongly affected.

The oxidative chemicals used in pulp bleaching have different potentials for affecting pulp properties. These chemicals can both depolymerize the hemicellulose and cellulose polymers and introduce new functional groups into these polymers. Some depolymerization can occur without strength loss but, beyond a certain point, strength properties decrease sharply as the polymer molecular weight decreases. Depolymerization is often monitored by empirical measurements of the solution viscosity of the pulp in selected solvents, but changes in the chemical composition of the pulp also affect the results of this test.

By proper selection of bleaching chemicals and operating conditions, it is possible to minimize changes in pulp strength properties during bleaching. Usually, the most active chemicals, such as oxygen and ozone, are applied in the early stages of bleaching, where the larger amounts of residual lignin present in the pulp rapidly consume the chemical and protect the carbohydrates. Hypochlorites, when used, are applied in intermediate stages of bleaching. The amount of undesired chemical attack by hypochlorites is reduced by controlling the reaction pH and by limiting the amount of the chemical used. Hydrogen peroxide bleaching can be a relatively mild process and is often applied in the final bleaching stages.

Chlorine dioxide has the least effect on pulp strength properties and is favored for the final stage of bleaching when pulps having high brightness and high strength are desired.

3. Biotechnology in Pulping and Bleaching

Application of biotechnology in pulping and bleaching has been evaluated extensively for both chemical and mechanical pulp processes. A commercial product uses a fungus to degrade extractives in wood chips before pulping to prevent later deposition of pitch on process equipment. Biomechanical pulping uses lignin-degrading microorganisms, primarily white-rot fungi, to pretreat wood chips prior to refining. Significant reductions in energy requirements and increases in strength properties have been reported, with biomass losses up to 25%. Many fungi strains have been screened to take advantage of the natural differences in the lignin- and carbohydrate-degrading ability of these organisms. Fungal pretreatments have also been evaluated for improved delignification and bleachability in sulfite and kraft pulping (Messner 1998).

Isolated xylanase enzymes are used to enhance chemical pulp bleaching. Xylanase treatments before bleaching result in higher brightness after bleaching or lower bleaching chemical costs.

4. Process Effects on Pulp Properties

The physical properties of chemical pulps depend markedly on the pulping yield. The strength of wood pulp fibers is primarily caused by the high-molecular weight, highly oriented cellulose polymer in the fiber. Since the cellulose component is less affected by the pulping processes, the fraction of cellulose in the pulp increases as the yield decreases. Also, the number of fibers per unit weight of pulp increases as more material is removed by pulping. Pulp strength properties thus improve as yield decreases, up to a point where chemical attack on the cellulose becomes significant.

In addition to the basic fiber strength, hydrogen bonds formed between the fiber elements in the paper affect the strength developed from a pulp. The development of hydrogen bonds in paper is determined to a great extent by how the fiber swells in water during the preparation of the fibers for papermaking. Many of the effects of pulping and bleaching on pulp properties can be understood in terms of the relative amounts of the hydrophobic lignin polymer removed and the hydrophilic hemicellulose retained in the pulp fiber. The location in the fiber structure and degree of crystallinity of hemicellulose can also be affected by the pulping process.

Mechanical action during processing of pulps, such as occurs when pulps are discharged by hot blowing from high-pressure pulping vessels, pumped, mixed,

or conveyed, can decrease fiber strength. Such mechanical action may cause undesired "dislocations" or weak spots in the fiber wall or formation of fiber debris by mechanically disrupting the basic fiber structure.

5. Conclusions

Many alternatives for production of pulps with wide ranges of end-use specific properties have been developed and are applied commercially. Environmental issues are being addressed with new technologies, alternative chemicals, and progressive reduction of process emissions.

Paper: Strength and Stiffness

Paper is the material of choice for a host of products such as books, graphic products, packaging materials, shipping containers, and personal care products. In part, paper is used because the physical properties can be tailored to fit the end-use in the most economical way. For example, paper can be produced with high stiffness and strength for use in a box or high compliance for tissue paper. Examples of standards used in the paper industry are ISO and national standards such as TAPPI and SCAN.

1. Definitions

Consider a uniaxial tensile test of a paper test specimen that yields as shown in a stress-strain diagram (Fig. 1). For tensile testing of paper, emphasis must be placed on the grips to minimize slippage. In standard practice, rectangular test pieces are used, often with special line-load clamps.

The compressive strength of paper is a more ambiguous measurement, with the results dependent on the test method. The obstacle in compression is the low buckling resistance of a sheet of paper. Several compressive strength tests are commonly used including ring crush and short-span compressive strength. To evaluate the entire stress–strain curve in compression, special equipment is used (see *Paper: Creep**).

For tensile properties, the in-plane stiffness is evaluated from the initial slope of the curve. The paper industry often utilizes the terms tensile stiffness index
Figure 1

Stress-strain curves for paper in tension and compression. MD is the machine direction. CD is the cross machine direction. (Based on results by Fellers and Norman 1996.)

E^w to characterize in-plane stiffness and tensile index σ_T^w to characterize in-plane strength. These properties equal force divided by test piece width b and grammage w (mass per unit area). Alternatively, tensile stiffness E^b and tensile strength σ_T^b are used, with dimensions in force per unit width. The practical reason for using these properties is that paper is judged by its properties per unit mass rather per unit width and thickness (cross-sectional area). Furthermore, the rough surface and low stiffness in the thickness direction produces thicknesses that are highly dependent on the techniques employed. By this approach, thickness measurements are avoided.

Tensile stiffness index E^w and tensile index σ_T^w are related to elastic modulus E and tensile failure stress σ_T, each divided by density ρ:

$$E^w = \frac{E}{\rho} \,(\mathrm{N\,m\,kg^{-1}}) \qquad (1)$$

$$\sigma_T^w = \frac{\sigma_T}{\rho} \,(\mathrm{N\,m\,kg^{-1}}) \qquad (2)$$

These terms are useful when comparing properties of different materials. In many publications, tensile strength is expressed as breaking length σ_T^l, which is equal to the length of paper that would break under its own mass. The relationship between breaking length and tensile index is given in Eqn. (3), where g is the acceleration due to gravity, $9.81\,\mathrm{m\,s^{-2}}$:

$$\sigma_T^l = \frac{\sigma_T^w}{g} \,[\mathrm{m}] \qquad (3)$$

For compressive properties, the in-plane stiffness is the same as in tension. In order to avoid the use of

two terms for the same property, the term tensile stiffness is often used instead of compressive stiffness. The compression index σ_C^w is on the order of 30% of the tensile index.

The bending stiffness per unit width S^b is related to elastic modulus E and the thickness t by:

$$S^b = \frac{Et^3}{12} = \frac{E^w w^3}{12\rho^2} \, (\text{N m}) \tag{4}$$

Bending stiffness index S^w, stiffness related to the grammage of the material, consequently may be defined as:

$$S^w = \frac{S^b}{w^3} \, [(\text{N m})^7 \text{kg}^{-3}] \tag{5}$$

Table 1 gives examples of how different materials may be ranked based on force per cross sectional area (stress) or based on properties per width and mass (index). If materials are ranked based on stress, steel and glass are much stiffer and stronger in the plane of the sheet material than are paper and wood. If properties are based on index, the in-plane properties are in the same order for all four materials. The great difference appears when comparing the bending stiffness at equal mass of the materials, where much higher values are achieved for paper and wood.

There are many other different mechanical properties that are routinely measured for paper and paper products including other in-plane and out-of-plane properties; compressive properties, burst strength, and tearing strength. The amount of information that has been recorded on this subject is extensive and the interested reader is referred to the bibliography for in-depth discussions of the mechanical properties of paper. The discussion below will be restricted to the relationships among stiffness, tensile, and compression properties; and effects of the paper structure; and the papermaking process.

2. Orthotropic Nature of Paper

The mechanical properties of machine-made papers exhibit anisotropy, and the assumption of orthotropy appears to be reasonable. Figure 1 shows uniaxial stress strain curves for paper tested in the machine direction (MD) and the cross machine direction (CD) in tension and compression. Typically, the MD stiffness and strength are 1.5 to 3 times greater than the CD values, but much higher stiffness ratios can be achieved. Note that Fig. 1 also shows that paper is weaker in compression than tension. The directional dependence of properties is due to a combination of fiber orientation produced when the fibers are laid on the forming wire and MD restraint imposed during drying. Stiffness and strength in the thickness direction, ZD, is typically 50 to 100 times smaller than the in-plane stiffnesses. The Poisson ratios for the coupling between the in-plane and ZD directions are very close to zero. Typically, the two Poisson ratios for in-plane deformation have a geometric mean in the range of 0.1 to 0.4. Handsheets are typically isotropic with a 0.3 Poisson ratio.

Mann *et al.* (1980) have used ultrasonic techniques to measure the nine elastic constants that fully characterize the 3-D elastic behavior of paper. For in-plane properties, Baum *et al.* (1981) found that the in-plane shear modulus is 0.387 of the geometric mean of the two longitudinal stiffnesses. The implication of this relation is that paper is considered to have only three independent in-plane stiffness properties. For a given furnish, Htun and Fellers (1982) determined that the geometric mean of the two longitudinal moduli is approximately invariant with fiber orientation and drying restraint.

3. Stiffness Measurements

Standard mechanical techniques are considered the reference methods for determining stiffness properties of paper. Alternatively, nondestructive measurement

Table 1
Comparison of stiffness and strength indexes of different structural materials. (Gordon 1979, completed with data for paper by the authors.)

Material	Density (kg m^{-3})	Elastic modulus (GPa)	Tensile stiffness index (MN m kg^{-1})	Tensile failure stress (MPa)	Tensile index (kN m kg^{-1})	Bending stiffness index ($(\text{N m})^7 \text{ kg}^{-3}$))
Structural steel	7800	210	25	1500	192	0.04
Glass	2400	73	24	150	63	0.44
Wood (spruce) along the grain	500	14	25	103	206	9.33
Paper, linerboard, MD	700	9	13	75	107	2.19

of in-plane stiffnesses can be obtained by ultrasonic measurements. Since paper is a viscoelastic material, the ultrasonic modulus is typically greater than the stiffness measured from a tensile test. The much slower tensile test permits relaxation and creep to occur, therefore, the modulus measured in tension is a function of the strain rate, which is always specified.

The bending stiffness of paper is usually obtained using a two-point bending method or by strip resonance. In these tests, the level of loading must be kept small so that the material does not yield.

As seen from Eqn. (5), high bending stiffness of paper can be achieved by selecting fibers and papermaking processes to produce a low density structure as well as a high tensile stiffness index. For heavier grades, the paper is produced in several layers to optimize performance. High tensile stiffness is readily obtained by preventing shrinkage during drying.

4. Development of Strength in Paper

The strength of paper is affected by the fiber source, papermaking conditions, and environmental factors. The following discussion of these parameters will focus on tensile strength, however, the same general trends apply to other strength properties. Page (1969) developed a now classical equation that expresses the effect of the fiber and network structure on tensile index:

$$\frac{1}{\sigma_T^w} = \frac{9}{8\sigma_{ZS}^w} + \frac{12}{\tau_s l \alpha} \qquad (6)$$

where $\sigma_{ZS}^w =$ zero span strength (a measurement of the fiber strength), $\tau_S =$ shear bond strength, $l =$ fiber length, and $\alpha =$ relative bonded area per gram of fiber. The strength of a sheet will always be less than zero-span strength. The key components are the strength of the individual fibers, the shear strength of the bonds between fibers, and the degree of bonded area. If either bond strength or bonded area is low the sheet is bond-strength limited. If bond strength is high and bonded area adequate, the sheet is fiber-strength limited. Figure 2 illustrates the fracture zone for these two extreme cases.

The Page equation was developed for an isotropic sheet produced from straight fibers. If the fibers are very curly or have many defects or microcompressions that lowers the strength, the equation must be used with caution. Process variables can have a dramatic effect on sheet stiffness and strength. Figure 3 shows tensile and tensile stiffness index vs. density for a selected number of handsheets made from different pulps.

Beating fibers increases fiber flexibility, which in turn increases the bonded area, producing a greater density and a stronger sheet. Pressing also increases
Figure 2
The fracture zones in papers subjected to tensile loading up to break. The upper figure shows a bond-strength-limited situation. The fibers are pulled out of the network with few fiber breaks. The lower figure shows a fiber-strength-limited situation. Few fibers are pulled out. Instead fiber fractures occur (after Fellers and Norman 1996).

the bonded area and produces similar strength improvement. Much of the strength of a machine-made sheet is developed in the drying process. MD tension in the web acts to restrain the sheet, keeping fibers straight and greatly increasing the strength. CD shrinkage produces a highly undesirable shrinkage gradient, causing gradients in strength and stiffness. It is possible to improve the smoothness of paper without significantly changing its mechanical properties by reducing the thickness and increasing the density by mechanical actions, such as calendering. Although calendering increases the density, it does not increase the bonded area, however, it has a tendency to reduce ZD strength, but with little effect on the in-plane properties.

Figure 5 illustrates the mechanism of failure in compression for paper, where strength is limited by the compressive properties of the individual fibers.

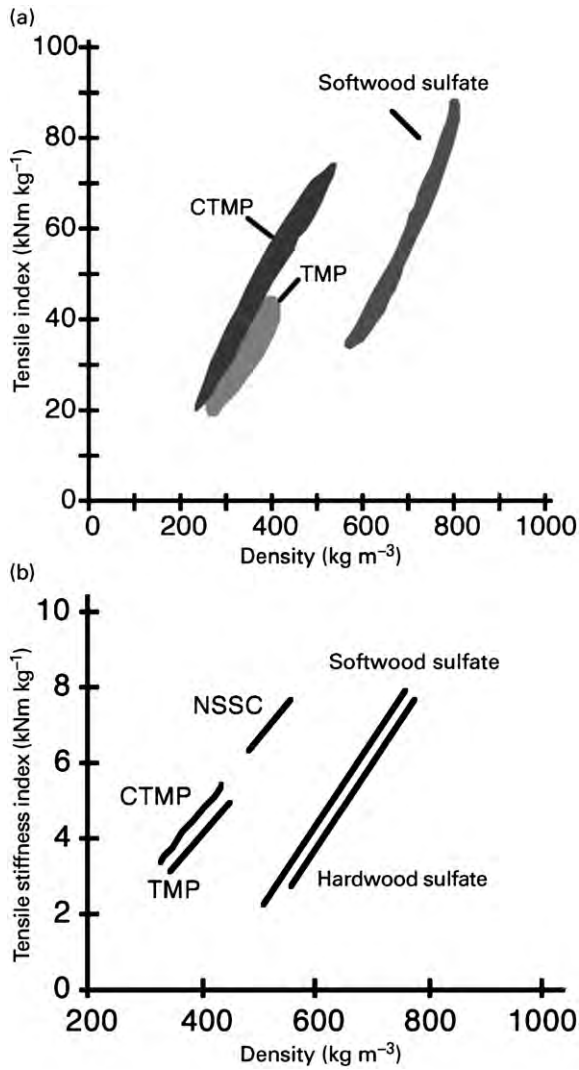
Compressive strength follows the same trends as tensile strength with papermaking factors, Fig. 4, but


Figure 3
Tensile index and tensile stiffness index versus density for a selected number of handsheets made from different pulps (after Fellers and Norman 1996).

is limited by the compressive strength of the fibers, as shown in Fig. 5. Compressive strength is a fundamental property for the corrugated board components, linerboard, and corrugated medium.

5. Environmental Effects

All the mechanical properties of paper are highly dependent on the moisture content and temperature of the specimen, but moisture is by far the more important. As either the moisture content or temperature increases, the mechanical properties of the sheet
Figure 4
Compressive strength is a fundamental property for corrugated board components, linerboard and corrugated medium. Increased density by beating or pressing greatly improves the property (after Fellers and Norman 1996).
Figure 5
Compressive failure of paper. The strength is limited by the compressive strength of the individual fibers (after Fellers and Norman 1996).

decrease (see *Paper: Effects of Moisture and Temperature**). Therefore, it is very important that paper properties be reported at standard conditions of 50% relative humidity and 23 °C.

6. Summary

There is a substantial amount of literature on strength and stiffness properties of paper, therefore, this article is an introduction to the subject. Stiffness and strength of paper are highly dependent on the source of fibers and the papermaking process, and a vast range of properties can be developed for paper, which is truly an engineered structure.

Paper: Structure

The mechanical behavior of a fiber network, such as a paper sheet composed of pulped wood fibers, depends on the fiber and fiber-to-fiber bond properties and the geometrical structure of the bonded fibrous network. The principal objective of a mathematical model is to predict the mechanical properties of the fiber network in terms of the properties of the fibers, bonds, and structure of the fiber network. In paper, the fibers are often collapsed, ribbon-like structures, which are bonded together primarily by hydrogen bonds formed when the sheet is pressed and subsequently dried.

The first attempt to develop a mathematical model for predicting the mechanical behavior of a fiber network such as paper was made by Cox (1952), who demonstrated how fiber orientation distribution influences the elastic behavior of the system. The analysis predicted all the elastic constants of a fiber mat in terms of the fiber orientation distribution expressed as a Fourier series.

Cox assumed that the fibers experience an axial strain corresponding to the sheet strain acting in the direction of the axis of the fiber. Cox's original theory has been subjected to numerous refinements and extensions which take into account the structure of the fiber network, the modeling of the fibers, the effects of drying-induced strains, the modeling of bond deformation, the nonlinear constitutive effects of the deformation response of the fibers and bonds, and the effect of fiber buckling for fibers that experience compressive strains.

The Cox model was modified by Qi (1997) to account for transverse normal and shearing components of strain in the fiber by assuming that the fiber takes on the same strains as those of the sheet. This assumption is equivalent to that used in laminate theory; therefore, if the fibers are assumed to lie in the plane of the sheet, the Qi model gives the same result as that predicted by laminate theory.

Early work regarding the development of mathematical models can be found in Algar (1966), Dodson (1973), Kallmes (1972a, b), and Van den Akker (1970, 1972). General aspects of paper physics can be found in books by Niskanen (1998) and by Deng and Dodson (1994). A review of research involving the modeling of the mechanical behavior of paper was given by Ramasubramanian and Wang (1999).

In this article, the basic assumptions and results of current mathematical models for predicting the in-plane mechanical behavior of paper are presented. The approach that is presented is based on the mesomechanics of the fibers that comprise a fiber network following the work of Perkins (1983, 1990).

1. Basic Elements of the Mathematical Model

The choice of the mesoelement that is used in the construction of a mathematical model depends on the
Figure 1
Typical fiber of length, λ_f, and orientation, θ, showing the angle of crossing fibers, β.

density of fiber sheet. In the case of low to medium density paper (to be defined subsequently), a typical mesoelement can be taken as an individual fiber along with the portions of crossing fibers that cross it and bond it to the fiber network. In order to develop a set of simple, closed-form expressions for the elastic moduli of the paper sheet, it is necessary to assume that the fibers are straight and that they lie in the plane of the paper. As discussed in the sequel, these assumptions can be relaxed, however, it is then necessary to perform the prediction of sheet properties numerically. Restricting attention to the low-density system comprised of straight fibers, the typical mesoelement of length, λ, and orientation, θ, is shown in Fig. 1. The mesoelements are coupled to the network by means of the crossing fibers. The strains in the sheet are presumed to be transmitted to the mesoelements by bending and shearing deformation of the crossing fibers and by shearing deformation of the fiber–fiber bonds. Thus the axial strain in the mesoelement fiber is not uniform but varies from the ends, where it is zero, to the middle, where its value is at its maximum. If the mesoelement is long enough and if the coupling is weak, the mesoelement strain is less than that associated with the sheet.

The model is further illustrated by Fig. 2, which shows a portion of a fiber that is coupled by two crossing fibers to the remainder of the network. The boundary between the element and the network is depicted by a dashed line. This boundary is assumed to be located a distance, $l/2$, from the centerline of the primary fiber, where l represents the center–center distance between bonds, l_b is the bond length along the fiber, and w_f and t_f are the width and thickness of the fiber, respectively. If l is small in comparison with w_f, as would be expected in moderately dense paper, the coupling is primarily attributable to the shearing deformations of the fiber–fiber bonds. In a very low-density system such as tissue paper, the bending and shearing deformation of the crossing fibers may be substantial.
Figure 2
Portion of a fiber segment along a mesoelement showing the bond centroid distance, l, the bond length, l_b, and the fiber width, w_f. The mesoelement boundary applicable to low-density networks is shown as the dashed line.

On the assumption that the fiber is linearly elastic, the stress, σ_f, at any point along the fiber is related to the fiber strain, ε_f, at that point by

$$\sigma_f = E_{af}\varepsilon_f \tag{1}$$

where E_{af} is the effective axial modulus of the fiber. The effective axial modulus depends not only on the inherent properties of the fiber but also on how the fiber is bonded to other fibers in the network. Thus, there is a stiffening effect due to the reinforcement of other bonded fibers. E_{af} can be considered as an inherent property of the paper system, or its value can be estimated in terms of an idealized paper network. For example, if the fibers are idealized (Figs. 1 and 2) as thin rectangular strips (e.g., perfectly collapsed thin-walled springwood fibers), and if the density of the network is low enough so that on average the fiber surface is only half (or less) in contact with other fibers in the network, then it can be shown that

$$E_{af} = \frac{(l/l_b)(E_{fL} + E_{fT})}{C_B\left(\dfrac{E_{fL} + E_{fT}}{E_{fL}}\right)\left(\dfrac{l - l_b}{l_b}\right)} \tag{2}$$

where

$$C_B = 1 + \frac{E_{fT}}{E_{fL}}\frac{\tanh B}{B} \tag{3}$$

and

$$B = \frac{l_b}{2}\sqrt{\left(\frac{k_b}{t_f}\left(\frac{E_{fT} + E_{fL}}{E_{fT}E_{fL}}\right)\right)} \tag{4}$$

Here E_{fl} and E_{fT} represent the elastic moduli in the axial and transverse directions of the fiber, respectively; t_f is the thickness of the collapsed fiber; and l and l_b are as previously defined.

The factor C_B determines the amount of reinforcement associated with fiber bonding. The constant k_b in the factor B (Eqn. (4)) determines the stiffness of the fiber–fiber bond. It is expected that these factors are related to the degree of fiber refining which roughens the fiber surface and causes damage or separation of the S1 layer of the cell wall. As the bond stiffness becomes very small, C_B tends to a value of 2 and the reinforcing effect vanishes. At the other extreme, the bond becomes infinitely stiff and the factor C_b tends to unity.

The bond stiffness can be measured directly as shown by Thorpe *et al.* (1976) where individual fibers are bonded to a fiber shive which is supported and the fiber is loaded by an externally applied axial load. The value of k_b measured in this way is on the order of $10^{13}\,\text{Nm}^{-3}$.

The modeling of the elastic properties of the fiber depends on a number of factors related to whether or not the fibers are thin-walled and collapsed in the paper sheet and whether or not it is considered necessary to include the effects of the S_1 and S_3 layers of the cell wall. Refer to the work of Mark and Gillis (1983) and Salmen and de Ruvo (1985) for detailed information regarding the modeling of the fiber. Note that the transverse fiber modulus, E_{fT}, should be computed based on the crossing angle that the crossing fibers make relative to the primary fiber as discussed in the following.

The strain in the fiber, ε_f, is determined by the sheet strain and the degree of coupling between each fiber and the other fibers in the sheet. As shown in Fig. 1, a fiber of length λ_f is coupled to the rest of the network through the crossing fibers. The equilibrium equation for fiber mesoelement based on the equilibrium of a typical element along the fiber length is

$$\frac{d}{d\xi}\left(E_{af}\frac{d\varepsilon_f}{d\xi}\right) - k_f\varepsilon_f = -k_f\varepsilon_s \qquad (5)$$

where

$$\varepsilon_s = \varepsilon_x\cos^2\theta + 2\varepsilon_{xy}\sin\theta\cos\theta \qquad (6)$$

Equation (6) represents the normal component of strain in the sheet in the direction θ corresponding to the orientation of the fiber. The factor k_f is the effective stiffness of the coupling between the fiber of orientation θ and the other crossing fibers that couple the fiber to the network. The stiffness k_f includes the flexibility of the fibers in bending (which may be discernible for low-density sheets) and the flexibility of the fiber–fiber bond. If the idealized system of rectangular cross section straight fibers is considered,

$$k_f = \frac{2}{l\left[\dfrac{(l-l_b)^3}{12E_{fL}I_f}\left(1 + \dfrac{12fE_{fL}I_f}{G_fA_f(l-l_b)^2}\right) + \dfrac{2}{A_bk_b}\right]} \qquad (7)$$

where I_f represents the moment of inertia associated with the fiber cross-section, G_f represents the cell wall shear modulus, f is a factor that depends upon the fiber cross-sectional shape (it is 6/5 if the fiber is rectangular), A_b is the area of the fiber–fiber bond, and k_b is the bond stiffness.

Equations (2)–(4) and (7) can be used to estimate values of E_{af} and k_f in an idealized case. These quantities can also be considered as fundamental parameters of the system which are to be determined by mechanical property testing. In the latter case, direct measurement of paper mechanical response is used with the theoretical property relations to calculate "experimental" values of E_{af} and k_f.

It should be noted that the values of the effective axial modulus, E_{af}, and the coupling stiffness, k_f, are dependent on the orientation angle, θ, inasmuch as the network lengths, l and l_b, and the bond area, A_b, are dependent on orientation angle. In order to permit the subsequent closed-form expressions for the moduli of the sheet it is necessary to take the network lengths as their average values for the sheet. These values are dependent on the orientation distribution of the fibers as shown below.

For a prescribed sheet strain given by ε_x, ε_y, ε_{xy}, the normal component of sheet strain in the direction of the fiber, ε_s, is known. Equation (5) can be solved by assuming an arbitrary value of ε_s. The factors A_f, E_{af}, and k_f should properly be considered as varying in some random fashion. In this case, the solution to Eqn. (5) is very difficult. An alternative procedure is to select average values for A_f, E_{af}, and k_f and to determine an average fiber response. When this procedure is followed, the solution of Eqn. (5) is easily obtained as

$$\varepsilon_f = \varepsilon_s\left(1 - \frac{\cosh a\xi}{\cosh aL}\right) \qquad (8)$$

$$a = \left(\frac{k_f}{A_fE_{af}}\right)^{0.5} \qquad (9)$$

L is half the fiber length and A_f is the cross-section area of the fiber.

The strain energy of a typical segment element is calculated as

$$W_e = \tfrac{1}{2}E_{af}A_f\lambda\varepsilon_s^2\eta_L \qquad (10)$$

where

$$\eta_L = 1 - \frac{\tanh aL}{aL} \qquad (11)$$

and can be identified as a coupling efficiency. For strong coupling and long length, η_L approaches unity. At the other extreme of very short length or

very energy of the system can be written

$$W = \int_0^x \int_0^\pi D_0 f_{\theta\lambda}^* W_e \mathrm{d}\theta \mathrm{d}\lambda \qquad (12)$$

where D_0 represents the number of segment elements per unit area and $f_{\theta\lambda}^* W_e \mathrm{d}\theta \mathrm{d}\lambda$ represents the probability of finding a segment having a length in the interval λ, $\lambda + \mathrm{d}\lambda$ and orientation in the interval θ, $\theta + \mathrm{d}\theta$.

Suppose that $f_{\theta\lambda}^*$ can be expressed in the form

$$f_\theta^* = [f_\theta(\theta,\, a_1,\, a_2,\, a_3,\, \ldots,\, a_m)]$$
$$\times [f_\lambda(\lambda_s,\, b_1,\, b_2,\, b_3,\, \ldots,\, b_m)] \qquad (13)$$

Here, f_θ describes the fiber orientation distribution as a function of θ depending on the m parameters, a_1, a_2, ..., a_m. Likewise, the distribution of fiber lengths, λ, depends on n parameters b_1, b_2, ..., b_n. In general, the parameters a_1, a_2, ..., a_m are assumed to be functions of λ, while the parameters b_1, b_2, ..., b_n are functions of θ.

The evidence available suggests that coupling between the two distributions is weak and therefore as an approximation, valid for at least certain papers, it can be assumed that the length and orientation distributions are independent. For this assumption, the parameters a_1, a_2, ..., a_m and b_1, b_2, ..., b_n are constants, and the strain energy per unit sheet area can be written in the form

$$W = \frac{1}{2} \frac{\omega_s}{\rho_{af}} \int_0^\pi \phi_\lambda E_{af} \varepsilon_x^2 f_\theta \mathrm{d}\theta \qquad (14)$$

where ω_s represents the basis weight, E_{af} represents the apparent fiber density and

$$\phi_\lambda = \int_0^\infty \eta_L f_\lambda \mathrm{d}\lambda \qquad (15)$$

The length of parameter ϕ_λ and the apparent fiber modulus, E_{af}, may depend upon the orientation direction, θ, as a result of the stresses imposed on the fibers during drying of the sheet. Analytically, it can be assumed that the apparent fiber modulus, E_{af}, depends upon the shrinkage and restraint conditions present during drying in the following way:

$$E_{af} = E_{af_0}(1 + H\varepsilon_{ND}) \qquad (16)$$

where E_{af_0}, a constant, represents the apparent fiber modulus in the absence of drying restraint, H is a constant that predicts the magnitude of stiffening, and

$$\varepsilon_{ND} = (\alpha_x M + \varepsilon_{xD})\cos^2\theta + (\alpha_y M + \varepsilon_{yD})\sin^2\theta \qquad (17)$$

Here $\alpha_x M$ and $\alpha_y M$ represent the sheet shrinkage strains during unrestrained drying in the x and y directions, and ε_{xD} and ε_{yD} represent the sheet strains

applied or allowed during drying. Thus, for unrestrained shrinkage conditions, $\varepsilon_{xD} = -\alpha_x M$ and $\varepsilon_{yD} = -\alpha_y M$. It is evident that ε_{ND} is related to the magnitude of restraint that a fiber of orientation θ would be subjected to during the drying of the sheet. In the following analysis, it is further assumed that ε_{ND} is positive, that is, the fibers are loaded in tension as a result of any drying restraint.

Experimental results of the effects of drying restraint were performed by Setterholm and Chilson (1965). Data taken from their work (cf. Perkins and Mark (1981)) indicates that the parameter H has values that lie in the range of 10 to 30. Experimental evidence of the effect of drying restraint on the properties of the fibers in the network was shown by Wuu *et al.* (1991).

With the help of Eqn. (16), integration of Eqn. (14) can be easily carried out, if the length factor, ϕ_λ, is independent of θ. In fact, ϕ_λ does depend on θ, because the coupling parameter a that appears in η_L depends on E_{af}. If one assumes that the influence of variation in E_{af} through θ in ϕ_λ has an insignificant effect on the prediction of the elastic moduli of the sheet, there is no serious analytical error committed in assuming the ϕ_λ is independent of θ.

The stress–strain relations for the sheet can be obtained from the strain energy function W after carrying out the integration through the relations

$$\tau_x = \frac{\partial W}{\partial \varepsilon_x} \qquad \tau_y = \frac{\partial W}{\partial \varepsilon_y} \qquad \tau_{xy} = \frac{1}{2}\frac{\partial W}{\partial \varepsilon_{xy}} \qquad (18)$$

where τ_x, τ_y, τ_{xy} represent the force per unit edge length of the paper sheet.

To express conveniently the resulting elastic moduli it is desirable to express the orientation distribution $f_\theta(\theta)$ in terms of its Fourier series expansion. When the x direction is one of the axes of elastic symmetry, for example the machine direction, and $\theta = 0°$ corresponds to this direction,

$$f_\theta(\theta) = \frac{1}{\pi}[1 + a_1 cos2\theta + a_2 cos4\theta$$
$$+ a_3 cos6\theta + \cdots + a_n cos2n\theta + \cdots] \qquad (19)$$

After substitution of Eqns. (19) and (16) in Eqn. (14) and subsequently using Eqn. (18), the Young's moduli E_x^*, E_y^*, the shear modulus G_{xy}^*, and the Poisson ratios v_{xy}, v_{yx} corresponding to plain stress loading of the sheet are found to be

$$E_x^* = \frac{1}{16}\frac{\omega_s}{\rho_{af}}\phi_\lambda E_{af_0}[(1 + \langle e \rangle)(6 + 4a_1 + a_2)$$
$$+ \frac{e_\Delta}{2}(8 + 7a_1 + 4a_2 + a_3)]\left[1 - v_{xy}v_{xy}\right] \qquad (20a)$$

$$E_y^* = \frac{1}{16} \frac{\omega_s}{\rho_{af}} \phi_\lambda E_{af_0} \Big[(1 + \langle e \rangle)(6 - 4a_1 + a_2)$$
$$+ \frac{e_\Delta}{2}(8 - 7a_1 + 4a_2 - a_3) \Big] [1 - \nu_{xy}\nu_{xy}] \quad (20b)$$

$$\nu_{xy} =$$

$$\frac{(1 + \langle e \rangle)(2 - a_2) + \frac{e_\Delta}{4}(a_1 - a_3)}{(1 + \langle e \rangle)(6 - 4a_1 + a_2) - \frac{e_\Delta}{2}(8 - 7a_1 + 4a_2 - a_3)} \quad (20c)$$

$$\nu_{yx} =$$

$$\frac{(1 + \langle e \rangle)(2 - a_2) + \frac{e_\Delta}{4}(a_1 - a_3)}{(1 + \langle e \rangle)(6 + 4a_1 + a_2) + \frac{e_\Delta}{2}(8 + 7a_1 + 4a_2 + a_3)} \quad (20d)$$

$$G_{xy}^* = \frac{1}{16} \frac{\omega_s}{\rho_{af}} \phi \lambda E_{af_0}$$

$$\times \Big[(1 + \langle e \rangle)(2 - a_2) + \frac{e_\Delta}{2}(a_1 - a_3) \Big] \quad (20e)$$

where

$$\langle e \rangle = \tfrac{1}{2}H[(\alpha_x M + \varepsilon_{xD}) + (\alpha_y M + \varepsilon_{yD})] \quad (21a)$$

$$e_\Delta = \tfrac{1}{2}H[(\alpha_x M + \varepsilon_{xD}) - (\alpha_y M + \varepsilon_{yD})] \quad (21b)$$

An inspection of Eqns. (20a–e) indicates that the elastic constants depend only on the first three parameters, a_1, a_2, a_3, that occur in the Fourier series expansion for f_θ. Furthermore, if the influence of drying restraint is not incorporated or if the sheet is dried under conditions of no restraint, the elastic moduli depend only on the parameters a_1 and a_2. For this condition, Eqns. (20a–e) are essentially the same as those given by Cox (1952) when $\theta = 0°$ corresponds to a direction of elastic symmetry in the sheet. (Note, however, that the effects of fiber–fiber bonding and the effect of finite fiber length are taken into account.)

The number of coefficients of the Fourier series expansion for f_θ that are necessary for predicting the elastic properties, therefore, depends on the functional relation between the apparent fiber modulus, E_{af}, and orientation, which in turn depends on the procedures and conditions of drying. Incorporation of any other phenomena affecting the angular dependence of the strain energy stored in the sheet may change the number of Fourier coefficients appearing in the elastic constants.

It is theoretically possible to describe any fiber orientation distribution in terms of the parameters a_1, a_2, a_3, … of the Fourier series expansion. However, a single-parameter function would simplify the expressions for the elastic moduli. The reduction to one parameter can be accomplished very simply by truncating the Fourier series and retaining the single parameter a_1. However, reduction to a coefficient in the Fourier series expansion can have some significant effects. For example, for freely dried paper, the shear modulus should decrease with increased anisotropy, but this reduction effect will be predicted only if the coefficient a_2 is retained in the expansion of Eqn. (19). A single-parameter function would predict the shear modulus to be independent of the degree of anisotropy of the paper.

An alternative approach is to employ a distribution function that has only one shape parameter. For a general discussion of fiber orientation distribution refer to Perkins and Mark (1981). The two most suitable single-parameter distributions are the elliptical and the von Mises distributions. The distributions and their corresponding values of a_1, a_2, a_3 are given in Table 1.

2. Application of Theory to Prediction of Elastic Moduli of a Paper Sheet

Equations (20a–e) can be used to estimate the effects of changes in structural parameters on the elastic properties of paper, or to estimate from experimental measurements the parameters of the system. As an

Table 1
Parameters for the elliptical and von Mises fiber orientation distributions.

	Parameter		
	a_1	a_2	a_3
Elliptical $f_\theta = \dfrac{\zeta}{\pi}\left(\dfrac{1}{\cos^2\theta + \zeta\sin^2\theta}\right)$	$2\left(\dfrac{\zeta - 1}{\zeta + 1}\right)$	$2\left(\dfrac{\zeta - 1}{\zeta + 1}\right)^2$	$2\left(\dfrac{\zeta - 1}{\zeta + 1}\right)^3$
von Mises[a] $f_\theta = \dfrac{1}{\pi I_0(\kappa)}e^{\kappa\cos2\theta}$	$2\dfrac{I_1(\kappa)}{I_0(\kappa)}$	$2\dfrac{I_2(\kappa)}{I_0(\kappa)}$	$2\dfrac{I_3(\kappa)}{I_0(\kappa)}$

[a] $I_n(\kappa)$ = modified Bessel function of the first kind and order n.

example, if the values of E_x and E_y can be obtained from measurements of the Young's moduli in the machine and cross-machine directions, the remaining in-plane elastic moduli can be estimated.

To use Eqns. (20a–e) in this example, it is necessary to investigate the influence of drying restraint. The stiffening parameter H of Eqn. (21) has been estimated by experiment (Setterholm and Chilson 1965) to lie in the range 10–30. From a knowledge of the drying restraint conditions and sheet shrinkage behavior, the values of $\langle e \rangle$ and $\langle e_\Delta \rangle$ can be calculated. The ratio of the experimental Young's moduli for the machine and cross-machine directions can be equated to the ratio E_x^*/E_y^* from Eqns. (20a,b). The elliptical or von Mises distribution can be written in a Fourier series form (Table 1). The first three coefficients of the expansion can then be taken as a_1, a_2, a_3, respectively. The inversion of this relation would yield a value of the concentration parameters for orientation ζ or κ can then be used to obtain a_1, a_2, a_3 and subsequently the values of v_{xy}, v_{yx}, and G_{xy}. The measurement of two Young's moduli then permits all the in-plane elastic moduli for the sheet to be estimated. The calculation is best performed for several different assumptions regarding the variable in Eqn. (21), to ascertain the reliability of the assumptions.

The choice of fiber orientation distribution function can have significant effects on predictions obtained from Eqns. (20a–e). For a given fiber orientation, predictions of v_{xy}, v_{yx}, and G_{xy} from experimental measurements of E_x and E_y may be different for the elliptical distribution from those for the von Mises distribution. While the elliptical distribution or the single-parameter cosine distribution is the easiest to apply, the von Mises distribution is considered to provide more accurate estimates (Perkins and Mark 1981).

In the case of fiber segment length distributions, the Erlang distribution has been found to be quite satisfactory. This, the function f_{λ_s} can be taken as

$$f_{\lambda_s} = \frac{(\lambda_s/b)^{c-1}\exp(-\lambda_s/b)}{b[(c-1)!]} \qquad (22)$$

Here, b and c are determined by fitting the distribution to the experimental data. The product bc is equal to the mean value of λ_s. The standard deviation for the distribution is $b\sqrt{c}$. For further information, refer to Perkins and Mark (1981).

The distance between fiber crossings of fiber-to-fiber bonds along a given fiber, $l(\theta)$, is an important property of the fiber network. Assuming that the fibers are all straight, the bond centroid distance depends on the direction of the fiber and the overall orientation distribution of the fibers in the network. The bond centroid distance is determined by the number of fibers that cross a given fiber. This problem was studied by Kallmes and Corte (1960) and by

Komori and Makishima (1977) who showed that

$$n(\theta) = \frac{2D_f N\lambda^2}{V}J(\theta) \qquad (23)$$

where

$$J(\theta) = \int_0^\pi f(\theta)|\sin(\theta - \alpha)|d\alpha \qquad (24)$$

Here, D_f denotes the fiber diameter, or in the case of a flattened fiber, the z-direction thickness of the fiber. N represents the number of fibers in a volume V. The function $J(\theta)$ represents the average value of the sine of the crossing angle, $\theta - \alpha$, for a fiber of orientation θ. The function $J(\theta)$ can be expressed in series form as shown by Chang (1983)

$$J(\theta) = \frac{2}{\pi}\left[1 - \sum_{n=1}^{\infty} \frac{a_n}{(2n-1)(2n+1)}\cos(2n\theta)\right] \qquad (25)$$

The rationale for Eqn. (23) follows from the observation that $2D_f\lambda(\lambda\sin\beta)$ represents the volume occupied by the two crossing fibers times the projected length of the crossing fiber. Thus, the average number of contacts is the number of fibers, N, in a volume, V, times the ratio of the volume associated with one crossing to the total volume of fiber material.

The average distance between bond centroids, $l(\theta)$, along a fiber of orientation θ is taken as the reciprocal of the average number of crossings per unit length. Therefore,

$$l(\theta) = \frac{V}{2D_f N\lambda J(\theta)} \qquad (26)$$

The average number of crossings considered over the set of all fibers is

$$\bar{n} = \frac{2D_f N\lambda^2}{V}I \qquad (27)$$

where

$$I = \int_0^\pi f(\alpha)J(\alpha)d\alpha \qquad (28)$$

or in series form as shown by Chang (1983)

$$I = \frac{2}{\pi}\left[1 - \sum_{n=1}^{\infty} \frac{a_n}{(2n-1)(2n+1)}\right] \qquad (29)$$

The overall average distance between bond centroids for the network is

$$l = \frac{V}{2D_f N\lambda I} \qquad (30)$$

The quantity $N\lambda$ represents the total length of fiber in a volume, V. If $M = \rho_f A_f N\lambda$ represents the mass in

volume V, then the expressions for bond centroid distance can be written,

$$l(\theta) = \frac{\rho_f}{2\rho_s} \frac{A_f}{D_f} \frac{1}{J(\theta)} \tag{31}$$

$$l = \frac{\rho_f}{2\rho_s} \frac{A_f}{D_f} \frac{1}{I} \tag{32}$$

When the fibers are assumed to be completely flattened, then D_f is the thickness t_f and $A_f = w_f t_f$ and the bond centroid distances can be written

$$l(\theta) = w_f \frac{\rho_f}{2\rho_s} \frac{1}{J(\theta)} \tag{33}$$

$$l = w_f \frac{\rho_f}{2\rho_s} \frac{1}{I} \tag{34}$$

The fiber crossing angle can be obtained from the definition of $J(\theta)$ since this quantity represents the average value of the sine of the angle between two crossing fibers for a fiber of given orientation angle θ relative to the reference direction. Therefore, the average crossing angle β is given by

$$\beta = \arcsin(J(\theta)) \tag{35}$$

The bond area is calculated from the crossing angle. Therefore,

$$A_b(\theta) = \frac{w_f^2}{J(\theta)} \tag{36}$$

and the average bond area for fibers of all orientations is

$$A_b = \frac{w_f^2}{I} \tag{37}$$

These network properties are to be used in the calculations for the fiber coupling parameter k_f and the effective fiber modulus E_{af} in Eqns. (2) and (7), respectively.

When the relations provided in Eqn. (20) are to be used to predict the sheet elastic moduli, the values of l, and A_b are to be taken from Eqns. (34) and (37) because these relations relate the average properties of the sheet over all directions. The portion of the fiber that is bonded, l_b, is defined using Eqns. (36) and (37) as the apparent length necessary in order that the product $l_b w_f$ is equal to the bond area. On the other hand, the methods leading to Eqn. (20) can be performed numerically with the angle dependence of bond centroid distance, bond length, and bond area taken into account using Eqns. (33) and (36) in the expressions for E_{af} and k_f. The numerical approach makes it possible to avoid the simplifying assumption

of independence of angular dependent and fiber length effects that are discussed above.

Using the relations above, it can be shown that when the sheet density, ρ_s, is equal to one-half the fiber density, ρ_f, the fibers will be in contact with adjacent fibers on one side of the fiber or the other and the unbonded length goes to zero. Given that the fiber density is $1500\,\mathrm{kg\,m^{-3}}$, the network relations above predict that fibers will have no unbonded or free length when the sheet density is above $750\,\mathrm{kg\,m^{-3}}$. For paper sheets characterized by a density in excess of this figure, the mesoelement model depicted by Fig. 1 should be modified so that there is no free fiber length. This would suggest that the mesoelement should be taken as the fiber itself. Therefore, for sheet density in excess of $750\,\mathrm{kg\,m^{-3}}$ the relations for the elastic moduli (Eqn. (20)) can still be used as long as the effective axial fiber modulus from Eqn. (2) is taken as the axial fiber modulus, E_{fL}, and the network coupling stiffness, k_f, is taken as

$$k_f = \frac{A_b k_b}{l} \tag{38}$$

When the procedure described above is used for predicting the elastic moduli of sheets with sheet density in excess of $750\,\mathrm{kg\,m^{-3}}$ it is clear that the prediction neglects the transverse and shearing strains in the fiber. The laminate approach was explored by Schulgasser and Page (1988) and by Page and Schulgasser (1989) in order to take into account the transverse and shearing contribution. They showed that the transverse properties of fibers are especially important as regards the prediction of the in-plane shear modulus and the Poisson ratios of the sheet. In the works of Lu *et al.* (1995), Lu and Carlsson (1996), and Lu *et al.* (1996) the authors develop what they refer to as a mosaic model that incorporates the in-plane axial and transverse elastic moduli of the fiber. This approach makes use of the finite element method to analyze a representative element that is characteristic of the fiber segments and bonds that comprise the paper network. A model for moderate to high density paper was also proposed by Uesaka (1990) where the transverse strain effects were taken into account by modifying the theory leading to Eqns. (20) to incorporate transverse fiber strain in a similar fashion to the modeling of the axial strain. This work takes into account the contribution of the fiber-to-fiber bonds, but neglects the fiber Poisson and shearing effects. An approximate model that accounts for transverse strain, Poisson and shearing effects, and the fiber–fiber bonding has been proposed by Perkins (1999).

3. Nonlinear Geometry and Constitutive Effects

The assumption of linear elastic behavior of the fiber and bond materials can be relaxed while using essentially the same approach as that outlined above. The

mechanical response of paper when loaded uniaxially, as in the example of a simple tensile test, was studied by Ramasubramanian and Perkins (1988) who developed algebraic expressions for predicting the uniaxial stress–strain response. The expressions are sufficiently complex that their evaluation by computer is necessary. This work was extended to account for moderate to high density papers by Perkins *et al.* (1991). Subsequently, Sinha and Perkins (1995) adapted the mesoelement approach to provide a constitutive model for use in finite element analysis.

The basic approach outlined above can be modified to take into account a number of nonlinear effects if one does not require that closed form expressions be obtained for the prediction of mechanical response. In other words, the mesoelement approach can be extended by performing the calculations numerically rather than in algebraic form. The effects of fiber curl, fiber buckling, nonelastic constitutive models for the bond and fiber components, as well as certain aspects of failure at the mesoelement level can be studied when the mesoelement model is analyzed by the finite element method. The basic approach has been presented by Perkins (1999).

Papermaking

The operations involved in converting fibers (see *Paper: Pulping and Bleaching[*]*; *Pulp and Paper: Nonwood Sources[#]*) and other materials (see *Pulp and Paper: Nonfibrous Components[*]*) into a sheet of paper or paperboard are collectively known as papermaking. Paper having a width up to 10 m is manufactured on a continuous basis on paper machines as long as 150 m. Production speed is 33 m s^{-1} for some grades.

Papermaking has evolved from an art practiced by hand to a complex and technical manufacturing process with a high degree of automation (see *Paper: History of Development*[#]).

The principal steps of papermaking include stock preparation, forming to create a uniform wet web, pressing to remove liquid water, drying to evaporate most of the remaining water and consolidate the product, calendering to reduce the sheet thickness and improve the surface smoothness, and reeling to collect the dry product. All these operations are carried out on a single, large paper machine. Additional operations, such as winding to produce smaller rolls of paper suitable for printing or for further converting, the application of various additives onto the sheet, or supercalendering, may be carried out on- or off-machine to produce different grades of paper (see *Paper Products: Classification**).

Many of the papermaking operations involve water removal. The development of sheet dryness as it proceeds along a typical paper machine is shown in Fig. 1. In the forming section, about 95% of the water ejected from the headbox is removed as the web solids content is rapidly increased from less than 1% to a value ranging anywhere from 13% to 25%. This is followed by pressing, which typically achieves a web solids content somewhere between 38% and 50%. Drying is used only for the last stage of water removal, resulting in a final moisture content of the paper between 2% and 10%.

Paper is truly an engineered material that is manufactured according to the requirements of its final use. Many properties, such as surface texture, color, strength, stretch, absorbency, permeability, translucency, grease or moisture resistance, electrical conductivity, permanency, and stiffness, can be imparted by carefully tailoring the manufacturing process.

1. Forming

Forming is the critical step of the papermaking process. The objective of forming is to drain water from a dilute fiber suspension deposited on a forming fabric, and to create a uniform fiber mat that has a sufficient consistency to be passed to the press section of the paper machine. Forming has a strong influence on a range of paper properties. A sheet with ideal formation would have a uniform mass distribution in the plane of the sheet with no flocs and no difference in fiber orientation at all points across the machine. Forming sets the fiber orientation in the sheet, which
Figure 1
A large amount of dewatering occurs as the paper web proceeds down a typical paper machine, which includes forming, pressing, drying, calendering, and reeling sections.

will influence the directionality of paper properties. As well, forming determines the fines and filler distribution in the *z* direction, which determines the two-sidedness and surface smoothness of the product. The characteristics of the web created in the forming process can be linked to many of the final paper properties (see *Paper: Strength and Stiffness**). It is thus useful to consider not only the process and equipment but also how the forming and drainage processes are coupled to quality.

Stock preparation is a series of operations in which the paper machine furnish is prepared for papermaking (see *Paper: Pulping and Bleaching**). The operations involved might include dispersion of dry pulp or paper in water, refining of pulp, blending of several pulps and the addition of fillers, dyes, or other additives (see *Pulp and Paper: Nonfibrous Components**). The prepared stock at a consistency of about 3% is stoved in a machine chest and is referred to as ''thick stock.''

1.1   Approach Flow System

The approach flow system includes all pumps, pipes, and apparatus through which the stock flows from the machine chest to the headbox. The function of the approach flow system is to provide a continuous, uniform flow of cleaned, screened, and deaerated fibrous suspension to the paper machine. Screens and centrifugal cleaners in the approach flow system remove large and heavy contaminants from the pulp. Some additives such as retention aids might be added to the pulp in the flow approach system. Dissolved and dispersed air may interfere with the formation, and is often removed from the pulp suspension. In the approach flow system, water drained during forming is used to dilute the thick stock from the machine chest from a mass concentration, or consistency, of about 3% to 1%. This low consistency is required to minimize fiber flocculation, which impairs the quality of formation.

1.2   Distributor and Headbox

The stock arrives through a pipe at the side of the paper machine. The function of the distributor and headbox is to convert the flow from the cross-direction to the machine direction and to spread the pipeline flow into a jet of full machine width, but only a few centimeters thick. The jet is then deposited onto the forming fabric. The uniformity of the jet has a considerable effect on the quality of paper formation. It is critical that the thickness and velocity of the jet is uniform across its full width, since this determines the uniformity of product basis weight.

Tapered headers are the most common type of flow distributor. The flow turns from the incoming pipeline into a bank of tubes, or holes in a drilled plate.

The taper provides a uniform pressure across the entries to the tube bank, so that the flow will spread equally across the paper machine. The recirculation flow at the narrow end of the manifold is adjusted to ensure a uniform pressure across the machine.

The stock flows through holes or tubes directly into the headbox, which may be either an air pad or hydraulic headbox. The air pad headbox was dominant until the early 1970s. In this design the flow from the tubes emerges into a chamber equipped with one or several rotating, perforated rolls. These rolls disperse flocs of fibers and provide a flow resistance that blends the jets emerging from individual tubes and minimizes side flows within the headbox, which could cause nonuniformity in the jet flow. This dampens out pressure disturbances in the incoming flow, which might otherwise produce basis weight variations. This headbox design is inappropriate for modern, wide, high-speed paper machines because its large chamber is not compatible with high stock pressures, and the long perforated rolls are easily deformed.

Hydraulic headboxes, commonly installed on modern paper machines, have no perforated rolls and usually no air pads. Instead, the flow from the distributor proceeds through deflocculating elements into a converging section, where it is accelerated to a speed close to that of the paper machine. Since the hydraulic headbox does not have a large-volume chamber, it can withstand the high stock pressures required to accelerate the jet to a high machine speed.

The jet of fiber suspension leaves the headbox through an adjustable slice consisting of two thin metal plates, referred to as the upper and lower lips. The basis weight, or amount of fiber mass deposited per unit area, is proportional to the flow of thick stock from the machine chest. The consistency of the suspension is controlled by the slice opening. Large adjustments to the slice lip opening are made when switching between different paper grades. Smaller adjustments are used to provide a uniform basis weight profile in the cross-machine direction. These adjustments are made at discrete locations, typically every 10–15 cm across the paper machine width. However, a local correction at one slice position can lead to secondary effects in the flow of adjacent control zones, resulting in nonuniformities in the paper basis weight and fiber orientation. Very uniform basis weight profiles can be accomplished only with the assistance of sophisticated computer control.

The uniformity of basis weight profiles can also be adjusted by adding varying amounts of fresh water or white water entering the headbox, to modify the local consistency rather than the flow rate. Dilution control thus provides basis weight uniformity without affecting the local flow patterns. The positioning of the slice lips are also used to set the discharge angle of the jet with respect to forming fabric. This angle affects formation, porosity, and other properties.

1.3 Formers

There are four main classes of former: cylinder-vat-formers, fourdriniers, top formers, and gap formers.

(*a*) *Cylinder-vatformers*. Cylinder vatformers were common in the past, but they are not suitable for high speed operations. Today they are used mainly on multiply board machines.

(*b*) *Fourdrinier formers*. The fourdrinier was dominant from the early 1800s until the late 1960s. In the classic fourdrinier design, the jet from the headbox impinges on the forming fabric at the forming board. Substantial dewatering occurs due to the momentum of the jet. Small differences in the speed of the jet and the fabric speed (termed "rush" or "drag") will induce a machine direction alignment in the fibers. Consequently, the tensile strength will be much greater in the machine direction of the paper than in the cross-machine direction.

The forming fabric carries the suspension over foils, which generate pulses of suction and promote drainage of the water. The leading edge of successive foils skims water from the fabric surface. The pulses also cause lateral movement of the fiber suspension, which promotes even distribution of fiber and improved formation. In the past, table rolls were used to support the forming fabric. However, at high machine speeds table rolls generate excessive pressure pulses, which can disrupt the fibrous mat. Table rolls can still be found on some old, slow machines.

The resistance of the mat to drainage increases as water is drawn off. The mat is then drained over suction boxes with progressively higher levels of vacuum to a consistency of 8–10%, and over a suction couch to reach a solids content of 15–25%. The design of the forming fabric, the size of the individual filaments, their weave, and the number of layers in the forming fabric will affect the drainage rates, retention of fines and fiber, the surface quality of the paper, and other paper properties. Fabrics must be carefully selected for each application.

A significant problem with the fourdrinier is that drainage occurs through only one side of the fiber mat. This side might be depleted of fines, filler, and other small particles, which can lead to problems with print quality, curl, and other properties.

(*c*) *Hybrid or top formers*. The top former or "hybrid" former reduces the two-sidedness of paper, and increases the dewatering capacity of a paper machine by draining water from both sides of the mat. This style of former consists of a conventional fourdrinier table having a second fabric applied on top of the mat at the point where consistency of the web is about 2%. The fibrous mat sandwiched between the lower and upper forming fabrics proceeds around a curved forming roll and/or series of forming blades to produce positive drainage pressures. The pressures can be applied to either side so that an appropriate program of pressures minimizes two-sidedness.

Top formers were installed on many conventional fourdriniers in the early 1980s. However, they did not completely eliminate two-sidedness, since the initial drainage still occurs from only one side.

(*d*) *Gap or twin wire formers*. The gap former uses two fabrics for the full length of the forming section to minimize two-sidedness and maximize drainage. It is the dominant choice for new formers where surface quality and machine speed is critical.

A typical configuration has a hydraulic headbox with the jet impinging at the nip where two fabrics come together. The previous discussion of fabric selection, jet impingement, and jet to fabric speed differentials apply in a similar manner to the fourdrinier. However for a gap former, the fiber mat is contained between the two forming fabrics that wrap around a forming roll and a series of forming blades, mounted on a forming shoe, before going over suction boxes and the couch roll. The tension of the fabrics and the curvature of the forming roll and blade shoe create a positive dewatering pressure. Associated pressure gradients provide an opportunity to redistribute fibers and improve formation. The quality of the paper sheet is strongly dependent on the quality of pulp, the uniformity of the headbox jet, and the design of forming fabrics. While roll–blade formers are most common on new machines, some gap formers have only blades or only a pair of rolls.

2. Pressing

The key objective of pressing is water removal from the wet web, although two other results of pressing, namely improvements of wet web strength and product quality, are of equal importance. On a modern paper machine, the web leaving the former is weak and readily damaged or broken as it proceeds at high velocity through the subsequent machine parts. In the press section, the solids content of the sheet is increased to about 43% on machines using roll presses, and up to 50% on machines using at least one shoe press. The sheet compaction and water removal that occur in pressing cause a three- to fourfold increase in wet sheet tensile strength.

Pressing also has an important influence on the finished product properties. The network of wet fibers leaving the former is bulky and contains a large volume of air. The product obtained by drying an unpressed, is deficient in wet web has a low density, strength, and smoothness, and is poorly suited for use as a printing base or packaging product. Only some hygienic tissue papers are made from unpressed webs.

Upon pressing the wet web, malleable wet fibers are forced into close proximity, air and most of the water separating the fibers are expelled, tubular fibers are flattened, and the fiber-to-fiber contact area is greatly increased. Paper obtained by drying a pressed web is much denser, stronger, and smoother than that obtained from unpressed webs.

2.1 Roll and Shoe Presses

The press section of a paper machine generally consists of two to four press nips, each consisting of two counter-rotating hydraulically loaded press rolls. The wet sheet is compressed in each press nip at linear loads ranging from $30\,kNm^{-1}$ to $200\,kN\,m^{-1}$. The sheet is usually pressed along with a permeable press fabric to provide a means for removing the water expelled from the sheet. The press fabric is an endless loop that continuously passes through the press nip. In single-felted presses, one side of the sheet is in a direct contact with a press roll, while the other contacts the press fabric. The press roll backing the press fabric is usually vented, that is, equipped with holes or grooves to receive the water escaping from the press fabric. Some press rolls have a shell made permeable by drilled holes and a suction box located inside the roll. Elastic covers made of hard rubber or polyurethane often cover the vented rolls. The press roll contacting the wet web must be smooth, since any roughness of the roll will be replicated on the paper surface.

The press nip formed by a roll press is about 20–40 mm wide, resulting in a nip residence time of only 1 ms at a machine speed of $30\,m\,s^{-1}$. If the nip residence time is too short for adequate water removal the moisture content of the sheet leaving the press may be too high. Excessive hydraulic pressure generated in a nip under these conditions may damage or break the sheet by so-called "sheet crushing." A sheet with a higher solids content can withstand higher pressure and the press nip load is thus increased from the first to the last press.

Two strategies are used to improve water removal and to prevent sheet crushing, especially on machines with very short nip residence times such as those machines operating at high speeds or those producing heavy grades of paper and board which require a lot of dewatering. Press nips of such machines may be double-felted, which means that the sheet is pressed between two permeable press fabrics, allowing water to leave the sheet through both sides. The second strategy is the replacement of one of two press rolls with a hydraulically loaded shoe. The shoe is shaped in such a way that it matches the contour of the press roll. The nip formed in this manner can be about 300 mm wide, and the time available for sheet compression and water removal is about 10 times greater than in nips formed by conventional roll presses.

2.2 Press Section Configurations

Sheet breaks are a common problem that limits the speed and productivity of many machines. Most frequently, the sheet break occurs when the weak wet web is for the first time transferred unsupported between two machine parts in a so-called "open draw." Until the 1950s the first open draw occurred between the former and the first press, and frequent breaks at this point limited the machine speed to about $11\,m\,s^{-1}$. On modern paper machines the first open draw occurs in the press section, and therefore this is the point where most sheet breaks occur.

Modern paper machines often employ a cluster of three or four rolls that form two or three press nips, respectively. These multinip presses are more expensive to build and to operate, but they press the sheet in several nips before the first open draw. The repeatedly pressed sheet has a higher solids content and is stronger, which improves the paper machine runnability. Open draws have been eliminated from the wet end of some new paper machines of the future to permit higher operating speeds.

2.3 Press Fabrics

The role of press fabrics is to distribute evenly the pressure applied by grooved or drilled press rolls and to receive water expelled from the web in the press nip. In spite of its much heavier weight, the press fabric normally has a greater permeability than the wet web. Press fabric structures are carefully engineered to remain permeable to water even under compression. Modern press fabrics consist of a woven base covered by a batt of loose fibers. During its life, which might range from 10 days to 60 days, a press fabric passes through the press nip several million times. To prevent plugging of the fabric by various contaminants associated with the expelled water, continuous cleaning with showers, vacuum suction boxes, and, occasionally, chemical agents is required. When the fabric permeability can no longer be restored by chemical or other cleaning methods the fabric must be replaced.

2.4 Mechanism of Pressing

Water remaining in the fibrous web at the end of the forming section is located on the surface of the fibers, in the fiber lumens, and inside the swollen fiber walls. As the wet web and the adjacent press fabric start entering the press nip, the air contained in the sheet–fabric sandwich is expelled, and the nip becomes saturated with water. Further compression of the sheet and press fabric is possible only if some water escapes into cavities in the press roll. Water flow out of the sheet is driven by the hydraulic pressure in the press nip, but is limited by the low permeability of the sheet and its resistance to compression.

The compressed sheet and fabric, saturated with water in the midpoint of the press nip, begin to expand on the outgoing side of the nip. During this expansion, capillary forces transfer some of the water located within the press fabric back into the more compact wet paper in a process referred to as rewetting. Various authors have reported different estimates of the extent of rewetting in the outgoing side of the nip, but the real value is unknown. If the sheet is not separated from the press fabric immediately upon its exit from the nip, rewetting continues and can decrease the solids content of the pressed sheet by as much as 3%.

Numerous mathematical models with various degrees of complexity have been developed to describe water removal in the press section. Difficulties in modeling wet pressing include the short duration of the press pulse, the nonlinear variation in the permeability of the compressed sheet and press fabric, rewetting, and other factors. Models can be used to calculate the effect of pressing only by employing some experimentally derived factors, and the results are often not very accurate. Most models contain in some form the nip impulse, which is a product of nip pressure and the duration of pressure pulse. A practical form of the nip impulse is expressed by dividing the press nip load by the machine speed.

In addition to nip load and machine speed, the extent of pressing is strongly influenced by the sheet temperature. Increasing the temperature has a similar effect on the results of pressing as does increasing the press nip impulse, namely that the sheet solids content is higher and its thickness is reduced. On many machines, the sheet is heated directly at the entrance of the press nip by a steam shower or by infrared radiation. A heated press roll can also be used to heat the sheet, but this method is not commonly used. Considerable development of a technique commonly referred to as "impulse drying" has been carried out. In this approach the sheet is pressed using a press roll heated to a temperature around 300 °C. Impulse drying, which is more closely related to pressing than it is to drying, has yet to be used on a commercial machine. It is likely that the potential for improving pressing by further increasing the sheet temperature will be exploited in the future.

2.5 Problems Associated with Pressing

Pressing difficulties can be related to the press section operation or to the product quality. One common operational problem is press vibration, often caused by variations in the properties of roll covers or press fabrics. Sheet breaks can be caused by excessive sheet adhesion to the press roll at the outgoing side of the nip. Press fabric life can be drastically limited by incorrect cleaning or operating procedures. Unscheduled machine shutdowns, for premature replacement

felts or press rolls, are a common cause of low machine efficiency.

While pressing of the wet web improves the quality of finished paper and board, it can also generate several types of defects. In particular, excessive pressing in the first nip can cause sheet crushing and holes in the product. Uneven moisture distribution across the paper width can be caused by unequal nip load distribution or by a variation in the press fabric quality. Sheet two-sidedness can arise when the side contacting the press fabric in the last press nip becomes rougher than the side contacting the smooth press roll.

3. Drying

In drying, the web is heated and moisture is removed by evaporation. The principles of heat and mass transfer are integral aspects of the process. The high energy requirements of the dryer section make it the most expensive part of the paper machine to operate, and paper is dried only when a large portion of water is removed by drainage, suction, and pressing. Typically, the web leaves the press section and enters the dryer section of a paper machine at a moisture content around 60%. The final moisture content after drying is 10% or less, depending on the grade and the desired properties (see *Paper: Effects of Moisture and Temperature**). During drying, bonding of the pressed and consolidated cellulosic fiber network occurs without the use of additional binders. Capillary forces developed during drying draw the fibers into close contact, providing in the fibrous network numerous sites for bonding (see *Paper: Structure**). The final product quality is greatly dependent on drying.

3.1 Multicylinder Dryers

The conventional multicylinder drying section used to dry most paper and paperboard is the longest part of the paper machine, sometimes having up to 90 cylinders. Paper is dried in a conduction-based process by contacting the hot surface of steam-heated cast iron cylinders with diameters of 1.2–1.8 m and shell thickness of 2.5–4 cm. The cylinders are pressure vessels typically rated for about 1.1 MPa. The pressure is gradually increased as the paper proceeds through the dryer. The steam is introduced into the cylinders through rotary joints, and condenses inside the cylinder. The condensate is evacuated from the cylinder through a rotary or stationary siphon along with some of the uncondensed steam, known as blow-through steam. The dryer is usually covered by a canopy or hood that may be partly or fully closed. This serves to exhaust the humid drying air and facilitates the recovery of energy for reuse. Hot, dry make-up air is continually supplied to the hood.

A typical cylinder dryer consumes 1.5 kg of steam per kilogram of water evaporated. The overall drying rate depends on the grade and the basis weight of the paper, and varies between 3 and 8 g s^{-1} m^{-2} for steam temperatures in the range 100–190 °C.

The cylinders are usually arranged in sections having upper and lower tiers, through which the paper travels in a serpentine fashion. The configuration, in which each tier has an endless felt or fabric to press the sheet against each dryer to maximize heat transfer, is known as a double-felted dryer section. The unsupported portion of the web is called a draw, and two neighboring draws together with the felt form a pocket. The sheet is not restrained in the draws, leaving it vulnerable to fluttering and breaks and allowing the sheet to shrink. The vapor released in the pocket induces localized high humidities that will retard further evaporation unless the pocket is ventilated with hot, dry air.

Over the years, incremental improvements to multicylinder drying have been primarily driven by the desire to increase the machine speed. Dryer felts were replaced by more permeable drying fabrics, and double-felted sections are being progressively replaced by single-felted ones, where a single drying fabric rather than an upper and lower fabric is used. Some single-felted dryer sections are built with a single tier of heated cylinders. Since the cylinders coming into contact with the fabric rather than the paper in a single-felted system provide little heating of the sheet, they are often replaced by plain or vacuum rolls. Single-tier sections are sometimes arranged in such a way as to provide alternate heating for both sides of the sheet.

The dryers for the fastest machines are now being designed as one long single tier with no alternating sections; thus one side of the sheet is always in contact with a fabric and the other in periodic contact with the drying cylinders. The sheet is heated from one side only. The single-tier arrangement improves machine runnability, which becomes critical as machine speeds approach 33 m s^{-1}. Drying rate on some new machines is enhanced by blowing of hot combustion gas onto paper from a hood that surrounds the drying cylinder. This drying technique is expected to be widely used in the future.

It is important to achieve a uniform moisture profile across the width of paper. The web has a tendency to become wetter in the center, where the hood air is more humid than at the edges. If a uniform moisture profile is critical, the sheet can be overdried to a very low moisture level at the expense of operating efficiency. However, nonuniformities in moisture profile are usually corrected through the appropriate use of steam showers in the press section, remoisturizing showers in the dryer section, or infrared profiling units. Nonuniform moisture profiles cause difficulties in the subsequent operations such as coating, calendering, and winding, and may result in over dried

or grainy edges, baggy or slack areas, and poor reel building. Other drying-related defects may include the following: blisters caused by an overheated cylinder; brittleness and loss of strength from over-drying; machine direction dryer wrinkles from a variety of causes, including misalignment, improper tension, or excessive flutter in the draw; felt seam marks or holes in the sheet from dripping of condensed vapor in the hood; and poor surface finish because of dirt on the cylinder.

3.2 Yankee Dryers

Drying of tissue and towel is carried out in contact with a single large polished cast iron cylinder called a Yankee dryer, which has a diameter of 3–6 m and a shell thickness of around 7.5 cm. Apart from their size and the special design considerations that this imposes, Yankee dryers are similar to the cylinders used in multicylinder drying and are heated with steam. Circumferential grooves inside the cylinder are used to provide more condensate heat transfer area, as well as decreasing the shell thickness through which heat must transfer before reaching the paper. Yankee dryers are almost always equipped with gas-fired impingement hoods or caps that greatly increase the drying rate by blowing jets of hot gas onto the paper surface. Jet velocities of around 200 m s^{-1} and jet temperatures up to 700 °C can be found on the most modern impingement hoods. Drying rates are around 560–1400 g s^{-1} m^{-2}, which is one order of magnitude greater than those for multicylinder drying.

The wet web is pressed onto the hot dryer with a rubber roll, and the dry paper is detached from the dryer by means of a creping doctor. The microridges induced in the paper by the creping doctor create bulk and softness. Most Yankee dryers use a spray system to apply adhesion and release agents to the surface of the cylinder prior to the press roll. The proper adhesion and release of the sheet is critical to the drying and creping processes. Tissue and towel typically have a much lower basis weight than other paper grades, and are manufactured and dried at speeds beyond those of other paper products.

Machine glaze (MG) cylinders are similar in all respects to Yankee dryers except that the creping doctor is not used and the surface of the cylinder is more highly polished. The impingement hood is optional since the principal function of this type of dryer is to impart a smooth and glossy finish to one side of the paper or paperboard, rather than achieve a high drying rate. MG cylinders may be used in conjunction with conventional cylinder dryers, although more and more they are being replaced by special calendering processes that achieve the same finish and are simpler to operate.

3.3 Other Types of Dryer

Alternative drying methods using convective or radiation heat transfer, or a combination of pressing and drying, have found niche applications for certain paper grades. Coated papers requiring noncontact drying use combined convective and infrared drying systems. The quality of the coated surfaces is sensitive to the drying method, and the absorption of radiant energy in the infrared region is confined to a very thin layer especially suitable for coating drying. Sack grades requiring nonrestrained drying to induce product strength properties use air flotation drying. This technique uses high-velocity hot air streams from alternate air bars on both surfaces of the web for simultaneous floating and drying. Air flotation dryers are commonly used for drying thick sheets of market pulp. Microwave or dielectric drying is especially effective in correcting moisture profile for all grades.

Some tissue manufacturers use through-drying of an unpressed web to enhance softness and bulk. Hot air is drawn through the web, which is supported on a perforated cylinder under a vacuum. The drying rate is similar to that obtained on a Yankee dryer.

Much effort has been devoted to the development of press drying and impulse drying since the 1980s. In these concepts the distinction between pressing and drying is blurred since they are performed simultaneously to achieve high drying rates and special product properties. A few commercial designs have been applied in the manufacture of board grades.

There are now several applications using gas- rather than steam-heated cylinders in multicylinder dryers. This approach permits much higher surface temperatures than can be obtained with steam heating, and increases the drying rate.

3.4 Heat and Mass Transfer During Drying

Paper is dried at temperatures well below the boiling point of water. When wet paper is dried, simultaneous heat and mass transfer take place. For optimal drying, heat and mass transfer must be maximized while at the same time respecting the various operational and energy efficiency constraints. For multicylinder drying, the rate of heat transferred from the hot steam inside the cylinder to the cooler paper on the outside depends on the overall temperature gradient and the different resistances to heat transfer. These include the condensate inside the dryer, shell thickness, contact resistance at the paper–cylinder interface, and the web itself.

Increases in the drying rate can be achieved by increasing the heat transfer to the paper, which is the rate-limiting step for the greater part of the drying. This can be done by increasing steam pressure, which increases the overall temperature gradient, or by decreasing the resistances to heat transfer. The latter approach may include minimizing the thickness of the condensate layer rimming the inside of the cylinder through appropriate siphon arrangements, increasing the turbulence of the condensate layer through the use of longitudinal dryer bars inside the cylinder, keeping the inside and outside surfaces of the shell clean, and decreasing the contact resistance by increasing the fabric tension.

For Yankee dryers, heat transfer occurs not only from the steam-heated cylinder but also by convective heat transfer from the impinging jets. The contact resistance is low because the paper is pressed on the surface rather than being held with a fabric, and the heat transfer resistance of the web itself is low because of the low basis weights used for these grades.

After a sufficient amount of heat has been transferred to the wet web, a given mass of water vapor is transferred from the paper through a boundary layer to the air in the dryer section. This can occur by molecular diffusion, convective diffusion, and bulk movement or ventilation. The driving force for mass transfer is a vapor concentration (or partial pressure) difference between the web and the surrounding dryer air. The evaporation rate can be maximized by reducing the thickness of the boundary layer through proper pocket ventilation, keeping the vapor pressure of water in the sheet at a high level by keeping the sheet temperature elevated, and maintaining a low vapor pressure in the ambient dryer air by keeping it hot and dry.

3.5 Effects of Drying

For most applications, the rate of drying does not significantly affect the properties of paper, and the most important objective is to achieve a uniform moisture profile so that subsequent operations such as calendering, surface treatment, and printing will produce uniform results.

During drying, shrinkage of individual fibers in the radial direction induces shrinkage and cockle unless paper is restrained. Shrinkage begins to occur at about 65% solids content. The action of restraining the sheet during drying leads to the development of drying stress or tension, the extent of which depends on the degree of imposed restraints. Tension in the machine or cross-machine direction increases the tensile strength and reduces the toughness and stretch-to-failure in that direction. Restraint during drying reduces hygroexpansivity, and improves the dimensional stability of the sheet. Nonuniform drying stress in the thickness direction of the paper, as occurs in single-sided drying, causes the sheet to curl. Pressure in the thickness direction during drying increases the sheet density and lowers its porosity.

Multicylinder drying results in high machine direction tension although the sheet is relatively free to shrink intermittently in the cross-direction in the open draws. This cross-direction shrinkage is not

uniform and is greater at the edges, resulting in non-uniform strength profiles. Air floatation drying used for sack grades allows shrinkage to occur in all directions with essentially no stress or strain on the sheet, resulting in high stretch and toughness but lower strength than is obtained in multicylinder drying.

4. Calendering, Winding, and Reeling

4.1 Calendering

Improving paper smoothness is the primary objective of calendering for printing and writing papers, and also for some packaging grades of paper and board. The dry web leaving the dryer section is bulky and has a rough surface. For most printing processes, print quality is proportional to paper smoothness. Even paper that is not used for printing or which is used as a base for coating is often calendered to improve roll building, since small differences in sheet thickness accumulate, causing variations in reel diameter and wrinkles in the sheet.

A calender consists of a vertical stack of 2–10 polished steel or chilled cast iron rolls. The paper passes in a serpentine fashion through the nips between each roll starting at the top of the stack. The pressure in each calender nip is generated by the weight of the rolls above the nip, or the calender might be hydraulically loaded or relieved. Linear nip loads do not usually exceed 150 kN m^{-1}. The paper is repeatedly compressed as it passes through each nip. After each compression, the paper expands but does not recover its original bulk. The surface of the calender roll is replicated onto the paper surface, and calender rolls must be periodically reground to maintain their smoothness as well as to correct any variations in their diameter caused by unequal wear.

Calendering is enhanced by all factors that render fibers less rigid and more malleable. Therefore, paper made from chemical pulp requires less calendering than paper made from mechanical pulps, and calendering can be improved by increasing the sheet moisture content and temperature. The effect of calendering is increased by increasing the number of nips or the nip load, and is decreased by increasing the machine speed or roll diameter.

The high nip loads in the calender can result in product damage. Calender blackening occurs at very high nip loads when fiber flocs are compressed to the extent that they lose their opacity. This defect occurs more readily if the sheet moisture content is high. Printing papers made from mechanical pulp may lose as much as 30% of their tensile strength during calendering, since compression of the sheet in the dry state causes destruction of fiber-to-fiber bonds. Creases in the paper entering the calender usually results in calender cuts. Any damage or scratch on the roll surface can be replicated on calendered paper.

In a supercalender, highly polished steel rolls alternate with rolls covered with a soft cover made from a plastic material or from heavily compressed cotton. The softness of this cover helps to prevent calender blackening, and therefore supercalenders can be loaded up to about 400 kNm^{-1}. Supercalenders are usually self-standing machines, used on coated paper and board to obtain high-gloss products.

Hot–soft calenders installed at the end of a paper machine can also be used to obtain gloss and smoothness values approaching those produced by supercalenders. These calenders usually consist of two or four nips formed by a metal roll heated to 160–200 °C and a "soft" roll with a synthetic cover.

4.2 Reeling and Winding

At the end of the paper machine, the dried and calendered sheet is reeled onto a large-diameter spool to produce large reels of paper called parent or jumbo rolls. The full machine width rolls obtained on the reel weigh several tonnes and are not suitable for final use. Therefore, a winder is used to unwind the jumbo rolls, slit the sheet, and convert the jumbo roll into smaller rolls suitable for shipment to press rooms or for further conversion to a final product. The basic principles of reeling and winding are similar.

During reeling, the spool of paper is pressed against a drum to obtain the desired roll density. The correct roll density profile is important for good final product quality. Roll density should be highest near its core and gradually decline toward the periphery of the roll. The density profile is controlled by the pressure between the spool and the drum and by the tension of the incoming paper. The top paper layers of the roll are under tension, and this belt of strained paper compresses the paper wound closer to the core. A well-wound roll is rigid and resists deformation by external forces.

Incorrect density profiles can result in various defects of the press roll, including bursts and excessive stretching of the outside plies of the roll. Rolls with too low a density near the core and a large paper tension at the perimeter can collapse in a star pattern when subjected to even modest external pressure. Therefore, reeling and winding are as important for the final product quality as any other papermaking operation.

5. Surface Treatment

The most common forms of surface treatment after drying involve application of sizing agents to increase the water repellency of the sheet and improve printability, barrier agents for packaging grades, and coating formulations required for various grades to improve surface optical and physical properties (see *Paper, Wetting and Penetration of Liquids into*[#]; *Pulp and Paper: Nonfibrous Components**; *Paper Products: Classification**).

Sizing agents such as starches and binders can be applied to dry paper or board using flooded nip, gate roll, or film transfer size presses. The degree of sheet rewet is minimized in film transfer size presses, requiring less sheet strength to prevent breaks and less after-drying. Precautions must be taken to prevent picking and sticking of the sheet on the first dryers following the size press.

Coating of the sheet with formulations containing pigments, minerals, binders, and other additives can be achieved off- or on-machine. Both sides of the sheet may be coated sequentially (with drying of the first side prior to coating of the second) or simultaneously after the calendering operation. Roll, blade, and metered film transfer coaters can be used to spre-read coating onto paper. Coatings are very delicate when wet, and initial drying must set the coating without disrupting it. For this reason, convective- and radiation-type dryers are used immediately after coating, although conventional dryers may be used after the initial drying.

PES and PEEK

The development of advanced polymer technologies is a crucial step in the application of biomedical polymeric materials, since common technologies require refinement in order to meet the stringent requirements for medical end use. Composite technology, plastics processing, and polymer synthesis are three well-known areas that, with adaptation, readily find use in biomedical applications. Biomaterials must survive the harsh chemical and mechanical environment of the body with minimal chance for revision once in place. Certain biomedical devices are expected to be biostable and have long-lasting properties in these harsh biological environments. Unlike in several other industries where a material is replaced after a defined time, the objective of the ideal implantable biomedical device is to be long lasting in a closed environment. Poly(ether ether ketone) (PEEK) and poly(ether sulfone) (PES), two advanced engineering thermoplastics, are examples of such materials and have been investigated for use in demanding medical applications.

1. Synthesis and Characteristics of PEEKs

PEEK is a linear, aromatic, thermoplastic, semicrystalline (about 20–30% crystallinity) material. It is hydrolytically stable, resistant to wear, stable in solvents, and abrasion resistant. Select properties are listed in Table 1. PEEK is synthesized by a condensation reaction (Fig. 1) and may be processed using standard melt-processing techniques such as roll forming, hydroforming, pultrusion, injection molding, and casting. Photodegradation of PEEK can occur with main chain scission and cross-linking occurring simultaneously below the glass transition temperature, while cross-linking largely occurs above the glass transition temperature. PEEK is commercially available in several grades according to different molecular weights (or melt viscosities) to meet the requirements of different melt-processing methods. It has been found that different grades of PEEK may be oriented in the solid state using compressive stresses to achieve uniaxial or biaxial orientation, thus yielding high modulus machinable stock for use in medical devices (Shalaby *et al.* 1996).

2. PEEK Applications: Past, Present, and Future

PEEK is commonly used in composites, both for biomedical and nonbiomedical applications, and it finds use as chromatography tubing or as wire and cable insulators. PEEK can be sterilized by autoclaving, by treating with ethylene oxide, or by high-energy radiation. Hollow fiber PEEK membranes can be produced by solution spinning. PEEK is a

Table 1
Representative properties of PES and PEEK.

Property	PES	PEEK
Density (g cm^{-3})	1.41	1.31
Tensile strength at yield (MPa)	99.4	90.0
Elongation to break (%)	30.2	39.2
Flexural yield strength (MPa)	140	150
Modulus of elasticity (GPa)	4	3.6
Impact strength, Izod (J cm^{-1})	0.8	0.74
Compressive yield strength (MPa)	100	120
Water absorption (%)	0.89	0.13
Deflection temperature at 1.8 MPa (°C)	210	170
Glass transition temperature (°C)	230	145
Melting temperature (°C)	350	330
Thermal conductivity (W m^{-1} K^{-1})	0.24	0.25
Electrical resistivity (Ω cm)	3.1×10^{16}	4.6×10^{15}
Dielectric constant	3.8	3.4
Figure 1
Molecular structure of PEEK.

promising candidate for hip stem manufacture, since its modulus is much lower than traditional metallic materials and it possesses much closer features to an isoelastic implant, as predicted by finite element models, thus minimizing potential for stress shielding-related problems most commonly associated with traditional metallic implants (Corvelli *et al.* 1996, 1997, 1999). PEEK is most commonly combined with glass or carbon fibers to form composite intramedullary devices. Select carbon fiber/PEEK systems, tested at various temperatures in solution up to 5000 hours, show no significant loss in compressive strength, modulus, and Poisson ratio as a function of time or temperature (Zhang *et al.* 1996). Carbon fiber/PEEK composite wear debris has been assessed in simulated physiological environments with a zirconia femoral head, PEEK wearing into particles of the order of 2.2 μm and carbon fiber into particles of the order of 153 μm. Carbon fiber/PEEK plates have been tested for *in vitro* biocompatibility and exhibit a nonspecific foreign body reaction only.

Biocompatibility tests of PEEK do not show signs of cytoxicity and they do show increased osteoblast cell protein content, which may be indicative of
Figure 2
Molecular structure of PES.

improved ingrowth performance (Morrison *et al.* 1995). Studies have also indicated that PEEK, processed in specific roughnesses, has relatively good biocompatibility, enhancing proliferation of osteoblastic cells and increasing production of osteocalcin (Lin *et al.* 1997). Attempts have been made to plasma spray hydroxyapatite onto PEEK/carbon fiber surfaces, a process commonly used with metallic implants to improve ingrowth and adhesion of an implant material. This method is not successful with thermoplastics, the hydroxyapatite in the PEEK composite systems demonstrating low shear strengths (HA) and fast debonding or delamination times. Hydroxyapatite may have application as a reinforcing agent for PEEK and preliminary studies have addressed the appropriate ratio and configurations of a composite using these two components (Abu Bakar *et al.* 1999).

Novel surface modification techniques have been developed in an effort to encourage osseointegration of PEEK implants with surrounding bone tissue. Two novel surface modification techniques have been employed to create microtextured surfaces, the first through microtexturing and the second by covalently bonding phosphonate groups (Shalaby and Rogers 1996, Shalaby and McCaig 1996, Shalaby and Roweton 1999). To achieve surface microtexturing with microporosity, the PEEK implants are subjected to so-called crystallization-induced microphase separation. To introduce phosphonate moieties on the PEEK surface that mimic a hydroxyapatite surface, PEEK is first acylated with propionic anhydride, then phosphonylated with PCl$_3$/O$_2$, and then hydrolyzed in the presence of aqueous calcium oxide. These investigations show that osseointegration can be achieved with transcortical tibial and mandibular implants in the rat and goat models, respectively.

3. Aromatic PESs

Polysulfones are engineering thermoplastics with desirable properties for use in biomedical applications. They are hydrolytically, thermally, and oxidatively stable and are unaffected by oil or grease. A commonly used PES is formed by a polycondensation reaction of a sulfonyl chloride and diphenyl ether to produce macromolecules with the repeat unit depicted in Fig. 2. Select properties of PES are listed in Table 1. PES is an amorphous thermoplastic material with high glass transition temperature. It can be obtained in a transparent grade and it can be rendered conductive. PES may be sterilized by autoclave, by

treating with ethylene oxide, or by radiation. Compared to other amorphous polymers, it has one of the highest resistances to chemicals.

4. PES Applications: Past, Present, and Future

Typically, PES is used in the filtration industry as hollow fiber membranes as well as in respirator nebulizers. Due to its ability to survive high temperatures for sustained periods, PES is finding applications as an electrical insulator. Due to its grease and oil resistance, it also is used in the automotive and aircraft industries. PES has also found biomedical applications, where it is used as a resin material in composite intramedullary hip stems, material in instrument holders, reusable syringe injectors, prosthesis packaging, sterilizer trays, and dental tools. PES has been tested with varying boron ion doses to modulate the surface characteristics. Ion beam irradiation or glow discharge of its surface can improve cell adhesion (Pignataro *et al.* 1997, Tanahashi *et al.* 1996). Sliding tests of up to 10 000 cycles can actually increase the hardness of the polymer, in a manner proportional to the dose and beam energy (Rao *et al.* 1993). This therefore produces important wear characteristics, a critical issue for articulating implant surfaces. PES can be coated with apatite to improve its bioactivity (Nagano *et al.* 1996, Tanahashi *et al.* 1994, 1996) and bonding to bone. PES membranes have been used as hollow fibers in hemodialysis applications with some concern due to their thrombogenic features. Because of this property, the injection of an anticoagulent has become a necessity. New areas of interest therefore address blending the PES with other materials and thus improving its blood biocompatibility. PES has been tested as a hollow fiber encasing alginate and endothelial cell growth factor, with potential application to promote surrounding vasculature (Hunter *et al.* 1999). PES is used as dialysis membranes in order to attenuate reverse transfer of dialysate contaminants into the blood compartment.

5. Comparisons of PEEK and PES

Comparisons between select carbon fiber-reinforced PEEK and carbon fiber-reinforced PES show that the former maintain higher compressive and flexural strengths in simulated body environments (Strait *et al.* 1991). PEEK and PES with 30% short carbon fibers tested in saline show that select PEEK systems exhibit no change in flexion and fracture toughness while the PES system significantly decreases in mechanical properties with exposure (Brown *et al.* 1990). Interfacial bond strength in both microdroplet systems showed that the bond strengths significantly decrease following exposure to saline (up to 5000 hours) and are dependent on time and temperature.

Following saturation, the immediate bond strength loss stabilizes at the temperature-dependent equilibrium bond strength level (Meyer *et al.* 1994). Biocompatibility studies of both matrix materials induce a low cellular response, indicating the promise of future use (Wenz *et al.* 1990). PES and PEEK grow competitive amounts of fibroblasts and osteoblasts as compared to traditional metallic materials and promote adhesion competitively (Hunter *et al.* 1995).

Plastic Deformation of Cellular Materials

Foams made from materials which have a plastic yield point (rigid polymers, or metals, for instance) *collapse plastically* when loaded beyond the linear-elastic regime. Plastic collapse, like elastic buckling, gives a long horizontal plateau to the stress–strain curve, though the strain is not recoverable.

Plastic collapse in an open-cell foam occurs when the bending moment exerted on the cell walls exceeds the fully plastic moment (Thornton and Magee 1975, Gibson and Ashby 1997), creating plastic hinges like those shown in Fig. 1. Closed-cell foams are more complicated; in them, the plastic-collapse load may be affected by the stretching of cell faces as well as by the bending of the cell edges, and by the presence of a fluid within the cells. The simpler case of open cells is examined first.

1. Open-cell Foams

Plastic collapse occurs when the moment exerted by the force F (Fig. 1) exceeds the fully plastic moment of the cell edges. For a beam with a square section of
Figure 1
The formation of plastic hinges in an open-cell foam.

side t, this fully plastic moment is:

$$M_p = \tfrac{1}{4}\,\sigma_{ys}t^3 \tag{1}$$

where σ_{ys} is the yield strength of the cell wall material. If the force F has a component normal to the cell edge (of length l), the maximum bending moment is proportional to Fl. The stress on the foam is proportional to F/l^2. Combining these results gives the plastic-collapse strength of the foam:

$$\sigma_{pl}^* \propto \frac{M_p}{l^3}$$

For open-cell foams, the relative density $\rho^*/\rho_s \propto (t/l)^2$ (where ρ^* is the density of the foam and ρ_s is that of the solid of which it is made) giving the collapse stress of the foam σ_{pl}^*:

$$\frac{\sigma_{pl}^*}{\sigma_{ys}} = C_1\left(\frac{\rho^*}{\rho_s}\right)^{3/2} \quad \text{(open cells)} \tag{2}$$

where the constant C_1 contains all the constants of proportionality. At higher densities the dimensions of the cell corners must be subtracted from the length of the beam, and corrections must be made to the equation for the density. When this is done (Gibson and Ashby 1997) the last equation becomes:

$$\frac{\sigma_{pl}^*}{\sigma_{ys}} = C_1'\left(\frac{\rho^*}{\rho_s}\right)^{3/2}\left(1 + \left(\frac{\rho^*}{\rho_s}\right)^{1/2}\right) \tag{3}$$

(open cells, including density correction)

Two limits on this behavior are worth noting. At large relative densities ($\rho^*/\rho_s > 0.3$), the beam-bending concept breaks down. The cell walls are now so short and squat that they yield axially (in compression or tension) before they bend. Above this density the material is better thought of as a solid with holes in it, not as a foam. At the other extreme—that of very low relative density—it is possible for elastic collapse to precede plastic collapse, even though the subsequent large-strain behavior (and thus the plateau stress) may be determined by plasticity.

2. Comparison with Data for Open-cell Foams

Data for the plastic-collapse strength and for the plastic indentation of foams (discussed further on) are plotted in Fig. 2. Open symbols are for open cells; full symbols are for closed cells. They are adequately described by Eqn. (2) with $C_1 = 0.3$ (full line, Fig. 2); Eqn. (3) with $C_1 = 0.23$ does marginally better (broken line). Each set of data follows the theory well, but with differing values for C_1, probably because of the errors in the value taken for yield strength of the solid, which is used as a normalizing parameter. In summary:

$$\frac{\sigma_{pl}^*}{\sigma_{ys}} \approx 0.3 \left(\frac{\rho^*}{\rho_s}\right)^3 \quad \text{(open cells)} \tag{4a}$$

or

$$\frac{\sigma_{pl}^*}{\sigma_{ys}} \approx 0.23 \left(\frac{\rho^*}{\rho_s}\right)^{3/2} \left(1 + \left(\frac{\rho^*}{\rho_s}\right)^{1/2}\right) \tag{4b}$$

(open cells, including density correction)

3. Closed-cell Foams

Closed cells have membranes spanning their faces. Plastic collapse causes the membranes to fold and crumple in the compression direction; being thin, the force required to crumple them is small. But at right angles to this direction the membranes are stretched, and the plastic work required to extend them contributes significantly to the yield strength of the foam. This is assessed by calculating the work done in an increment of deformation and equating it to the plastic dissipation in bending the cell edges and stretching the cell faces.

Consider the collapse of a cell like that shown in Fig. 3. The cell edges and faces have thicknesses t_e and t_f, respectively; they are related to the fraction of solid in the edges, ϕ, by:

$$\frac{t_f}{l} = 1.41(1 - \phi) \frac{\rho^*}{\rho_s} \tag{5a}$$
Figure 2
Data for the compressive yield strength of foams, normalized by the yield strength of the solid, plotted against relative density. The solid line represents the theory for open-cell foams; the dashed line represents that for open-cell foams with an additional density correction. They are almost indistinguishable.
Figure 3
Plastic stretching of the cell faces of a closed-cell foam.

and

$$\frac{t_e}{l} = 0.93\phi^{1/2}\left(\frac{\rho^*}{\rho_s}\right)^{1/2} \qquad (5b)$$

(Gibson and Ashby 1997).

A compressive plastic displacement δ of one cell allows the applied force F to do work $F\delta$. The angle of rotation at the four plastic hinges is then proportional to δ/l, and the plastic work done at these hinges is proportional to $M_p\delta/l$. The cell face is stretched by a distance which is again proportional to δ, doing work which scales as $\sigma_{ys}\delta t_f l$. Summing these and equating to $F\delta$ gives:

$$F\delta = \alpha M_p\frac{\delta}{l} + \beta\sigma_{ys}\delta t_f l$$

where α and β are constants. Replacing F by σl^2, and M_p by $\sigma_{ys}t_e^3/4$ (Eqn. (1) with $t = t_e$) gives:

$$\frac{\sigma_{pl}^*}{\sigma_{ys}} = \frac{\alpha}{4}\left(\frac{t_e}{l}\right)^3 + \beta\left(\frac{t_f}{l}\right).$$

Finally, using Eqns. (5a) and (5b) we obtain:

$$\frac{\sigma_{pl}^*}{\sigma_{ys}} = C_1\left(\phi\frac{\rho^*}{\rho_s}\right)^{3/2} + C_1''(1-\phi)\left(\frac{\rho^*}{\rho_s}\right) \qquad (6)$$

(closed cells, including membrane stresses) where C_1 and C_1'' contain the earlier constants. In the limit of $\phi = 1$ (open cells), we already know that $C_1 = 0.3$; in the other limit of $\phi = 1$, σ_{pl}^* must become equal to σ_{ys} when $\rho^* = \rho_s$, so that $C_1'' \approx 1$. A density correction factor can be applied to the first term if desired (see "open cells," above), but its influence is small.

Equation (6) describes the combined effect of the plastic bending of cell edges and plastic stretching of their faces. To it must be added the contribution of the fluid contained in the cells. If the cell fluid is a gas at atmospheric pressure, p_{at}, the contribution is usually small (because $\sigma_{ys} \gg p_{at}$). But if the cells contain fluid at a pressure p_0 much larger than atmospheric, this pressure must be added to the right-hand side of Eqn. (6).

4. Comparison with Data for Closed Cells

The limited data for the plastic collapse of closed-cell foams are plotted in Fig. 2 as solid symbols. The scatter is considerable, due largely to uncertain values of σ_{ys}. The data are adequately described by Eqn. (4a); there is no evidence here for the influence of membrane stresses or of cell fluid. This may be because the cell faces rupture before full plastic collapse: then the closed-cell foam will behave like one with open faces. Or it may be because, in these foams, $\phi \approx 1$, and the contribution of the faces, though present, is small. It should not, in our judgement, be

ignored even though direct evidence for it is lacking. The best current description of the collapse strength of closed-cell, plastic foams is then:

$$\frac{\sigma_{pl}^*}{\sigma_{ys}} \approx 0.3\left(\phi\frac{\rho^*}{\rho_s}\right)^{3/2} + (1-\phi)\frac{\rho^*}{\rho_s} + \frac{p_0 - p_{at}}{\sigma_{ys}} \qquad (7)$$

(closed cells, including membrane stresses and gas pressure contribution).

5. Densification

Large plastic strains in compression cause the cell walls to crush together, and make the stress–strain curves rise steeply to a limiting strain ε_D. To an acceptable approximation,

$$\varepsilon_D = 1 - 1.4\left(\frac{\rho^*}{\rho_s}\right) \qquad (8)$$

6. Plastic Indentation

Unlike dense solids, which do not change their volume when deformed plastically, foams compact when compressed. The cells of the foam collapse as the foam is squeezed, so that axial compression produces very little lateral spreading once collapse has begun: the ratio of the lateral spreading to the axial compression is, typically, 0.04.

When a foam is compressed by a flat punch, the cells beneath the punch collapse in the direction of punching, but expand sideways hardly at all. Because of this the material in the plastic zone is not constrained by its surroundings in the way that the zone in a dense solid would be. An analysis of this problem
Figure 4
The ratio of indentation hardness to the uni-axial yield strength as a function of the effective plastic Poisson's ratio during plastic yielding.

(Wilsea *et al*. 1975) shows that, for relative densities less than about 0.3, the indentation pressure, or "hardness," *H*, of the foam is simply:

$$H = \sigma_{pl}^* \tag{9}$$

(instead of the value $H = 3\sigma_{ys}$ which characterizes a dense solid). The result is obvious: the lack of sideways expansion makes the indentation test exactly like a compression test. As the effective Poisson's ratio (the negative ratio of the lateral strain to the axial compressive strain) increases, the hardness increases from σ_{pl}^* to $3\sigma_{pl}^*$, as shown in Fig. 4.

Polymer Composites, Friction and Wear of

Polymer composite materials, one of the most rapidly growing classes of materials, are being used increasingly for technical applications, especially where their low density and high specific strength and stiffness are of great interest. Another advantage is that their properties can be varied and optimized over a wide range with regard to the requirements of the respective technical problem. Polymeric materials containing different fillers and/or reinforcements are also being used increasingly in different tribological applications (Friedrich 1986, 1993, Lancaster 1983, Zum Gahr 1987).

Some of these applications, such as sliding elements, require low friction and wear, whereas for other applications, for example in clutches or brakes, high friction combined with low wear is necessary. In all cases friction coefficient and wear rate are not individual material properties but are properties of the whole tribological system in which the materials function. This means that the tribological behavior of a material is operatively determined by the microstructure and the surface morphology of the materials in contact, the stress and speed conditions involved, and many other parameters of the tribosystem employed (Czichos and Habig 1992, Uetz and Wiedemeyer 1985). In such applications, composite materials are of particular interest since these materials contain highly tailored combinations of materials, the nature, geometry, and spatial distributions of which can be designed with considerable freedom, and controlled with considerable precision in processing.

1. Tribological Properties of Polymer Composites

The polymer-based composite–steel tribological system is of particular interest for technical use. In this context there are relatively few polymers that have valuable tribological properties, and most research is focused on these. Common thermoplastic polymers with actual or potential tribological function are listed in Table 1 together with their basic mechanical characteristics (Stachowiak and Batchelor 1993).

In general, the friction and wear behavior of polymeric matrix materials can be improved by a lower surface tension and a higher stiffness and strength. This can be achieved quite successfully by using special fillers. To reduce the adhesion, internal lubricants, such as PTFE or graphite, are frequently incorporated. Short aramid, carbon, or glass fibers are used to increase stiffness, strength, impact resistance, thermal conductivity, and creep resistance of the polymer system. In this way, excellent friction and wear properties can be achieved by a composite material consisting of a high-performance polymer matrix with lubricants and fibrous reinforcement (Häger and Davies 1993, Reinicke *et al*. 1998).

2. Wear Mechanisms

For a comprehensive understanding of the tribological behavior of polymer composite materials a close look at the possible wear mechanisms is important. Quite often the latter are subdivided into adhesive, abrasive, surface fatigue, and tribochemical mechanisms (Czichos and Habig 1992). For fiber-reinforced polymer composites a further classification of the various wear features is useful (Fig. 1). Besides material removal due to fiber and matrix sliding wear, a great amount of wear debris is generated by fiber cracking and fiber/matrix interfacial separation (Friedrich 1993). For unidirectional fiber-reinforced polymer composite under normal fiber orientation

Table 1
Tribological characteristics of selected thermoplastic polymers (Stachowiak and Batchelor 1993).

Polymer	Tribological characteristics	Temperature limit (°C)	Tensile modulus (GPa)	Tensile strength (Mpa)
Polytetrafluorethylene (PTFE)	Low friction, high wear Reinforcing component necessary High operating temperature limit	260	0.7	25
Polyamides (PA11/12, PA6/66)	Moderate to high friction, low wear Wear accelerated by water Moderate temperature limit	80–130	1.8–3.3	50–90
Polyacetals (POM)	Performance similar to polyamide Durable in rolling contacts High friction, low wear	100	3.3	70
Polyetheretherketone (PEEK)	Very high load bearing capacity High operating temperature limit Moderate friction, low wear	250	3.6	97
Polyethylenes (e.g. UHMWPE)	Low wear also in water Low operating temperature limit Moderate friction, low wear	100	0.6	20–40
Polyimides (PI, PAI, PEI, PBI)	Very high load bearing capacity High operating temperature limit	170–300	2.8–4.9	95–190
Figure 1
Wear mechanisms in composite materials (Friedrich 1993).

(N), where fiber ends are protruding at the sliding surface, a possible sequence of wear steps is that the softer polymer matrix between the much harder fibers is removed first, followed by cracking of fiber pieces, leading to a repetition of the wear cycle. It should also be mentioned here that the whole process can be superimposed by the formation of cushioning layers of consolidated wear debris, by which the surface contact conditions are modified and the resulting wear processes frequently alleviated (Williams *et al.* 1997).

According to variations in wear mechanisms different fiber orientations relative to the sliding motion can cause a drastic change in the wear behavior of composite systems. In principle, three ideal fiber orientations exist. Beside the normal (N) fiber orientation mentioned already, parallel (P) and antiparallel (AP) fiber orientations, with fibers laying in the contact plane, exist (Fig. 1). The effect of fiber orientation on the tribological behavior also depends strongly on the type of fiber employed. Experimental studies on the interaction of various fiber-reinforced polymer composites with steel counterparts have shown that, depending on the type of fiber (aramid (AF), carbon (CF), glass (GF)), the optimum fiber orientation relative to the sliding direction differs. Aramid fibers, which also interact less abrasively against the steel surface (Friedrich 1993), exhibit, due to their tendency for fibrillation and their poorer bonding to the polymer matrix, a better performance under N-orientation, whereas carbon fibers have proved to be most beneficial for wear resistance of the composite under P-orientation. The reason for the higher wear rate for CF-composites under N-relative to P- or AP-orientations is based on the fact

that the upper load limits (strength) of the fibers (under the same external load enhancement) are reached inside the composite earlier under N-orientation (Friedrich *et al.* 1999, Varadi *et al.* 1999). Another effect restricting the applicability of CF-composites with normal fiber orientation is a severe wear or seizure of the counterpart that can be initiated by exposed fiber ends.

3. Tribological Behavior of Short-fiber Reinforced Polymers

To characterize the tribological behavior of polymer composite materials standard tests are used based on the tribotechnical system under consideration. The pin-on-disk test, one of the most frequently used test configurations, is described in detail in Czichos and Habig (1992) and in Uetz and Wiedemeyer (1985). The results of such a pin-on-disk test on three high-temperature-resistant polymers (polyethernitrile (PEN), polyetheretherketone (PEEK), polyetheretherketoneketone (PEEKK)) with different internal lubricants and short fibers are shown in Fig. 2 (Friedrich *et al.* 1995, Lu and Friedrich 1997).

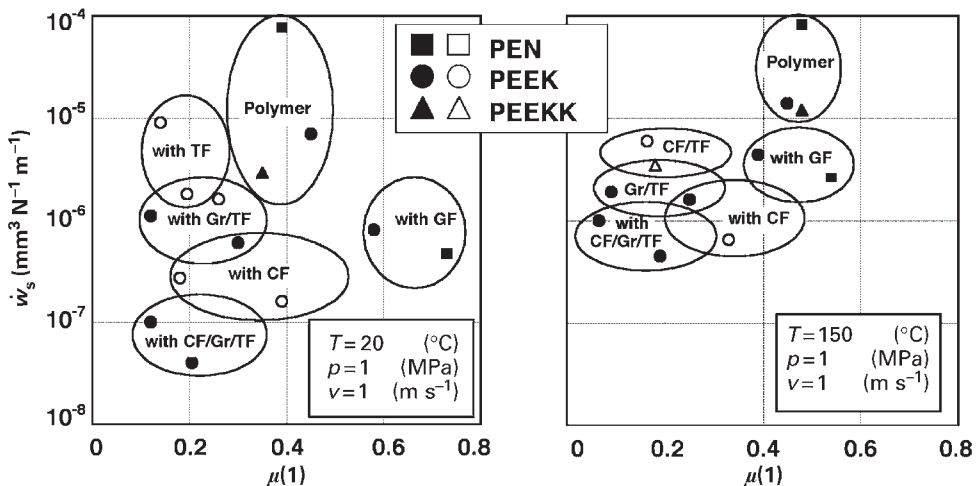
This figure illustrates for two different testing temperatures that the fibers primarily reduce the wear rate, whereas the internal lubricants, such as polytetrafluoroethylene (TF) and graphite (Gr), result in a reduction of the coefficient of friction. According to both the coefficient of friction and the specific wear rate, a system consisting of a PEEK-matrix with 10% each of CF, TF, and Gr seems to be the best compromise. In the temperature range under consideration (20–50 °C) a low coefficient of friction ($\mu < 0.2$)


Figure 2
Tribological behavior of PEN, PEEK, and PEEKK composites (same symbols in one circle refer to samples with different filler volume fraction) (Lu and Friedrich 1997).

and a low wear rate $(\dot{w}_s < 1.5 \times 10^{-6}\,\text{mm}^3(\text{N m})^{-1})$ can be achieved for an applied pressure $p = 1\,\text{MPa}$ and a sliding velocity $v = 1\,\text{m s}^{-1}$.

When considering the choice of a certain composite material for technical applications, two questions are of concern: (i) Which material can bear the load considered? (ii) How can a given component be produced from this material? Although the first question is of primary concern, the question of economics will ultimately lead to the choice of a particular material (Hornbogen 1993). For technical applications there are always several requirements, a so-called requirement profile, to be fulfilled. Within the scope of the requirement profile, there are properties of primary concern e.g., a low coefficient of friction and a low wear rate for sliding elements. Secondly, high stiffness and strength could be required. Furthermore, the demand for high hardness is often combined with the requirement for sufficient fracture toughness. As an example, consider sliding shoes attached to heavy metallic chains in textile drying machines. These must operate under extreme conditions, including elevated temperature and impact events, so an injection-moldable polymer composite with high fracture toughness as well as low friction and wear is required. An evaluation of various potential material systems (PI, PBI, PEEK) leads to the final choice of a short-fiber (fiber length $\sim 300\,\mu\text{m}$) reinforced PEEK matrix composite (including 10% each of carbon fibers, PTFE particles, and graphite flakes) (Lu and Friedrich 1997). In particular, the PEEK system performs quite well within a wide range of the pressure $(p) \times$ velocity (v) product, at various testing temperatures. It also exhibits a high fracture toughness and is injection moldable into complex geometries.

4. Tribological Behavior of Continuous-fiber Reinforced Polymers

For applications requiring extremely high stiffness and strength, high-performance polymer composites are frequently used. The main characteristics of these composites are a continuous (endless) fiber reinforcement, a high fiber content (up to 60 vol.%), and a single (unidirectional) fiber orientation. For a systematic development of such a high-performance composite with regard to an optimum wear resistance, various unidirectional composites have been tested with respect to their wear behavior as a function of matrix material, type of fiber reinforcement, and orientation of fibers relative to the sliding direction. Several matrices, comprising one rather brittle one (epoxy resin) and two very tough thermoplastics (PEEK, PA66), and three different fiber materials (glass, carbon, and aramid) were chosen for this investigation (Table 2, Friedrich 1993, Cirino *et al.* 1988). The wear resistance ratios are normalized to that of neat EP $(\dot{w}_s^{-1} = 1.8 \times 10^4\,\text{N m mm}^{-3})$, so a higher ratio means a better wear resistance relative to the EP standard.

The results of Table 2 indicate that:

(i) Tougher matrices can quite often be expected to show a higher wear resistance than brittle ones.

(ii) In a matrix with a lower wear rate, the beneficial effect of the fiber reinforcement on the wear resistance of the composite is not as pronounced as in an easily wearing matrix.

(iii) For most of the fiber orientations, carbon fibers give better results than glass fibers, while aramid fibers are somewhere in between.

(iv) As mentioned before, in the case of carbon fiber reinforcement, higher values of the wear rate are measured for N-orientation than for P- and AP-orientations. The opposite is true for aramid fibers.

The wear resistance (inverse of the wear rate) of these materials can be utilized to design a composite material with a generally good wear performance. Optimum wear resistance can be expected from a composite with a PEEK matrix and carbon fibers parallel to the sliding direction. If multidirectional sliding is the case in practical application, additional carbon fibers in antiparallel orientation will probably be helpful. In fact, a study of such a material, PEEK

Table 2
Wear resistance of UD composites (normalized to neat EP, $\dot{w}_s^{-1} = 1.8 \times 10^4\,\text{N m mm}^{-3}$).

Matrix	Orientation	CF	GF	AF	Neat matrix
EP	N	65.4	0.5	122.4	1
	P	99.8	2.1	44.1	1
	AP	44.1	1.1	46.3	1
PEEK	N	65.1	5.1	61.4	11.8
	P	158.1	5.5	46.1	11.8
	AP	94.8	2.0	44.1	11.8
PA66	N	57.0	1.8	145.5	27.7
	P	122.9	16.3	60.8	27.7
	AP	80.2	8.9	73.7	27.7
Figure 3
Synergistic effects for wear resistance of 2D hybrid composites with normal (aramid fibers) and parallel (carbon fibers) orientation.

with carbon fiber woven fabric reinforcement, resulted in even better wear factors than those of the two basic orientations of the unidirectional material. This synergistic effect is probably a result of fiber interlocking in the contact area due to the woven structure of the reinforcement.

A composite with good overall wear resistance can be made by three-dimensional (3D) hybridization, with interwoven carbon fibers in the *xy*-plane and aramid fibers in the *z*-direction. The matrix should be a very tough, highly wear-resistant polymer such as PEEK. Although such a 3D hybrid structure could not be verified by the studies of Cirino *et al.* 1988, other works with simpler 2D hybrid composites point in the direction predicted. Krey *et al.* 1989 have manufactured different laminates from amorphous polyamide-impregnated carbon and aramid strands (J2-Polymer, Du Pont, Wilmington, USA). Sliding these materials against rotating steel rings resulted in synergistic effects of the wear rates of hybrid composites with aramid fibers under normal and carbon fibers under parallel orientation (Fig. 3).

There are also some indications in the literature that composites with 3D fiber arrangement and a high-temperature polymer matrix with lubricants as inclusions have excellent wear resistance. In the particular case mentioned, glass or carbon fibers were used as reinforcements. The 3D structure was studied for different geometries of the sliding elements e.g., as flat blocks and circular bearings produced by 3D weaving technology with fibers in radial, tangential, and axial directions (Gardos 1986).

5. Conclusions

The study and examination of the tribological behavior of fiber-reinforced polymer composite systems has become an important contribution to the general field of tribology. Besides the general choice of the materials used for the composite system, a crucial

parameter affecting the wear performance is the fiber orientation relative to the sliding direction. Therefore, a basic understanding of the different wear mechanisms involved in the wear process is essential for the interpretation of the tribological behavior of composites.

Interest in polymers and polymer-based composites for technical applications has grown rapidly. Fiber-reinforced high-temperature-resistant thermoplastic materials can now be used as sliding elements where only metallic components were used before. For high-performance thermoplastic matrix systems applications are limited to temperatures of up to about 250 °C depending on the loading conditions employed. Improvements in the tribological properties of these composites are usually attained through the incorporation of different fillers as internal lubricants. By the specific choice of material composition, it is possible to tailor the performance of polymer composites according to the special demands of different requirement profiles. Further improvements in the tribological behavior can be achieved by optimizing the design of continuous-fiber reinforced, high-performance composites. A three-dimensional arrangement of aramid and carbon fibers with different fiber orientations relative to the sliding direction gives a strong improvement in the wear behavior through synergistic effects between the two fibers. For these composites the load limits, which ultimately determine the limits of application, can be further increased. In conclusion it can be stated that advances in the tribological behavior of polymer composites offer new arrays of potential applications. One innovative example is the development of functionally graded tribomaterials, in which the wear resistance along with other properties varies over the cross-section of a part due to intentional variations in the microstructure of the material (Klingshirn *et al.* 2000).

Polymer Fiber Processing: High-performance Fibers

Many studies have aimed to improve properties such as strength and modulus of polymer fibers to those of steel in strength and modulus Jiang *et al.* (1993). After the invention of nylon as the first man-made fiber, many fibers, including polyethyleneterephthalate and polyethylene (PE), have been developed and commercialized. Even these generic polymers can, however, achieve high strength levels by drawing. In order to make further progress it is necessary to design the molecular structure and fiber morphology from basic principles. Conditions to fulfill the above mentioned progress are as follows: (i) selecting materials with a molecular backbone linkage that is strong enough (double bond, heterocyclic ring, etc.)

and that have a linear conformation and an occupied volume in crystal state that is small and compact; and (ii) drawing the molecules into a fiber such that they are made parallel to the fiber axis, to form a so-called *extended chain structure*.

1. Molecular Design and Morphological Picture

First we illustrate the design of molecule for achieving a high modulus. Relationships between chemical molecular structures and mechanical properties have been discussed since the 1960s (e.g., Tashiro *et al.* (1996) who performed theoretical calculations). In general, a polymer chain can take various forms, such as planar zigzag, helical, linear, and heterocyclic conformations. Theoretical predictions suggest that a strong linkage backbone with linear conformation is one of characteristics for molecules that show high mechanical properties.

Fiber morphological design is discussed next. To explain the relationship between fiber properties and morphology schematically, Hosemann (1962) and Peterlin (1969) derived some models. If a disordered structure exists in the fiber, such as a long-period structure formed by lamella blocks (crystal and amorphous alternating structure), molecular ends, voids, and/or a skin-core structure, they will become sources of strain and stress concentrations once the fiber is deformed. Molecular orientation is one of factors to control the fiber modulus (Northolt and Sikkema 1990). Even chain ends give modulus reduction (Jones and Martin 1995) and actual fiber strength and modulus fail to reach their potential limit values. In the ideal structure of a high-performance fiber, infinitely long molecules make up the crystalline state and are aligned perfectly to the fiber direction.

As examples of fibers that possess the above ideal structure, ultra-high molecular weight PE (UHMW-PE) fibers (Dyneema and Spectra), poly-p-phenyleneterephthalamide (p-aramid) fiber, (Kevlar, Twaron), polypyridobisimidazole (PIDP) fibers, and poly-p-phenylenebenzobisoxazole (PBO) fibers (Zylon) have been developed and commercialized. Their properties are summarized in Table 1 and their repeat units are shown in Fig. 1. It is possible to estimate how much a developed fiber approaches the ideal structure by comparing its mechanical properties with the theoretical values. Theoretical and measured crystal modulus values have been obtained and accumulated systematically on many polymers. Various methods such as lattice mechanics (Tashiro *et al.* 1978, Tashiro and Kobayashi 1996) and a method solving a quantum mechanical equation with approximation Shoemaker *et al.* (1992) are used for this purpose. The crystal modulus can be measured by detecting a change of diffraction spots of fibers under deformation as a function of the applied stress

Table 1
Mechanical properties of typical high-performance fibers.

Fibers	PE	p-Aramid	PBO	Technora	Vectran	PET	Steel
Fiber strength (GPa)	3.0	3.5	5.8	3.1	2.9	1.2	2.8
Fiber modulus (GPa)	172	186	280	70	69	12	200
Measured crystal modulus (GPa)	235	156	480	91	126	95	—
Theoretical modulus (GPa)	295	182	460	—	—	108	—
Figure 1
Molecular repeat units.

(Sakurada *et al*. 1962). It has been confirmed that the fiber modulus of p-aramid realizes its theoretical value, while there is still a difference between theory (higher) and experimental values for UHMW-PE and PBO fibers. There are some ideas to explain this difference in terms of structural defects such as molecular misorientation and structural inhomogeneity along the fiber axis, which will be discussed later.

2. Production

In order to make molecules aligned to the fiber axis two well-known methods have been developed. In the gel-spinning method flexible chain molecules such as UHMW-PE are spun and drawn with reduction of entanglement densities. The liquid-crystal spinning method makes use of the rigid-rod molecular nature, such as in p-aramid and PBO, that shows liquid crystal state (domains with an alignment of molecules) spontaneously in a certain thermodynamic condition of solution.

2.1 Gel-spinning Method

The development of the gel-spinning method dates back to the invention of ultra-drawing of gel-like fibers by Smith and Lemstra (see *Processing Flexible Polymers to High Performance Fibers**). The fiber is spun from a UHMW-PE solution with a dry-wet, or airgap spinning technology, followed by a drawing process. One of key points of this method is that UHMW-PE (with a molecular weight in excess of one million) is dissolved in a solvent (e.g., xylene) and a quasi-dilute solution is prepared. Being different from the melt state of UHMW-PE, the molecules in the quasi-dilute solution are isolated relative to each other, while only some entanglement between the molecules is present. A gel fiber is then made from this solution by cooling. Molecules in the fiber take on a swollen network structure and the density of the entanglement network is kept low. In addition, the interaction force between PE molecules is so low that an increase in drawing stress of the gel fiber is suppressed even when orientation-induced crystallization occurs. Due to this the gel fiber can be drawn up to by more than 30-fold and the process is called *ultra-drawing*. After drawing the fiber shows high molecular orientation in x-ray diffraction and an absence of a long period in small-angle x-ray scattering (SAXS, Ohta *et al*. 1988) which is characteristic to a melt spun PE fibers.

2.2 Liquid-crystal Spinning Method

As the molecular conformation becomes more rigid, the molecule behaves more like a rod than a coil when in solution; therefore, the excluded volume increases. The thermodynamic state of the solution becomes unstable beyond a certain concentration, and the liquid-crystal domains in which molecules are aligned in a certain direction starts to coexist with the isotropic solution, spontaneously (see *Liquid Crystalline Polymers: An Introduction*[#]). Molecules in p-aramid and PBO fibers can be extended by utilizing the above feature. The fibers are spun from strong acid solutions with a dry-jet/wet (air gap) spinning method. After extrusion of the spinning solution from a spinneret, the fiber is drawn in the air gap (between the spinneret and the coagulation bath) in which the molecular orientation is increased by the extension flow. Subsequently the drawn molecules are fixed in a coagulation bath with a nonsolvent, followed by a washing process to wash out residual solvent and nonsolvent in the fiber, and dried. The rigid-rod molecules have such a long relaxation time that the extended structure obtained in the air gap

can be retained without molecular relaxation. Being different from UHMW-PE fibers, these as spun fibers show a high modulus. To raise the fiber modulus even more, fibers are heat-treated under tension in some cases. Better orientation makes the modulus higher (Northolt and Sikkema 1990).

2.3 Other Methods

One of disadvantages in spinning p-aramid and PBO is that strong acids are required to prepare the spinning solutions. This makes the production equipment longer and more complicated (e.g., the extruder needed to obtain the spinning solution and the coagulation baths) than in a melt spinning process. By reducing the molecular rigidity, by copolymerizing with a flexible spacer into the molecular backbone, the above disadvantage can be moderated. Technora is spun from an isotropic (organic) solution. To raise the molecular orientation of the as-spun fiber, it is drawn up to ×10 with a special drawing technique (Ozawa 1987). The resulting fiber shows a high molecular orientation by x-ray diffraction pattern Nakamae *et al.* (1987). Vectran is spun with a melt spinning method (Chung 1986). Because of the semi-flexible nature in the molecular structure, a quasi-liquid crystal state can be realized in the extension flow in the drawing process and the resulting fiber shows a high modulus and strength.

3. The Relationship Between Fiber Morphology and Properties

The influences of molecular misorientation and of inhomogeneity along the fiber axis to the fiber modulus are surveyed in this part. Figure 2 shows an x-ray diffraction pattern from a PBO (Zylon HM+) fiber. Sharp reflection spots exist on the equator, which demonstrate a high molecular orientation along the fiber axis. The Herman's orientation coefficient has been introduced to express the degree of molecular orientation quantitatively, and measured values of more than 0.99 are reported to be common for UHMW-PE (Busing 1990), p-aramid (Northolt and Sikkema 1990) and PBO Kitagawa *et al.* (1998) fibers. Northolt and Sikkema (1990) treated the relationship between molecular orientation and fiber modulus with a simple model. The method can predict the crystal modulus from measured fiber modulus values in a certain range of molecular orientation by removing the orientation-dependent factor by extrapolation. There exists an agreement between the extrapolated crystal modulus based on this estimation and the crystal modulus directly measured by x-ray diffraction in the p-aramid fiber, while PBO fiber shows a difference. It means that there is still a missing factor, other than the orientation, to explain this gap in PBO fibers having an extended structure.
Figure 2
X-ray diffraction pattern of PBO HM + fiber.

Next, structural inhomogeneity along the fiber axis is discussed. It was reported that the intensity of the SAXS pattern has a strong relationship with the presence of a long-period structure and modulus in PE fibers Wu *et al.* (1980). UHMW-PE and p-aramid fibers do not give such SAXS scattering, while PBO HM fiber (heat-treatment under tension) show a four-point SAXS pattern. The PBO molecule is so rigid that there is much less chance to form lamella blocks made of folding molecules, which normally can be detected as the long-period structure. There is still a periodical inhomogeneity along the fiber axis, which gives the SAXS four-point pattern in the PBO case and that also may be the source of hindrance for the fiber modulus to reach the value of its crystal.

As other methods to inspect fibers, such as scanning and transmission electron microscopes are often used. As a method to estimate molecular alignment directly, high-resolution transmission electron microscopy (lattice imaging) has been made available. The fact that p-aramid fiber takes the extended chain structure was first proved by this method Dobb *et al.* (1977). In Fig. 3 a lattice image of a PBO fiber (Zylon HM+) is shown. It can be confirmed that there are fringes parallel to the fiber axis, which reflect the alignment of molecules and persist over 30 nm. It can

Figure 3
Lattice image of PBO HM + fiber.

There are some theoretical studies to relate these with the strength Termonia *et al.* (1985). The compressive strength of fibers containing an extended structure is also one of important properties to be improved. It is noteworthy that PIDP fibers give a higher value (1.6 GPa) than any of the other super fibers (~0.6 GPa) (Sikkema 1998). It is plausible that hydrogen bonding in PIDP fiber forms interactions between neighboring molecules and reinforces the compressive strength, while p-aramid fiber (also having hydrogen bonding) shows a lower value than PIDP. Further study is needed to explain the above discrepancy quantitatively from the viewpoints of morphology and theory.

4. Concluding Remarks

Selecting a suitable molecule is the first step to start developing a high performance fiber. The fiber should take an extended structure that shows high molecular orientation and homogeneity along the fiber axis. As far as the Young's modulus is concerned, a high crystal modulus is the target to be achieved in developing high performance fibers and it is realized as the actual modulus in some fibers. Existing theories can estimate the theoretical modulus with fair accuracy. But concerning other properties, they need to be further refined to estimate, for example, compressive strength.

be also seen in the figure that some part showing no fringes coexists with crystal regions. This indicates that there still remain defects, such as molecular ends, and conformational disorder. Some models that express the fiber structure features have been proposed and they include all results of inspection of fibers with analytical equipment, for high-performance fibers (Dobb *et al.* 1977, Northolt and Sikkema 1990, Yabuki *et al.* 1975). In the main, attention is paid to the molecular orientation and inhomogeneity along the fiber axis to understand the fiber modulus. Fiber strength is also governed by structural defects.

Polymer Fibers: Formation and Structure

Conventional fiber formation starting from semi-crystalline polymers consists of three processes: melt-spinning, drawing, and annealing. The drawing and annealing processes are usually combined, as shown schematically in Fig. 1. The spinning and the drawing and annealing processes also can be conducted continuously, and are then known as a spin-draw process.

In the spinning process, either melt- or solution spinning, polymers are extruded through tiny orifices to form thin threads and taken up using a winder. Since polymer molecules are not well aligned along the fiber axis at this stage, as-spun fibers usually exhibit poor mechanical properties such as low modulus, low tenacity, and high elongation. Therefore, the drawing and annealing processes are necessary to fabricate fibers with well-developed structure.

In the drawing and annealing processes, as-spun fibers pass through several sets of rolls with different surface velocities. Fiber temperature is controlled either by heated rolls, plate heaters, or some other heating device. Drawing brings about molecular orientation and mechanical anisotropy, whereas annealing enhances the crystallization and thermal stability. Both properties are needed as fundamental characteristics of the finished fibers.

If the take-up velocity is increased significantly in the melt spinning process, the extensional stress applied to the spinning line increases and the as-spun fibers start to have high molecular orientation. At the same time, since the crystallization rate increases with an increase in molecular orientation, crystallization can be promoted in the spinning line even though the cooling of the molten polymer is extremely fast. This type of crystallization is defined as orientation-induced crystallization. Because of significant fiber structure development, a high-speed melt-spinning process can provide fibers directly applicable for their end use (Ziabicki and Kawai 1985).

1. History of the Fiber Structure Model

Fiber structure models were initially developed for natural fibers. A model proposed for cellulose fibers was the "fringed micelle model". The most important structural difference between synthetic and natural fibers is in the existence or nonexistence of periodic structure along the fiber axis (Kaji 1997).

The "fringed-micelle micro-fibril model," however, cannot explain (i) the SAXS intensity on the equator, and (ii) the mechanical properties of fibers. The "paracrystalline layer structure model," in which the concept of folded-chain crystal is introduced, was for the crystalline region.

"Shish-kebab structures," in which extended chains form the "shish," and crystalline lamellae epitaxially grown from the side surface of the shish form the "kebab," have become widely accepted. This structure was originally called the "row structure," as all the shish are oriented along the flow direction. Considering the overlapping of lamellae grown from adjacent shish, the "shish-kebab model"
Figure 1
Schematic illustrations of (a) melt spinning and (b) drawing and annealing processes.

is also referred to as the "interlocking shish-kebab model" (Bashir *et al*. 1986).

Although the shish-kebab structure has been widely observed in highly oriented polyethylene (PE), polypropylene (PP), and polyamide 66 (PA66), further investigation may be necessary concerning the applicability of this model for polymers with lower crystallizability, such as aromatic polyesters.

2. Aromatic Polyesters

2.1 Fiber Processing and Structure Development

Melt-spinning processes can be applied to the production of fibers from aromatic polyesters such as poly(ethylene terephthalate) (PET), poly(trimethylene terephthalate) (PTT), poly(butylene terephthalate) (PBT), and poly(ethylene naphthalate) (PEN). These polymers have relatively low crystallization rates. The glass transition temperatures of these polymers are higher than room temperature except for PBT, which has a glass transition temperature close to room temperature. Therefore, the ordinary melt-spinning process of aromatic polyesters provides amorphous fibers with low molecular orientation. Development of the fiber structure can be achieved by the drawing of as-spun fibers at a temperature near the glass transition temperature, followed by the annealing of the drawn fibers at a temperature between the glass transition and melting temperatures.

A temperature close to the maximum-crystallization-rate temperature may be preferable for the annealing process.

In high-speed melt spinning of these polymers, molecular orientation increases with an increase in the take-up velocity. Changes in the birefringence of various aromatic polyester fibers with an increase in the take-up velocity are summarized in Fig. 2. The difference in birefringence development behavior originates from the differences in molecular rigidity, intrinsic birefringence, etc. In these polymers, orientation-induced crystallization starts to occur at the take-up velocities of around $2-5 \, \text{km} \, \text{min}^{-1}$. In each polymer, the starting point of crystallization varies slightly, depending on the extrusion and cooling conditions and the molecular weight of the polymers. After the onset of orientation-induced crystallization, a higher take-up velocity generally yields higher molecular orientation, higher crystallinity, and higher ordering in the crystalline region. Conversely, molecular orientation in the amorphous region is relatively low in comparison with that in the fibers produced through conventional drawing and annealing processes.

As a typical example, structural changes in PET fibers from the high-speed melt-spinning process are summarized in Fig. 3. Initiation of orientation-induced crystallization is represented by the change in the WAXS pattern and a sudden increase of density at around $4 \, \text{km} \, \text{min}^{-1}$. Birefringence of as-spun PET
Figure 2
Birefringence development of various aromatic polyester fibers with increasing take-up velocity in the high-speed melt spinning process.
Figure 3
Change in fiber structure of PET in high-speed melt spinning process.

fibers is roughly predictable from the stress–optical coefficient and the tensile stress acting on the spinning line near the solidification point. When the take-up velocity exceeds $7 \, \text{km} \, \text{min}^{-1}$, however, molecular orientation, crystallinity, and mechanical properties start to decrease. The development of significant structural variation was found in the cross-section of PET fibers prepared in this take-up velocity region.

2.2 Crystal Modification

The crystal unit cell of all the aromatic polyesters discussed above is triclinic. No polymorphism is reported for PET and PTT, while PBT and PEN are known to have α- and β-form crystals. In comparison with PET, PTT has an extremely low crystalline modulus in the chain direction. This is because the aliphatic part of the crystalline structure of PET has a trans conformation, whereas that of PTT has a highly coiled structure of gauche–gauche conformation (Desborough 1979). Therefore, the unit cell parameters of PTT show a distinct mechanical response upon the application of tensile stress to the fibers (Jakeways 1975).

PBT fibers prepared both through the conventional process and the high-speed melt-spinning process have α-form structure (Fujimoto *et al.* 1988). The crystal form changes from α to β when a tensile strain of about 12% is applied, but reverts to α form upon the removal of strain (Yokouchi *et al.* 1976). As the c-axis length of the β-form unit cell is about 8% longer than that of the α form, the stress–strain curves of PBT fibers exhibit a remarkable yielding behavior showing a distinct plateau region. The yielding stress corresponds to the critical transition stress from α to β form (Tashiro *et al.* 1980).

In the case of PEN, α-form crystals are formed in the conventional spinning and drawing processes, whereas the coexistence of α and β form crystals is confirmed in the high-speed spun fibers. Even though the β-form unit cell of PEN has a shorter c-axis length and higher crystalline density than the α form, the amount of β-form crystals increases with an increase in the take-up velocity, that is, with an increase in the tensile stress applied during the orientation-induced crystallization. In the quiescent state, β-form crystals can be developed only when the crystallization temperature is higher than 220–245 °C, whereas the formation of the β form occurs at much lower temperatures in the high-speed spinning line (Miyata *et al.* 1997).

3. Tilting

Another interesting feature in the structure of aromatic polyester fibers is the tilting of the c-axes of the crystalline unit cell away from the fiber axis. This means that the molecular chains on average are not
Figure 4
Schematic illustration explaining the tilting of c-axis along ($\bar{2}$30) plane in PET fibers.

Figure 5
Bimodal orientation of α form crystals of PHB in drawn and annealed P(HB/HV) fibers. Coexistence of β form crystals is also indicated.

aligned parallel to the fiber axis. The direction and degree of tilting can be analyzed from the shifts of crystalline reflections from layer lines in the WAXS pattern. In PET fibers, tilting of the c-axis occurs along the ($\bar{2}$30) plane as shown schematically in Fig. 4. The tilt-angle of conventional PET fibers is about 5°, whereas that of high-speed spun fibers is reported to decrease from 10° to 2° with an increase in the take-up velocity (Shimizu *et al.* 1984). In PBT fibers, tilting of about one degree was found both in α- and β-form crystals. The direction of tilting is along the ($\bar{2}$10) and (1$\bar{3}$0) planes, respectively. The tilt-angle of high-speed spun PBT fibers also decreases with an increase in the take-up velocity (Fujimoto *et al.* 1988). In PET and α-form PBT fibers, tilting is essentially parallel to the crystallographic plane containing the benzene ring. On the other hand, tilting of about 3–5° occurs along the ($\bar{1}$20) plane in PTT fibers, although the molecular chain in the crystal is in 2_1 helix conformation.

4. Aliphatic Polyesters

Some of the aliphatic polyesters, which generally have lower glass transition and melting temperatures in comparison with aromatic polyesters, attract interest because of their biodegradability. Melt spinning of these polymers, however, is difficult to control, as the extruded fibers tend to reach the take-up device in a rubbery state. This is caused by a combination of two factors: the low crystallization rate, and the glass transition temperature being lower than the room temperature. Crystallization of these polymers may be controlled through the installation of a hot tube or hot water-bath into the spinning line.

4.1 Poly(3-hydroxybutylate)

Poly(3-hydroxybutyrate) (PHB), and copolymers of PHB with 3-hydroxyvalerate (P(HB/HV)), are produced by certain bacteria. The fiber structure of PHB and P(HB/HV) is mainly composed of α-form crystals of PHB, but small amounts of β-form crystals are known to coexist. The molecular chain in the α-form crystal is in 3_1 helix conformation, whereas that in the β-form crystal is almost in the planar zigzag conformation (Orts *et al.* 1990). The α- and β-form crystals usually exhibit ordinary c-axis orientation, and the amount of β form varies depending on the drawing and annealing conditions (Furuhashi *et al.* 1998) or the take-up velocity in the high-speed spinning process (Schmack *et al.* 1999).

In some cases, the α-form crystals in drawn and annealed fibers exhibit peculiar bimodal orientation, which is represented by the coexistence of diffraction spots and rings in the WAXS pattern. Some rings are complete, with a higher intensity near the meridian, while other rings are incomplete, with a lack of intensity near the meridian, as shown in Fig. 5. Detailed

analyses of the ring pattern reveal that the c-axis is preferentially oriented perpendicular to the fiber axis, whereas the a- and b-axes are randomly distributed around the c-axis (Furuhashi *et al.* 1998).

4.2 Polylactide

Poly(L-lactide) (PLLA) has a glass transition temperature higher than room temperature. PLLA fibers prepared through conventional fiber formation processes and high-speed melt-spinning processes are known to exhibit α-form crystals, whereas the β-form crystals can be developed in the fibers drawn to extremely high draw ratios (Hoggsteen *et al.* 1990). The molecular chain in the α- and β-form crystals is in 10_3 and 3_1 helix conformation, respectively.

5. Aliphatic Polyamides

5.1 Fiber Processing and Structure Development

Fiber formation behavior in aliphatic polyamides (PA) is sensitive to the ambient conditions. This is due to the highly hygroscopic nature of the polymers. Structural parameters and mechanical properties are also sensitive to humidity because of the change in water content in the fibers.

In ordinary melt-spinning processes with polyamide 6 (PA6) and polyamide 66 (PA66), amorphous as-spun fibers can be obtained, as the glass transition temperature of these polymers is around 40 °C, which is higher than room temperature. (In the case of PA66, which has a significantly higher crystallization rate than PA6 in the quiescent condition, spherulitic structures may be developed in the spinning line if the spinning conditions result in a relatively low cooling rate.) On exposure to moisture after spinning, however, diffusion of water into the amorphous as-spun fibers results in crystallization. This process is referred to as the conditioning process.

When as-spun fibers of PA6 and PA66 are prepared at take-up velocities from 1 to $3 \, \text{km} \, \text{min}^{-1}$, birefringence increases significantly and fibers elongate spontaneously during the conditioning process. The amount of spontaneous elongation may be suppressed through the enhancement of crystallization in the spinning process, by applying water to the surface of running fibers before winding. Drawing of the as-spun fibers of PA6 and PA66 usually is conducted at room temperature. Therefore, the drawing process is called cold drawing. The reduction of the glass transition temperature by moisture uptake and heat generation during the drawing process provides enough mobility to molecules for the formation of crystalline fiber structure. Higher annealing temperatures are necessary for the production of high-strength polyamide fibers, and highly oriented and crystallized

fibers can be obtained in a similar manner to the aromatic polyesters.

5.2 Crystal Modification

PA66 has crystal modifications of α and β forms. Both the drawn and annealed fibers and high-speed spun fibers (Shimizu *et al.* 1985) exhibit α-form structure. Very weak (002) reflections of the β form were found to coexist in the WAXS pattern of high-speed spun fibers.

Various crystal modifications such as α, β, γ, and smectic (pseudo-hexagonal) forms have been reported for PA6. A reasonable rationalization is that there are only two basic crystallographic forms, α and γ. Although there are some differences in reflection intensities, the unit cell parameters of α and β forms are identical. Although γ and smectic form crystals have different thermal stabilities, these two forms exhibit similar WAXS patterns. In drawn and annealed PA6 fibers, α and β forms coexist, and the proportion of α form increases with increases in the crystallization temperature and applied tension.

In high-speed melt-spinning processes, orientation-induced crystallization starts to occur at take-up velocities of around $3–4 \, \text{km} \, \text{min}^{-1}$. In this region, the γ form dominates the crystalline structure of as-spun fibers, and the proportion of α form increases with an increase in take-up velocity (Shimizu *et al.* 1985). Higher molecular weight also yields greater proportions of α-form crystals (Koyama *et al.* 1986). These results suggest that the higher tensile stress and higher crystallization temperature lead to the preferred formation of the α form. Heuvel *et al.* (1976) confirmed that orientation distribution of PA6 α-form crystals is axis-symmetric with respect to the fiber axis, and there is no predominant direction in the rotation of the unit cell.

6. Polyolefins

Polyolefins such as polyethylene (PE) and polypropylene (PP) have high crystallization rates and their glass transition temperatures are below room temperature. Therefore, these polymers need to be crystallized in the spinning line to obtain solid fibers. Although the usage of PE fibers is limited, PP fibers are widely used as nonwoven fabrics and other applications such as carpets. In the spun-bond process, which is one of the important technologies in producing nonwoven fabrics, melt-spun fibers are directly spread on a wire mesh to obtain fabrics.

Although a wide range of drawing temperatures can be applied for the drawing of as-spun PE and PP fibers, drawing temperatures near the crystalline dispersion temperature may be preferable because the starting fibers already have high crystallinity.

6.1 Polyethylene

When the tensile stress applied to the spinning line is low or the take-up velocity is low, the crystallographic b-axis tends to orient perpendicular to the fiber axis, whereas the a-axis tends to orient along the fiber axis. The orthorhombic unit cell rotates around the b-axis gradually with an increase in the tensile stress or the take-up velocity, and eventually ordinary c-axis oriented crystals can be formed, as shown in Fig. 6. It should be noted that the density or crystallinity of PE fibers hardly changes, irrespective of the extensive variation in fiber formation conditions. Drawn PE fibers usually exhibit high molecular orientation with high c-axis orientation of the crystals.

Recent improvements in polymer synthesis technologies have brought high spinnability to PE polymers. Structure development in PE high-speed spinning processes varies slightly depending on the type of PE polymers: high density PE, linear-low- density PE, or metallocene-catalyzed linear low-density PE. In the case of linear low-density PE, formation of a-axis oriented crystals in the low speed region was not detectable (Cho *et al.* 2000).

6.2 Polypropylene

PP generally has a lower crystallization rate than PE. More importantly, the crystallization rate of PP is comparable to the cooling rate the polymer experiences in the spinning line. Therefore, the development of crystalline structure in the melt-spinning process depends strongly on the spinning conditions and polymer characteristics.

When the take-up velocity is low, and therefore the cooling rate and the applied tensile stress are low, monoclinic crystals can be formed in the as-spun fibers. The crystalline orientation is nearly isotropic in these fibers. Formation of monoclinic crystals suggests that the crystallization proceeds at relatively high temperatures. When the take-up velocity is increased, the crystalline structure changes to the smectic (pseudo-hexagonal) form, because of the enhancement of cooling and a reduction in the crystallization temperature. There can be additional development of smectic crystals even after the spinning process, because the glass transition temperature of PP is below room temperature. Further increase of the take-up velocity leads to a significant development of molecular orientation. The molecular orientation enhances the crystallization, and because of the increase in the crystallization temperature, the crystal structure changes from isotropic smectic crystals to highly oriented monoclinic crystals (Cao *et al.* 1989).

The full series of structural changes described above can be observed when the molecular weight is low, and the extrusion temperature and throughput rate are high. Under these conditions, the mechanism of orientation-induced crystallization becomes dominant only at high take-up velocities. If molecular weight is high, the extrusion temperature and throughput rate are low; then the crystalline form simply remains monoclinic, and the crystalline

Figure 7
Bimodal orientation in PP fibers.

631

orientation changes from nearly isotropic to a highly oriented state with an increase in the take-up velocity.

Another important feature of PP fibers is the development of bimodal orientation, i.e., the coexistence of c- and a*-axis oriented monoclinic crystals. Bimodal orientation can be confirmed from WAXS patterns in which the (110) reflection splits to two peaks, one on the equator and the other near the meridian, whereas (040) reflection remains on the

equator as shown in Fig. 7. This structure resembles the so-called crosshatch structure, in which epitaxial growth of daughter lamellae occurs on the side-surface of oriented parent lamellae.

On-line measurements of the development of crystalline structure were conducted utilizing a synchrotron radiation source (Kolb *et al.* 2000). The experimental results suggested that the development of c- and a*-axis-oriented crystals proceeds almost simultaneously. The amount of a*-axis-oriented

crystals varies depending on spinning conditions, whereas the highly drawn and annealed fibers usually exhibit only the c-axis-oriented crystals.

Although the molecular orientation of as-spun fibers strongly depends on the tensile stress applied to the spinning line, birefringence of as-spun fibers is significantly larger than that predicted from the applied stress and stress-optical coefficient of the polymer melt (Shimizu *et al.* 1985). The nonvalidity of the stress-optical rule suggests that crystallization is accompanied by a significant development of molecular orientation.

7. Concluding Remarks

Fiber structure in semicrystalline polymers has been explained, based on the degree of molecular orientation and differences in crystalline structure. Crystal modifications appearing in the fiber structure are summarized in Table 1. It is still difficult to find a general rule between the unit cell and the type of crystal modifications appearing in the fiber processing. It appears, however, that the crystal form with higher density is preferred in high-speed melt-spinning, especially in the extremely high-speed region. The only exception in Table 1 is PA66. It should be noted here that the unit cells with longer fiber repeat distances are not necessarily preferred, although the crystallization is strongly accelerated by high tensile stress.

There are more complicated and hierarchical aspects in fiber structure. Important features that could not be included in the previous explanations are the concepts of entanglement and network structure.

Long and Ward (1991) found that the true-stress vs. true-strain curves of PET fibers prepared under a wide range of processing conditions can be superposed by simply shifting the curves along the true-strain axis, as shown in Fig. 8. The entanglement density estimated from the network draw ratio, which can be estimated from the amount of shift for curve matching, and thermal shrinkage stress are roughly comparable to those obtained from the plateau modulus measured through the rheological measurements of the polymer melt. These results indicate that PET fibers retain a level of high-order structure that is not affected by processing.

Fundamental studies of orientation-induced crystallization behavior suggest that the starting of crystallization is not controlled simply by the degree of molecular orientation, but that the nonlinear characteristics of elongational viscosity and the state of molecular entanglement also play an important role (Okamoto *et al.* 1998). In this context, the "shish" in the "shish-kebab" structure corresponds to the tightened molecules between two adjacent entanglements, that is, the starting point of the crystallization. Therefore, the role of entanglement should be considered
Figure 8

Superposed curve corresponds to the network draw ratio of unity. λ_{std}, network draw ratio of standard fibers; λ_{shift}, draw ratio corresponding to axial shift along the true strain axis needed for curve matching.

more extensively for the better understanding of the mechanism of fiber structure development. Several types of mechanical measurements have been proposed for the analysis of entangled structures. However, at present there are no structural measurement techniques applicable for the direct analysis of the state of entanglement.

Polymer Matrix Composites with Roughly Equiaxed Reinforcements: Microstructure and Mechanical Behavior

Mineral particulate fillers are finely divided solids (with an aspect ratio of about unity) which are added to a polymer matrix in relatively large amounts to modify its properties and/or to reduce the cost of the resulting compound. Generally, a filler material is stiffer than the matrix and depending on its nature, shape, and treatment, it is reinforcing or not. In the latter case one speaks of extenders. Fillers or extenders are primarily used with three goals in mind, namely to improve dimensional stability (heat distortion temperature, shrinkage, thermal expansion), mechanical properties (sample stiffness, compressive strength, and—if possible—toughness), and/or the optical or electrical properties of the composite material. The most frequently used isomorphic fillers are calcium carbonate, silicates, and glass spheres. For comparison, occasionally data will be cited concerning kaolin, talc, or hydrous alumina, which have a flake-like shape.

The addition of particulate fillers influences all stages of the fabrication, and the structure and performance of the resulting composites. Since, as mentioned above, fillers and extenders are generally stiffer than the polymer to which they are added, the focus here is on the effects of a stiff second phase on the matrix structure and on deformation, creep, and failure mechanisms of the composite. Thus, elastomeric modifiers, polymer blends, and filled elastomers are not considered; these are discussed elsewhere. Only a brief reference will be made to stress analysis of heterogeneous composites and to the various approaches to estimate their elastic properties, since these are treated elsewhere (*Composites, Physical Properties of* *).

A concise description of particulate mineral fillers is given in many publications (e.g., Katz and Milewski 1978, Schlumpf 1993, Rothon 1995, *Mineral Fillers in Thermoplastics* 1999, Eurofillers 1999, Pukanszky 1995). The main filler characteristics to be considered when used in a polymer matrix are the following:

• chemical composition (mineralogical origin and purity, possible catalytic actions);
• shape, often characterized by the aspect ratio (spherical, irregular, fibrous, plate-like);
• mean particle diameter, size distribution, largest particles (top cutoff diameter);
• hardness, density; and
• particle surface properties (surface energy, specific surface area, surface treatment through adhesion promoters or release agents, type of bonding that can be engaged with the matrix, affinity to humidity or stabilizing agents, and also matrix nucleation efficiency).

When optimizing the above parameters attention must be paid to synergistic effects, and also to

indirect and frequently nonlinear effects on polymer structure and mobility. The main effects resulting from the addition of (particulate) fillers comprise:

- an influence on processing (compounding, melt or resin viscosity, abrasive action, sedimentation and dispersion behavior, change of reactivity and heat capacity, dimensional stability, and industrial safety problems like dust);
- structure modification (effects on morphology, density, and optical and electrical properties);
- small strain behavior (stress distribution, elastic moduli, stiffness);
- deformation and rupture (creep, interfacial de-bonding, micro shear yielding, crack pinning); and
- physical and environmental aging (humidity effects, chemical degradation).

The microstructure of a particulate-filled polymer (see Fig. 1) is characterized by two main parameters: the filler volume fraction, $\Phi = V_f/V_c$, where the subscripts f and c refer to filler and composite, respectively, and V is volume; and the average particle diameter, d, or the average interparticle distance, D (these two parameters are interrelated for a given Φ_f and filler particle distribution, and the latter parameter is also quantifiable, see *Composites, Microstructure of: Quantitative Description**). A microstructural feature more difficult to quantify is the possible alteration of the intrinsic matrix microstructure that may result from the presence of filler particles. One example of such an alteration is the formation of an interlayer of matrix material having a higher density or a specific morphology through epitaxial growth on the filler surface.
Figure 1
Typical microstructure of a polymer composite filled with irregularly shaped particles (polished surface of an epoxy resin filled by 40 vol.% of quartz powder with an average particle size of 50 μm, loaded in tensile creep at 105 °C).

Both the nature of the filler and the microstructural parameters exert a significant influence on the mechanical properties of the resulting polymer matrix composite, ranging from small strain elastic properties (see *Composites, Physical Properties of** and Rothon 1995, 'Mineral Fillers' 1999, Eurofillers 1999, Pukanszky 1995, Nielsen and Landel 1994) to the ultimate properties at large deformation.

1. Elastic and Viscoelastic Properties and Matrix Morphology

1.1 Influence of the Filler on Elastic and Viscoelastic Properties

To a first approximation, the effects of inert, non-interacting filler particles on scalar properties of a composite can be correlated with the volume fraction, Φ_f, of the filler particles (see *Composites, Physical Properties of**). Thus the density, ρ, and the heat capacity, c_p, of a composite are calculated in a straightforward manner from the rule of mixtures (attention must, however, be paid to the possible inclusion of air or humidity into the compound during mixing).

The static elastic moduli (shear, Young's, or bulk) of a polymer filled with rigid particles increase with the filler volume fraction, Φ_f. The effect of apparently inert, isomorphic particles is well represented by the modified Kerner equation (see Nielsen and Landel 1994):

$$E_c = E_1 \frac{1 + AB\Phi}{1 - B\Psi} \quad \text{with} \quad A = \frac{7 - 5v}{8 - 10v} \quad \text{and}$$

$$B = \frac{(E_f/E_m) - 1}{(E_f/E_m) + A} \tag{1}$$

where

$$\Psi = 1 - \exp\left(\frac{-\Phi_f}{1 - \Phi_f/\Phi_{max}}\right)$$

and the subscripts c, m, and f refer to the composite, the matrix, and the filler respectively, v is Poisson's ratio of the matrix, and Φ_{max} is the maximum packing fraction of the filler particles in the given situation. This modified Kerner equation has been shown to be valid for a range thermoplastic and thermosetting matrices (Nielsen and Landel 1994, Vollenberg and Heikens 1989, Stricker *et al.* 1997). However, there are also a number of alternative approaches for the calculation of composite moduli (see *Composites, Physical Properties of**).

The combined effects of time and the presence of fillers on the viscoelastic behavior are frequently considered separately. Thus, the time-dependent compliance, $D_c(t)$, of a particulate composite is to a first

approximation proportional to the matrix creep deformation, $\varepsilon_m(t)$, and the ratio of the (instantaneous) elastic moduli, E_m/E_c (Nielsen and Landel 1994):

$$\sigma_0 D_c(t) = \varepsilon_c(t) = \varepsilon_m(t)E_m/E_c \qquad (2)$$

The relaxation moduli, $G(t)$ and $E(t)$, can be represented in a similar way. In dynamic experiments, however, it is frequently found that the damping peak is broadened (or that new peaks arise) and that the phase lag of internal friction, defined by the term tan δ, increases nonlinearly with extension owing to strain concentrations at and between particles, and decohesion at particle–matrix interfaces. Thus, Stricker *et al.* (1997) have observed in sPP filled with glass beads a peak some 50 K above the glass transition temperature of 6 °C that is purely related to interfacial loss. Dewetting also occurs during creep, contributing a strain component, ε_d, which is superimposed on the viscoelastic strains, $\varepsilon_m(t)$, of the matrix material. Notwithstanding the different origins of these two contributions, the resulting creep compliances agree with the prediction of the time–temperature–stress superposition (TTSS) principle (see Sect. 3.2).

1.2 Filler Effects on Thermoplastic Matrix Microstructure

Filler particles provide a very large (specific) surface area, and their interaction with the surrounding matrix gives rise to different interfacial phenomena (cf. *Composites: Interfaces*[#]). Of particular importance in the present context are wetting and adhesion and effects on polymer organization and morphology. These effects can be amplified and, to a certain extent, controlled by adequate filler surface treatment.

Several colloidal metals and salts as well as active fillers such as talc and aluminum oxide act as nucleating agents in crystallizable polymer melts (Galeski 1995, Pukanszky *et al.* 1994). The most frequently used extender, $CaCO_3$, has relatively low nucleation efficiency (Pukanszky *et al.* 1994). The important feature of a good nucleating agent seems to be the existence of alternating rows of polar and nonpolar groups at the seed surface (Galeski 1995). The main effects resulting from the presence and homogeneous distribution of a large number of crystallization nuclei are a higher crystallization temperature and a much finer spherulitic structure. The overall crystallinity, x_c, is influenced in different ways. Glass beads in sPP (Stricker *et al.* 1997) lead to a decrease of x_c since the total interspherulitic or impingement area (which has a lower degree of crystallinity) is increased. $CaCO_3$ in PP (Pukanszky *et al.* 1994) has very little influence on x_c and talc-filled composites show a diverging behavior (Stricker *et al.* 1997, Pukanszky *et al.* 1994). Evidently for any given filler, nucleation effects should be proportional to the total

interface area. However, there seems to be a lower limit to particle size. Very small particles in a coarse spherulitic material are observed to congregate in the interspherulitic regions giving rise to brittle interspherulitic fracture (Friedrich 1978).

The morphology of the matrix material in contact with a structured surface may be influenced by epitaxial or transcrystalline growth. Heteroepitaxial growth is well known to occur at polymer–polymer interfaces (e.g., PE–iPP (Petermann 1995, Yan *et al.* 1998)). Here the criterion for secondary nucleation to occur is that the substrate crystal dimension in the matching direction must be greater than the crystal thickness of the depositing polymer. Once this requirement is satisfied, subsequent epitaxial growth is based on the lamellar growth habit of the depositing polymer itself (Petermann 1995, Yan *et al.* 1998). Epitaxial phenomena have also been found in a number of mineral-filled semicrystalline thermoplastics (HDPE, PP, and PA filled with $CaCO_3$ or SiO_2 particles, see Sect. 5.1 and Galeski 1995, Michler 1992, Bartczak *et al.* 1999, Walter *et al.* 1997). Filler surface modification is also used for the selective formation of a given crystal phase structure in replacement of another. Thus the β-crystallization of polypropylene is favored by the presence of surface-treated calcium carbonate (a mixture of equal amounts of pimelic acid and calcium stearate acts as a β-nucleator for PP) (Tjong *et al.* 1997, Labour 1999). Whereas the above elements of sample morphology generally have a modest effect on the small strain properties, they influence more strongly the deformation mechanisms and thus the yield behavior and toughness of the filled polymer (see Sects. 4.2 and 5).

The presence of an interface in amorphous as well as in semicrystalline polymers frequently causes local modifications which are more difficult to detect than nucleation or epitaxial growth. These interfacial effects concern the reduced segment mobility, improved local packing, and modified forces of attachment. Thus the strong effect of filler size and composition on Young's modulus of polystyrene composites is ascribed to segmental orientation and improved packing in the neighborhood of the filler surfaces (Vollenberg and Heikens 1989). An increase of density of an interfacial matrix region (by some 10%) has an exponential effect on the stiffness of that region— and thus of the composite. The interlayer (or interphase) concept is essentially based on a micromechanical analysis of filler effects (Michler 1992, Bartczak *et al.* 1999, Walter *et al.* 1997, Tjong *et al.* 1997, Labour 1999, Jancar *et al.* 1992, Pukanszky 1993, Vörös *et al.* 1997). Typically interphase thicknesses of 0.1 µm (PP) to 0.5 µm (PVC) have been assigned (Vörös *et al.* 1997). Large specific surface areas help to increase the elastic moduli and reduce creep rates. High free energy surfaces (metals, mineral fillers) induce crystallinity and provide stronger physical

bonds. However, for the same reason these may give rise to unwanted adsorption (of water or additives such as stabilizers or cross-linking agents). Depending on their chemical composition, fillers may catalyze secondary or degradative reactions that influence the molecular structure and stability of the surrounding matrix (Katz and Milewski 1978, Eurofillers 1999, Joppien 1978). However, finely ground $CaCO_3$ may also adsorb and deactivate remnants of catalysts. Therefore, much effort has been concentrated on filler surface modification by impregnation, grafting, or addition of a (elastomeric) compound susceptible to form an interphase around the particles (Katz and Milewski 1978, Schlumpf 1993, Rothon 1995, 'Mineral Fillers' 1999, Eurofillers 1999, Pukanszky 1995, Nielsen and Landel 1994, Schlumpf 1994, Michler 1992, Jancar *et al.* 1992, Pukanszky 1993, Vörös *et al.* 1997). These techniques result in better control of filler–matrix adhesion and interfacial activity and an improvement in processing conditions (particle dispersion, rheology) and final performance.

2. Creep and Damage Mechanisms

2.1 Basic Filler-related Deformation and Damage Mechanisms

Small strain deformation of a filled composite is essentially borne by the matrix. With increasing strain, the strongly heterogeneous deformation will give rise to local damage at the site of the largest stress concentration. The basic damage mechanisms observed are particle–matrix debonding (often termed "dewetting" even though the matrix is a solid), void formation and coalescence (see Fig. 2(a)), and plastic deformation of the matrix material (Fig. 2(b)). The essential intrinsic parameters governing these mechanisms and the stress level at which they occur are particle size and distribution, interfacial adhesion, and matrix deformability. Small, well-dispersed and weakly adhering particles initiate a large number of small and stable voids, which permit further deformation of the matrix ligaments between particles (Fig. 2(b)). Voids created from large particles in a brittle matrix may give rise to a critical crack and to instantaneous brittle fracture (Fig. 2(c)). This is one of the (evident) reasons why the top cutoff value of the particle size distribution should be well controlled. Similar problems are created by aggregates and by matrix-free interfacial regions at high degrees of filling (Fig. 2(d)).

Interfacial void formation in composites with well-bonded fillers requires larger strains. The stability of the strained composite then depends on particle size and ligament properties. Again, large particles are susceptible to act as defects giving rise to brittle fracture—although at a much higher stress than the non-adhering particles. Small, well-bonded particles may delay void formation to such a stress level that the
Figure 2
Schematic representation of void formation from filler particles of different sizes: (a) particle–matrix debonding, matrix void formation, and coalescence; (b) fibrillar deformation of interparticular ligaments; (c) critical voids form around large particles or (d) agglomerates (Michler 1992).

first debonding event gives rise to brittle fracture. Thus the formation of voids that are well distributed in space and time contributes to toughness (see Sect. 5). The above general remarks are valid for both thermoplastics and thermosets; characteristic differences only become apparent when discussing fracture phenomena.

2.2 Creep Behavior

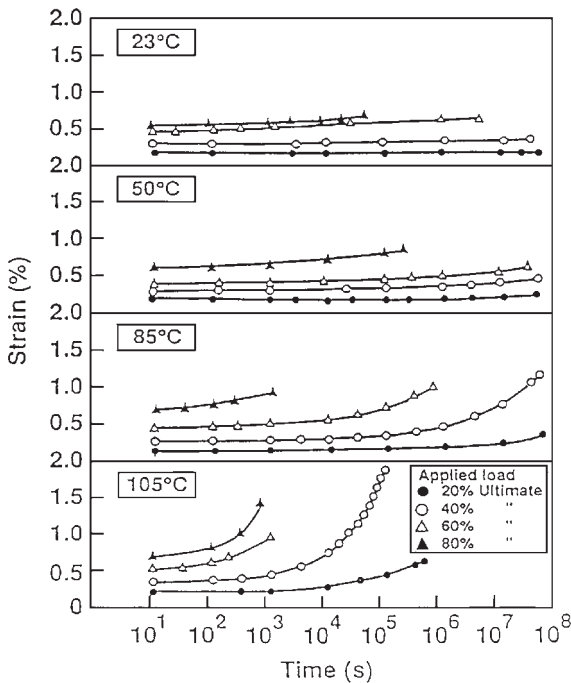
At short times and small loads, creep is dominated by the viscoelastic strain, $\varepsilon_m(t)$, of the matrix material (Eqn. (2)). This means that at identical stresses the creep rate of the composite is smaller than that of the pure matrix by a factor of E_m/E_c. The response of the composite is linear up to a critical threshold strain, ε_{th}, which will vary with the system and the external parameters σ and T (Smith 1989, Kaiser *et al.* 1989, Gregory *et al.* 1999, Vogel *et al.* 1994). (Vogel *et al.* (1994) used a cyclic loading method to determine the incurred damage from the loss of stiffness. For a glass mat-reinforced vinyl ester resin no damage was observed below a threshold strain, ε_{th}, which at room temperature amounted to 0.48%. For the same material, damage has also been assessed by plotting isochronal creep strains (Gregory *et al.* 1999); the deviation from linearity starts at the same value of 0.48%.) The threshold strain generally marks the onset of interfacial debonding, which contributes a strain component ε_d. The interfacial debonding strain, ε_d, is superimposed on the viscoelastic creep deformation increasing the nonlinearity of the response. As an example the creep behavior of a quartz flour-filled epoxy resin (CY 225 from


Figure 3
Tensile creep response of a (42 vol.%) quartz flour-filled epoxy resin (temperature range 23–105 °C and for stresses between 20% and 80% of the respective short-time strengths) (Smith 1989, Kaiser *et al.* 1994).

Ciba-Geigy, a difunctional hydantoin-based epoxy resin cured with anhydride hardener Hy 925 filled with varying degrees of quartz flour (W10 from Quarz-werke Frechen, Germany)) is considered (Fig. 3).

Notwithstanding the different origins of the two contributions to creep, such creep curves can still often be reduced by TTSS to a single creep compliance master curve (Smith 1989, Kaiser *et al.* 1989). (A successful reduction of creep data has also been achieved for a vinyl ester resin charged with glass fiber mat (Gregory *et al.* 1999).)

3. Effects of Filler on "Strength"

The term "strength" designates the engineering stress at failure. Depending on the nature of the matrix material and the filler parameters (degree of filling, particle size, bonding), failure occurs in a brittle or in a ductile manner. Consequently, one has to distinguish between brittle strength, σ_{cb}, the strength, σ_y, at the yield point (in tension or compression), and the ultimate strength, σ_{ub}, after appreciable plastic deformation and/or stable crack growth. The latter phenomena and filler effects on toughness are discussed in Sect. 5.
Figure 4
Tensile strengths of differently filled epoxy resins: $\times$, 50 μm silica particles (Moloney *et al.* 1987); and 62 μm glass beads: $\blacklozenge$, treated with A 187; $\blacksquare$, treated with release agent; $\square$, untreated (Spanoudakis and Young 1984).

3.1 Brittle Fracture

In tension, most particulate-filled cross-linked resins and rigid thermoplastics break in a brittle manner before reaching the yield point. Brittle fracture is generally triggered by the appearance and/or activation of a critical defect. Several criteria have been proposed to estimate the brittle strength of such composites.

(*a*) *Critical matrix strain,* ε_{mb}, *in the stress direction.* Provided there is good adhesion between a rigid matrix and filler particles, it can be assumed (Katz and Milewski 1987, Pukanszky 1995, Michler 1992, Jancar *et al.* 1992) that the composite breaks when the average matrix ligament in the stress direction attains its ultimate failure strain, ε_{mb}. The overall composite strain, ε_{cb}, at this moment is

$$\varepsilon_{cb} = \varepsilon_{mb} \left(1 - \sqrt[3]{\frac{3}{\pi}} \, \Phi_f^{1/3} \right) \qquad (3)$$

The composite breaking stress, σ_{cb}, then equals $\varepsilon \cdot E_c$. In most—but not all—composites σ_{cb} decreases with increasing filler contents and average particle size (Fig. 4) (Schlumpf 1994, Spanoudakis and Young 1984, Moloney *et al.* 1987, Cantwell *et al.* 1988, Nakamura and Yamaguchi 1993, Karger Kocsis 1995, Kinloch and Young 1983). The above approach suffers from the fact that the ligaments which break first are not average ligaments, that ligament fracture is in competition with interfacial debonding and microshear banding (see below), and that the composite can most probably tolerate several

interfacial debonding events. Much more than Young's modulus, composite strength is sensitive to the quality of adhesive bonding, to particle size and distribution, to the presence of defects (inherent flaws), and to matrix properties (see below).

(*b*) *Inherent flaws.* Using a linear elastic fracture mechanics approach, brittle fracture of any material containing a defect of size *a* can be related to the toughness, K_{Ic}, of the material through

$$\sigma_{cb} = \frac{K_{Ic}}{Y\sqrt{a^{1/2}}} \qquad (4)$$

The limited strength of a homogeneous material is then explained through the existence of inherent flaws, of which the size, *a*, has been related to that of pre-existing heterogeneities or defects such as the particle diameter, poorly bonded or weak particles, or flaws generated during sample preparation. Unfortunately, the resulting values of *a* turn out to be systematically too large; for example, for epoxy resins filled with particles between $5\,\mu m$ and $50\,\mu m$, the values of *a* range between $36\,\mu m$ and $522\,\mu m$ (Moloney *et al.* 1987, Kinloch and Young 1983).

Closer approximations of elastic properties and strength can be obtained in several ways, by statistical mechanical analysis (Nairn 1999), finite element analysis, and numerical calculations (Pukanszky 1995, Jancar *et al.* 1992, van Mier *et al.* 1993) (see also *Composites, Physical Properties of*[*]). Such approaches also consider internal stresses resulting from the thermal mismatch of fillers and matrices. In any event, failure prediction requires knowledge of the relevant failure mechanisms and of adequate failure criteria.

3.2   Yield Stress and Ductile Failure

There exist several models to predict the yield stress of particulate composites (Pukanszky 1995, Nielsen and Landel 1994, Stricker *et al.* 1997, Pukanszky *et al.* 1994, Jancar *et al.* 1992, Pukanszky 1993, Vörös *et al.* 1997, Joppien 1978, Nicolais and Narkis 1971, Liang and Ly 2000). Of these, the modified approach originally proposed by Nicolais and Narkis, the composition-dependent model of Pukanszky 1993 and Vörös *et al.*, and the finite element calculations of Jancar *et al.* will be discussed here.

Any homogeneous or filled (polymer) specimen yields if and when local shear deformation initiates and extends sufficiently far before crazing and/or fracture dominate the deformation behavior. In the simplest model it is considered that the stresses are transmitted by the matrix and by inclusions in proportion to their effective cross-sections. In tension, the composite yields (at a stress σ_{yt}l) when the average matrix stress reaches the matrix yield stress σ_{ym}.

Stress concentration (caused by unbonded inclusions or aggregates) are taken into account through a factor $S<1$ and the quality of bonding and possible effects on the surrounding matrix material by the stress component σ^* transmitted through the particles (Pukanszky 1995, Stricker *et al.* 1997, Jancar *et al.* 1992, Vörös *et al.* 1997, Nicolais and Narkis 1971, Liang and Ly 2000):

$$\sigma_{yt} = \sigma_{ym}(1 - 1.21\Phi_f^{2/3})S + \sigma^*1.21\Phi_f^{2/3} \qquad (5)$$

For unbonded particles, σ^* is zero. The remaining term can be considered as a lower bound of σ_{yt} (Nicolais and Narkis 1971). Syndiotactic polypropylene (sPP) of low stereoregularity filled with $5\,\mu m$ glass beads (Stricker *et al.* 1997) and LDPE and PVC filled with $3.6\,\mu m$ $CaCO_3$ filler particles (Vörös *et al.* 1997) comply quite well to the upper bound of the above equation (Pukanszky 1995, Stricker *et al.* 1997, Vörös *et al.* 1997).

Considering the composition dependence of tensile yield stress including crystallinity, crystal size, possible filler anisotropy, and the quality of adhesion, Pukanszky *et al.* (1994) arrived at the following relationship:

$$\sigma_{yt} = \sigma_{ym} \frac{1 - \Phi_f}{1 + 2.5\Phi_f} \exp(B\Phi_f) \qquad (6)$$

where *B* is an empirical parameter characterizing the degree of particle–matrix interaction (it increases with the specific surface area and the adhesive strength of the interphase).

As stated above, macroscopic yielding requires that the local yield zones grow, overlap (between neighboring particles), and finally extend into a larger volume. Sjoerdsma (1989) and Jancar *et al.* (1992) used finite element simulation to analyze the stress distribution within a regular array of particles. From the octahedral shear yield criterion they then determined the shape of the yielded zone around each particle as a function of external stress. Knowing the interparticle distance they obtained the overlap distance, *c*, and the overlap *area*, *F(c)*, within each cell. From their analysis they derived the following equation for a yielding composite:

$$\sigma_{yt} = \sigma_{ym}^*[1 + 0.33F(c)\Phi_f^2] \qquad (7)$$

where σ_{ym}^* is the yield strength of the matrix material containing a few isolated filler particles. There are three restrictions to the validity of Eqn. (7): the quality of adhesion between matrix and fillers, the competition with crazing and brittle fracture (especially at moderate and high filling fractions), and the existence of an upper limit of yield stress if σ_{yt} approaches $1.33\sigma_{ym}^*$ (Jancar *et al.* 1992). Data from experiments at $80\,°C$ with maleated PP filled with $CaCO_3$ (Jancar *et al.* 1992) comply well with Eqn. (7).

3.3 Ultimate Strength

The effect of fillers on the ultimate properties of a thermoplastic composite is situated between two extremes. Nonadhering particles in a ductile matrix have little influence on *ultimate* tensile fracture behavior. Thus plasticized PVC shows no change in ε_{cb} (about 365%) and tensile strength σ_{cb} (19.5 MPa) up to 35% by weight of $CaCO_3$ (Nielsen and Landel 1994). Strong improvements in strength (especially of PE and PP) owing to strain hardening of the matrix material can be obtained with suitably chosen particulate charges. Introducing a strain hardening parameter, λ^n, into Eqn. (7), Pukanszky (1990) obtained in such cases the following empirical equation for tensile strength:

$$\sigma_{ub} = \lambda^n \sigma_{ym} \frac{1 - \Phi_f}{1 + 2.5\Phi_f} \exp(B\Phi_f) \qquad (8)$$

3.4 Compressive Strength

Failure in compression occurs generally in shear. For modest filling fractions and a ductile polymer matrix one can expect the compressive strength to increase with the filling fraction and to be superior to the yield strength, σ_{yt}, in tension. This is owing to two effects: the increase in matrix shear strength owing to hydrostatic compressive stresses and the increase in shear viscosity owing to the presence of filler particles. The difference between tension and compression is even larger with brittle matrices, which in tension are sensitive to crazing and/or to brittle fracture owing to internal flaws or interfacial debonding effects. Thus for 40% glass beads in PA 66, strength values in tension of 98 MPa and in compression of 252 MPa have been reported (Nielsen and Landel 1994) (the compressive strength of the pure matrix is 29 MPa). The corresponding data for a 40% silica-filled epoxy resin are 64 MPa in tension, 154 MPa in compression, and 98 MPa for the pure resin (Moloney *et al*. 1987).

4. Filler Effects on Crack Propagation and Toughness

The term toughness of a composite is understood to mean its resistance to crack extension. Toughness is traditionally expressed by either of the fracture mechanics quantities K_{Ic} or G_{Ic}. It should be noted, however, that G_{Ic} is much more sensitive to particle–matrix adhesion than K_{Ic}. It is necessary, therefore, to discuss the mechanisms leading to crack extension. In view of their differences it is appropriate to discuss crack extension in thermoplastics and in cross-linked resins separately.

4.1 Filled Thermoplastics

The main deformation mechanisms of an unfilled semicrystalline thermoplastic subjected to dilatational strains are elastic dilatation—and eventually cavitation—of the amorphous regions and concomitantly straining of the crystal lamellas. The material will be tough if, at this stage, crystal plastic deformation (fine shear, block shear, decrystallization) and subsequent formation of fibrillar structures dominate with respect to localized crazing and/or brittle fracture (Michler 1992, Kinloch and Young 1983, Kim and Michler 1998a, 1998b, Kausch *et al*. 1999). The essential point in filling a semicrystalline thermoplastic to improve toughness is to favor microplastic deformation at a high stress level. This requires, first, good adhesion of the matrix to the filler particles so as to attain high stress levels and avoid premature crack extension through void coalescence (see Fig. 2(b)). Good adhesion can be obtained from adhesion promoters, surface treatment, or by increasing the amorphous component of the polymer—which often adheres more easily to mineral substrates (Katz and Milewski 1978, Schlumpf 1993, 1994, Rothon 1995, 'Mineral Fillers' 1999, Eurofillers 1999, Pukanszky 1993, 1995, Stricker *et al*. 1997). Secondly, particle size and volume fraction should be controlled to favor ductile deformation of interparticle ligaments.

Generally, the toughest material is obtained with incompletely monodispersed medium-sized particles (but the definition of medium sized has to be discussed). At low rates of deformation where local yielding takes place, K_{Ic} or G_{Ic} usually increase up to filling fractions of 15% (Pukanszky 1995, Jancar *et al*. 1992, Fekete *et al*. 1999).

In impact loading, however, toughness tends to decrease strongly with increasing Young's modulus (as shown by α- and β-PP (Stricker *et al*. 1997, Labour 1999)). A number of HDPE compounds give a more surprising response. Studies (Bartczak *et al*. 1999) have shown that both toughness and Young's modulus of a calcium carbonate-filled HDPE can be increased *simultaneously*. A similar enhancement of toughness by small, well-bonded particles has been found (Walter *et al*. 1997). These observations have been explained by the particle-induced formation of an interphase favoring extensive matrix plastic deformation (Michler 1992, Bartczak *et al*. 1999, Walter *et al*. 1997, Kim and Michler 1998a, 1998b).

4.2 Filled Thermosets

The network structure of cross-linked polymers is characterized by the higher density of cross-linking points (as compared to the density of entanglement points in thermoplastics) and the consequent reduced deformability of the chain segments. As indicated in Sect. 3.1, in a strained filled thermoset essentially two

local deformation mechanisms are observed: particle–matrix debonding and microshear banding.

Basic fracture mechanisms can be well observed in creep at constant load. Fracture starts from a pre-existing defect (frequently at the surface and not always visible). The defect grows (often rather slowly) forming a subcritical crack. The tip of this crack constitutes a process zone, which—as in a pure resin (Moloney *et al.* 1987, Kinloch and Young 1983, Cantwell and Roulin-Moloney 1989)—is subject to stress concentration and local plastic deformation leading to crack tip blunting. In addition it can be concluded from fractographic and microscopic analyses (Smith 1989, Cantwell *et al.* 1988) that debonding occurs ahead of the crack tip. During this phase of growth the crack extends from one debond to the other more or less within a plane. The resulting fracture surface of such a debonded zone is rather smooth. This phase of crack growth is thermally activated, strongly time dependent, and generally consumes most of the time to fracture of the specimen. In a constant load experiment, the stress intensity factor, K_c, and energy release rate, G_c, will grow with crack length, a. At a certain critical crack length a_{II}, G_c becomes larger than the material resistance and the excess released energy is used to drive the crack even faster: the crack therefore accelerates (Cantwell *et al.* 1988). This acceleration marks the transition from the second to the third phase of crack growth. The associated crack length, a_{II}, can be used to calculate K_{Ic} from Eqn. (4). In fact, there is a rather good correlation between the stress intensity factor, $K_c(a)$, and the rate of crack propagation, da/dt, which can be used to evaluate the expected lifetime of a loaded sample by integration over da up to a_{II} (Beer *et al.* 1986).

The above conclusions are confirmed by an analysis of the stress-induced damage in the bulk material. Depending on the volume damage ahead of the crack, on the toughness of the matrix, and on temperature, there are three modes of crack extension, which are illustrated in Fig. 5. For the same quartz flour-filled epoxy resin discussed in Sect. 2.2, it has been concluded (Smith 1989, Smith *et al.* 1988) that at low temperatures, high stresses, and short times to fracture a single debonding event can initiate rapid brittle fracture (Fig. 5(a)). The main sample volume then remains essentially undamaged. At intermediate temperatures a limited number of debonding events occur before the onset of crack propagation (in this case there is limited volume damage). The crack then jumps from one debond to another, more or less within a plane and a smooth subcritical crack zone is formed (Fig. 5(b)). The third fracture mode occurs at high temperatures and/or when the matrix is less brittle. In this case extensive volume damage is done before the crack propagates and its extension by void coalescence involves further ductile matrix
Figure 5
Schematic representation of crack propagation mechanisms in a highly filled epoxy resin. See text for details (after Smith 1989).

deformation (microshear banding). This mechanism leads to a rather rough zone of subcritical crack growth (Fig. 5(c)). The energy consumption and thus the toughness of the material *decrease* from Fig. 5(a) to Fig. 5(c) (Smith 1989, Smith *et al.* 1988).

In compressive loading (of the same quartz flour-filled epoxy resin) matrix shear, particle–matrix debonding, particle fracture, and matrix microcracking by linking up of debonded zones are observed in this order. The latter three mechanisms are irreversible, and create the volume damage that is first observed close to the yield point.

The presence of well-bonded particles influences the toughness, K_{Ic}, positively (by crack pinning and bowing, void formation, and crack bridging). For many systems K_{Ic} and E are seen to increase linearly with Φ_f up to moderate filling fractions (Spanoudakis and Young 1984, Moloney *et al.* 1987). The linear relationship between K_{Ic} and E points to a crack opening displacement (COD) criterion for crack propagation (Spanoudakis and Young 1984). In comparing different filler materials one observes that K_{Ic}
Figure 6
Modeling of the reinforcing effect of well-bonded particulate charges on subcritical crack propagation in filled thermosets through (a) crack pinning (Lange 1970, Evans 1972) and (b) crack deviation (Spanoudakis and Young 1984).

depends on the specific surface area of the fillers and very little on interfacial adhesion (Spanoudakis and Young 1984, Moloney *et al*. 1987, Nakamura and Yamaguchi 1993). In the case of rather weak filler materials (such as dolomite) toughening will be limited by transverse particle fracture. The energy release rate, G_{Ic}, of a filled resin generally is also larger than that of the pure resin; however, the relationship between G_{Ic} and Φ_f depends on filler size and interfacial adhesion. A strong interfacial bond is seen to be not always beneficial for a large G_{Ic}.

The notable increase in toughness of particulate-reinforced resins has been associated with the crack pinning mechanism (Spanoudakis and Young 1984, Moloney *et al*. 1987, Cantwell *et al*. 1988, Cantwell and Roulin-Moloney 1989, Lange 1970, Evans 1972). Well-bonded, rigid particles act as an obstacle and force the crack to bow (or to deviate) as it passes between neighboring filler particles (Fig. 6).

Evans (1972) has extended the line tension concept used in dislocation theory as suggested by Lange (1970). He has related the increase in toughness to the ratio of particle size, *r*, to spacing, *c*. Silica and

alumina composites correspond quite well to the approximation thus obtained for rectangular particles (Moloney *et al*. 1987, Cantwell and Roulin-Moloney 1989, Evans 1972).

5. Conclusion

The formation of composites by blending filler particles of low aspect ratio with thermoplastic and thermosetting polymers leads to several beneficial effects. Young's modulus is considerably increased through active fillers of large specific surface area and through their influence on the structure of the surrounding matrix material (crystallinity, density). Time-dependent moduli can be derived from static ones by the separation of variables. The creep resistance is significantly increased, and the time–temperature–stress reduction principle has been applied successfully. To produce composites with adequate strength, fillers must show good bonding, but even then strength generally decreases with filler content. Toughness is less sensitive to the quality of adhesion, such that particle–matrix debonding (causing void formation) can be tolerated provided the formation of voids is well distributed in space and time. Apart for cost reduction, fillers are advantageously used if high strength, dimensional stability, and/or special thermal, optical, and electrical performances are required. Automotive and tribological components, lightweight garden furniture, opalescent packaging films, and high-voltage circuit breakers are some examples.

Polymer Matrix Composites, Recycling of

The debate on sustainable development and on the use of nonrenewable resources has wide-ranging implications for polymer-based materials. The polymer industry is often targeted for its perceived role in the "throw-away society," in part because of the high visibility of polymers in municipal solid waste. As a consequence, the environmental performance of polymers has become an important aspect of product development.

Recycling of polymer composites is a particular challenge since these are materials that have been developed to provide highly tailored specific properties (see *Composite Materials: Overview*[#] and *Polymer Matrix Composites: Matrices and Processing*[*]). Recycling is one of several options for their reuse. To determine the most efficient revaluation strategy, the environmental impact of the material over its whole life cycle should be evaluated, taking into account all the stages of its production and use.

Figure 1 shows the evolution of the durability of a composite over its life cycle. Several key points determine the durability of polymer composites (see *Composite Materials: Environmental Effects*[*]). First, their organic matrices tend to degrade under thermomechanical loading, and this effect is aggravated in the presence of oxidative agents, solvents, and radiation. They are also macromolecular assemblies that display time- and temperature-dependent properties. Finally, they are seldom in thermodynamic equilibrium, which results in aging phenomena and microstructural evolution during service life.

Over the life cycle of a composite degradation occurs at both high temperatures, during processing, and at low temperatures, during service. The cumulative influence of both regimes can be significant in closed-loop recycling.

The two dominant causes of degradation in polymer composites during processing are thermomechanical degradation of the matrix and fiber attrition. All commercial polymer matrices contain antioxidant additives, to protect against thermally activated oxidative degradation, which results in a decrease of molecular weight and/or cross-linking. Viscous or adiabatic heating of the polymer melt, due to the combination of intense shear rates and low thermal conductivity, further contribute to such degradation phenomena. In natural fiber composites, chemical degradation during processing can involve thermal degradation and solvolysis reactions such as hydrolysis, as reviewed by Bledzki *et al.* (1998) for thermoplastics reinforced with wood fillers.

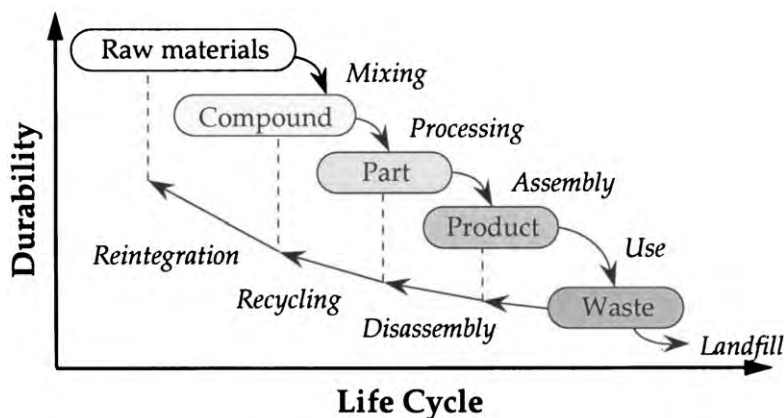
In processes that submit the matrix to strong shear or elongational deformation, mechanical degradation of the matrix may occur in the form of unfolding and scission of the polymer chains. Also, in thermoplastic extrusion compounding and molding techniques,


Figure 1
Polymer life cycle (Månson 1994).

fiber attrition is induced by the shear flow of the highly viscous polymer.

Thermo-oxidation is also a key feature of service-induced degradation of polymer composites. Tsotsis (1995) and Tsotsis and Lee (1998) reported comprehensive analyses of the thermo-oxidative degradation of carbon fiber-reinforced epoxy composites, which demonstrate the respective importance of matrix and interface degradation, matrix toughness, ply interaction, and edge effects. Furthermore, environmental aging combines the action of oxygen in the air, light, moisture, and temperature, and, possibly, mechanical loads. The action of oxygen appears to be the dominant factor in the evolution of the mechanical response of both reinforced-reinforced thermosetting and thermoplastic composites during long-term environmental exposure (Parvatareddy *et al.* 1995). Tant *et al.* (1995) reviewed the high-temperature properties and applications of polymers and polymer composites.

1. Recycling Technologies

The automotive and the electrical and electronics industries are the main sources of polymer composite waste streams, and the waste composites have interesting economic value for recycling. Although in Fig. 2 the principal recycling routes developed for plastics are shown, the techniques so far practicable for polymer composites are limited to the recovery of materials by chemical processes, the incorporation of regrind during compounding, and energy recovery through incineration.

1.1 Chemical Routes to Recycling

Chemical recycling is applied to the polymer matrix, and can be divided into four categories: solvolysis, oxidative processes, pyrolysis and similar thermal decomposition processes, and reductive processes. Solvolysis is a generic term for reactions with a solvent, and includes glycolysis, methanolysis, alcoholysis, ammonolysis, and hydrolysis. It is used mainly to depolymerize condensation-type polymers such as PET, PA, PMMA, and PC, and certain addition polymers such as polyurethanes, back into oligomers and original monomers, which can then be repolymerized into virgin materials. Addition polymers including polyolefins can be treated according to the three other processes. The potential and unique benefits of chemical recycling, and promising research directions, have been outlined by Tesoro and Wu (1995).

1.2 Mechanical Recycling

The mechanical recycling of polymer composites is evolving rapidly, driven by increasing legislation on waste treatment.

As a consequence of the reprocessing operation, process-induced fiber attrition and possible matrix degradation, as well as subsequent service-induced degradation and matrix aging after repeated process cycles, an inevitable reduction in material quality will occur. A thorough analysis of these effects is necessary to determine the durability and reliability of the recycled material.

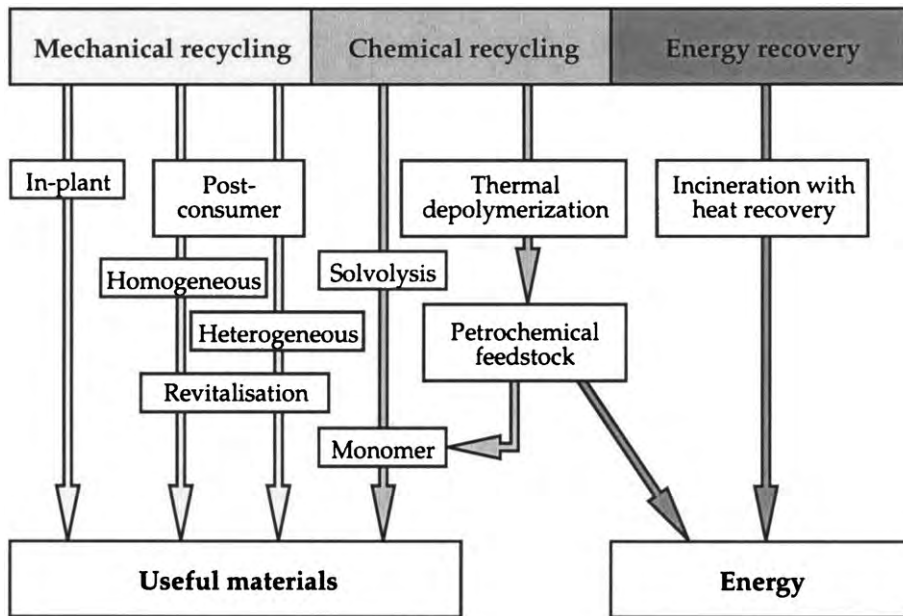
Recycling of glass fiber-reinforced polyamide developed for under-the-bonnet automotive applications has particularly motivated research efforts. Dzeskiewicz *et al.* (1993) examined the recycling potential of glass reinforced-reinforced polyamides, and measured a systematic drop in mechanical properties (tensile strength, elongation, and impact) after multiple regrinding and injection molding operations. Eriksson *et al.* (1996a, 1996b, 1998) studied the


Figure 2
Recycling routes for polymer composites (after Lundquist *et al.* 2000).

recycling and durability of short glass fiber-reinforced polyamide 66. It was found that fiber length distribution, rather than matrix or interfacial thermal degradation, controls the short-term performance of the recycled composite. Fiber attrition is significant during initial compounding and first injection molding, but is less severe during further regrinding and remolding. The deterioration rate of recycled composites containing up to 25 wt.% regrind is similar to that of virgin samples during thermal aging but slightly faster during coolant aging. Critical sizes and concentrations of impurities are defined, below which a safe mechanical behavior is achieved.

Chu and Sullivan (1996) showed that recycled reinforced-reinforced polycarbonate possesses comparable or even better properties than the comparable commercial grade. Injection and extrusion compression molding yields recycled composites with good tensile properties, at the expense of impact strength, whereas the opposite is true for compression-molded samples, due to corresponding fiber orientation distributions.

As an alternative to mechanical grinding, which is systematically associated with mechanical recycling, selective dissolution of the polymer fraction has been proposed, followed by filtration under pressure to recover separately the fibers from the polymer solution (Papaspyrides and Poulakis 1997, Papaspyrides *et al.* 1995). The technique allows the removal of contaminants and degraded species such as cross-linked molecules.

To reuse thermoset resins and their composites, shredding and grinding the material into flakes or powder fractions with controlled sizes is necessary. Kelderman (1995) showed that these techniques are capable of generating a large variety of regrind fractions containing defined fiber length distributions. Whereas initially regrind was mostly used as filler, either in uncured thermoset resins or in virgin thermoplastics, its potential as a reinforcement has subsequently been favored. Major efforts have been directed to recycling sheet molding compounds (SMCs) and bulk molding compounds (BMCs), which account for about 50% of all composites used.

1.3 Incineration and Energy Recovery Routes

Incineration significantly reduces the volume of waste materials and, as such, has been promoted as an alternative to landfill, nowadays prohibitively expensive and subject to negative public opinion and legislation. Both of these waste management routes lead to a total loss of the material value, and are not free from environmental impacts. Incineration associated with energy recovery is, however, receiving increasing support as a viable recycling method.

Most of the efforts devoted to energy recovery of polymer composites have involved automotive shredder residues. Since 1990 the SMC Automotive Alliance, with 30 suppliers of the automotive industry, has promoted the combination of pyrolysis processes

with mechanical recycling as the most realistic mid-term disposal options for ASR (e.g., *Automotive Engineering* 1994). Pyrolysis for recycling SMCs as an alternative to mechanical recycling was investigated by Demarco *et al.* (1997); it was found that temperatures in the range 400–500 °C are the most suitable, and for a glass fiber-reinforced orthophthalic polyester SMC, yields of 9–16 wt.% of nonpolluting liquid fuels with a high gross calorific value can be obtained, which can then be used alone or mixed with fuel oils.

2. Conclusion

The polymer industry is under strong pressure to provide viable recycling scenarios for their materials, and as a result life cycle issues have become an integral part of product design. The recycling of polymer composites, which are inherently tailored materials, requires tailored solutions: an optimum recycling strategy must be defined for each specific material combination.

In spite of many advances, much work is still necessary. A key aspect of future success will be the comprehensive evaluation not only of technical factors but also of economic, organizational, and legislative considerations.

Polymer Matrix Composites: Applications

The successful introduction of polymer matrix composite structures in competition with well-established and optimized solutions in metal, wood, or concrete, is a complex process. To varying degrees, depending on the economical sector, for a composite to replace an existing alternative material requires dual satisfaction of economical and technological requirements. Composite materials feature significant advantages over conventional materials in several respects. For example, their stiffness and strength are high while their density is low, their internal architecture and anisotropy can be controlled towards the implementation of innovative functional and structural design concepts, and their corrosion resistance is often excellent. They are also attractive materials from the economical standpoint: their fabrication processes allow for the production of complex shapes, raw materials can be inexpensive (e.g., when using reinforcements such as glass fiber), and their use can generate significant savings during service of the components produced.

Nonetheless, materials substitution generally proves a long and complex process; with composites this process can be rendered more so. Designing with composites is often a challenging task, because designing composite products means designing the materials too, and because composite properties are often highly anisotropic. The wide array of possible constituent materials and fiber architectures, and the wide range of specific applicable manufacturing techniques, further increase the relative difficulty of materials choices with composites. Economical advantage is also difficult to establish, and depends on the viewpoint adopted, in particular on whether the sale price of the component is the sole consideration or whether, on the contrary, the entire lifecycle of the component is analyzed. Finally, with composites, manufacturing is an important issue, in which the production of defect-free material at low cost still can be challenging.

Despite these challenges, composites are now part of everyday life, and have entered nearly all major industrial sectors, including aerospace, ground

transport, packaging, the sports industry, and civil engineering. Most applications of composite materials are modern; however, some are in fact quite ancient.

1. Composites as Ancient Engineering Materials

Since prehistoric times the application of composite materials and the development of laminated structures have been related to local evolutions of craftsmanship. Wattle and daub or straw-reinforced clay became important building materials for permanent and more protective settlements. The earliest laminated composite structures, like lightweight composite bows and chariots, were glued layered structures of wood, hide, bone, sinew, and horn (Fig. 1).

The use and combination of those natural materials, polymeric and fibrous, based on chains of protein, cellulose, collagen, and keratin was a development

ear

Figure 1
Ancient composites. Far Eastern composite bows may have been in use about 5000 years ago and reached perfection about 200 BC. Their design did not change until they became obsolete as a war weapon in the nineteenth century (Mesopotamian stele). The composite bow represents the first advanced (pretensioned) laminated composite machine. The bow was fabricated from a core of laminated wood steamed into a curved shape, to which were glued (glue made of boiled out fish skins, hides, and bones) on the outer side lengths of elastic animal (goat) tendon and on the inner side strips of compressible (ox) horn. Sensitivity towards delamination was eliminated by encapsulating the laminated structure with wet tendon, which shrinks after drying.

made by prehistoric people who understood that by a proper combination of different materials they could explore their typical beneficial properties, while the poor capacities and drawbacks of the individual components often disappeared when these were combined into a composite material (Gordon 1991, Keegan 1993).

2. Modern Polymer Matrix Composites: Design Benefits and Considerations

With modern synthetic polymer matrix composites the high mechanical performance of fibers and their environmental resistance provide the basic ingredients towards the production of materials with outstanding properties for structural applications, particularly where low weight is desired. By combining such fibers with a polymeric matrix, the low mechanical properties of unreinforced polymers and the poor compressive strength of unbonded fibers essentially disappear. While in ancient times and also in military applications the implementation of composites has derived chiefly from performance improvement, generally the use of frequently expensive polymer composite materials can only be justified in designs where added value in function(s) and performance or by cheaper manufacturing leads to competitive price–performance ratios. Therefore, successful development and design of composite engineering structures must be guided by maximizing functional added value and minimizing the use of materials, energy, and cost over a lifetime.

Compared to "traditional" metal designs, modern well-designed and manufactured composite structures (as opposed to structures which duplicate ones designed for metals) offer higher mass-specific stiffness and strength, and better resistance to fatigue and environmental degradation (e.g., aircraft propeller blades, helicopter and windmill rotor blades). When crash or impact energy absorption is a leading design parameter, composite solutions can become vastly superior (e.g., Formula 1 racing cars, trainfronts, armor). When damage resistance or damage tolerance criteria are dominant concerns, even laminated polymer matrix composites become, if correctly designed and manufactured, superior to most steel and aluminum designs without weight penalties. Examples of this are provided by the wings and fuselages of modern military fighters and commercial aircraft.

Of all, however, the biggest potential benefits of polymeric composite materials are found in the possibility of improving the structural efficiency and effectivity (structural performance per unit weight and per unit cost) by almost unlimited geometrical and material "shapeability," and the possibility of integrating the required mechanical, physical, and chemical properties of the structure using proper material design. Examples of this are relatively abundant, and

include the B2 stealth bomber (Fig. 2), sailplanes, pressure vessels, temperature-conditioned transport, packaging, bridges, and canal locks. Awareness among future designers of functional and structural designs using composites, no matter for which product groups, of which fibers and polymers are applicable, including the possibilities offered by the many possible different "fiber architectures" and in relation to all available manufacturing techniques, are important factors in the engineering application of modern polymer matrix composites (Beukers and van Hinte 1998).

3. Polymer Matrix Composite Products: The Crucial Role of Industrial Manufacturing Techniques

In the nineteenth century the rapid introduction of electricity in communities and somewhat later of modern wheeled transport was made possible by the industrial capabilities of transforming natural fibers and fillers, phenolic polymers, and natural rubber into insulating structures for cables, switches, and electrical equipment. Automotive transport was revolutionized by the production of low-noise, lightweight, inflatable wheel tires made of fiber-reinforced natural rubber structures. Although labor was comparatively inexpensive, the successful breakthrough of these applications relied on the development of industrial techniques capable of ever-growing mass production. Ultimately, the parameter that has the most significant effect on the price–performance ratio of commercial products is the manufacturing cost; helmets or liquid petrol gas tanks provide examples of this. Once new materials and products have been accepted and established, the performance per unit weight gains importance and must be optimized. Decreasing structural "dead" weight is, of course, beneficial for performance improvement: this is applicable in packaging, transportation, and in "gravity"-limited structures such as tall bridges and buildings. In addition, minimizing the quantity of material leads to reductions in material cost, production time, and consequently in the cost of manufacturing (a liquid petrol gas tank is a good example (Fig. 3)). Increasingly, the success of polymer matrix composites in applications, by volume and by number, can be ranked by accessibility and reproducibility of the applied manufacturing techniques (Miravete *et al.* 1999).

3.1 Short and Discontinuous Fiber-reinforced Polymers

The introductory (pioneering) period for processes like injection molding and flow and form pressing of short fiber-reinforced polymers was based on thermosetting polymers, ranging from phenolics, polyesters,
Figure 2
Polymer matrix composite in an aerospace application. The Northrop B-2 Spirit bomber is a new paradigm in aircraft design: 80% of its skin structure is made of carbon and glass fiber-reinforced thermosets. Its aerodynamic, functional, and structural design is trend setting for future aircraft design in general. Using the shaping possibilities and the mass-specific mechanical properties of carbon fiber-reinforced thermoset polymers has resulted in new structure development including more efficient flying wing configurations and improved stealth technology, and has given new impetus to aerodynamics (three-dimensional blended body aerodynamics) and stimuli for active stability and control solutions (tailless configurations). (Courtesy of Northrop Grumman.)
Figure 3
Polymer matrix composite in packaging. A wheel-shaped ultralight composite pressure vessel designed to store liquid petrol gas for cooking or car driving in urban areas. Pressure vessel design in polymer fiber composites can lead to more functional forms, like this carbon fiber-reinforced container (8550 g, 57 l). Separating the functions, like impermeability for gas and liquids, pressure tightness, and protection against impact and fire, makes possible a manufacturing strategy that can compete with metallic pressure vessel manufacturing. (Courtesy of Delft University/Advanced Lightweight Engineering.)

vinylesters, to epoxies. In the case of injection molding with short fibers (lengths less than about 10 mm, glass and sometimes carbon fibers) and in matched-die pressing with longer, discontinuous fibers (lengths less than about 100 mm, mostly glass fibers), thermosetting polymers are gradually being replaced by more expensive but technically equivalent or superior thermoplastics. The main reason for this is the cost reduction that results from cycle time reduction, which is crucial for mass-produced products. Fiber reinforcement is limited with respect to length, fiber content by volume (below 35%), and orientation control. Injection-molded products are generally small, but they can be complex in shape and produced with very close tolerances. A good example of the application of such composites is in camera housings.

Matched-die flow molding of larger plate and shell structures has also gained in importance. Stacked prefabricated sheets of discontinuous fiber-reinforced thermoset polymers (glass–polyester, sheet molding compound ("SMC")) or thermoplastic polymers (polypropylene, glassmat-reinforced thermoplastics ("GMT")) are formed and shaped by pressing at the right temperatures into medium-sized products. Compared to injection-molded composites, the length (shorter than 100 mm) and volume percentages (below 45%) of the reinforcing fibers, typically of chopped E-glass, are increased resulting in stronger reinforcement of the matrix and higher composite in-plane stiffness and strength. The control of fiber orientations is similar to injection molding and based more or less on keeping the fiber distribution as random and uniform as possible, in this case mainly in the in-plane directions. Typical applications of products of this processing route include parts for trucks and cars, as well as garden furniture.

For both techniques, heavy machinery is indispensable, rigid heated (cooled) molds are kept closed or are closed with a force sufficient to overcome the pressure of the process (for injection molding <1000 bar and for pressing 100–200 bar) multiplied with the projected part area, which can frequently be rather high. To cover the ensuing investment costs, large numbers of the composite parts have to be sold. Therefore, automotive components, housings for cameras, popular electrical and electronic equipment, furniture, and leisure and sporting goods have become popular applications for this class of polymeric matrix composites, typically displacing metal and wood.

3.2 Continuous Fiber-reinforced Polymer Matrix Composites

The short and discontinuous fiber-reinforced thermosets and thermoplastics are responsible for the biggest share of successful applications of polymer matrix composite materials, whether measured by number of parts or quantity of material used. Less visible, however, but growing enormously since the early 1990s, are the applications of continuous fiber-reinforced polymers. Instead of mass-produced polymer-based products, the applications of continuous fiber-reinforced composite parts are in general in advanced, capital-intensive, thermoset-based materials and products. Except for fast (reciprocating) machine parts and expensive and fashionable leisure and sporting goods (alpine sports, motorcar racing, angling, tennis, golf, and cycling), most of the applications of continuous fibers are bigger in size and take the form of plate and shell structures. For big structures (low numbers, large volumes) thermoset polymers such as phenolics, polyesters, and, increasingly, epoxies are mostly used, both for the relative low polymer cost per unit weight and the relatively low pressures and temperatures necessary for curing the structures.

In aerospace applications, continuous carbon fibers are increasingly replacing glass fibers to reduce structural weight, unless low material cost, good performance in impact protection, or specific electric or dielectric properties are required. For structural applications, up to temperatures of 200 °C, epoxies are mostly used as polymer matrix materials. In the case of interior applications, the domain of stringent fire, smoke, and toxic gas regulations, the phenolics are

very popular. For low-weight, highly loaded structures a well-controlled and optimized fiber placement is essential. Designers and manufacturers often still depend on labor- or capital-intensive techniques with such composites. For example "laminating" can be done manually or by sophisticated automatic equipment, depending on the number of parts to be produced and on the design. In the stages of fiber (pre-)impregnation and in the cutting of patches of unidirectional tapes or woven fabrics, human labor is being replaced by cost-reducing and accurate machines. The most successful techniques in terms of composite material usage are filament winding of pressure vessels and pultrusion of composite profiles as intermediate structural elements applied in civil engineering: cables, bridges, and electricity masts provide examples of such applications. Except for carbon fibers in pretensioned cables, glass fibers are the most popular in this class of relatively large polymer composites. In pressure vessels, aramid and carbon fibers are becoming strong competitors, supported by the necessity of additional weight reduction and winding cycle time reduction to speed up production or to reduce the machine cost (Reinhart *et al.* 1987).

Also for continuous fiber-reinforced products, press forming is gaining in importance. For example, woven fabrics can in this process be draped into three-dimensional shape making use of a certain amount of thermoplastic binder material to keep the fabric "frozen" in the final shape. The result is a high-quality, preformed fiber structure that can be impregnated and cured in a following stage. The impregnation can be done in closed molds by resin transfer molding (RTM). Low-pressure vacuum-assisted RTM can be executed in simple (female) molds, the counter half or closing being just a flexible film material. In cases where additional pressure is used, relatively heavy and rigid matching dies are needed. Vacuum-assisted RTM is in particular becoming popular in the building of very large composite structures, such as hulls and decks for ships and windmill rotor blades, these structures having characteristic lengths up to about 30 m. "Pressurized" RTM is applied in the manufacturing of small propellers and helicopter rotor blades. Cost reduction and improvement of labor, product, and environmental quality are here combined when compared to traditionallaminating and impregnation techniques. For some applications, fabrics can be preimpregnated with a thermoplastic polymer (powder, melt, or solvent impregnation), and after heating these prepregs can be deformed (draped) and (re)consolidated in a mold. High fiber volume fractions and complete fiber orientation control is typical for this process and the speed is comparable to injection molding and other industrial forming processes used for short fiber-reinforced polymers. The pressure levels, however, are very low: for forming (draping) 1 bar or less is
Figure 4
Polymer matrix composite in lightweight armor. Press formed (draped) aramid fiber-reinforced helmet, featuring improved functionality and weight reduction. Military helmets have traditionally been made out of steel, but like ancient (Mongol) multilayered textile armor, this helmet contains about 20 layers of plain woven aramid fibers, poorly bonded together (more than 65% fiber by volume) to absorb a maximum of ballistic impact energy. The latest thermoplastic polymer "blue" helmets manufactured by press forming (draping) are a compromise between protection against flying shrapnel and wearing comfort. They must be as light as possible (200 g less than their metal predecessors) and function in extreme cold and hot weather conditions alike. (Courtesy of Delft University/ Sumitomo.)

used, and for (re)consolidation 10–40 bar is needed. Helmets (Fig. 4) provide a good example of an application based on this process. When heating and cooling times are considered (a matter of seconds or minutes) it is clear that press forming of continuous fiber-reinforced composites is not only attractive because of the manufacturing speed, but also for the lightweight equipment and minimum energy required.

4. Conclusion

The scale of application of polymer matrix composites is very extensive. These structural materials have entered most major technological sectors including aerospace, automotive, leisure, consumer goods, electrical, electronic, and industrial manufacturing equipment, as well as many large-scale structures including ships and civil engineering structures. Factors determining the implementation of polymer matrix composites in engineering applications include both the intrinsic performance of the materials and the economic advantages that can be gained through their use. These factors, in turn, are strongly dependent on

the somewhat specific nature of designing with composites, and also on the increasingly important role played by materials processes and part manufacturing procedures. Given the sustained rate of progress in these areas, it can be anticipated that composite materials will continue growing in importance in engineering for many years to come.

Polymer Matrix Composites: Matrices and Processing

Polymer matrix composites, and fiber-reinforced plastics (FRPs) in particular, are commonplace in the industrialized world; their applications range from primary structural aircraft components to tennis racquets, and many household appliances incorporate some form of fiber reinforcement. The development of engineering FRPs began once significant quantities of glass fiber became available in the 1940s, and was initially performance driven (e.g., for aerospace). Since then, reduction of materials costs has greatly widened their range of applications, and the impetus for continued development stems mainly from economic factors such as efficient fabrication and transformation, and a need for the energy savings possible with low-weight, high-strength, and high-modulus materials. However, FRPs have the major disadvantage with respect to metal- and ceramic-based structural materials that their service temperatures are limited to below 400 °C, even for the most advanced matrices.

An overview is given in this article of the most widely used FRP matrix materials and their relative merits. The various stages of processing to form composite parts are discussed, with reference to cost forecasting, life cycle engineering, and developing technologies. Finally, the important question of

process–structure–property relationships in thermoset- and thermoplastic-based FRPs is addressed.

1. Matrix Materials

Apart from injection molding thermoplastics, which typically contain short (<1 mm) fibers, most FRPs are based on thermoset resins. Thermosets can be cured catalytically, thermolytically, or photolytically over a wide range of temperatures to give highly cross-linked solids. One of their principal advantages for FRPs is their low initial viscosity, which facilitates fiber impregnation, particularly where the base "A-stage" resin consists of monomeric or oligomeric components. Partial cure may then be used to produce solid "B-stage" prepregs used as precursors for a variety of processing routes. There is nevertheless great interest in thermoplastic polymers; although the high molar mass of thermoplastics implies that higher processing temperatures or specialized techniques are needed for impregnation, this may be outweighed by other factors: (i) they are generally nonreactive, implying an indefinite shelf-life for precursors; (ii) forming processes are reversible, facilitating recycling and repair; and (iii) cycle times are not limited by reaction kinetics, and mixing steps, which may involve toxic precursors and need careful control to ensure reproducibility, are eliminated. Table 1 summarizes the main trends, although it should be stressed that there is considerable overlap, the toughness of FRPs based on both classes of resins being highly sensitive to, for example, fiber morphology, interfacial adhesion, and the presence of additives (see *Composites: Interfaces**, *Continuous Parallel Fiber Composites: Fracture**). Moreover, each class of resins encompasses a wide variety of materials and materials properties, which will now be presented in more detail along with typical applications. A more systematic discussion of the applications of polymer matrix composites is to be found in *Polymer Matrix Composites: Applications**.

1.1 Thermoset Resins

There are several main types of thermosets, distinguished by their chemistry, curing mechanisms, and

Table 1
Property and process characteristics of thermosets and thermoplastics.

Property	Thermoset	Thermoplastic
Modulus	High	Medium
Service temperature	High	Medium
Toughness	Medium	High
Viscosity	Low	High
Processing temperature	Low	High
Recyclability	Limited	Good

final properties (Charrier 1990). Those discussed here are the most important for FRPs, namely polyesters, epoxies, and high-performance thermosets, although other thermosets, including polyurethanes (PUs), silicone rubbers, and phenol–formaldehydes (PFs), are also sometimes used as FRP matrices (e.g., PF–aramid composites for aircraft interiors).

(*a*) *Unsaturated polyesters.* Unsaturated polyesters (UPs) are the most widely used thermosets for FRPs. They consist of prepolymers cross-linkable by addition, initiated photolytically or by thermal decomposition of peroxides. Processing involves most of the methods described in the next section, and indeed UPs were originally developed for use in FRPs. However, to ensure adequate flow behavior, up to 50 wt.% styrene co-reagent is often added to give a so-called UPE resin. Environmental concerns have since led to the use of low styrene emission additives in UPEs. These segregate to, and seal, the surface during the final stages of cure, compromising adhesion in some cases. Another potential difficulty is excessive shrinkage, but this is largely avoided by the use of thermoplastic low profile additives. Once cured, unsaturated polyesters have heat deflection temperatures (HDTs) ranging from 80 °C to 150 °C in certain vinylester resins (the HDT is a softening temperature measured according to industrial norms and marks the approximate upper limit to the range of service temperatures). Their main composite applications include the construction industry, the transport industry (boats, car body panels), furniture, and chemical storage tanks.

(*b*) *Epoxy resins.* Epoxy resins may also be used in conjunction with most composite processing techniques, and are particularly suited to B-stage processing. Cure generally involves polyaddition with a multifunctional co-reagent, referred to as the "hardener," to produce a three-dimensional network with low shrinkage, and excellent adhesion and environmental resistance. Drawbacks of conventional resins include somewhat higher viscosities than in UPEs, long cure times, and moisture uptake. A wide range of resins and co-reagents is nevertheless available, products ranging from tough low-temperature epoxies to more brittle, high-temperature epoxies for advanced FRPs (prepregs for aircraft components account for around 30% of total production). Commonly used aliphatic amine hardeners permit room temperature cure, but the reaction is strongly exothermic, causing problems in thick moldings. Aromatic amine hardeners require higher curing temperatures but are better suited to large parts and give relatively high HDTs (up to 230 °C). Anhydride hardeners are less toxic and less polar than amines, but need an accelerator. With suitable catalysis,

epoxies may also be cured thermally or photolytically without a co-reagent.

(*c*) *High-performance thermosets.* High-performance thermosets include allyls, cyanate esters, and liquid crystalline thermosets. Among the most successful are addition polyimides, developed mainly for the aerospace and electronics industries. Their HDT may reach 400 °C after cure, and they have excellent stiffness and environmental resistance. The cure mechanism is thermally induced free radical addition of a polyimide precursor via reactive end groups in the presence of peroxide, avoiding problems with the volatile by-products of conventional condensation reactions. Applications include jet and automobile engine components, heat-resistant panels, etc. However, some potential future applications of high-performance FRPs, such as reusable launch vehicles, will require HDTs in excess of 500 °C, setting the standard for the next generation of thermoset matrix materials.

1.2 Thermoplastic Resins

Both semicrystalline and amorphous glassy polymers form viscous melts that need to be processed at temperatures well above the glass transition temperature, T_g. However, since semicrystalline polymers melt well above T_g, it is the melting point, T_m, that defines the processing window. Whereas thermoset designations tend to be generic, most thermoplastics have well-defined linear architectures that undergo little change during processing. Their property profiles are generally adjusted for different processing routes by varying the molar mass or additive package (Charrier 1990); however, it should be borne in mind that other important properties such as toughness and ultimate tensile strength are also highly sensitive to changes in molar mass.

(*a*) *Semicrystalline thermoplastics.* Semicrystalline thermoplastics are tough and resistant to organic solvents, but many inexpensive and easy-to-process low T_g polymers, such as polyethylene, also show poor adhesion owing to their lack of functionality, and low softening temperatures, often associated with excessive creep. A good compromise between cost and performance is provided by polypropylene (PP, $T_m \approx 170$ °C), for which functionalized additives are available to improve adhesion. PP is widely used in FRP applications in the automotive industry, for example, owing notably to glass mat thermoplastic technology. Polyamides (PAs or nylons), such as PA6 and PA6,6, are also popular, having higher HDTs than most thermosets, although they are moisture sensitive and more than twice as expensive as PP. Another polyamide of interest for FRPs is PA12, the

versatile synthesis and functionality of which make it especially attractive for reactive FRP processing.

High T_g semicrystalline polymers such as poly(phenylene sulfide) (PPS) and poly(ether ether ketone) (PEEK) require correspondingly high processing temperatures, PEEK melting at about 345 °C, for example. However, these polymers have outstanding properties, including exceptional toughness and fatigue resistance. Particular effort has gone into PEEK–carbon fiber composite technology, leading to the so-called aromatic polymer composite (APC) prepregs, considered to be a major step in the development of advanced thermoplastic matrix FRPs (Cogswell 1992). However, PEEK is nearly two orders of magnitude more expensive than PP (Charrier 1990).

(*b*) *Amorphous glassy thermoplastics.* Aromatic high-performance amorphous thermoplastics such as poly(ether sulfone) (PES, $T_g \approx 230$ °C) or poly(ether imide) (PEI, $T_g \approx 215$ °C) have also attracted interest as advanced FRP matrix materials. They are less expensive than PEEK and tougher than thermosets, but there remain (arguably unjustified) concerns over their solvent resistance.

2. Processing

Figure 1 summarizes the various routes by which raw materials (resin plus fiber) are transformed into the final part (Månson 1994). A description of the most important of these now follows. Further details concerning specific types of reinforcement, and glass fibers in particular, are to be found in *Fibrous Reinforcements for Composites: Overview** and *Glass Fibers**.

2.1 Fibers, Prepregs, Feedstocks

Fibers are usually supplied in the form of rovings (glass fibers) or tows (carbon fibers). Rovings consist of straight continuous glass-fiber strands or bundles of about 200 filaments; the number of strands depends on the end use, and these may be several kilometers long. Tows are likewise available in various configurations. The fibers are typically sized (coated) during production to promote wetting and adhesion, silane coupling agents being widely used for glass fibers. They may be woven into fabrics if required, including *ad hoc* fiber preforms for specific applications. Chopped fiber lengths range from less than 1 mm for injection, to around 50 mm in randomly oriented mats for laminates.

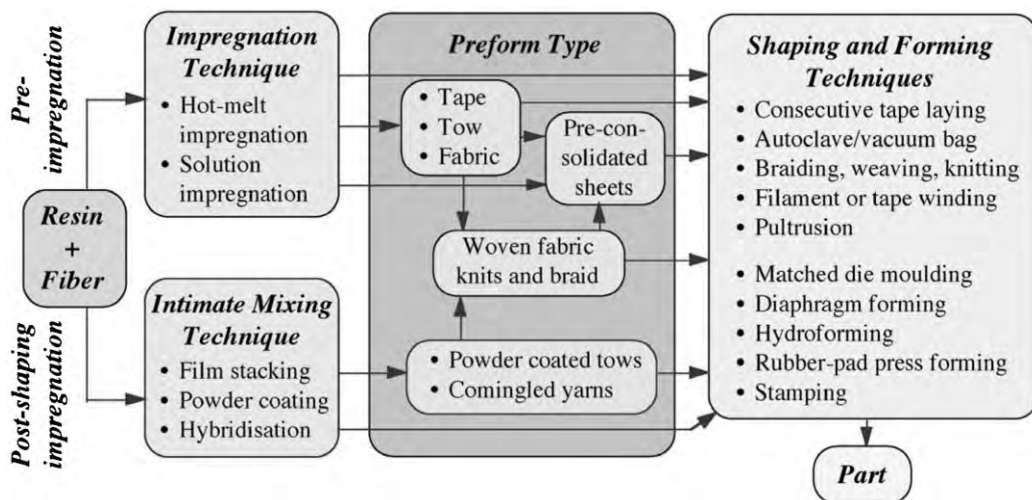
Of major concern in FRP processing are trapped air and volatiles, since voids substantially reduce the final strength. Low-viscosity resins, vacuum outgassing, and consolidation all help reduce porosity. Use of preconsolidated sheets or prepregs also facilitates certain processes (see Fig. 1). These are available as impregnated fabrics or continuous warp sheet typically containing 60–65 vol.% uniaxially oriented fibers. Impregnation with thermosets may be achieved by dipping or hot melt processing (rolling of the fibers together with a resin film). When the viscosity is high, flow distances must be kept to a minimum, and intimate mixing of fine polymer powders or fibers with the fiber reinforcement often precedes melt processing of thermoplastic composites. Solvent processing is one alternative; it may lead to problems


Figure 1
Alternative manufacturing routes: from resin and fiber to finished part (after Månson 1994).

with residual solvent in the later stages of fabrication but has been used with success for PEI prepregs, for example. Another possibility is to chain extend relatively low molar mass precursors *in situ* by reaction of suitable end groups, an approach frequently used for high-performance thermoplastic FRPs.

Sheet and dough molding compounds are mostly based on unsaturated polyester resins containing filler and chopped fibers. Sheet molding compounds (SMCs) are produced from chopped strand mat placed between layers of filled resin containing thickening agents to promote moldability. Impregnation involves rolling of the resulting sandwich structure. SMCs usually contain 25–35 wt.% fibers but the fiber content can be up to 65 wt.%, in which case they are called HMCs. XMCs are similar to SMCs, but incorporate surface layers containing continuous fiber rovings. Dough molding compounds (DMCs), or bulk molding compounds (BMCs), contain shorter fibers than SMCs and are produced by mechanical mixing, which results in a more markedly three-dimensional fiber orientation distribution. Glass mat thermoplastics (GMTs) can be produced in a similar manner to SMCs, but the high matrix viscosity means that success is very dependent on the choice of fiber mat. Powder processing routes are an interesting alternative in this case.

It is sometimes advantageous to preassemble reinforcing fibers to fit a given shape, rather than rely on flow to distribute them throughout a mold. If displacement of the fibers during subsequent introduction of the resin is a problem, they can be anchored in place by spraying with a binder, or substituted by a preimpregnated fabric shaped into a suitable perform.

2.2 Shaping and Forming Techniques

The simplest forming technique is hand placement, where woven fabric or chopped strand mat is placed on a nonstick former and premixed liquid thermoset resin added with a brush, say, or by spraying. It is versatile and requires low investment, but the resulting mechanical properties are limited and the manufacturer may fall foul of legislation against volatiles. It is used for one-off or short production runs, including large objects, such as boat hulls. However, for reproducible, high-quality, cost-effective production other techniques must be considered.

(a) Press molding. Press molding using matched male and female tools is the most widely used technique for volume production of FRPs, being suitable for most types of precursor. With SMCs or DMCs, complex shapes can readily be formed at pressures of 3–15 MPa with cycle times of the order of minutes depending on the cure rate and the part size. It is also used for continuous fiber FRPs, but the limited flow restricts the practically attainable range of wall thickness and curvature. For mass production, steel tools and hence additional capital investment may be necessary, but for short runs, epoxy composite tools are often adequate. Variations include rubber-pad press molding, hydroforming, diaphragm forming, and cold stamping.

(b) Vacuum and autoclave molding. In vacuum molding, atmospheric pressure consolidates the material during cure, avoiding the need for a press. A prepreg or fabric laminate is placed on a mold, covered with a flexible membrane and the assembly sealed and evacuated. It provides a low-cost alternative to press molding for large, thin shells. If further consolidation is needed, cure may be done in an autoclave. Autoclaves usually operate at up to 1.5 MPa pressure and are widely used in the aerospace industry, having the advantage over press molding of cheap tooling for large parts and being ideal for complex structures such as honeycomb core sandwich composites. Indeed almost all prepreg material used in the aerospace industry is autoclaved. It is less suited to high-volume manufacture, although progress in automatic cutting and lay-up operations has led to considerable cost reductions and new market opportunities.

(c) Resin transfer molding, reaction injection molding. In resin transfer molding (RTM), the fiber reinforcement (either dry fibers or a preform) is placed in the mold cavity, and the resin then introduced by injection. RTM generally requires low-viscosity resins, but impregnation can also be improved by vacuum-assisted injection. It is used to produce large moldings such as car body shells, and the low injection pressures mean the molds themselves can be made from FRP, with considerable cost savings. However, although RTM is cheaper than prepreg processing, it is more limited in its range of application. Reaction injection molding (RIM) makes use of rapidly reacting components mixed just prior to injection, permitting very short cycle times, and short fiber reinforcement can also be introduced in one or both reagents (this is called reinforced reaction injection molding (RRIM)). It is competitive with press molding for the manufacture of a variety of automotive and domestic components.

(d) Pultrusion. Pultrusion is the continuous fiber FRP equivalent of extrusion, permitting continuous production of constant profile parts such as fishing rods, antennas, and channel profiles (or constant section parts, if the profile is modified *in situ*). Unlike in extrusion, however, the reinforcing fibers themselves are used to *pull* the material through a heated forming die, as shown schematically in Fig. 2. Rovings or tows are passed through a resin bath followed by a series of carding plates or "preformers," which force
Figure 2
Schematic of the pultrusion process.

the resin into the fibers. The impregnated fibers are then pulled through the die, where the resin gels and cures. Preheating by radio-frequency methods may be used to increase throughput, resulting in production rates of up to several meters a minute. In some cases the resin is also injected directly into the die, eliminating the need for a preimpregnation step.

(*e*) *Filament winding*. Strong, stiff shell structures can be made by winding bands of continuous fibers impregnated with resin onto mandrels, which are removed after cure. Filament winding is widely used for the manufacture of reinforced plastic pipe and other cylindrical objects. However, modern filament winding techniques can also be used to produce complex structures such as aircraft fuselages. In such cases, the fibers must be wound along constantly changing nonrepetitive geodesic paths to prevent slippage. Automation of this technique has led to the development of advanced computer-based integrated design and manufacturing methods.

(*f*) *Developing technologies*. Some representative examples are now be given of developing technologies aimed at improving, or providing alternatives to established processing routes. The resin infusion process (RIFT) and its variants, in which a vacuum is

used to draw resin into a preform or fiber bed (cf. RTM), has been successfully applied to large objects such as boat hulls. Large injection molding body technology (LIMBT), offers a viable alternative to press molding of SMCs and GMTs, contrary to the widely held notion that injection molding facilities become prohibitively expensive as part sizes increase; for example, it has been used to make large automotive body components from various thermoplastic FRPs (Argeropoulos *et al*. 1999). Integrated processing (IP) is aimed at improving manufacturing flexibility and adding value to composite products by combining different processes and materials; selective placement of reinforcement and integration of functions are thus achieved in short cycle times (Månson *et al*. 1995, Bourban *et al*. 1998). Reactive thermoplastics processing, developed for PA12-based composites, uses monomeric precursors for impregnation followed by polymerization *in situ*, avoiding the problems associated with the use of melt or solution impregnation techniques for thermoplastics (Schmid and Eder 1997, Bourban 2000).

2.3 Choice of Materials and Processing Routes: Composite Processing Maps

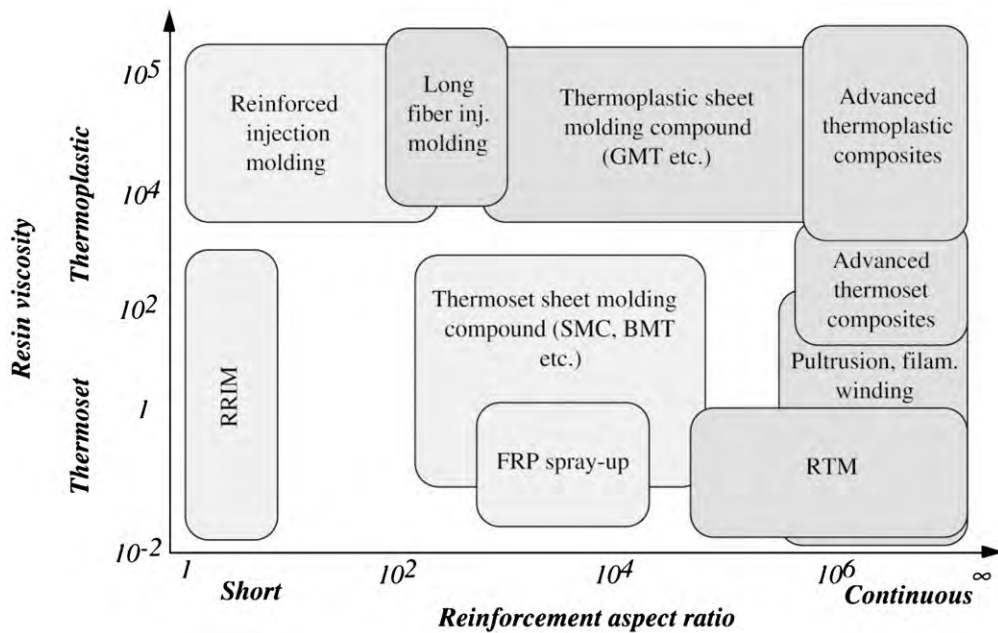
Figure 3 shows a map of various composite processing methods arranged according to the combination


Figure 3
Composite processing map: viscosity and reinforcement aspect ratio (after Månson 1994).

of resin viscosity and reinforcement aspect ratio to which they are most suited. If viscosity is an over-riding consideration it will generally dictate the choice between thermoplastics and thermosets, but it is immediately clear from Fig. 3 that the range of processes is broad enough for solutions to be available for thermoplastics or thermosets for any required reinforcement aspect ratio. Such "composite processing maps" may be based on other parameters, such as the potential for control of reinforcement orientation and aspect ratio; injection molding, for example, gives little orientation control and is limited to low aspect ratios, whereas three-dimensional control and long fiber orientation require techniques such as filament winding, hand lay-up and RTM/preform technologies. Figure 4 gives a further example that is particularly important for costing (see below), namely the relationship between the suitability of a given process route for complex shapes and its suitability for high-volume production, as defined by the cycle time.

2.4 Cost Modeling, Life Cycle Engineering

Since material costs are now substantially irreducible, and given that manufacturing often represents close to 60% of expenditure on FRP composite parts, the processing route is generally the most critical factor in cost-effective production. Assessing the economic viability of a processing route requires comparative cost analysis and hence reliable data and cost estimation methods. A variety of approaches for evaluating manufacturing costs have been proposed (Månson *et al.* 2000): comparative studies, process-oriented cost models, parametric cost models, and process flow simulation. Comparative studies are based on historical data and may suffice when envisaging the use of a standard technique for a component similar to those already in production. Process-oriented cost models are better adapted to new processes, and incorporate identification and quantification of cost drivers, but require detailed process information and a precise definition of the components. Parametric models are more versatile and allow easy manipulation of process and economic factors; however, they are based on the assumption of independent manufacturing steps, and may consequently underestimate costs. Such difficulties may be avoided by using process flow simulations, which take into account interactions between the different manufacturing steps, and provide forecasting tools that are also suitable for improvement studies, identifying bottlenecks and estimating repair costs. Given the growing concern for environmental issues, the successful introduction of a new product or process may also require establishment of a life cycle plan, particularly for the large-volume applications. As well as the impact of material on the environment during manufacture, service, and disposal, it is important to consider conservation of raw material value. This is

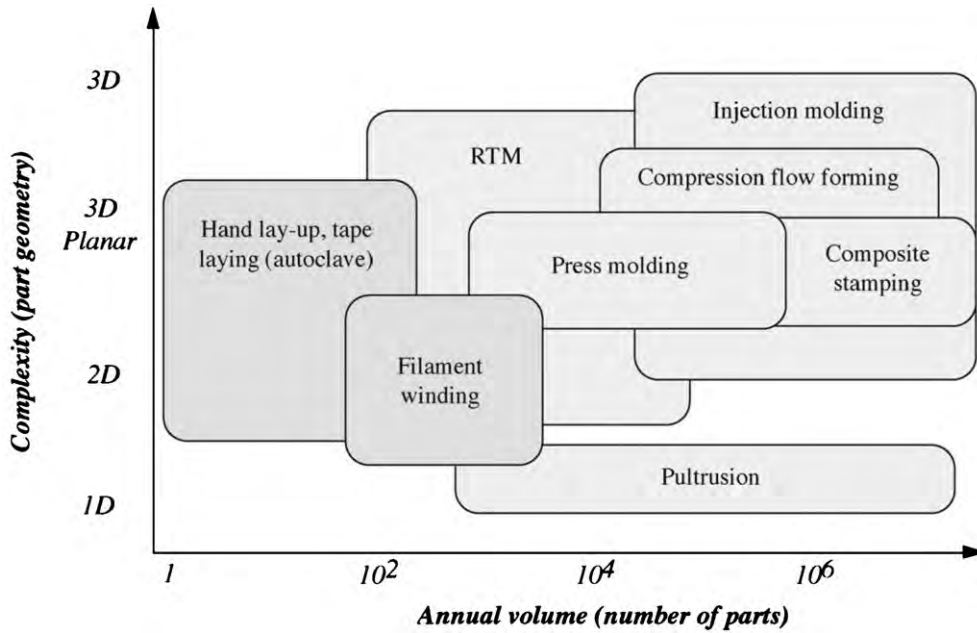
a potentially important issue when choosing between thermosets and thermoplastics, since recycling of the former is severely limited. Furthermore, recovery from continuous fiber FRPs is difficult even for thermoplastic matrices. One alternative under consideration is recovery of the monomer via tertiary recycling (see *Polymer Matrix Composites, Recycling of**).


Figure 4
Composite processing map: complex shaping and volume production (after Månson 1994).
Figure 5
(a) Typical thermal cure history for a thermoset composite. (b) Isothermal TTT diagram associated with the cure of a thermoset polymer.

657

3. Process–Structure–Property Relationships

The thermal cure history shown in Fig. 5(a) is typical of prepreg and autoclave processing sequences for a thermoset FRP. During impregnation, the resin viscosity first decreases owing to the rise in temperature, then increases as cross-linking proceeds. The reaction is interrupted by cooling, and the resulting B-stage material is stored at low temperature to inhibit further reaction. During final processing, the viscosity again passes through a minimum, tending to infinity as the gel point is approached. A two-step final cure is often used to improve consolidation and dimensional stability, after which the part is cooled and removed from the mold or former. The final properties of thermoset FRPs are strongly dependent on the details of such time–temperature trajectories. Figure 5(b) shows a schematic time–temperature–transformation (TTT) diagram illustrating the main trends (Pang and Gillham 1990). During isothermal cure at temperatures between T_g^{gel} and T_g^{∞}, the polymer gels and then vitrifies, defining optimum conditions for final processing. Isothermal cure between T_g^{gel} and T_g^0, the initial glass transition temperature (or melting point), would cause the polymer to vitrify prior to gelation, hindering further reaction.

In a typical processing cycle for a thermoplastic FRP, the components are first heated to above T_m of the resin (or T_g for a fully amorphous resin). Pressure is applied for long enough to give adequate consolidation, and the resulting composite is cooled with the pressure maintained. Optimum processing conditions may be defined with the aid of processing windows, such as that shown schematically in Fig. 6. The lower bound for the cooling (and heating) rate is fixed by economic constraints on the cycle time. Slow cooling and heating may also result in prolonged exposure of the resin to high temperatures, leading to thermal degradation. At very high cooling rates, however, considerable thermal gradients may develop through the thickness of the component, leading to pronounced skin–core morphologies in semicrystalline resins, and excessive thermal stresses, as well as changes in primary morphological parameters such as spherulite size, lamellar thickness, and the degree of crystallinity. Increasing the hold pressure may help suppress defects resulting from internal stresses, but a maximum pressure will be imposed either by the performance of the press, or by the cost of high-pressure molds. High pressure may also damage the fiber bed and/or cause resin starvation.

4. Conclusion

Although the initial driving force for the development of FRP composites was performance, economics is now the overriding consideration. Raw material costs are generally higher than for metals, but this is offset by weight reduction, increased design freedom, and reduced "part count" in a given application; even image can be a strong selling point for sports goods. Nowadays, it is innovation in processing that offers the greatest scope for increasing the engineering viability of polymer matrix composite materials, and for paving the way to new applications of these materials. Doubtless some of the techniques under development will shortly join or supplant the "standard methods" referred to here.

Polymer Melt Mixing: Agglomerate Dispersion

It is well known that the addition of fillers to polymeric materials can greatly improve their physical properties (see also *Elastomers, Reinforcement of* *). Many of the additives used in the plastics and rubber industry are particulate in nature and exist in the form of aggregates composed of primary particles permanently fused together. In turn, aggregates cluster together under the influence of surface forces in collections of aggregates, referred to as agglomerates. A typical example is carbon black, with aggregates on the order of 0.1 μm in size and agglomerates in the range of 10–100 μm and up. The purpose of the mixing process is to break up the agglomerates into smaller size fragments and uniformly distribute these throughout the polymeric matrix. The process of dispersing particulate solids in a molten polymer involves a number of sequential, although most of the time overlapping, steps. These are: incorporation, deagglomeration, and distribution. In the incorporation step, the melt wets the particle surfaces, and the two phases are combined into a single coherent mass. At the end of this step, the loose filler particles disappear, and part of the air, introduced in the compound by entrapment with the agglomerates, has been replaced by the polymeric media. The polymer wets the filler, and it may penetrate into the void spaces of the agglomerate and also within the aggregates. In the deagglomeration, or dispersive mixing step, agglomerates or clusters of particles are broken down in size, either into their constituent particles or into smaller agglomerates. It is generally recognized that this is the most difficult step, and therefore the rate-determining one in any mixing operation. Once the filler agglomerates have been broken, separation of the closely spaced fragments and their distribution throughout the polymeric matrix should be accomplished.

In general, in polymer melt mixing operations, it is desirable, and for many applications it is essential, to eliminate large agglomerates, and therefore dispersion is regarded as the critical step in the mixing process. In order to investigate dispersion mechanisms, numerous experimental and theoretical studies of the breakup of agglomerates have been carried out. Bolen and Colwell (1958) were the first to propose that agglomerates rupture when the hydrodynamic drag forces acting on the surface of the cluster induce internal stresses which exceed a certain threshold value. Many investigators extended this basic idea and tried to develop models for the mixing process. Most of these models concentrated on the breakup of agglomerates into relatively large fragments. In general, however, it has been observed experimentally that the breakup of agglomerates can proceed by two distinct mechanisms (Rwei *et al.*

1990). One is the aforementioned rupture model, whereas in the other mechanism, erosion, individual particles or small clusters of particles are eroded from the surface of the parent agglomerate.

Any analysis of the agglomerate dispersion process must consider both forces involved in agglomerate breakup: namely, the forces of cohesion within the clusters and the hydrodynamic forces inducing their breakup. In the following we will briefly discuss these forces separately.

1. Cohesive Forces

Most of the present models for agglomerate cohesive strength treat the structure of the agglomerate in a very simplistic manner, as either a uniform porous sphere or as a uniform assembly of spheres, and link the strength of the agglomerate to interparticle forces. One example is the model developed by Rumpf (1962). For equal sized spherical particles assembled into an agglomerate, Rumpf derived an expression of the form:

$$T = \frac{9}{8} \frac{1 - \varepsilon}{\varepsilon} \frac{H}{d^2} \qquad (1)$$

where T is the tensile strength, d is the diameter of the spherical particles, ε is the agglomerate porosity, and H is the mean interparticle force. The model is based on certain important assumptions: (i) there are a large number of bonds in the fracture section; (ii) the bonds are randomly distributed over the fracture section and have random orientation in space; (iii) the particles in the agglomerate are randomly distributed in space; and (iv) all interparticle forces can be approximated by a single mean effective force.

A more complex model of agglomerate structure was developed by Sonntag and Russell (1987), who built agglomerates of polystyrene latex spheres as porous spheres with a position-dependent internal structure. The internal volume fraction within the floc, $\phi(r)$, at a local position r with respect to the center of mass, varies as r^{D-3}, where D is the mass fractal dimension of the floc. However, effects of fluctuations in volume fraction due to the presence of structural heterogeneities were ignored. Later on, Horwatt and co-authors (1992b) developed a method to analyze the influence of structural heterogeneities on agglomerate cohesivity. The authors simulated a number of different fractal and nonfractal structures. They searched through the different structures and identified the fragment(s) requiring the lowest stress to break. Such fragments were designated as critical fragments, determining the overall cohesivity of the agglomerate.

The interparticle forces depend on the mechanisms of adhesion between particles. Considering van der Waals interactions only, and making use of the Hamaker theory for the interaction potential between

two spheres (Hamaker 1937), the expression for the mean interparticle force can be approximated by:

$$H = \frac{Ad}{24z^2} \qquad (2)$$

where A is the Hamaker constant and z is the effective separation distance between particles. However, agglomerate porous structure may allow for the surface-driven infiltration of the surrounding polymeric matrix into the cluster. The infiltration of fluid can cause some rearrangement of the packing structure, or alter the cohesive forces binding the agglomerate together. Schubert *et al.* (1975) describe how liquid bridges within agglomerate may lead to increased cohesivity, due to the presence of capillary forces. For partially infiltrated agglomerates, the cohesivity can be calculated from:

$$T = S \frac{1 - \varepsilon}{\varepsilon} \frac{6\gamma \cos\theta}{d} \qquad (3)$$

where γ is the fluid surface tension, θ is the contact angle and S is the degree of saturation within the agglomerate.

2. Hydrodynamic Forces

In developing an analysis of agglomerate dispersion by an applied flow field, one has to take into consideration the effect of the applied hydrodynamics on the mechanics of the agglomerate. If agglomerates are viewed as homogeneous, impermeable spheres, undergoing bulk motion as single entities, the hydrodynamic stress acting on them can be derived using concepts originally suggested by Bagster and Tomi (1974). For linear flows of low Reynolds number, the hydrodynamic stress acting on the agglomerate surface, $\boldsymbol{\tau}$, can be written in the form:

$$\boldsymbol{\tau} = 5\mu(\mathbf{E} \cdot \boldsymbol{r}) \qquad (4)$$

where $\mathbf{E}$ is the rate of strain tensor for the bulk flow field, μ is the viscosity of the polymer melt and $\boldsymbol{r}$ is the orientation vector relative to the sphere center. The approach taken to examine the stresses within the sphere is to consider any plane that divides the sphere into two parts. The fluid surface forces induce a total force on each of the two parts, from which a net hydrodynamic force on the dividing plane can be computed.

An extension of this model, accounting for the flow inside the porous agglomerate, was given by Adler and Mills (1979). The hydrodynamics is governed by the Stokes equation in the bulk fluid:

$$\nabla p = \mu\nabla^2\boldsymbol{u} \qquad (5)$$

and the Brinkman equation within the porous agglomerate:

$$\nabla p = \mu\nabla^2\boldsymbol{u} - \frac{\mu}{\kappa}(\boldsymbol{u} - \boldsymbol{u}_\text{s}) \qquad (6)$$

In the above equations, p is the pressure, $\mathbf{u}$ is the fluid velocity, κ is agglomerate permeability and $\mathbf{u}_\text{s}$ denotes the cluster velocity. The equations can be solved with boundary conditions of velocity and stress vector continuity on the surface of the sphere. To calculate the stresses inside the porous agglomerate, a condition of mechanical equilibrium in the solid can be applied:

$$\nabla \cdot \boldsymbol{\sigma} - \frac{\mu}{\kappa}(\boldsymbol{u} - \boldsymbol{u}_\text{s}) = 0 \qquad (7)$$

where $\boldsymbol{\sigma}$ is the solid stress tensor. The second term represents the body force transmitted to the solid by the percolating fluid. More recently, Levresse and co-authors (1998), extended the analysis of stress distribution within partially-infiltrated agglomerates subjected to controlled flow conditions.

3. Models for Agglomerate Dispersion

In developing models of agglomerate dispersion, one must consider the agglomerate structure and cohesivity, as well as the effect of the applied hydrodynamics on the mechanics of the agglomerate. Either simple or more complex models can be used to describe the hydrodynamics and the cohesiveness of the agglomerate and to predict the locus of breakage.

Combining Rumpf's model for the cohesive strength of an agglomerate with a simple hydrodynamic analysis of two touching rigid spheres (suggesting the two halves of an agglomerate), Manas-Zloczower *et al.* 1982, 1985) derived a model for agglomerate dispersion in simple shear flows. The fraction of agglomerates broken by the applied flow field was found to be dependent on a dimensionless parameter scaling the strength of the flow field relative to the cohesive strength of the agglomerate. Agglomerate breakage was modeled as a repetitive process, with cleavage to occur always at the midplane, where the effect of hydrodynamic tension is largest.

Horwatt and co-authors (1992a, b), extended Bagster and Tomi's hydrodynamic analysis to study the influence of agglomerate structural heterogeneity on its dispersion behavior. Critical conditions for dispersion and ultimate fragment size distributions were found to be dependent on the connectivity of the agglomerate, and the intensity of applied stress relative to the strength of the connecting bonds.

The kinetics of agglomerate dispersion and the dynamics of particle size distribution will depend on the mechanism of dispersion i.e., erosion or rupture. In turn, the dispersion mechanism is controlled by system characteristics (clusters size and cohesivity, polymer melt viscosity, and interfacial properties), as well as by the geometry and strength of the applied flow field. In addition, in industrial polymer melt mixing equipment, conditions of agglomerate dispersion are space-and time-dependent. Thus, a comprehensive model for agglomerate dispersion has to consider the kinetics of the dispersion process in combination with a detailed analysis of the mechanics of flow in the mixing equipment.

Polymer Modified Wood

Polymer modified woods (PMWs) are kiln-dried, permeable lumber (such as birch, beech, red oak, maple, pine, poplar, rubberwood, and alder) or composites (such as plywood, oriented strandboard, particleboard, and fiberboard) that contain polymer (plastic) in their cell cavities or cell walls. PMWs are different from wood–plastic composites, which are largely a blend of thermoplastic resins and wood particles.

1. How PMWs Are Made

PMWs are made by impregnating the wood with liquid monomer or prepolymer mixtures and then polymerizing the liquid within the wood. Many monomers that contain vinyl groups (a carbon–carbon double bond) have a viscosity useful for wood impregnation at room temperature and also react well to form the polymer within the wood. The monomer most widely used for PMWs is methyl methacrylate.

Impregnation is carried out in a pressure vessel. First, a vacuum is drawn to remove air from the cells of the wood. Next, the liquid monomer is admitted to the pressure vessel while maintaining the vacuum. Atmospheric pressure is then restored to the vessel and additional pressure may be applied to help move the liquid uniformly into the wood. After impregnation the wood is removed from the vessel and placed in a curing chamber.

Curing (polymerization) of vinyl-type monomers starts with the generation of reactive groups using either temperature-sensitive catalysts or penetrating radiation such as gamma rays. The reaction proceeds with monomer molecules bonding together to form large polymer molecules and releasing heat as a by-product.

2. Types

There are three major types of PMWs. The cell-lumen type contains polymer, which fills cell cavities but has not reacted with the cell wall. Most vinyl monomers produce this type of PMW. Cell-wall PMWs are made using monomers, such as furfuryl alcohol monomer and phenol–formaldehyde prepolymer, which modify the cell wall. Phenol–formaldehyde prepolymer can be impregnated into thin veneers because of its high viscosity, and the impregnated veneers are glued together to make solid boards called "Impreg" and "Compreg." Cell-wall PMWs have high dimensional stability, weatherability, and resistance to chemicals but are more brittle than the wood from which they are made. Combination monomer formulations, the third type, are designed to make PMWs

with properties intermediate between those of cell-lumen and cell-wall PMWs.

PMWs are typically made by forcing as much liquid monomer into wood as possible, using what is called in the wood preservation industry the "full cell" process. Made this way, cell-lumen PMWs have a density very close to 1.1 g cm^{-3} and cell-wall PMWs ~ 1 g cm^{-3} regardless of the wood from which they were made. Because of this uniform density, PMWs have more uniform piece-to-piece properties than wood.

2.1 Cell-lumen PMWs

The hollow cavities in wood cells makes them susceptible to crushing in side-loading and buckling in longitudinal compressive loading. In cell-lumen PMWs the cavities are filled or nearly filled with polymer. The individual cells are thus reinforced by the polymer in their cavities, dramatically increasing hardness and compressive strength of the wood perpendicular to the grain. Since buckling of cells is the first failure mode in bending, the reinforcing effect of filled cell lumens in these PMWs is noticeable in bending-mode mechanical values. Toughness is also increased because the polymer adds more material to the wood which must be fractured.

The blocking of cell cavities in cell-lumen PMWs greatly retards moisture movement, lowering water vapor diffusion coefficient values, and causes longitudinal and transverse movements to be about equal. Blockage of cell cavities should have a retarding effect on wood-boring insects and marine organisms. Overall swelling in room-temperature water is lowered. Since moisture plays a strong role in weathering, PMWs are more resistant to weathering than wood. As cell cavities are the main route of fungal invasion, filling them with polymer greatly retards decay.

Dyes can be added to the monomer mixture to make colored PMWs, which have the same physical properties, except for color, as those made with clear polymer.

2.2 Cell-wall PMWs

The wood cell walls in cell-wall PMWs are chemically altered. Since the polymer in cell-wall PMWs also partly fills cell lumens, cell-wall PMWs have some of the characteristics of cell-lumen PMWs. The most noticeably changed properties of cell-wall PMWs are those which depend on moisture movement and uptake, including swelling, water vapor diffusion coefficient, and weathering. Wood-destroying organisms do not degrade them and they are highly resistant to acids and bases. However, cell-wall PMWs are more brittle than the parent wood cell wall, which is their chief disadvantage. The dark-brown color of furfuryl alcohol-based PMWs is useful for dark-colored products, but the darkness sometimes limits their usefulness.

2.3 Combination PMWs

Combination PMWs attempt to obtain some of the better properties of both cell-lumen and cell-wall PMW with less of their respective disadvantages. In moisture effects, toughness, and decay resistance they are intermediate.

2.4 Low Polymer Content PMW

There is a class of wood treatment that causes a chemical reaction to occur in the cell wall. These processes use either a small amount of chemical or no chemical and heat. Such material is called "modified wood." Examples that have reached the commercial stage are acetylation and heat treatment.

It has been recently shown that cell-wall PMW with low polymer content has reduced shrinkage and swelling and is resistant to microorganisms. A small amount of monomer or prepolymer reacts with the cell wall to provide protection. Weight gains as low as 15% have been shown to provide increased lifetime in adverse environments. Change in mechanical properties is small because there is so little polymer added. This class of modified wood falls between PMW produced by a full cell monomer impregnation process and modified wood that uses small amounts of chemical or heat. One such process that is being commercialized is called "furfurylation" because it is based on polymerized furfuryl alcohol. Another process under development uses phenol-formaldehyde prepolymers.

Low polymer contents are obtained by using a solution of the monomer or prepolymer in a solvent to impregnate wood with a full cell impregnation process and then causing the solvent to evaporate. Water is the preferred solvent. For furfurylated wood, polymerization can be accomplished by heating before or during drying.

3. Uses of PMWs

Cell-lumen PMWs made from vinyl monomers have been used for many years in flooring, stair parts, and sporting goods. It is called "acrylic-impregnated wood flooring" in industry because it is produced using methyl methacrylate monomer. There is interest in using alternative monomer formulations and curing methods in other products, particularly where hardness, wearability, corrosion resistance, weatherability, decay resistance, moisture resistance, stiffness, color choice, and nontoxicity are desired. Examples include railway ties, highway posts, outdoor furniture, and counter-tops. When sanded and polished, PMWs have a deep luster superior in performance and appearance to most surface coatings. Adding color increases style options. The attractiveness of PMW products has also generated interest

Table 1

mechanical dishwashing. It has potential as a substitute for some dark-colored tropical hardwoods.

Low polymer content PMW is similar in density, mechanical, and handling properties to untreated wood. Therefore, its potential is uses in which wood would be susceptible to decay and attack by insects and marine borers but a high polymer loading would be undesirable or unneeded.

4. Example Properties

Tables 1–4 give the properties of some PMWs and the woods from which they were made.

5. Conclusions

Filling wood with polymers produces a denser material with some properties noticeably enhanced over those of the parent wood. Therefore, making PMWs increases utility for some products for which wood is already used and also increases the applications in which wood can be used. Using low amounts of polymer to modify wood increases its moisture resistance and durability with little density increase or change to other properties.

Polymer Nanocomposites with Metal Dispersions

Polymer composite materials incorporating finely divided metal particles in the nanometer size regime combine a number of attractive aspects. Especially intriguing are the unique properties which can arise from the nanosized metal particles ("*size effects*"), resulting in materials possessing novel catalytic, magnetic, optical, or electronic properties. The polymeric matrix can contribute additional properties, giving, for instance, processibility and/or film-forming qualities. Furthermore, an improved protection from surrounding media (such as air or water vapor), or the prevention of agglomeration and precipitation of the metal particles, is provided.

1. Preparation Methods

The conventional way of obtaining polymer–metal composites involves mechanical routes, such as mixing, blending, or milling of the polymers and the metal components. Another approach involves the generation of the metal nanoparticles *in situ*, that is, in the presence of the polymeric matrix. In this case, well-dispersed metal particles in the nanometer size regime can be obtained. Before the generation of the particles the metal precursor has to be homogeneously incorporated into the polymeric matrix. This can be achieved in solution, by combining diluted solutions of the polymer and the metal precursor prior to reduction in solution (the *dispersion route*). Alternatively, the combined solutions containing the polymer and the metal precursor can be deposited onto a substrate, and the reactions (in most cases thermal or photochemical decompositions) are then performed within the solid film (the *deposition route*). A third approach involves the immersion of the solid polymer in a solution containing the metal precursor and allowing the precursor to diffuse into the swollen polymeric matrix (the *immersion route*). The three preparation routes for the metal–polymer nanocomposite materials are depicted schematically in Fig. 1.

The zerovalent metal colloids are frequently obtained by various wet-chemistry reductions. A large number of reducing agents have been investigated, common examples being tetrahydroborates, hydrazine, or formaldehyde. Nanoparticle features, specifically particle size, size distribution, shape, and morphology, can be strongly influenced by selection of the reducing agent. This is mainly due to the large effect it can have on particle nucleation and growth.

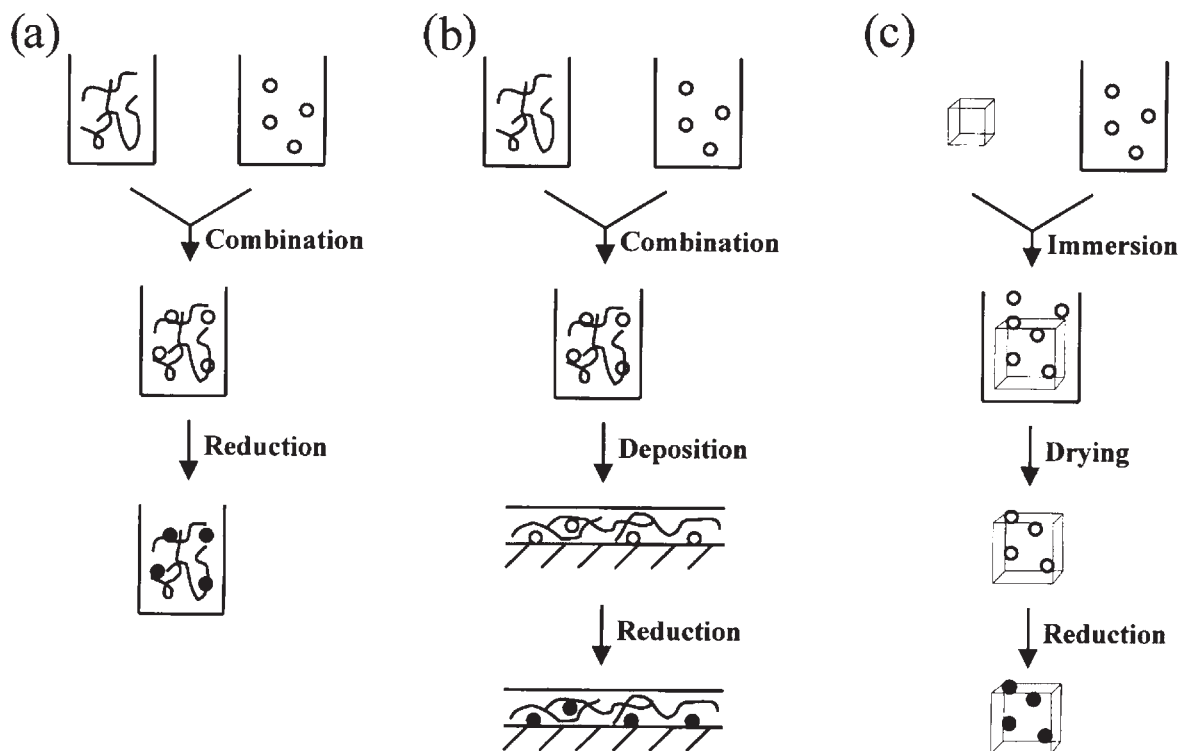
Other preparation methods include thermal decompositions or photolyses of labile metal precursors, photoreductions of light-sensitive precursors, such as silver and gold salts, or evaporation methods in a dispersing medium. The use of high-intensity ultrasound, e.g., for the generation of iron particles in the presence of poly(*N*-vinyl-2-pyrrolidone), has been demonstrated as well (Suslick *et al.* 1996).


Figure 1
Preparation methods for polymer–metal nanocomposite materials: (a) dispersion route, (b) deposition route, and (c) immersion route.

2. Polymeric Matrices

Frequently, the polymers are mainly employed as the dispersing and stabilizing media for the metal nano-particles (*protective polymers*). However, in many cases they can also influence the particle and materials properties directly, and thus provide a means to "fine tune" and tailor the materials for specific applications (*functional polymers*). For instance, since the polymer is present during colloid preparation, it can exert a direct influence on particle nucleation and growth. Such effects are usually due to interactions between certain polymer components and the metal species which are possible during various stages of preparation. For instance, complex or ion pair formation with the metal precursor species can lead to small particle sizes and narrow size distributions.

Figure 2 shows an example of a transmission electron micrograph, of platinum particles generated in the presence of the cationic polyelectrolyte poly(3-chloro-2-hydroxypropyl-2-methacryloxyethyl-dimethyl ammonium chloride) by reduction with potassium tetrahydroborate. In this case the negatively charged metal precursor species hexachloroplatinate, $[PtCl_6]^{2-}$, can form ion pairs with the positively charged ammonium side-groups of the polyelectrolyte. This results in the homogeneous distribution of the metal precursor and control of the nucleation process.

During reduction and particle growth it is also possible that the polymer or its components adsorb on the growing nanoparticle. With preferred adsorption along certain crystal planes this can result in the control of the nanoparticle shapes, by directing the particle growth in certain directions. For instance, the use of various polyacids as protective agents frequently leads to the formation of single-crystal features for gold nanoparticles generated in their presence by a mild reduction method. An example is shown in the transmission electron micrograph of Fig. 3, for gold nanoparticles obtained in the presence of poly(vinyl phosphonic acid) by photoreduction. Several gold nanoparticles exhibiting triangular profiles can be recognized, in addition to fewer hexagonal and pentagonal ones.

After reduction the polymer is responsible for the long-term colloidal stabilization of the metal colloids, which occurs frequently by hydrophobic interactions between hydrophobic segments of the polymer and the surfaces of the metal nanoparticles.

Figure 2
Platinum nanoparticles generated from a dihydrogen hexachloroplatinate (H_2PtCl_6) precursor by reduction with potassium tetrahydroborate in the presence of poly(3-chloro-2-hydroxypropyl-2-methacryloxyethyldimethyl ammonium chloride). Small platinum nanoparticles exhibiting a narrow size distribution are obtained (bar = 22 nm).
Figure 3
Gold nanoparticles generated from a chloroauric acid ($HAuCl_4$) precursor by photoreduction in the presence of poly(vinyl phosphonic acid). Several triangular particle profiles indicating the formation of single crystals can be recognized, in addition to a few hexagonal and pentagonal ones (bar = 245 nm).

A large variety of polymeric matrices are of interest, depending on the applications and the desired properties of the materials. Therefore, the types of polymer investigated cover a broad spectrum, ranging from nonionic homo- and random copolymers, to polyelectrolytes, to block and graft copolymers. The stabilization of the metal nanoparticles is usually based on *steric stabilization* (Bradley 1994), schematically shown in Fig. 4. Steric stabilization, both by homo- and random copolymers, and by block copolymers, is based on two effects: (i) the reduced configurational freedom of the polymer chains in the region between particles causes the lowering of entropy (*entropic effect*), and (ii) the increased concentration of the polymer in the interparticle region results in an increased local activity which is counteracted by solvation (*osmotic effect*) (Bradley 1994). Especially effective is the *electrosteric stabilization* provided by the use of charged polymeric species. In this case the effects for steric stabilization are combined with the electrostatic repulsion stemming from the charged polymers and associated counterions.

The polymers should ideally act as good protective agents for the stabilization of colloidal metal nanoparticles. A quantitative measure of the *protective function* of such agents was first introduced by Zsigmondy as the *gold number* (Zsigmondy 1901). The gold number is defined as the amount of the protective colloid in milligrams which just prevents $10 \, cm^3$ of a red gold sol from changing color to violet upon addition of $1 \, cm^3$ of a 10% aqueous solution of sodium chloride.

Especially when employing polar or aqueous solvents, polymers possessing a relatively hydrophobic backbone (which can interact with the surface of the metal colloids), and hydrophilic side-groups (which can interact with the polar medium and provide the solubility) have been found most suitable. Good

protective abilities have been reported for such polymeric species (Hirai and Toshima 1986). Flexible, water-soluble vinyl polymers, such as poly(*N*-vinyl-2-pyrrolidone) or poly(vinyl alcohol) are currently the most extensively studied representatives. For organic solvent media or thin-film applications, chemically stable and heat-resistant polymers such as poly(methyl methacrylate) or poly(vinylidene fluoride) have been employed.

Block copolymers are of particular interest. Due to the capability of this group of polymers for phase separation and formation of various morphologies, highly versatile composite materials can be developed. Especially promising is the use of spherical micelles as "*nanoreactors*" for the generation of metal nanoparticles (Bronstein *et al*. 1998). This involves the uptake of the metal precursor into the micelle core before reduction, which is usually achieved by complex or ion pair formation. This results in the localization of nanoparticle generation in or near the micelle cores, and can furthermore result in a tremendous size control of the metal nanoparticles, due to the spatial confinement created by the micelles (Bronstein *et al*. 1998).

3. Catalytic Properties

It is anticipated that nanometer-sized metal particles dispersed within a polymeric matrix will be especially useful for the development of tailored catalytic materials. Apart from novel catalytic properties and the possibility of tuning them, these materials are expected to provide additional advantages, such as facilitated handling and storage, and improved recoverability. Due to the small particle sizes, very large surface areas are provided, resulting in highly active catalyst systems.

The materials can be employed in various ways. A considerable amount of work has been performed using colloidal solutions for liquid phase catalytic reactions (Bradley 1994). However, the use as solids or gels is equally intriguing, and such materials have been investigated for catalytic gas phase reactions (Ciebien *et al*. 1998).

Noble metal particles protected by synthetic polymers and their use as catalysts have been already reported by Dunworth and Nord (1954) for the liquid phase hydrogenation of a large variety of unsaturated organic compounds, ranging from nitrobenzenes to unsaturated oils.

Several different catalytic reactions and materials have been explored. Most extensively studied are liquid phase hydrogenations of olefins, cycloalkenes, or acetylenes involving palladium, platinum, or rhodium nanoparticles. As expected, a dependence of the catalytic activity on the particle size has been found; however, the type of polymer is equally important for influencing the catalytic properties.

Area of entropic and osmotic effect
Figure 4
Steric stabilization of metal nanoparticles by polymeric protective agents.

Selectivity in such catalytic reactions has been demonstrated as well, mainly using water-soluble polymers, such as poly(*N*-vinyl-2-pyrrolidone), in liquid phase reactions. It has been generally found that the rate of hydrogenation depends on the structure of the substrates. Thus, the hydrogenation of terminal double bonds (e.g. 1-hexene) is usually preferred to cyclic (for instance, cyclohexene) and internal (e.g., 2-hexene) ones.

Similarly, the selective hydrogenation of acetylenes to olefins, and of dienes to monoenes, has been performed. It has been proposed that the selectivity is achieved by the steric and hydrophobic layer created by the polymer, which surrounds the metal particle and interacts with its surface. Apart from the diffusion of the reactant through the polymeric layer toward the catalyst surface, a certain geometry on the catalyst surface is required for a catalytic reaction to occur. Steric hindrance provided by adsorbed polymeric species prevents such necessary geometrical arrangement of the substrate, especially for certain hindered positions of the double bonds, or for larger reactants. Similarly, the steric hindrance provided by the polymer also decreases the mobility and possible conformations of the reactant close to the catalyst surface. This can be important for selective hydrogenations involving multiple double bonds or triple bonds. The selective hydrogenation of dienes to the corresponding monoenes was furthermore explained by the preferred adsorption of the dienes on the nanocatalyst surface, due to the small particle sizes involved. For particles below about 5 nm a larger number of surface atoms possessing a coordinatively unsaturated state are present, resulting in preferred adsorption of reactants possessing the larger number of double bonds (Hirai *et al.* 1985).

Selective catalytic reactions were also reported for solid film catalyst systems, which could be incorporated into a membrane (Ciebien *et al.* 1998). In these cases gas phase catalytic reactions were examined, involving a mixture of reactants. High catalytic activities and selectivities have been found for the gas phase hydrogenation of 1,3-butadiene, and for a mixture of ethylene and propylene (with the preferred hydrogenation of ethylene).

An option for the design of *intelligent catalyst systems* is provided by differences in the solubility of the polymeric matrix. Chen and Akashi (1997) have shown that variations in the catalytic activities are observed with the change of the solubility of the protective polymer in a respective solvent. With the use of poly(*N*-isopropylacrylamide) a temperature-sensitive polymeric matrix was chosen, which allowed the control of the rate for the liquid phase hydrogenation of allyl alcohol to 1-propanol, simply by changing the temperature of the reaction mixture. The observed differences in catalytic activity are explained by more or less strong adsorption of the polymer on the catalyst surface, due to changes in solubility of the polymer at different temperatures.

The investigations include not only monometallic systems but bimetallic systems as well. These materials are usually prepared by the simultaneous *in situ* reduction of a mixture of the metal precursors in the desired ratio. In this way, catalyst systems containing platinum–rhodium, rhodium–gold, palladium–platinum, platinum–gold, or palladium–gold colloids have been obtained. Usually these bimetallic catalyst nanoparticles exhibit core–shell structures, which have a profound influence on the catalytic properties of the systems. (Yonezawa and Toshima 1995). The catalytic activities and selectivities of these bimetallic systems are often increased in comparison to the respective monometallic catalyst systems, and also depend on the metal ratio and composition.

Especially interesting are results on the application of metal–polymer systems for the Heck reaction (Klingelhöfer *et al.* 1997), which demonstrate the utility of such metal–polymer systems for a large variety of catalytic reactions. The findings have shown the effectiveness of palladium colloids in block copolymer micelles for catalyzing the carbon–carbon coupling of aryl halides with alkenes (Heck reaction). A dependence of the catalytic properties on the size of the block copolymer micelles has been found, which allows further catalyst modifications by the choice of the polymer block lengths and types.

The catalytic properties of polymer-protected noble metal nanoparticles are furthermore significant for the evolution of hydrogen from water induced by visible light. This photochemical process offers a very attractive possibility for the conversion of solar energy into chemical energy, and therefore is of profound technological importance (Grätzel 1981, Bradley 1994). Usually, this process involves multicomponent systems containing (i) a photosensitizer which is excited by visible light, (ii) an electron relay system (consisting of an electron donor and an electron mediator), and (iii) a redox catalyst. The redox catalyst system is involved in the catalytic reduction of water, resulting in the generation of hydrogen. Stabilized noble metal colloids, in particular platinum colloids or bimetallic species (such as gold–platinum), have been found especially efficient as redox catalyst systems.

4. Magnetic Properties

Hybrid materials incorporating particles possessing magnetic properties are very promising for a variety of applications, including information storage/magnetic recording, ferrofluids, various biomedical applications (such as diagnostic systems), or the improvement of the mechanical properties of materials.

The most thoroughly investigated metals are iron, nickel, and cobalt; however, a larger amount of work

is available on magnetic materials involving metal oxides, such as iron oxides (Tannenbaum *et al.* 1985).

A common feature of these less-noble zerovalent metal colloids is their sensitivity toward oxidation in an ambient atmosphere. Therefore, their preparation is mostly performed in an inert atmosphere, and the oxidation of the outer layer of the particles occurs in most cases immediately upon contact with air. Usually, a core–shell structure is formed, possessing a metal core and a thin oxide layer. The oxidation process can be followed by the change of the magnetic properties of the materials (Griffiths *et al.* 1979).

The most prominent property of nanometer-sized ferromagnetic or ferrimagnetic metal particles is their *superparamagnetic behavior*, which is observed below a critical size of the particles (usually about 10 nm). Therefore these systems are also interesting as models of small magnetic particles. Below the critical size it is energetically favorable for a particle to contain a single magnetic domain. For such small particles the magnetic energy becomes comparable to the thermal energy, and the typical bulk magnetic characteristics, such as retentivity, coercivity and hysteresis, at room temperature disappear. Upon decrease of the temperature such superparamagnetic particles reach a *blocking temperature* at very low temperatures where their magnetic moment is fixed, and a hysteresis in the magnetization curve, due to magnetic anisotropy, appears (Ziolo *et al.* 1992, Sohn and Cohen 1997).

A general observation is made for fluids, such as colloidal solutions of nanometer-sized magnetic particles. They exhibit no anisotropic effects, and superparamagnetic behavior is usually found. This is caused by the ability of the colloidal metal particles to rotate and align under the application of a magnetic field. For sufficiently large particle sizes the magnetic dipole–dipole interaction energy becomes larger than the thermal energy, and a tendency of the particles to form linear chains is observed (Thomas 1966). For instance, for cobalt, such chain formation starts at particle sizes of about 10 nm. In colloidal solutions or at temperatures above melting of a polymeric matrix, the particles have sufficient mobility to allow chain formation to proceed to a high degree.

Such behavior has been employed for the alignment of magnetic metal nanoparticles dispersed in polymeric matrices hardened under the application of a magnetic field. This has caused formation of a "chain structure" of the ferromagnetic particles, resulting in anisotropic electrical conductivities of the metal-filled polymeric materials (Gul' and Golubeva 1967).

The incorporation of magnetic metal particles into polymers can furthermore be of interest for improving the mechanical properties of such composite materials. A variety of materials, mainly based on oxides, has been explored (Chow and Penwell 1986). Homogeneously dispersed palladium nanoparticles of about 10–20 Å diameter have been used as fillers in poly(methyl methacrylate), resulting in reinforcement and the increase of the elastic modulus (Nakano *et al.* 1993). It has been shown that the mechanical properties can increase remarkably with a decrease in the filler particle size. The incorporation of metallic species can also contribute to the cross-linking of the polymeric matrix. For instance, poly(vinylidene fluoride) has been cross-linked during the decomposition of iron carbonyls. This was apparent from a change in the polymer solubility properties and from mechanical measurements as well (Reich and Goldberg 1983).

The incorporation of metallic filler particles is interesting, especially when combined with magnetic properties, since these can influence the particle orientation and alignment under the application of a magnetic field. Furthermore, the application of a magnetic field can counter particle-settling due to gravity, which is especially important during solvent removal (Kusy 1986). In this way, highly homogeneous metal–polymer materials exhibiting improved mechanical properties could be obtained.

5. Summary

Polymer composite materials containing dispersed nanometer-sized metal particles can be readily prepared and are useful for a variety of applications. The unique properties of these materials, which mainly arise from the nanometer size dimensions, are promising not only for catalytically active and magnetic systems: the exploration of their optical and electronic properties is equally significant, and could lead to the development of intriguing novel materials. The presence of the polymeric matrix adds to the versatility by providing additional functions, such as the processibility or solubility of the composites. It can also profoundly influence the materials properties. This allows the development of polymer–metal nanocomposite materials which can be tailored for specific applications and needs.

Polymer Transcrystallinity in Composites

Transcrystallinity (TC) in composites can give rise to some of the most spectacular microstructures found in materials science and technology. Two examples of transcrystalline structures around aramid fibers in polypropylene, a thick TC layer in an isothermally crystallized specimen and a fine TC region for a fast-cooled specimen, are shown in Fig. 1. Even though TC layers have well-defined morphologies, it is a matter of some debate as to whether or not such microstructures have any effect upon the resulting properties of the fiber-reinforced composite. The interest in TC stems from the possible effects it could have on the interface between fiber and matrix in fiber-reinforced composites. Could TC at the interface enhance fiber/matrix adhesion? Could it form a layer around the fiber in which the matrix properties are slightly different from the bulk? If this were the case could it protect the fiber from bulk residual stresses, or perhaps it could increase the stress transfer to the fiber from the matrix? This article first defines and describes TC and then addresses the effect it has upon the fiber/matrix interface and composite properties.

1. Definition of Transcrystallinity

TC can be defined as a restricted crystalline growth from many closely spaced heterogeneous nuclei. The growth front must be a line, plane, or smooth surface parallel to the substrate initiating the nuclei. It has been proposed that geometric considerations determine that for a series of nuclei to produce TC the distance between the nuclei should be one-fifth, or less, of the distance from the nuclei to the growth front (Schoolenberg and van Rooyen 1993).

Another restricted crystalline growth resulting from many closely spaced nuclei, but which is not always differentiated from TC (Thomason and van Rooyen 1992a), is the cylindrite (Varga and Karger-Kocsis 1993). Though sometimes optically indistinguishable from TC, cylindrites are defined as being nucleated homogeneously, or nucleated by the imposition of shear at the interface. Cylindrites are created in polypropylene by inducing shear between substrate and melt, thus the homogeneous nuclei from which the cylindrite grows may be nucleated heterogeneously on the substrate.

A third way in which to generate a restricted crystalline growth from many closely spaced nuclei is to use a chemical additive at the interface to nucleate the matrix (Varga and Karger-Kocsis 1993). No specific name has been ascribed to the resulting structure.

2. Morphology

2.1 Transcrystallinity—Orientation

TC in polymers is a result of a semicrystalline oriented growth process (Folkes 1995). The orientation of the lamellas within TC (Waddon *et al.* 1987) is important because some physical properties, such as thermal expansion coefficients or moduli, could depend on lamella orientation. Stern *et al.* (1997)
Figure 1
Optical micrographs of TC in an aramid/polypropylene single fiber model composite. (a) Specimen crystallized isothermally at 130 °C to give a thick transcrystalline layer, (b) specimen cooled rapidly to give a narrow transcrystalline layer (fiber diameter 12 μm).

used x-ray diffraction on polyethylene TC and found that the morphology of the TC was dependent on the thermal history and identical, except for orientation, to that of the surrounding spherulites.

2.2 Cylindrites

Not all publications differentiate between TC and cylindrites. Some call shear-induced TC "transcrystallinity" (Thomason and van Rooyen 1992a,1992b), some avoid calling it TC and some, notably those written by Varga and Karger-Kocsis (1993), make a point of calling naturally induced structures, TC and shear-induced structures, cylindrites.

2.3 Kinetics

During the process of analysis of TC, the growth rate of TC had to be compared with that of spherulites in comparable circumstances. It has been found that the linear growth rate of TC is the same as the radial spherulite growth rate under the same conditions (Waddon *et al.* 1987).

3. Factors Affecting the Production of Transcrystallinity

3.1 Thermal Conditions

It is found that the temperature, T_m, at which the matrix is melted, the crystallization temperature T_c, the cooling rate, and the differential contraction providing orientation, all contribute to the presence or lack of TC in a composite.

Avella *et al.* (1992) found that by increasing the melt temperature and time in melt, the nucleation density on Kevlar fibers decreases for polypropylene. They also showed that by increasing T_c for

polypropylene the production of TC becomes less likely, and the interface becomes increasingly spherulitic. Thomason and van Rooyen (1992a) measured the growth rate of polypropylene TC with increasing T_c and found it to be comparable with the equivalent spherulite growth.

Faster cooling rates are found to be favorable to the formation of TC in polypropylene (Table 1). Thomason and van Rooyen (1992b) systematically compared the morphologies of single-fiber polypropylene composites produced using glass, carbon, and aramid fibers. Given a sufficiently high cooling rate ($100\,K\,min^{-1}$) even glass fibers induced TC (see Table 1).

An increasing probability of TC with increased cooling rate is due to the shear in the melt against the fiber induced by their different thermal contractions during cooling. Thomason and van Rooyen (1992a, 1992b) tested this assertion by comparing the morphology of a wide variety of fiber/polypropylene single fiber composites at one given thermal history (Table 2). The ability to nucleate TC was compared to the axial thermal expansion coefficients of the fibers. For the given thermal history, all the fibers (four nylon, two aramid, and three high modulus carbon fiber) with axial thermal coefficients, α, less than $-0.4 \times 10^{-6}\,K^{-1}$ produced TC. Fibers with larger axial thermal coefficients (high strength carbon, E-glass, and alumina) did not produce TC. The axial thermal coefficient of the polypropylene is $+300 \times 10^{-6}\,K^{-1}$, thus it was confirmed that the greater difference caused TC.

3.2 Surface Topology

The nucleation of TC has often been ascribed to the surface topology or characteristics of the fiber. This could be due to the melt nucleating against the fiber because the unit cells match sufficiently well for epitaxial growth to occur (Chen and Hsaio 1992) or because the fiber is sufficiently rough for the melt to be mechanically caught and nucleate there (Avella *et al.* 1992). The wide variety of matrices and fibers in which TC can be found, however, implies that a similarity in the crystallographic unit cell of fiber and

matrix is not necessary for TC to occur. In fact, Thomason and van Rooyen (1992a) produced TC in isotactic polypropylene (iPP) on a glass fiber (Table 1), which is amorphous, thus showing that crystallinity in the substrate is not even necessary.

Nonuniform surface topology is also known to generate TC as it is thought that the molecules in the melt may become aligned in cracks on the fiber surface. Avella *et al.* (1992) also suggested that TC nucleated on unmelted fragments of polymer nuclei hidden in the surface flaws of the fiber surface. Chen and Hsiao (1992), on explaining why high-modulus (HM) carbon fibers nucleate TC in a number of aromatic polymers, whereas high-strength (HS) carbon fibers do not, proposed that the larger graphite planes in HM fibers were the determining factors in inducing TC. Thomason and van Rooyen (1992a) compared several HM and HS carbon fibers for their ability to produce TC in polypropylene (Table 2). They found, however, that HS carbon fibers have higher axial thermal expansion coefficients than HM ones and are thus less likely to produce TC.

3.3 Molecular Weight

As the molecular weight of a polypropylene melt is increased, the tendency to transcrystallize is reduced. Thomason and van Rooyen (1992a) studied the effect of molecular weight on TC in polypropylene and concluded that higher molecular weights allows TC to be created at higher crystallization temperatures. This is explained by the reduced ability of a longer chain melt molecule to relax from an oriented state caused by the difference in axial thermal expansion coefficients.

3.4 Other Factors

A number of other factors have been associated with the formation of TC and several have been discounted. For example, the surface energy of the substrate per melt pair does not appear to control the nucleating ability of the substrate (Chen and Hsiao 1992).

Factors which are known to affect the nucleation process include the commercial source of a polymer, and the presence and nature of a coating or matrix nucleant on the fiber or in the matrix (Chen and Hsiao 1992). Thomason and van Rooyen (1992a, 1992b), after considering thermal history, axial thermal expansion coefficients, and molecular weight, also noted that TC did not form over the whole length of shorter fibers (since the center would not shear the melt sufficiently).

Strain in a molten polymer can cause row nucleation in the bulk melt by orientation of the molecules. Shearing a substrate within a melt can also cause multiple nucleation at the interface followed by oriented restricted growth (which is often called TC).

4. Physical Properties

There is accumulated evidence that the Young's modulus of TC material is higher than that of the bulk. Klein *et al.* (1995) proved experimentally (using microtomed dynamic mechanical thermal analysis specimens) that this was so for nylon 6,6 TC by comparing TC and bulk polymer made under the same conditions. Folkes and Hardwick (1987) found that polypropylene TC had a greater Young's modulus and tensile yield strength than the spherulitic morphology and that the flexural modulus and strength of TC material was a little higher than that for the spherulitic samples. The two morphologies that were compared were prepared using different thermal histories, however, and it is known that higher crystallinity can produce a higher flexural modulus, strength, and fatigue life.

Teishev and Marom (1995) found that the transverse tensile strength of PE/PE composites was smaller than expected. From scanning electron microscope (SEM) analysis of the failed composites they attribute this to weaknesses present at TC growth front interfaces. They also found that the longitudinal tensile strength appeared to be unaffected by TC.

Tregub *et al.* (1994) found that a carbon fiber PEEK composite was stronger in the longitudinal direction than was expected. It was suggested that the TC present reduced the residual stresses, thus strengthening the composite. Klein *et al.* (1995) postulated that an alignment of crystallites would reduce the thermal expansivity mismatch between fiber and matrix, and thus reduce the thermal stresses exerted on the fiber.

5. Adhesion Properties of Transcrystalline Materials to Substrates

5.1 Residual Stresses

High levels of residual stress can be induced in the fibers when TC structures are prepared (Heppenstall-Butler *et al.* 1996). This is because the microstructures are prepared at elevated temperatures and cooled to room temperature. The large difference in thermal expansion coefficient between the fiber and matrix (Table 2) and the volume shrinkage of the matrix on crystallization, lead to residual compression in the fibers. This is particularly apparent in single-fiber model composite specimens (e.g., by kink band formation as seen in Fig. 1(b)) where the fibers may even fail in compression due to matrix shrinkage (Heppenstall-Butler *et al.* 1996). Hence, care must be taken in extrapolating the behavior of single-fiber model composites to that of high volume fraction systems.

5.2 Chemical Modification of the Interface

The effect of chemicals at the fiber/matrix interface upon TC has been found to depend on the chemicals

and combination used. It is generally found that the interface is improved by the presence of silanes even though they can reduce the nucleating ability of the substrate and, hence, the appearance of the TC in the material. Without a coating the adhesion may be poor even when TC is present.

5.3 Shear

There have been a number of attempts to determine the shear strength of the interface in model composites with transcrystalline morphologies. The behavior depends upon the fiber/matrix system under consideration but, in general, large improvements in interfacial strength are not found with the presence of TC. The best way to determine the strength of the interface is to prepare single fiber TC pull-out specimens and then measure the stress required to pull the fiber out. Figure 2 shows the behavior of a single aramid fiber being pulled out of a TC polypropylene matrix. The point-to-point variation of stress in the fiber was determined from stress-induced Raman band shifts (Heppenstall-Butler *et al.* 1996). The strength of the interface in the aramid/polypropylene system was found to be about 10 MPa and independent of the presence or absence of TC.

5.4 Failure Modes in Samples with Transcrystallinity

The position of failure in a sample containing TC should indicate the weakest constituent of the composite which may be at one of four positions as indicated in Fig. 3. Waddon *et al.* (1987) found that failure in carbon-fiber/PPS films occurs between the TC and the spherulites rather than inside the TC due to boundary structural weakness (Fig. 3, position 3). In contrast, Tregub *et al.* (1994), using multi-fiber carbon-fiber/PEEK composites found that fracture took place through the TC region (Fig. 3, position 2).

Yue and Cheung (1993) presented SEMs of glass fibers after pull-out from polypropylene. These showed lumps of nuclei still adhered to the fiber surrounded by a fine array of radiating lines. From this they concluded that the nuclei adhered better to the fiber than the rest of the spherulite did, and thus suggested that TC would adhere better than a spherulitic morphology since there would be more nuclei at the surface.

Another TC failure process obtained after single fiber fragmentation was found by Wagner *et al.* (1993). They describe failure by *treeing*, a process where a crack propagates from the fiber perpendicularly up through the TC layer and continues into the spherulites beyond following the radial lamellas. On reaching the center the crack splays out down various radial paths (Fig. 3).
Figure 2
Pull-out of an aramid fiber from a polypropylene matrix, showing variation of fiber stress with distance along the fiber (position where the fiber enters the matrix, $x = 0$) at different level of applied stress. The specimen was cooled rapidly to give a microstructure similar to that shown in Fig 1(b). The level of residual stress in the fiber is indicated.
Figure 3
Schematic representations of possible positions of failure. (1) At the fiber/matrix interface, (2) in the TC material, (3) at the TC/spherulitic interface, and (4) in the bulk spherulitic material.

6. Concluding Remarks

To form TC in any fiber/matrix pair it is not necessary for the fiber to be crystalline. The formation of TC in a specific fiber/matrix pair is facilitated by large fiber/matrix thermal expansion coefficient mismatches, high cooling rates, and is molecular weight dependent. Inducing shear in the melt by pulling the fiber always results in a TC-like structure that is often referred to as a *cylindrite*.

TC has been found to possess a morphology similar to that of the bulk of the sample, but with different local molecular and lamellar orientation. The thermal expansion coefficient of TC has been found to vary parallel and perpendicular to the fiber. It is

also found that the elastic modulus of TC samples is higher than that of the bulk whereas the viscoelastic damping modulus is lower than that in the bulk. The physical properties of the matrices are found to vary with thermal history.

Most of the investigations undertaken so far into the effect of TC upon composites have employed single-fiber model specimens. The presence of TC in such test-pieces is found to have only a marginal effect upon the strength of the fiber/matrix interface. It remains to be seen if the findings upon single-fiber model composite specimens can be translated to high volume fraction composites where interfiber distances are finite and the behavior is dominated by fiber rather than matrix properties.

Polymer-based Nanocomposites by Sol–Gel Routes, Applications of

The fabrication of inorganic nanoparticles by chemical means has become an interesting route to prepare many kinds of nanostructured materials. For example, sol–gel techniques, which have been used for over 60 years for making inorganic materials, can be considered as an interesting basis for the synthesis of nanoparticles, since sols as colloidal systems in general are composed of stabilized nanoparticles in solution. With a few exceptions, for example, SiO_2 sols prepared from alkoxide precursors at low pH-values, most sols are of particulate nature. These sols can be not only prepared from alkoxide precursors through the sol–gel process but through many precipitation reactions carried out outside of the point of zero charge. In these regimes, depending on pH and the chemical nature of the surface, particles absorb ions and develop surface charges which prevent aggregation, precipitation, or gel formation. In Fig. 1, some principles for the stabilization of sols are shown. Whereas in aqueous solutions most of the precipitates carry surface groupings, for example OH-groups, which tend to react with each other by the formation of chemical or hydrogen bonds, the presence of surface modifiers which do not have groupings to form
Figure 1
Various types of stabilization of colloids.

strong bonds can prevent irreversible aggregation even at the point of zero charge. In Fig. 1, several types of surface modification are shown. The electrostatic stabilization is very effective in diluted sols and outside of the point of zero charge. In this case sols, stable over months, can be prepared. In the case of electrosteric stabilization, a surface is covered with groupings not able to form strong bonds to the next colloid, so that only van der Waals or weak polar forces are effective. In this case the aggregation leads to weak aggregates, which can be redispersed under appropriate conditions. The formation of strong and weak bonds is schematically shown in Fig. 2.

The preparation of surface-modified colloids is not only of interest for stabilization, but also for generating the desired reactivities of the colloids. In Fig. 3 several possibilities are shown. Acids (1) and bases (4) can be used to tailor an appropriate zeta-potential or to carry out condensation reactions to anhydrides, acid chlorides or acids. (2) and (3) (epoxides or methacrylates), represent polymerizable or polycondensable surface groupings which can be used for further reaction, for example, coupling reactions, but also for polymerizing the nanoparticles together with organic monomers in order to fabricate so-called polymer

matrix nanocomposites. The alkyl group (5) represents a class of nonreactive groupings which can be used for reducing the particle-to-particle interaction, and also to adapt polar nanoparticles to nonpolar matrices. The combination of these surface-modifying principles with the inorganic nanoparticles' properties leads to a wide range of possible new composite materials. Nanoparticles by themselves have interesting properties, as shown in Tables 1 and 2. In Table 1, basic properties mainly resulting from the particle size are shown. One of the very interesting properties is the large surface area, especially together with matrix materials, since interfaces, for example, between inorganic surfaces and organic polymers in general have a structure different from the polymer matrix structure.

In Table 2, some examples for the relations between colloid types, functional groupings, materials, and basic properties are shown.

1. Fabrication of Nanoparticles

This is based on the rules of colloidal chemistry in connection with surface modifying agents, which at the same time act as thermodynamic stabilizers, and which not only prevent the reaction of the particles with each other, but also keep the particle size at a desired level during the colloid formation process (for example, precipitation). This approach has been successfully used for making various kinds of nanoparticles (Schmidt 1996, Schmidt and Nonninger 1998). This is schematically shown in Fig. 4. The figure also shows that by using small organic molecules, the volume fraction of the coating is rather low compared to the nanoparticle size. If the modifying agent is bifunctional, that means that not only is it linked to the surface by chemical bonds, as shown in Fig. 4 for complex bonds on oxidic particles by β-diketones, but the surface modification leads to the desired reactivities on the particle surface. In addition to this, and as also shown by Schmidt (1996) and Schmidt and Nonninger (1998), the desired crystallinity of the

particles can be obtained by subsequent hydrothermal treatment. This means that using the chemical approach with appropriate surface modifiers, nanoparticles with desired surface reactivities can be produced and used as a basis for the nanocomposite fabrication. If these particles are combined with or dispersed in appropriate matrices, for example, in polymers, organic monomers or other hybrid sol–gel precursors such as organic alkoxy silanes, nanocomposites can be fabricated by many different routes. If the nanoparticles are produced within a monomeric sol–gel or polymer precursor system, this is called the *in situ* route. If the nanoparticles are produced separately, isolated and then redispersed in appropriate

matrix systems, it is called the *separate processing* route. These nanoparticles have also been introduced into a polymeric matrix by compounding processes, and these processes have been already successfully applied to transparent coatings or bulk materials (R. Nonninger: personal communication, 1998).

In the following section, a series of examples is given showing how the nanoparticle route can be used for various material developments.

2. Optical Applications

2.1 Smart Materials (*Photochromics, Electrochromics, Luminescence*)

So-called smart materials are causing more and more industrial interest for many reasons. Photochromic materials are very common in the field of bulk glass, e.g., for ophthalmic glasses. A new approach in this field is photochromic nanocomposite hard coatings as wet coating systems, using photochromic dyes. The photochromic effect of common dyes like spirooxazines or spiropyrans is based on a change of the conformation, which changes the size of the organic π-bond systems and hence the electron energy levels of the dye molecule. With an increase in size of the π-system, the energy levels for the excitation of the electrons decrease in number. This means that the absorption may be shifted from the UV into the

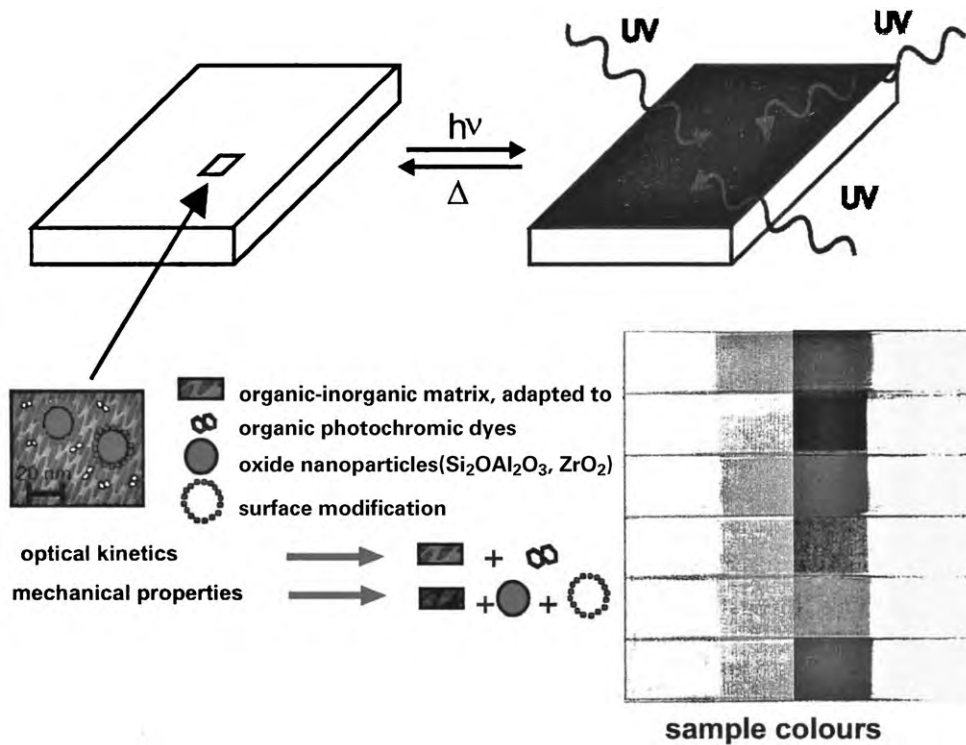
677


Figure 5
Photochromic coatings on glass without and with UV-irradiation (after Hou *et al*. 1994).

visible. This conformation change requires a soft "host matrix system," such as polymers with sufficient free volume. The more rigid the matrix system is, the more difficult it is for the molecule to change conformation. In order to use photochromic dyes in coatings, however, a high abrasion resistance is required. This in general can be obtained only by a very rigid matrix. In order to overcome these contradictory requirements, a nanocomposite coating material has been developed with ceramic nanoparticles—for example, from alumina or zirconia—which, when well dispersed in the matrix so as to obtain a good scratch resistance (where a soft matrix system made from polyacrylic components is synthesized in the voids between the nanoparticles), now provides sufficient flexibility for the photochromic dyes. The aim of the development is a photochromic coating material based on organic photochromic dyes with response times of seconds, which can be applied on transparent substrates (glass, polymers) or on nontransparent substrates (ceramics, polymers, paper) for the preparation of coatings with a thickness of 5–50 µm. The method is based on the incorporation of spirooxazines, pyrans, and fulgids into the matrix of an organic–inorganic composite, which is prepared by a specially developed sol–gel process as described elsewhere (Fig. 5; Hou *et al*. 1994).

The result of this development is that by using UV radiation, a darkening of from 90% to 10% transmission can be reached. By further modification of the components of the matrix, the kinetic behavior of the photochromic dye can be adapted to different applications: glasses, pane glass, plastic foils (transparent and opaque), paper, ceramics, etc. The half-life times for darkening and fading ($t_{0.5}$) can be established anywhere between 2 s and 10 min. Due to the modularity of the network structure, different photochromic dyes can be integrated, resulting in neutral tints (gray or brown).

One of the superior features of nanoparticles and transparent matrices is that Raleigh scattering can be neglected, if particle size and refractive index differences are appropriate. This is shown in Eqn. (1):

$$\gamma_{ext} = 32\pi^4 c \frac{n_p^2 - n_0^2}{n_p^2 + 2n_0^2} \frac{r^3}{\lambda^4} \tag{1}$$

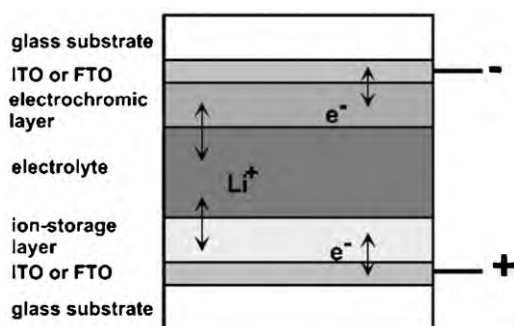
where n_p is the refractive index, n_0 is the reflective index of the matrix, r is the particle radius, γ is the scattering loss, λ is the wavelength, and c is a constant. From this equation a general rule can be deduced, which shows that if the particle size is below 1/20 of the wavelength, Raleigh scattering becomes


Figure 6
Schematic layout of an electrochromic (EC) device.

very low and can be neglected in most cases, at least in thin films. From this point of view, nanocomposites or nanoparticulate thin films can be used for optical purposes. The second very interesting feature is that the physical, optical, or electronic properties connected to the crystalline or inorganic structure of a nanoparticle are still present, and can be used for obtaining specific properties.

A very interesting example of nanoparticle technology is smart windows or electrochromic windows, based on tungsten oxide. In Fig. 6, the multilayer system of an electrochromic cell is shown. The glass substrates are coated with transparent electronic layers, made from for example ITO or FTO, which are in direct contact with the electrochromic layer, which is made from tungsten oxide, vanadium oxide, molybdenum oxide, niobium oxide, or nickel oxide. Due to an electrochemical reduction, mixtures of different oxidation states can be obtained, leading to high absorption in the visible range. For compensating the charges, protons or lithium atoms have to be diffused into the electrochromic layers. On the other side of the cell a similar process takes place which, in general, does not lead to a change of the visible spectrum. In this case oxides like those of cerium or titanium can be used. This layer also has to show a certain storage capacity for the charge-compensating ions like protons or lithium. In order to avoid electronic shortcuts, an electronically isolating layer, having a high ionic conducting capacity, has to be used. For this reason, polymers with a sufficient solubility for lithium sols or acids are used (for example polyethylene oxide). These systems have been stabilized by the introduction of nanoparticles, for example zirconia. At their surfaces, lithium or protonic transport takes place advantageously. Moreover, the nanoparticles help to improve the mechanical properties of these materials, because at the same time they have to be used as adhesives for gluing the layered systems together. It was demonstrated (Munro *et al.* 1998) that if the conductivity of the lithium containing nanocomposites reaches the region of

about 10^{-4} S, and the electronic conductivity in the ceria, titania, and tungsten oxide system can be kept low, the switching behavior of such cells based on nanotechnologies is almost independent of the thickness of the ionic conductor, and systems up to 1 mm in thickness can be used.

This is very important for the production of large areas, since the planarity of large glass panes is very difficult to establish at the micrometer level. The chemical nanotechnology allows the production of cheap devices, because it has become possible to produce large area wet coatings, of optical quality, with very reproducible film thicknesses (Mennig *et al.* 1998b). The reversible variation in transmission of such cells reaches 70% (550 nm, bleached state) down to 21–25% (coloured state), with switching times t_{80} (t_{80} = time taken for 80% of transmission change): of 120 s (coloration), 70 s (bleaching) for EC-cells of $50 \times 80 \, \text{cm}^2$. The benefits of this system are more comfort and energy saving in the architectural and automotive areas (e.g., air-conditioning costs in summer) and privacy effects.

By segmenting such an electrochromic device into pixels, and with an appropriate computer-controlled voltage supply, the fabrication of electrochromic displays becomes possible.

This opens up the possibility of the fabrication of large-area monochromatic displays between panes of glass, for example for displaying special sales offers in shop windows. Luminescent nanoparticles, such as those based on doped Eu^{3+}, have been developed, because there is a demand in industry for materials with high specific emission values. Interesting applications include photoluminescent displays, security tags on paper, plastic, luminescent textiles, etc. This development leads to materials in the form of redispersable nanoscaled powder, sols, coatings, and bulk materials, which present high luminescent emission under UV excitation. The main issue is the synthesis of rare-earth luminescent complexes (Eu^{3+}, Tb^{3+}, etc.), which perform the so-called antenna effect. These complexes can be incorporated into organic modified sols or attached on redispersable crystalline nanopowders. By this procedure, luminescent transparent coatings have been developed with thicknesses of up to 3 μm deposited on various glasses, polycarbonate, paper, or textiles.

2.2 Micropatterned Coatings

The fabrication of patterns in films is an interesting technology for many applications, such as the fabrication of holograms, the storage of information, the fabrication of microlens arrays, or even the microelectronic patterning and surface mounting device fabrication processes in microelectronics. Several basic techniques have to be distinguished. Etching techniques are very common in microelectronics. Patterning techniques using embossing

require moldable systems, for example thermoplastic polymers. Embossing of sol–gel layers, as shown by Lukosz and Tiefenthaler (1983) and Tohge *et al.* (1994), requires very high pressures. In most cases, there are serious restrictions on using thermoplastic polymers, since it is difficult to obtain high precision patterns, due to the relaxation of the patterns as long as the polymer temperature is above the glass transition temperature T_g; because of the limited film thicknesses, only patterns with a very low step height are possible. This means that it is very difficult to produce precise structures from pure inorganic systems like SiO_2, TiO_2, or glasses. In addition to this, polymers have low mechanical resistivity—for example, scratch resistance is poor.

The micropatterning of inorganic–organic nanocomposites in combination with UV-curing led to a process which allows the fabrication of micropatterns in a hard coating type of material, with a UV-curing during the embossing step. The curing is based on the use of methacryloxysilane, which can be photo-cross-linked. Microlens arrays and refractive gratings have been developed using this approach. Another approach is based on the fact that SiO_2 nanoparticles coated with methyl groupings lead to gels with a remarkably increased relaxation behavior, and s film thicknesses of $20\,\mu m$ and more are possible (Mennig *et al.* 1992). Due to the softness of these gels, they can be patterned with silicone rubber replicas and even curved shapes can be embossed. After embossing and densification at $500\,°C$, a transformation of the organically modified SiO_2 sol into almost pure SiO_2 glass (98% of the theoretical density) takes place. In Fig. 7(a), a profile of an embossed nanomer microlens is shown; in Fig. 7(b), a pyramidal structure of SiO_2 on glass as a light trap for the collection of light in solar collectors.

Through the application of a two-wave mixing process, holographic techniques have been developed. In this case, the intensity modulation of the incident light is used in a nanoparticle-containing film, with a nanoparticle surface modified with polymerizable groupings (Judeinstein *et al.* 1997). Before this, an inorganic backbone was built up in the system by hydrolysis and condensation, but care must be taken

that no cross-linking of the nanoparticles to the system takes place. In the highly irradiated zones, the polymerizable nanoparticles are consumed by the polymerization process, and from the darker zones unpolymerized nanoparticles diffuse into the irradiated zones. By this technique an increase in concentration of nanoparticles in the irradiated zones takes place. If the nanoparticles show a higher refractive index than the matrix—for example, if zirconia or tantalum oxide nanoparticles are used—then volume phase holograms can be prepared. Meanwhile, the fabrication of the holograms by a two-way fixing process can be performed within seconds, due to the high diffusion rates of the nanoparticles in the matrix. After the holographic process is finished, a fixation of the matrix by full-area photopolymerization takes place. In Fig. 8, some samples of the fabrication of such gratings are shown (diffraction gratings, Fresnel lenses). Alternatively, instead of being fixed after the holographic process, the gratings can be developed by dissolving the unradiated areas. An EDX-pattern of a holographically fabricated refractive grating is also shown in Fig. 8. The concentration fluctuation of the tantalum oxide as a function of the two-wave mixing irradiation is clearly demonstrated.

As a variation of these "moving nanoparticles," the nanoparticles also can be set into motion by electric fields, if the appropriate zeta potential is established in a non-fully-cross-linked matrix. Using this approach, gradient lenses up to $5\,cm$ in diameter have been developed (Oliveira *et al.* 1996).

2.3 Interference Coatings

The fabrication of interference coatings by sol–gel techniques on glass is very common for many purposes, for example anti-reflective coatings (AMIRAN 1998), and interference coatings on halogen bulbs. However, most of the coatings are produced by physical techniques like sputtering or waver condensation methods (such as for eyeglass lenses). This is because the technology for mass fabrication is considered to be more difficult than for physical techniques. One of the drawbacks of sol–gel techniques is that, in general, each coated layer has to be densified and prefired before the next layer can be employed. This means that a lot of time and energy has to be used in making multilayer coatings. For that reason, a technology has been developed which takes advantage of polymerizable nanoparticles, surface modified with methacrylic or epoxy groupings. Coatings fabricated from these sols can be photopolymerized a very short time after dipping or spraying, and are then insoluble against the next coating step. After the fabrication of an appropriate set of green layers, a one-step firing process can be employed on glass, which leads to multilayered interference systems. This is schematically shown in Fig. 9 with SiO_2 and TiO_2.
Figure 7
Lenses, produced by micropattering of SiO_2 films.
Figure 8

Figure 9
Scheme of the fabrication of interference layers by polymerizable nanoparticles (after Schmidt 1999).

Using this approach, a technology has been developed to produce anti-reflective layers for automotive glazings (Mennig *et al*. 1999). The technology can be employed also on plastics, as long as the photocuring process only is used. Due to the high package density of the "modified gels" (up to 90% of the theoretical density after UV-radiation), interference layers have also been obtained alternatively by using TiO_2 and SiO_2. Such coatings can be produced also on conventional hard coatings, and then show extremely high abrasion resistance. It can be shown also that the theoretical curves fit very well with the curves achieved in practice, by using the Landau–Lewich approach for calculating layer thicknesses. Taking into account the organic content, the calculations could be used for fired coatings on glass. This means that it is possible to design interference systems.

By using thicker layers, IR reflective coatings have been fabricated, which is an interesting approach for IR-shielding on plastics: for example, in the freezing industry. In this connection, it has to be mentioned that the dispersion of ITO nanoparticles, fabricated according to the processes described above, also leads to highly efficient IR-shielding coatings.

Using the nanocomposite approach, another type of anti-reflective coating was developed by the so-called "moth eye" process in nanomer surfaces combined with perfluorinated surfaces. The moth eye process leads to long-lasting anti-reflective systems only if the surface is equipped with easy-to-clean properties. Otherwise, the roughness in the nanometer range of the surface leads to dirt absorption filling out the voids and reducing the anti-reflective effect.

3. Functional and Mechanical Coatings

3.1 Hard Coatings

(*a*) *Thermally curable coatings*. The nanocomposite strategy for hard coatings is based on the fact that well-dispersed nanoparticles in hybrid matrices are considered to play a very important role in abrasion resistance. Schmidt *et al*. 1998 showed that boehmite particles, dispersed in an inorganic–organic hybrid network composed of epoxy silanes as basic components, catalyze epoxy polymerization at curing temperatures above 100 °C, leading to a highly transparent, very scratch-resistant coating. These coatings are successfully employed for the fabrication of abrasion resistant CR-39 eyeglass lenses, and have been developed for hard coatings on polycarbonate. The coating leads to very high abrasion resistance (2% haze, or 98% transparency, after 1000 cycles of taber abrader). For this reason, the coating has currently been further developed for the use of polycarbonate for automotive glazing, substituting for inorganic glasses.

(*b*) *UV-radiation curable coatings*. If UV or electron beam curing is employed (by using photocurable organic groupings like epoxides or acrylics in conjunction

with appropriate photoinitiators), photocurable hard-coatings are possible. Since these coatings are produced at low temperatures (around 60 °C), the degree of inorganic network condensation is lower than in the case of temperature-cured hard coatings, leading in general to a lower abrasion resistance; but by using 10–15% of nanoparticles (by volume), the taber abrasion numbers are reduced also to about 7% after 1000 cycles, an extraordinarily high value for UV-cured hard coatings. Based on these results, a coating system for plastic lenses has been developed and an industrial process has been built up. Similar results have been obtained by electron beam curing.

By appropriate control of the drying conditions, a dry but uncured photocurable system is obtained, which has sufficient deformability to be used in deep drawing processes. By coating PMMA plates, deep drawing processes have been performed in which subsequent UV-curing leads to highly abrasion-resistant coatings on PMMA, and an industrial process has been developed.

3.2 Low Surface Free Energy Hard Coatings

Low surface free energy hard coatings are a very interesting area of application for hybrid matrix nanocomposites. As described elsewhere (Schmidt *et al.* 1991, Kasemann *et al.* 1992a, 1992b, Kasemann and Schmidt 1994), it could be shown that, based on interfacial thermodynamics, a self-alignment in layers takes place if side chain perfluorinated silanes are added, which increase in concentration at the surface as long as the concentration exceeds the critical micelle concentration. This leads to very low surface free energies of about $19 \, \text{mJ} \, \text{m}^{-2}$ ($20–22 \, \text{mJ} \, \text{m}^{-2}$ with PTFE). The process is shown schematically in Fig. 10.

Based on this effect, various types of low surface free energy coatings have been developed (high- and low-temperature curing, UV curing, and two-component systems). All of these coatings form a gradient layer with an increased concentration of fluorine at the atmospheric side, as shown by ESCA or SNMS, and an adhesive layer to the substrates. Due to the homogeneous distribution of nanoparticles, these systems can also be obtained with high transparency and high abrasion resistance. The contact angles of
this type of coating with water are of the order of 110°, and with hexadecane in the range of 55–60°. If micro-patterned surfaces are used, the contact angles with water increase up to 160°, and with hexadecane up to 120°.

These surfaces can be obtained either by mechanical micropatterning or by the use of self-structuring effects based on appropriate nanoparticle sizes. Based on this technology, many industrial applications have been developed. These extend through anti-adhesive coatings; mold release coatings; zero-carryover coatings in capillaries, food technology, buildings and pavements; and anti-billposting coatings—all having the advantages of saving detergents and water. The coating material can be adjusted for glass, ceramics, enamel, polymers, and metals, with average thickness ranging from $1–5 \, \mu\text{m}$. A special variation of the system is the easy-to-clean application and anti-graffiti protection in public areas (house and public building walls, monuments, railways, subway, traffic signs, etc.).

Similar coatings have been developed for mold release processes in metal molds for polyurethane, polyethylene and polystyrene foams. Other applications have been developed for anti-adhesive coatings in carpet production, for easy-to-clean windows, and for ceramic sanitary ware which has been commercialized extremely successfully (Duravit Wondergliss coatings).

Another very interesting development involves the restoration of historic books and papers. Due to the content of sulfuric acid of paper (starting about 150 years ago, as a consequence of the change in production technologies), the paper slowly deteriorates, by hydrolytic decay of the cellulose fibers. This leads to a weakening of the papers, so that in serious cases the paper sheets may even become powderized. Many attempts have been made around the world to solve this problem, for example by leaching out the acid (Batelle process), or by using plastic foils as support. In the first case no strengthening is added, and in the second case a single-sheet process has been used, by dismantling the book and then binding it after fixing the foil support. For these reasons, investigations have been carried out with the aim of combining both processes, using an infiltration process with a polymerizable resin which shows a "smart" behavior, by knowing that it has to reinforce the cellulose fibers but at the same time prevent two pages from sticking together. The problem has been successfully solved by using the self-aligning fluorinated type of coating, in combination with acrylic groupings and a thermally activated initiator, by simply impregnating the book with a reinforcing system, drying it at temperatures of about 60–80 °C (starting temperature of the radical initiator) and then drying it. The scheme of this process is shown in Fig. 11, the mechanism of the formation of an anti-adhesive surface between two paper sheets is also depicted.

Figure 10
Scheme of a fluor gradient material.
Figure 11
Scheme of paper coating: build-up of separating surfaces and reinforcement.

3.3 Photocatalytic Coatings

TiO_2 nanoparticles show photocatalytic activities, as has been known for a long time. Suspensions of TiO_2 have been used for photocatalytic water cleaning processes. Interesting applications of TiO_2 nanoparticles have been reported by Watanabe *et al.* (1999a, 1999b), in which TiO_2 is wet coated on ceramic tiles and sanitary ware for self-cleaning and microbiocide purposes. Similar systems have been developed, based on work by Schmidt *et al.* 1995. Watanabe *et al.* 1999a showed that TiO_2 compositions have a self-cleaning effect on various substrates, especially on plastic foils, organic paints, and polycarbonate sheets.

Another area of catalytic applications is so-called non-selective catalysts, as used in oxidation catalysis. It could be shown that by the use of nanoparticulate SiO_2-containing binder materials, transition metal oxides such as those of cobalt, nickel, and others show enhanced catalytic activities compared to systems made from pellets out of the pure oxides. This type of nanocomposite has been successfully used in exhaust systems for the deodorization of kitchens.

3.4 Conductive Coatings

Electrically conducting transparent coatings are of interest for the development of antistatic coatings, heat insulating coatings, electromagnetic shielding, and displays (touch screen panels). Polymer-based wet coatings again offer the possibility of cheap, large-area coating technologies, which up until now have not been achieved by sputter techniques. It could be shown that by use of the surface modified nanoparticle approach, thicker films and lower sheet resistances could be obtained, as compared to the classical sol–gel route. The development of transparent electrical conducting coatings of ZnO:Al (AZO), SnO_2:Sb (ATO), and In_2O_3:Sn (ITO) with a defined sheet resistance, high optical transmission and good homogeneity, using the sol–gel process, led to coatings which can be obtained by dip- or spin-coating processes using stabilized sols. The sheet resistance can be adjusted by varying the layer thickness and the sintering temperature. These systems provide an adjustable sheet resistance ($\pm 2\%$) with high homogeneity of the thickness (± 2 nm). The sheet resistance can be minimized, down to 150–200 Ω on float glass at 550 °C for ATO and AZO, and on borosilicate and silica glass at 600–650 °C. For an ITO double layer, the sheet resistance is below 200 Ω, sintered at 900–1000 °C on silica glass. Substrate sizes of 1 m^2 have already been dip coated. The temperature stability ranges up to 800 °C for ATO coatings, and up to 900 °C for ITO coatings. In the visible range, a high transmission could be derived (Fig. 12).

3.5 Metal Colloid-containing Coatings

Metal colloids have been used for two different purposes. As known from gold ruby glass, metal colloids show high coefficients of extinction due to plasmon frequencies. The coefficients of extinction are up to
Figure 12
(left) Sheet resistance vs. sintering temperature of dip-coated SnO_2: Sb (ATO, 10 layers), In_2O_3 (ITO, 2 layers) and ZnO: Al (AZO, 10 layers) on silica glass; (right) transmission (—) and reflectance spectra (- -) of dip-coated ATO, AZO and ITO coatings.

$10^6 \, \mathrm{l\,mol^{-1}}$ which even exceeds those of highly absorptive organic dyes. If these colloids are developed within a glass matrix by nucleation and growth, intensive colors can be obtained within thin sol–gel coatings. Based on this technology, an industrial process has been developed for the coloration of silicate eyeglass lenses, using different metals for different colors (gold colloids for red, silver colloids for yellow, copper colloids for green, and palladium colloids for brown). In the industrial process (Mennig *et al.* 1998b), a lead silicate glass matrix is doped with metal colloid precursors in a complexed form, and by a spin coating process a 200 nm thick coating is applied. After firing these coatings under reductive conditions, nucleation and growth take place, followed by the formation of the glass-like colored coatings. Mechanical properties of these coatings are similar to those of the substrate glass. Another interesting application of these particles is in non-linear optical materials based on gold particles (Mennig *et al.* 1994a). The fabrication of nanoparticle-containing coatings can be carried out by doping of the sol–gel precursors with gold complexes, and gold colloids can be grown in a glass matrix as well as in hybrid matrices. Other developments for materials with high χ^3-nonlinear optical effects have been obtained by growing gold nanoparticles in hybrid matrices. For this process, precursor complexes from aminosilanes with $AuCl_3$ were synthesized. After dispersing these complexes in TEOS and methacryloxysilane-containing systems, coating liquids were fabricated by hydrolysis and condensation. After coating and drying, photopolymerization of the methacrylic groupings was carried out. During this period a nucleation and growth process of gold particles took place, and gold particles of several nm in diameter were produced (Mennig *et al.* 1994b). The χ^3 coefficient of $\chi^3/\alpha \approx 10$ $(10^{-14} \, \mathrm{esu\,m})$ could be obtained.

3.6 Coatings for Corrosion Protection

The possibility of the molecular design of polymer-based composites on the nanometer scale allows the adhesive forces to the substrate to be optimized. Various systems have been developed in order to stop corrosion processes on metallic substrates. The corrosion process itself occurs in the presence of an electrochemical couple, i.e., in the presence of metals that have a high tendency for the exchange of electrons. This setup is equivalent to an electrochemical cell, with electron donors and acceptors. Due to the change of the ionic state at the metal surface, chemical reactions take place (passivation). Metal oxides are formed, which lower the metallic properties of the components (strength, toughness, color, etc.). The transport of electrons takes place effectively in the presence of a polar liquid, e.g., water. Therefore, an effective corrosion protection system will prevent contact of water with the metal surface and so prevent electron transfer and the formation of corrosion products. Polymer-based nanocomposites have been developed which provide excellent adhesion forces, which can be tailored to various metals.

Additionally, anti-adhesive "easy-to-clean" properties can be built into these coatings. Many other systems have been developed, e.g., as tarnish protection on silver, brass, and magnesium. The nanocomposite works without primer and has good adhesion to metals, offering high mechanical resistance at low coating thickness (approx. 5–10 μm). A special development is based on surface-modified SiO_2 nanoparticles, as described in Sect 3.2. These films can be densified at 500–600 °C. Highly scratch-, tarnish-, and corrosion-resistant coatings for stainless steel have been prepared. The coatings are 3–5 μm thick and very flexible. Another coating composition has led to anti-fingerprint coatings on stainless steel.

Further advantages of this system lie in the application as an electrical isolation layer for high temperature applications on stainless steel, mild steel, copper, brass, and aluminum alloys. Compared to hardening of steel chromium plating, the glass coating shows an increased wear resistance. The decorative appearance of glossy steel surfaces is obtained up to 600 °C.

4. Hybrid Nanoparticles

4.1 Processing Aids

As described before, the surface modification of hybrid particles is one of the key issues in processing these particles to obtain desired materials and desired functions. In many cases, the particle consists of an inorganic core and an organic shell. These particles can also be defined as hybrid nanoparticles. This definition is used if the hybrid particle plays an important role in processing or in the final properties. In the field of ceramics, sintering temperature and mechanical performance play an important role. Many investigations have been devoted to reducing the sintering temperatures by reducing the particle size. However, in most cases the package density becomes a serious problem. For this reason, it was investigated how to use hybrid nanoparticles as ceramic precursors. As shown by Nass *et al.* (1995), with titanium nitride as an example, nanotitanium nitride coated with guanedinocarboxylic acid leads to package densities in colloidal shaping processes up to 60% by volume. These relatively densely packed matrices could then be densified to titanium nitride compacts or coatings at temperatures from 1200–1350 °C, showing that by hybrid nanoparticle processing, substantial reductions of sintering temperatures could be obtained; and it could be shown also that grain growth could be "separated" from the densification step. The grain growth takes place mainly above 1350 °C.

In the case of silicon carbide, it could be shown that nanometer-size carbon particles coated with carboxylic acids could be linked to silicon carbide surfaces containing amino groups, in such a way that wet processing did not lead to bleeding of the carbon black during slip casting. By using an appropriate concentration of carbon black, suitable for the stoichiometric reduction of the SiO_2 always present on silicon carbide particle surfaces, a slip casting processing route was developed which leads to near net-shaped large silicon carbide parts (Nass *et al.* 1994). Silicon carbide igniters based on this technology shows superior properties to those previously available (500 000 ignition cycles without rupture).

4.2 Medical Applications

Nanoparticles are interesting for medical applications for many reasons. One is that for *in vivo* applications they can be transported in the blood stream without any problems, can even pass important barriers and are not filtered out very easily. Moreover, with appropriate surfaces they may penetrate even cell membranes. Based on these considerations, amino-grouping-modified superparamagnetic iron oxide nanoparticles have been fabricated, and investigations have been carried out for transporting them into tumor cells (Lesniak *et al.* 1998). It has been shown that billions of nanoparticles penetrate tumor cells. By employing an alternative magnetic field, heat could be introduced into the cells and they could be selectively destroyed by heat. It was also shown (H. Jordan, personal communication 1998) that if the tumor cells divide, both daughter cells share the load of iron oxides.

Another technology is the use of SiO_2 nanoparticles, the surface charge of which is tailored by amino grouping modification in such a way that genes can be concentrated on top of the nanoparticles, leading to gene–plasmid clusters of about 80 nm in diameter. This is a substantial reduction from the original gene plasmids with a diameter of 200–250 nm. At this size, the nanoparticles could be used for the transfection of gene plasmids into cells with a very high transfection rate (Kneuer *et al.* 1999). The advantage of this technology is the fact that the SiO_2 is completely non-poisonous compared to polyethylene imines as gene carriers. An example of this coupling is the electrostatic bonding of glycoproteins (e.g., avidin) on top of a negatively charged SiO_2-nanoparticle. Avidin provides four sites for the chemical bonding of other groupings (like biotin/WGA-complexes) or DNA-fragments or genes (like WGA: wheat germ agglutinin). The aim of this approach is the destruction of cancer cells by pharmaceuticals. The coupling of biomolecules can be proved by electron microscope investigations.

Hydroxylapatite has been fabricated from nanoparticulate calcium phosphate precipitates and, using sol–gel binders, these nanoprecipitates have been used for fabricating thin films on titanium implants in thicknesses of about 5 nm. This thickness has great advantages compared to plasma- or flame-sprayed thick films, because it adheres very well on the surface and no cracks are formed. First results in using these implants show that a very fast incorporation into the tissue takes place (Nonninger *et al.* 2001).

5. Conclusion

Nanoparticles are of great interest for many applications, either for use by themselves or by being processed to parts such as in ceramics, or by being used in the form of nanocomposites in various matrices. Because nanoparticles of many different compositions can be used, a wide range of properties can be developed for materials. Chemical fabrication routes

for nanoparticles are very interesting, since they are mainly based on precipitation techniques which can be performed quite cheaply. One of the key issues is the surface modification of nanoparticles, since that is the crucial point in controlling aggregation. The application of these principles to the development of materials will be a very important and interesting prospect for the future.

Polymer–Ceramic Nanocomposites: Catalysts

Polymers can be incorporated into ceramics at a molecular level using the sol–gel process. In this, a ceramic phase is generated by an inorganic polymerization reaction of forming a metal oxo (M-O-M) polymer using organometallic precursors. The reaction generally includes two steps: (i) the hydrolysis of molecular precursors such as metal alkoxides $M(OR)_Z$, where M is a metal or transition metal such as Si, Ti, Zr, Al, Sn, Ce, etc., R is alkyl, phenyl, or hydrogen, and Z is the valence or the oxidation state of the metal; and (ii) the condensation of the hydroxyl groups and the residual alkoxyl groups to form a three-dimensional network. Once the hydrolysis reaction has been initiated, both hydrolysis and condensation reactions occur simultaneously. Depending on the relative reaction rates, the structure

and morphology of the ceramic phase will be different. Many chemical species such as acids, bases, and some neutral salts have a large impact on the reaction mechanisms and the relative reaction rates, and can thus be used as catalysts in the process of making polymer–ceramic nanocomposites through the sol–gel process.

1. Catalytic Mechanisms

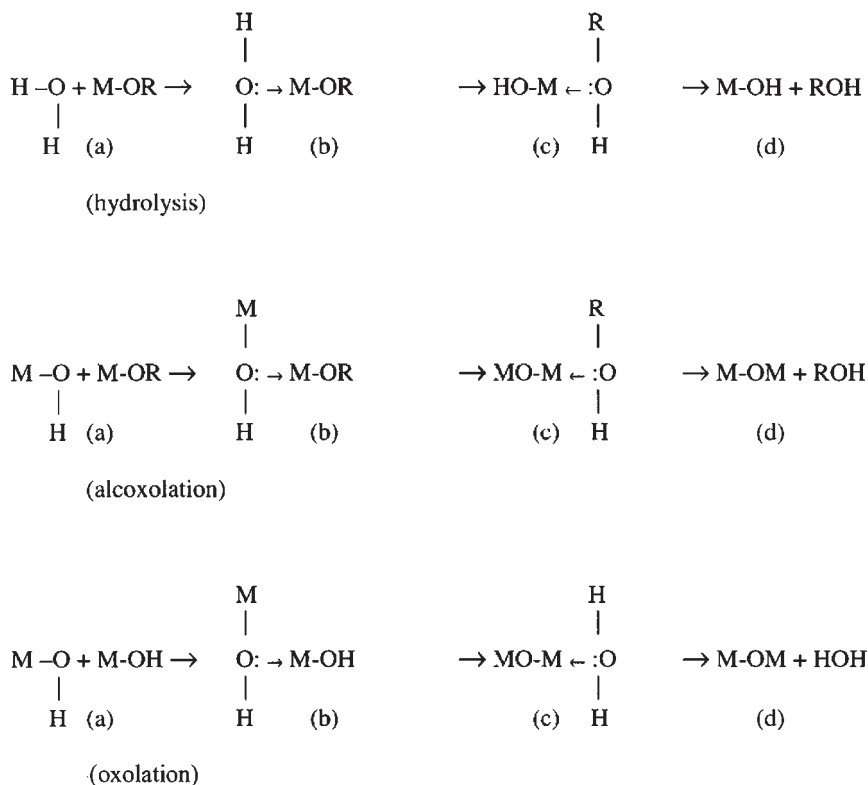
The sol–gel process and the reaction mechanisms have been extensively studied since the early 1980s (Brinker and Scherer 1990). However, a brief discussion on the reaction mechanism is helpful to explain the catalytic effects.

In the absence of catalysts, hydrolysis and condensation both occur by nucleophilic substitution (S_n) mechanisms involving nucleophilic addition (A_n) followed by proton transfer from the attacked molecule to an alkoxide or hydroxo-ligand within the transition state. This is then followed by the removal of the protonated species as either alcohol (alcoxolation) or water (oxolation) (Scheme 1).

When the coordination of the metallic center is not fully saturated, condensation can occur by olation based on a nucleophilic addition mechanism:

$$MOX + MOX \rightarrow M - (OX)_2 - M$$

$$X : \underset{\text{(olation)}}{H} \quad \text{or} \quad R$$
The thermodynamics of hydrolysis, alcoxolation, and oxolation are governed by the strength of the entering nucleophile, the electrophilicity of the metal, and the partial charge and the stability of the leaving group. The kinetics of these reactions are governed by the extent of coordination undersaturation of the metal, and the transfer ability of the proton. Greater acidities of the protons reduce the associated activation barriers and enhance the kinetics. The thermodynamics of the olation depends on the strength of the entering nucleophile and the electrophilicity of the metal, and the kinetics of olation is systematically fast. This is because of the undersaturation, and the fact that no proton transfer occurs in the transition state.

Any of these reactions can take place in the sol–gel process. Depending on the relative contribution of each of these reactions, the structure and the morphology of the resulting ceramic phase are different.


Scheme 1

The nature of the metal atom, the alkyl groups, and the molecular complexity are the internal factors. Catalysts as well as the water ratio, concentration, solvent, and temperature are external factors that can also be used to control the reactivity and thus tailor the structure of the composite.

The chemical reactivity of metal alkoxides mainly depends on the electrophilic character of the metal atom (electronegativity), and its ability to increase its coordination number. The reactivity of the commonly used tetravalent metal alkoxides has the sequence

$$Si(OR)_4 <<< Sn(OR)_4 < Ti(OR)_4$$

$$< Zr(OR)_4 < Ce(OR)_4$$
The reactions of silicon alkoxides are much slower than those of nonsilicon alkoxides. Catalysts are normally needed in silicon–alkoxide systems. In non-silicon systems, inhibitors or chelating ligands are sometimes used instead, to control or slow down the sol–gel reactions of these alkoxide precursors (Livage *et al.* 1988).

During hydrolysis, the acids protonate negatively charged alkoxide groups. Electron density is then withdrawn from the metal atom, making it more electrophilic and thus more susceptible to attack by water. It enhances the reaction kinetics by producing good leaving groups. Under basic conditions it is likely that water is first dissociated to produce nucleophilic hydroxyl anions. The hydroxyl anion then attacks the metal atom. Although both acid and base conditions promote the hydrolysis, acids are more effective.

During condensation, it is generally believed that the acid also protonates the MOH species which are more electrophilic and more susceptible to nucleophilic attack. Basic conditions on the other hand produce nucleophiles via deprotonation of the hydroxo ligand, which systematically enhances the condensation. The condensation pathway is influenced by the relative ease of protonation of different alkoxide ligands. The ease of protonation is related to the electron-providing power of the ligands, which decreases in the order alkoxy (-OR), hydroxo (-OH), and oxo (-O-). Under acidic condensation, easily protonated ligands such as OR and OH are favorable, thus the condensation reaction occurs preferentially among them, resulting in more-extended, less-branched ceramic phases. Under basic conditions, the more acidic ligands, such as oxo, are favorable, therefore the final ceramic phase is more compact and highly branched. Many different reaction mechanisms have been proposed for these catalytic conditions (Brinker and Scherer 1990). In addition to acids and bases, some salts, especially F^- salts, are very effective catalysts. Their catalytic effect suggests that F^- may have the same role as OH^-.

2. Applications

Many acids, bases, and other species have been used to catalyze the sol–gel process for preparing polymer–ceramic nanocomposites. Substances with high volatility, such as ammonia and diethylamine, are normally used to permit their easy removal from the resulting systems. Acids, bases, and some neutral salts have been used to promote the generation of silica particles in an elastomeric network using metal–alkoxide precursors to improve its mechanical properties (Mark 1989). The morphology of the resulting silica-filled polydimethylsiloxane (PDMS) network strongly depends on the catalysts used. It has been found that silica generated in PDMS elastomer networks has a good particle definition with a smooth surface when the catalyst is a base, whereas an acid catalyst gives poorly defined fuzzy particles. The latter may be an advantage with regard to good interfacial bonding. The mechanical properties of the resulting composites are correspondingly different.

Another type of polymer–ceramic hybrid has been prepared from simultaneous formation of silica networks and PDMS networks. The resulting hybrids can be very rubbery when a polymer is the continuous phase, or ceramic-like with polymer as a toughing agent. The acid content is very crucial in determining the structure of the final products when oligomeric PDMS is incorporated into inorganic glass made by the sol–gel process of tetraethoxysilane (TEOS) (Huang *et al.* 1987). As the acid content increases, PDMS is better dispersed into the system. Higher polymer content can be obtained in making transparent homogeneous hybrid materials.

When several different metal–alkoxide precursors are used in the process, catalysts can also be used to match or control the reactivities among the precursors, and thus to tailor the structure and properties of the composites. One example is that the hydrolysis rate of a methyl-substituted silicon alkoxide is much faster than that of a pure silicon alkoxide in an acidic medium, but the rate is reversed in a basic one. The reaction medium thus can be used to match the reactivities of alkoxysilane and methyl-substituted alkoxides (Schmidt 1984). Different pH values can also be used to tailor the compositions of the resulting composites when different metal alkoxides are used (Dire *et al.* 1992).

Polymeric acids can also be employed, and the choice of its molecular weight can be used to control the viscosity of the reacting system (Brennan and Wilkes 1991).

The sol–gel process makes it possible to make polymer–ceramic composites at the molecular level. The use of acids, bases, and many other chemical species can be used to control reaction rates and reaction pathways. In this way, the structure and morphology of the resulting polymer–ceramic nanocomposites can be tailored.

Polymer–Ceramic Nanocomposites: Ceramic Phases

The sol–gel process has been extensively studied and employed as the most important route in forming new hybrid inorganic–organic materials (Mark 1996, Mark *et al.* 1995, Sharp 1998, Sanchez and Ribert 1994, Novak 1993, Chujo and Saegusa 1992, Schmidt 1994, Schaefer and Mark 1990). This is because this process can introduce ceramic phases into composites through chemistry. Very mild reaction conditions and low reaction temperatures are particularly useful for incorporating inorganic moieties into organic materials or organic materials into inorganic matrices. Thus, the organic polymers involved can survive during the sol–gel process that eliminates sintering temperatures used in the preparation of typical inorganic ceramics ($>1200\,^{\circ}$C).

The sol–gel process begins with alcoholic solutions of metal or semi-metal alkoxide precursors $M(OR)_n$ and water, where M is a network-forming element such as Si, Ti, Zr, Al, B, etc. and R is typically an alkyl group. Metal alkoxides are compounds in which elements are bonded to hydrocarbon groups through oxygen.

Hydrolysis and condensation of metal alkoxides can lead to the formation of inorganic networks in the presence of an acidic or basic medium. The natures of the catalysts and pH in the sol–gel reaction have very significant effects on the hydrolysis and condensation reactions and the morphology of the inorganic network formed. Such a sol–gel process can lead essentially to an alloy-like material if molecular dispersion is obtained or, in most cases, more of a nanophase morphological structure. It is known that physical and optical properties of inorganic–organic composites are enhanced by the reduction of the domain size. As the domain size is reduced, the interfacial surface area increases. Substantial improvement in performance can be achieved with domains on the nanometer scale.

1. Precursors for the Formation of Ceramic Phases

Some metal alkoxides used as precursors for the sol–gel process to form ceramic phases and their molecular association degrees are listed in Table 1. They may be considered either as derivatives of alcohols or as derivatives of metal hydroxides or inorganic acids (Bradley *et al.* 1978). The molecular association or oligomerization of metal alkoxides is a very important parameter that can influence many of the physical and chemical properties of these compounds and affect the sol–gel process. The degree of oligomerization can directly induce differences in processing and in final morphologies of hybrid inorganic–organic composites, such as inorganic phase domain sizes and phase separations. The degree of the molecular association depends on the nature of the central metal elements and on the nature of the ligands. When the same alkoxy ligand is used, for example, $(OEt)_4$, it has been found that the degree of oligomerization is a function of the metal size in the order $Th > Hf > Zr > Ti > Si$. It has also been found that the degree of oligomerization is a function of the length and branching of the alkoxy ligand (Guglielmi and Carturan 1988).

2. Metal Alkoxides Commonly Used for Hybrid Inorganic–Organic Nanocomposites

2.1 Silicon Alkoxides

Silica is one of the most important ceramic phases, and has been widely studied in the sol–gel process to create inorganic–organic nanocomposites. The tetraalkyl orthosilicates most commonly used in the sol–gel process are either tetramethoxysilane (TMOS) or tetraethoxysilane (TEOS). The general reaction steps are given in Scheme 1. Besides the nature of the catalysts used, pH has a dramatic effect on the reaction rates and the morphology of the resulting silica network. During hydrolysis and condensation of tetraalkyl orthosilicates under basic conditions, the rate of condensation is faster relative to the hydrolysis rate, resulting in more of a dense cluster growth leading to dense particulate-like structures. In contrast, if the

Hydrolysis:

$$Si(OR)_4 + H_2O \rightleftharpoons HO\text{-}Si\text{-}(RO)_3 + ROH$$

$$HO\text{-}Si\text{-}(RO)_3 + H_2O \rightleftharpoons (HO)_2\text{-}Si\text{-}(RO)_2 + ROH$$

$$(HO)_2\text{-}Si\text{-}(RO)_2 + H_2O \rightleftharpoons (HO)_3\text{-}Si\text{-}(RO) + ROH$$

$$(HO)_3\text{-}Si\text{-}(RO) + H_2O \rightleftharpoons (HO)_4\text{-}Si + ROH$$

Condensation:

$$-\overset{|}{\underset{|}{Si}}\text{-}OH + HO\text{-}\overset{|}{\underset{|}{Si}}- \longrightarrow -\overset{|}{\underset{|}{Si}} \text{-} O \text{-} \overset{|}{\underset{|}{Si}} \text{-} + H_2O$$

$$-\overset{|}{\underset{|}{Si}}\text{-}OR + HO\text{-}\overset{|}{\underset{|}{Si}}- \longrightarrow -\overset{|}{\underset{|}{Si}} \text{-} O \text{-} \overset{|}{\underset{|}{Si}} \text{-} + ROH$$

Overall reaction:

$$Si(OR)_4 \xrightarrow[H^+ \text{ or } OH^-]{H_2O, \text{ solvent}}$$

Scheme 1

hydrolysis and condensation reactions are carried out in the presence of acid, it is believed that the hydrolysis rate is higher than the condensation rate. As a result, more linear or polymer-like chain structures are formed (Brinker and Scherrer 1990) (see *Polymer–Ceramic Nanocomposites: Catalysts**).

2.2 Aluminum Alkoxides

The fundamental process that transforms aluminum alkoxides into a porous transparent alumina was developed by Yoldas (1975). An aluminum alkoxide, $Al(OR)_3$, normally $Al(OBu^s)_3$ or $Al(OPr^i)_3$, is first hydrolyzed in a large excess of water at 80–100 °C, resulting in precipitation of fibrillar boehmite, followed by peptization with a mineral acid to yield a clear sol. Cold-water hydrolysis leads to an amorphous precipitate that converts to bayerite upon aging through a dissolution–recrystallization process. Gelation is generally obtained by concentration of the sol via boiling or evaporation. The hydrolysis and condensation of aluminum alkoxides are complicated in the Yoldas process, but the overall reaction is shown simply by

$$2Al(OR)_3 + 3H_2O \rightarrow Al_2O_3 + 6ROH \tag{1}$$

Acids and bases can influence the above hydrolysis and condensation reactions. Acids protonate OR or OH ligands creating good leaving groups and eliminating the requirement for proton transfer in the intermediate, while bases deprotonate water or OH ligands creating strong nucleophiles.

2.3 Titanium Alkoxides

In general, the hydrolysis and condensation reactions of titanates are complicated, but the overall

reaction scheme is

$$Ti(OR)_4 + 2H_2O \rightarrow TiO_2 + 4ROH \tag{2}$$

The reaction rate of normal titanium alkoxides generally decreases with increasing alkyl chain length. The reactivity of isomeric alkyl derivatives is tertiary > secondary > normal.

2.4 Zirconium Alkoxides

The process to prepare ZrO_2 from $Zr(OR)_4$ consists of at least two reaction steps:

$$Zr(OR)_4 + H_2O \rightarrow ZrO(OR)_2 + 2ROH \tag{3}$$

$$2ZrO(OR)_2 \rightarrow ZrO_2 + Zr(OR)_4 \tag{4}$$

The nature of the alkyl groups can significantly influence particle sizes and phase morphologies. ZrO_2 made from zirconium *n*-butoxide annealed below 300 °C is amorphous. Its local order is similar to that of the tetragonal crystallite phase. The amorphous phase can crystallize into the tetragonal and monoclinic zirconia nanophases at 300–350 °C, with the monoclinic crystals having a smaller size. Annealing zirconia at temperatures higher than 350 °C transforms the tetragonal phase into the monoclinic phase.

3. Organofunctional Metal Alkoxides

Organic functional and inorganic groups can be linked by stable chemical bonds, thus producing organofunctional metal alkoxide derivatives. There is a wide variety of ways to make organofunctional alkoxide derivatives (Schmidt 1994, Schubert *et al.* 1995). A general molecular formula, $(RO)_n$–M–X–A, can be written, where A represents an organic functional group and X is a chemically stable spacer linking A and the metal alkoxide moiety $M(OR)_n$. For example, alkoxide silanes, in which A is a reactive vinyl group, are extremely interesting for the synthesis of hybrid inorganic–organic composites by polymerizing the vinyl groups. In this approach, an organic network is formed in the matrix of the inorganic network. If A is a nonlinear optic chromophore group, inorganic–organic composites to be formed will have nonlinear optical properties. Theoretically, A can be any organic functional group. Therefore, there can be an unlimited number of organofunctional metal alkoxides.

4. Properties and Applications of Some Ceramics

Table 2 lists some physical properties of the ceramics which can be prepared by the sol–gel process along with their applications. There are many studies showing that incorporating silica into hybrid inorganic–organic composites can increase mechanical

Table 2
Some ceramic phases created in inorganic–organic nanocomposites and their properties and applications.

Ceramics	Properties	Applications
SiO_2 (from silicates)	Optical, mechanical, dielectric constant	Optical elements wave guides integrated optics
	Surface treatment	Reinforcement Surface treatment Catalyst support Insulation
TiO_2 (from titanates)	High index, heat resistance, dielectric constant, piezoelectric	Capacitors light valves
Al_2O_3 (from aluminates)	Mechanical, thermal	High modulus High thermal conductivity
ZrO_2 (from zirconates)	Mechanical, heat resistance	High modulus High temperature
GeO_2 (from germanates)	High index, magnetic	Optical fiber
P_2O_5 (from phosphates)	Low temperature	Sensors
B_2O_3 (from borates)	Optical, mechanical, chemically durable	Optics Glassware
V_2O_5 (from vanadates)	Conductive	Semiconductor conductors varistors switching devices
Nb_2O_5 (from niobates)	Electro-optic, piezoelectric	Light valves modulator hydrophone
WO_3 (from tungstates)	Electrochromic	Displays

properties such as modulus and ultimate tensile strength, and improve interfacial bonding between the organic and inorganic phases. TiO_2 and GeO_2 can be used to produce high-refractive index optical films. TiO_2 can also increase the thermal stability of composites—for example, titania prepared from titanates can overcome a thermal degradation problem caused by the silanol groups on the surface of the silica at high temperatures. Al_2O_3-containing composites can have higher hardness and scratch resistance, while zirconia-based composites are light and able to withstand heat, corrosion, and wearing. Many of these zirconia-based composites have been used for coating turbine blades and for making engine blocks, body valves, cylinder liners, pistons, and bearings in automobile internal combustion engines. This is because composites based on zirconia have a high fracture toughness produced by martensitic transformation of the zirconia tetragonal phase into the monoclinic phase. The mechanical properties of these composites depend strongly on the size of the zirconia crystallite (Komarneni *et al.* 1997).

5. Nanocomposites Containing Various Ceramic Phases

In the case of the inorganic–organic nanocomposites, the goal is to carry out reactions of the sol–gel type in the presence of organic molecules which are generally polymers and have functional groups to improve their interfaces with the glass phase. There is a wide variety of ways to generate such a glass phase in polymers. In general, there are two classes of hybrid inorganic–organic nanocomposites based on inorganic and organic interactions (Sanchez and Ribert 1994). In class I, organic molecules, oligomers, or low-molecular weight polymers are simply embedded in inorganic matrices. Conversely, inorganic phases can be generated *in situ* in organic matrices. In this class, both components have relatively weak van de Waals, hydrogen, or ionic interactions. In class II, inorganic, organic, or inorganic–organic compounds are bonded through strong covalent or ionocovalent chemical bonds. In some cases, classes I and II are, in fact, mixed together.

5.1 Nanocomposites Containing Silica Phases

Mark (1996) employed several ways to incorporate silica-type fillers *in situ* into polydimethylsiloxane (PDMS) networks. The linear PDMS chains used were silanol-terminated or vinyl-terminated. The techniques employed were: (i) incorporating silica that has been precipitated *in situ* from a silicate in an aqueous dipersion with PDMS; (ii) precipitating silica directly into PDMS during its curing; (iii) precipitating silica into a swollen PDMS network after it has been cured; (iv) incorporating silica prepared from TEOS and containing some PDMS; and (v) incorporating silica prepared from partially hydrolyzed TEOS and also containing some PDMS. The morphology of the silica particles generated *in situ* strongly depends on the catalysts used. Good definition of nano-silica particles with a narrow size distribution generally occurs when the catalyst is a base, such as ethylamine or diethylamine. On the other hand, use of an acidic catalyst gives poorly defined "fuzzy" particles. This lack of definition is consistent with results in the sol–gel ceramics area, where it was concluded that acidic catalysts give structures that are less branched and less compact than those obtained using basic catalysts. These morphologies were observed by transmission electron microscopy (TEM). Moreover, at some compositions and under some hydrolysis conditions that included an acid, bicontinuous silica and PDMS phases or the silica and PDMS phases interpenetrating one another can be obtained. This was evidenced by small-angle x-ray scattering and small-angle neutron scattering. Another interesting phenomenon was also observed: under basic conditions silica particles remaining in contact with their aqueous catalyst solution can "age" or "digest." As a result, the particles became better defined and were more uniform in size. There seem to be interesting parallels with Ostwald ripening in the area of colloid science. In these *in situ*-precipitated silica systems, significant reinforcements have been obtained for PDMS networks under various deformations (see *Elastomers, Ceramic-modified** and *Polymer–Silica Nanocomposites**).

5.2 Nanocomposites Containing Other Ceramic Phases

In addition to silica, Mark (1996) also showed that some nonsilica fillers can also provide good reinforcement for PDMS networks. These include titania (TiO_2), alumina (Al_2O_3), and zirconia (ZrO_2). Using these nonsilica fillers can eliminate a problem associated with acidic hydroxysilyl groups on the silica surface that can cause PDMS chain cleavage at high temperatures. In the case of titania-reinforced PDMS systems it was observed, interestingly, that the stress–strain isotherms have much better reversibility.

Ceramics are often bonded to oligomers or polymers as modifiers. The majority of Wilkes' work (Wen and Wilkes 1996) has emphasized the oligomeric or polymeric species as the dominant component within the final network material. Hence, these materials tend to be flexible and have been called "ceramers" to indicate some combination of ceramic-like behavior with polymeric-like behavior.

Wen and Wilkes (1996) reported structure–property relationships for organic–inorganic hybrid systems prepared by the sol–gel process using either titanium isopropoxide or zirconium isopropoxide with silane end-capped poly(tetramethylene oxide) (PTMO) oligomers. These novel network materials can be monolithic and are optically transparent, as were ceramers prepared with PTMO and TEOS as the metal alkoxide. The dynamic mechanical behavior of the titanium- and zirconium-containing ceramers exhibits trends similar to those reported for the TEOS/PTMO ceramers. However, the stress–strain response shows yielding behavior and higher moduli and ultimate stress at break. Similarly, metal acetyl acetonates of aluminum and zinc were also incorporated into PTMO-modified TEOS based materials.

Clays are interesting as ceramic phases since polymers can be inserted into the interlayer spacing of some of these minerals, either expanding them or even exfoliating them (Okada *et al*. 1990). Relatively little clay is required to give large improvements in mechanical properties. The sheet-like structure of the dispersed phases is also useful for decreasing the permeability of the host polymer, which is important in applications such as fuel tanks (see *Clay-based Polymer Nanocomposites** and *Polymer–Nonsilica Ceramic Nanocomposites**).

5.3 Nanocomposites Containing Mixed Ceramic Phases

In many cases a single ceramic component cannot produce the desired properties. Therefore, two or more metal alkoxides are often used together, with balanced reaction rates, to tailor the desired properties. The hard contact lens material developed by Schmidt (Schmidt and Philipp 1984) is a good example. The structure of the material is illustrated in Fig. 1. In this system, an epoxide-substituted alkoxysilane and titatium alkoxides were used as precursors for the hydrolysis and condensation reactions. Titanium alkoxide was used to catalyze the silanol condensation. To achieve sufficient tensile strength, polymethacrylates were incorporated by using a methacryloxy-substituted alkoxysilane as a link between the siliceous network and the polymer chain. The incorporation of titania led to dense monolithic products that could be cured with only some minor shrinkage. Good wettabilities were due to glycol groups formed by the epoxide radicals. The
Figure 1

excellent oxygen permeability resulted from the siloxane structure. It can be seen that this hybrid inorganic–organic composite is a product based on a principle of molecular engineering.

This brief review shows that creation of an appropriate ceramic phase and achievements of useful functions depend on an appropriate choice of metal alkoxide. Similarly, the morphological structure of the ceramic phase is strongly related to the hydrolysis and condensation reactions. Through the combination of polymers and ceramics, new materials can be created and their properties can be tailored to a wide variety of applications.

Polymer–Ceramic Nanocomposites: Control of Shrinkage

One of the most complex aspects of sol–gel processing of polymer–ceramic nanocomposites is the drying process. Because of the cosolvents, liberated alcohol, and excess water used, volume shrinkages of 80% or more are common. Fibers and thin films can be dried fairly quickly and easily, but thick films and monoliths must be dried under carefully controlled conditions to avoid the formation of cracks, deformations, and residual stresses in the material. For a detailed account of the drying process see *Xerogels**. The homogeneous incorporation of organic polymers into the ceramic phase adds even more complexity to the problem. Not only must the drying rate be controlled to avoid mechanical failure of the sample, controlled drying is also necessary to prevent phase separation of the organic polymer from the inorganic matrix. Furthermore, the large volume shrinkage associated with drying precludes the use of standard forming processes such as extrusion, molding, or casting.

For these reasons, several important and useful methods have been developed to reduce or eliminate the shrinkage associated with sol–gel processing of polymer–ceramic nanocomposites. A typical sol–gel derived polymer–ceramic nanocomposite is prepared by dissolving the desired polymer in an organic solution with tetraethylorthosilicate (TEOS), water, and an acidic or basic sol–gel catalyst. After gelation of the silica network the solvent, water, and ethanol liberated during the hydrolysis and condensation of TEOS are typically removed by slow evaporation. This process can be altered in several different ways to control shrinkage. A two-step sol–gel process can

be used where the solvent is evaporated or distilled prior to gelation, so that after gelation less solvent will need to be removed, resulting in less shrinkage. Alternatively, the solvent can be displaced after gelation, but prior to drying, with a polymerizable solvent to produce solid monoliths or with a supercritical solvent to produce porous materials called aerogels (for more details of this process see *Organic Aerogels** and *Inorganic and Inorganic–Organic Aerogels**). In a more direct process, nonshrinking sol–gel composites can be prepared from ceramic precursors with polymerizable alkoxides and a polymerizable solvent so that all of the components in the solution are converted to either ceramic or polymer in a single step. Finally, preformed metal oxide oligomers and colloids can be suspended in a polymerizable solvent followed by subsequent polymerization of the solvent, which also converts all of the components to either ceramic or polymer.

1. Two-step Sol–Gel Process

In the two-step or two-stage sol–gel process, the hydrolysis and condensation step and the gelation step are accomplished in two separate and distinct operations rather than occurring simultaneously, as is the case in standard sol–gel processing. The first step in the process is to completely hydrolyze and partially condense the TEOS. This is accomplished by heating an acidic solution of TEOS in a water-miscible solvent such as ethanol or tetrahydrofuran (THF) with the polymer or polymer precursor in the solution. A portion of the solvent is removed by distillation, resulting in a viscous solution. In the second step, this solution is cast into a film or mold and allowed to gel either directly from the acidic solution, or the acidic solution can be rendered basic prior to casting to promote faster gelation. Since some solvent remains in the system, drying is still necessary and shrinkage is observed. However, since a portion of the solvent has been removed, the amount of shrinkage is reduced, resulting in less stress in the material during the final drying step.

Wei *et al.* (1996) describe a convenient technique for the preparation of transparent vinyl polymer–silica hybrid sol–gel composites with less than 20% volume shrinkage (Fig. 1). The first step in the reaction is the hydrolysis of TEOS in the presence of 2-hydroxyethyl methacrylate (HEMA) in THF solvent. A vinyl polymerization initiator such as benzoyl peroxide is added to the system and the solvent, water, and ethanol removed by vacuum stripping, resulting in a clear, viscous liquid. At this stage other reactive monomers, polymers, or silane coupling agents can be added to the system. The homogeneous fluid is then cast into molds followed by initiation of the vinyl polymerization and further formation of the inorganic network at elevated temperatures.
Figure 1
Reaction sequence for the preparation of low shrinkage polymer–ceramic nanocomposites by a two-step sol–gel process.

Composites containing up to 50 wt.% silica were prepared with less than 20% volume shrinkage. Higher silica content composites display higher percentage volume shrinkage, but in all cases the volume shrinkage is less than that observed using conventional sol–gel techniques. This same approach was also applied to the preparation of materials for multimode channel waveguides (Xu *et al.* 1996).

Using a two-step process, epoxy/poly(methyl methacrylate) (PMMA)/silica hybrids were prepared and evaluated for contact lens use (Phillip and Schmidt 1984). Composites were prepared by combining TEOS, methacryloxypropyl trimethoxysilane, an epoxysilane coupling agent, and methyl methacrylate (MMA) or HEMA. When the silica phase was sufficiently formed, the viscous solution was poured into a mold and cured at 150 °C to initiate the MMA polymerization and complete the silica network formation. The use of silane coupling agents in the process prevents phase separation during the drying process and also improves the mechanical properties of the composites.

2. Solvent Displacement

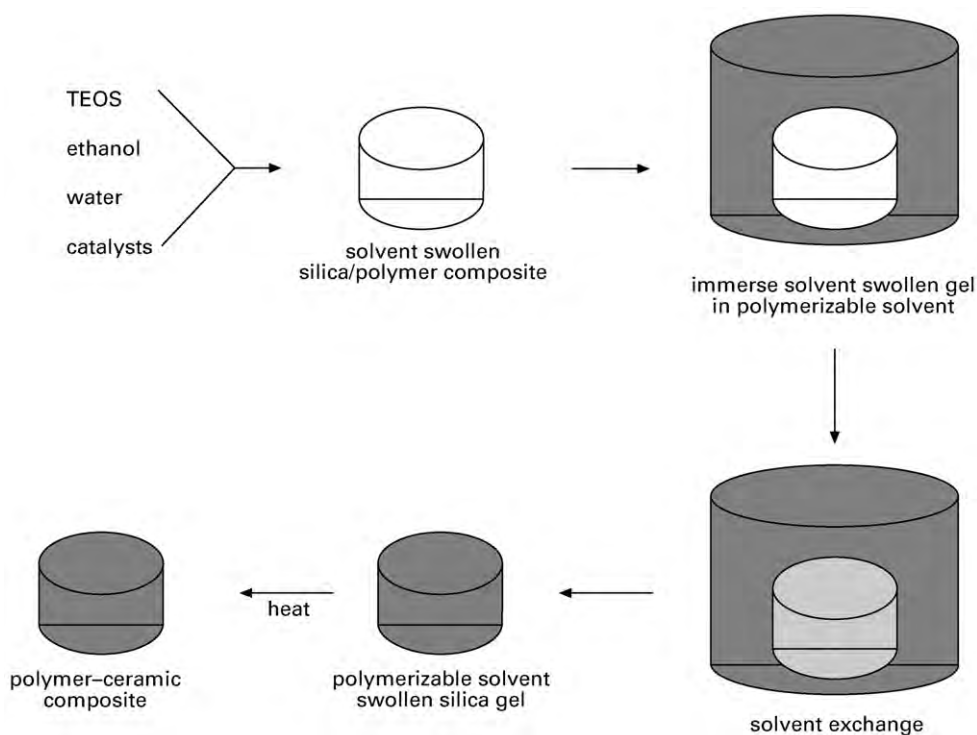
One method for eliminating the shrinkages associated with solvent evaporation is to replace the solvent with a reactive liquid which can be directly converted to a polymer (Fig. 2). The advantage of this approach is that the structure and morphology of the silica phase is controlled by the sol–gel processing conditions and no special adjustments of the process are required to accommodate the polymer during the formation of the silica network. An important limitation to this approach is that access to the silica gel monolith


Figure 2
The solvent exchange sequence for producing polymer–ceramic composites.

surfaces is required to effect the solvent exchange. This requires either a mold cavity with at least one open face, or handling of the very fragile solvent-swollen gel. Furthermore, achieving high ceramic ratios requires partial drying of the gel. The process of partial drying is complicated by the fact that some level of densification must be achieved in order to maintain the same network structure once the reactive solvent is introduced. If no further inorganic network formation has occurred in the partially dried gel, the material can swell to its original volume when reintroduced to a solvent. A final, but minor, limitation is that the polymerization of the reactive solvent is limited to addition polymerization since condensation polymerization would result in volatile by-products which cause unwanted shrinkage and porosity.

Pope *et al*. (1989) prepared sol–gel derived silica from TEOS in ethanol and then placed the solvent-swollen silica gel monolith into MMA. An equilibrium solution is established between the ethanol in the gel and the MMA resulting in diffusion of the ethanol out of the gel and infusion of the MMA into the silica gel matrix. By repeatedly decanting the MMA/ethanol solution from the silica gel monolith and adding fresh MMA, eventually all of the ethanol is removed. A free radical initiator such as a peroxide or azo compound is added to the system, followed by outgassing and heating to initiate the polymerization. After the polymerization is complete, excess PMMA is removed by polishing to obtain the finished silica–PMMA composite. The ratio of silica to PMMA is increased by partially drying the solvent-swollen silica gel prior to solvent exchange with MMA. In an extension of this approach, the silica glass was treated with methacryloxypropyl trimethoxysilane to provide a chemical bond between the PMMA and the glass.

In cases where the solvent used in the sol–gel process and the reactive solvent are not miscible, a secondary solvent exchange with a more general solvent, such as THF, is performed to replace the sol–gel solvent with a solvent that is miscible with the desired reactive solvent. If a porous composite is desired, the sol–gel solvent is exchanged with liquid carbon dioxide under supercritical conditions to produce composite aerogels (see *Organic Aerogels** and *Inorganic and Inorganic–Organic Aerogels**).

3. *Reactive Sol–Gel Precursors*

The two major components that are removed during the drying process of sol–gel derived composites are the solvent and the ethanol liberated during the hydrolysis and condensation of TEOS. By using a
Figure 3
Preparation of nonshrinking sol–gel polymer–ceramic nanocomposites from a silicone tetraalkoxide bearing polymerizable alkoxide groups.

tetraalkoxysilane derivative with polymerizable alkoxides, a polymerizable cosolvent and a stoichiometric quantity of water, all components in the reaction solution are converted to silica or polymer. Because all of the components are converted to solids, drying is unnecessary and the only shrinkage observed is the minor shrinkage associated with the bulk organic polymerization (Fig. 3). Because all of the components are converted to either ceramic or organic polymer in one step, processes such as reaction injection molding are possible, allowing for direct fabrication of monolithic composites and complex shapes.

This "nonshrinking" sol–gel composite process has been applied to silica-based systems using ring-opening metathesis polymerization (ROMP) (Ellsworth and Novak 1991) and free radical polymerization (Novak and Davies 1991). In order to achieve complete formation of both the inorganic network and the organic polymer network, the reaction rates of both the sol–gel polymerization and the organic polymerization must be carefully matched. If the inorganic network is allowed to form at a much faster rate than the organic polymerization, premature termination of the organic polymerization results, causing shrinkage in the composite due to the evaporation of unreacted monomer. This effect is most significant in transition metal catalyzed polymerizations such as ROMP. More importantly, the organic polymerization must not proceed faster than the inorganic network formation. In this case, large-scale phase separation of the polymer occurs and the inorganic network can no longer form in the solid organic polymer phase. Under ideal reaction conditions transparent polymer–ceramic nanocomposites are obtained, with no drying step needed.

4. Preformed Ceramic Oligomers and Colloids in Polymerizable Solvents

An important limitation to the polymerizable silicone tetraalkoxide approach described above is that the maximum inorganic content is limited to 10–18 wt.%

by the internal stoichiometry of the silica precursor (4 equivalents of polymer for every 1 equivalent of SiO$_2$). The glass content of nonshrinking sol–gel composites is increased by employing highly branched precondensed silica precursors such as poly(silicic acid) or colloidal silica. Poly(silicic acid) is prepared by the hydrolysis of sodium metasilicate in acidic aqueous solution resulting in a highly branched silica oligomer. The Stober process, which is used to prepare colloidal silica, involves the hydrolysis and condensation of TEOS in basic ammonium hydroxide/ethanol solution. Either form of silica is reacted with a polymerizable alcohol in an esterification reaction to produce an organically soluble, high silica content precursor for nonshrinking sol–gel composite preparation under the same reaction conditions employed in the polymerizable silicone tetraalkoxide approach. In both cases, all components in the reaction contribute to the inorganic network or the organic polymer network, but with higher inorganic content composites obtainable by using a preformed silica oligomer. Preformed ceramics such as colloidal silica and fumed silica have been used for many decades in the production of polymer–ceramic composites where only the polymer phase is continuous. The distinction in the systems described here is the simultaneous formation of an inorganic network within the polymer network resulting in levels of dispersion and stability not obtainable from conventional composites.

Poly(silicic acid) oligomers of varying molecular weight and degrees of branching are prepared by reacting sodium metasilicate in acidic aqueous solution. The molecular weight of the oligomers is controlled by increasing the reaction time to achieve higher molecular weights. By increasing the pH of the reaction solution, higher degrees of branching are achieved. Poly(silicic acid) esters are prepared from poly(silicic acid) and various polymerizable alcohols by a modified esterification process. The poly(silicic ester)s of acrylate derivatives in particular must be prepared under carefully controlled conditions to prevent spontaneous polymerization of the acrylate monomer. The degree of esterification must be high enough (greater than 50% of the total available reactive sites) for proper solubility of the poly(silicic ester) in a polymerizable cosolvent. Because the poly(silicic acid ester) still contains reactive silicone hydroxyl sites, the ester must be stored in dilute solution. The poly(silicic acid ester) is then used for nanocomposite preparation. For example, a poly(HEMA)–silica nanocomposite containing 50 wt.% silica was prepared by dissolving the HEMA ester of poly(silicic acid) in HEMA with benzoyl peroxide as a free radical initiator. A transparent nonshrinking composite was obtained after heating the sample under nitrogen to complete the formation of the inorganic network and to initiate the free radical polymerization. This process was applied to several

different acrylate esters as well as an oxanorbornene–
poly(silicic acid) ester polymerized by a transition
metal ROMP catalyst (Fig. 4).

Polymer–Ceramic Nanocomposites: Interfacial Bonding Agents

Organic–inorganic composites represent a special
class of materials with properties intermediate be-
tween organic polymers and inorganic ceramers (see

Polymer–Nonsilica Ceramic Nanocomposites*; *Poly-
mer–Silica Nanocomposites**). The primary goal of
preparing such composites is to achieve combinations
of properties from both components. One successful
approach for preparing organic–inorganic compos-
ites has been the *in situ* polymerization of metal alk-
oxides within organic polymer matrices via sol–gel
process. This process is based on hydrolysis of metal
alkoxides to produce metal hydroxides followed by
polycondensation of the hydroxyl groups to form a
three-dimensional network.

Unfortunately, incompatibility of two phases most
often tends to result in undesirable phase separation.
Thus, the interactions between the organic phase and
the inorganic phase is paramount in constraining
phase separation. The possible interactions between
the organic phase and the inorganic phase can be
achieved through hydrogen bonding, employing or-
ganic polymers with hydroxy or alkoxy terminating
chains which can participate in the hydrolysis reac-
tion used to generate ceramic, or bonding the dis-
similar phases with the use of a bonding agent
(O'Reilly and Coltrain 1996).

1. Interfacial Bonding

Bonding of organic polymers to inorganic surfaces
with the primary goal of preparing composites with
high strength-to-weight ratio has long been known
(Plueddemann 1991). In this approach, two dissimilar
phases are held together by use of a coupling agent,
also known as a bonding agent. This bonding agent,
in general, can undergo hydrolysis with the sol–gel
precursor forming the inorganic network, at the same
time it can react with the organic polymer. Improved
interfacial bonding between phases retards phase
separation, giving materials with enhanced proper-
ties. Thus, the overall quality of the composites can
be improved by the use of bonding agents, especially
under high-humidity and high-temperature condi-
tions. Silanes are most widely used as coupling agents
(Plueddemann 1991). However, other coupling agents
such as organotitanates, phosphorous-containing
compounds, and chromium coordination complexes
are also used.

2. Silane Coupling Agents

Silane coupling agents play an important role in the
preparation of composites from organic polymers
and inorganic fillers such as glass, minerals, and met-
als. The general structure of silane coupling agents
are $(RO)_3$-Si-R'-X, where X is an organofunctional
group, R' is a small alkylene linkage, and RO is a
hydrolyzable group such as an alkoxy group (Pape
1996). The organofunctional group and the alkoxy
group can form strong bonds with the polymer ma-
trix and with the filler particles, respectively. The

number of hydroxy groups resulting from the hydrolysis of alkoxy groups can be controlled by adjusting the rates of hydrolysis and condensation of the silane coupling agent to achieve optimal bonding effects (Premachandra *et al.* 1998). Figure 1 illustrates the mechanism of a silane coupling agent to improve the interfacial bonding between two phases.
Figure 1
Improved interfacial bonding by a silane coupling agent.

Organic groups such as vinyl, allyl, amino, methacryloxy, and epoxy groups, in general, react favorably with polymers (Stepek and Daoust 1983). Some commercially available silane coupling agents which can be utilized for different polymer systems are given in Table 1 (Stepek and Daoust 1983, Pape 1996).

3. Bonding in High-temperature Polymer–ceramic Composites

High-performance high-temperature polymers, in general, are difficult to treat in the usual sol–gel technique (see *Ceramic-modified High-temperature Polymers*). Because of their intractability, the processing is difficult, and their unreactivity often causes poor bonding between the organic polymer and the inorganic ceramic phase, resulting in undesirable phase separation. Therefore, improvements in bonding between the phases is critical in high-temperature polymers to achieve the desired properties.

Coupling agents used for high-temperature polymers should be of high thermal stability comparable with the polymer. Aromatic silanes, in general, have much better thermal stability and oxidative resistance

Vinyl-tris(β-methoxyethoxy)silane	$CH_2=CHSi(OCH_2CH_2OCH_3)_3$	

than aliphatic silanes. However, the aromatic silanes lack the high degree of reactivity which is required to function as coupling agents. High-temperature polymer composites have been prepared using some high-temperature polymers, including aromatic polyamides (Wang *et al.* 1993, Ahmad *et al.* 1997), polyimides (Morikawa *et al.* 1992, Wang *et al.* 1994), and some poly(benzoxazoles) (Premachandra *et al.* 1996), and poly(benzobisthiazoles) (Premachandra *et al.* 1996, Premachandra *et al.* 1999), with proper bonding between phases achieved by use of bonding agents.

3.1 Polyimide–ceramic Composites

Polyimide-silica hybrid materials prepared without using a bonding agent were transparent only up to a 8 wt.% of silica content (Morikawa *et al.* 1992). Scanning electron microscopy results demonstrated silica particles with diameters of approximately 5 μm in such films. However, increasing the chemical bonding between phases by using a bonding agent, specifically aminophenyltrimethoxysilane (APTMOS), increased dramatically the transparency of the materials was and the silica particle sizes were reduced (Wang *et al.* 1994). Thermal analysis showed no apparent decrease in thermal decomposition temperature by using APTMOS. Polyimide–silica hybrid materials prepared without a bonding agent showed an increase in the modulus but a decrease in the tensile strength. However, the improved bonding between the two phases increased both the modulus and tensile strength. The hardness measurements of hybrid materials with bonding between phases also showed an increase relative to the pure polymer whereas the hardness in hybrid materials prepared without the bonding agent decreased, as was the case for the tensile strength.

3.2 Polyamide–ceramic Composites

Poly(phenylene terephthalamide) have been used to prepare composites, in some instances, with improved interfacial bonding achieved by bonding agents. The composites prepared with the bonding agent APTMOS showed enhancements in the tensile strength and modulus with increases in the amount of the inorganic phase, silica (Wang *et al.* 1993, Ahmad *et al.* 1997). Composites prepared without the bonding agent, however, showed decreases in the tensile strength on incorporation of filler (Ahmad *et al.* 1997). Using a nonlinear polyamide with a large number of chain ends able to react with the inorganic network could increase the binding between two phases. The improvements in the tensile strength in this case were significant compared to the pure polyamide, which, however, showed a decrease in the tensile strength compared to the corresponding linear polyamide. The transparencies in both systems, linear and branched polyamides, in which the two phases were chemically bonded were improved compared to those composites prepared with no bonding agent.

3.3 Poly(benzoxazole)–ceramic Composites

Poly(benzoxazoles) (PBOs), in general, are intractable and insoluble in most organic solvents, causing difficulties when fabricating them into useful objects. By introducing specific functional groups and preparing functionalized copolymers, these polymers can be made somewhat more tractable. Hydroxy-functionalized copolymers of PBOs (HPBOs) which are soluble in tetrahydrofuran (THF) have been used to prepare composites using silica as the inorganic phase (Premachandra *et al.* 1996). HPBO–silica composites prepared without bonding could be redissolved in THF but the composites prepared with a bonding agent, specifically isocyanatopropyltriethoxysilane, were insoluble in THF. In addition, the transparencies of hybrid films were improved compared to those without the bonding agent. Substantial improvements in the tensile modulus and tensile strength for the composites could be achieved when a bonding agent is used.

3.4 Poly(benzothiazole)–ceramic Composites

Highly transparent hybrid materials prepared from sulfo-functionalized poly(benzothiazoles) (SPBTs) and silica have been reported (Premachandra *et al.* 1996). The insolubility of the resulting films in methanol suggests sufficient bonding between the polymer and silica phase. Substantial increases in mechanical and thermal properties were exhibited by the SPBT–silica composites compared to the pure polymer.

4. Summary

The improved interfacial bonding between phases can be achieved by using suitable bonding agents in the preparation of organic–inorganic composites. Thus, the macroscopic phase separation which is often a problem in the preparation of such composites can be suppressed. Improved interfacial bonding exerts a profound effect on the morphology of the resulting hybrid materials: it tends to suppress the agglomeration of ceramic particles, resulting in reduced particle sizes, thus increasing the surface area which can interact with the polymer. This allows the ceramic particles to interact with the polymer backbone at a molecular level, resulting in substantial reinforcement of the hybrid material.

Polymer–Ceramic Nanocomposites: Polymer Overview

Macroscopic inorganic–organic hybrids, notably fiberglass-reinforced epoxy, are well accepted composite materials. While they are essential to many industries, such as electronics, aerospace, and automotive, macroscopic composites have lost some of their glamour. Now the excitement in advanced materials is nanocomposites. Nanocomposites refer to the family of materials where the inorganic and organic components are mixed on the nanometer scale. This first section introduces the polymers that have been mixed in various ways with inorganic materials, mainly zeolites, clays, ceramics, and glasses. The details of synthesis and the discussions of structure–property relationships are left to the sections that follow.

This introduction includes both (i) simple textbook definitions of terms used in polymer technology and (ii) a "roadmap" to the literature on nanocomposites. Principal references and source materials in this field include special issues of the *Journal of Sol–Gel Science and Technology* (1995, 1996), Drzal *et al.* (1995), Coltrain *et al.* (1996), Laine *et al.* (1998), Klein *et al.* (1999) and Andrews and Najafi (1997). Also, see *Polymer–Silica Nanocomposites**.

By way of definition, a polymer is a long-chain molecule, a macromolecule, usually with a carbon backbone. The building block is the monomer. The polymer increases in molecular weight either by (i) addition polymerization or (ii) condensation polymerization. Addition polymerization involves the reaction of breaking a double bond to form two single bonds. A typical addition polymerization for ethylene is:

$$2(\overset{\overset{\textstyle H}{|}}{\underset{\underset{\textstyle H}{|}}{C}} = \overset{\overset{\textstyle H}{|}}{\underset{\underset{\textstyle H}{|}}{C}}) \rightarrow -(\overset{\overset{\textstyle H}{|}}{\underset{\underset{\textstyle H}{|}}{C}} \quad \overset{\overset{\textstyle H}{|}}{\underset{\underset{\textstyle H}{|}}{C}} \quad \overset{\overset{\textstyle H}{|}}{\underset{\underset{\textstyle H}{|}}{C}} \quad \overset{\overset{\textstyle H}{|}}{\underset{\underset{\textstyle H}{|}}{C}})- \quad (1)$$

with the application of heat or light. Typical addition polymers are polyethylene, poly(vinyl chloride) (PVC), poly(vinyl acetate) (PVAc), poly(methyl methacrylate) (PMMA), and polystyrene.

Condensation polymerization involves the reaction of two small molecules and produces a nonpolymerizable by-product. A polymerization for nylon is:

$$2NHRR'COOH \rightarrow \underset{\text{Aminoacid}}{NHRR'CO-NRR'COOH} + H_2O \quad (2a)$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\text{"B"}$$

$$\text{"B"} + NHRR'COOH \rightarrow$$

$$NHRR'CO-NRR'CO-NRR'COOH + H_2O \quad (2b)$$

where R is a univalent radical and R′ is a divalent radical ($(CH_2)_n$ where $n \geqslant 5$). The first step is carried out at $175\,°C$ with a catalyst and the second step is carried out at $250\,°C$ under vacuum. Typical condensation polymers include nylon (hexamethylamine and adipic acid), polyamides, polyimides, and polyesters.

The functionality of the polymer refers to the number of reaction sites available. A bifunctional monomer produces linear polymers. A trifunctional or tetrafunctional monomer produces network polymers. When polymerization occurs between two different monomers, the result is a copolymer.

A reasonable question to ask at this point is why combine organic and inorganic materials? Some obvious reasons are that (i) organic materials in inorganic ones reduce the overall density of the object, (ii) inorganic materials in organic ones improve their hardness and mechanical properties in elastomeric, glassy, and semicrystalline states, (iii) organic

polymers in porous inorganics produce pore-free materials without high-temperature treatment, and (iv) mixing inorganic and organic materials on the nanoscale introduces new phenomena we are just beginning to understand.

In the following sections materials are described that are designed, in some cases, for structural applications and, in other cases, for functional uses, for optical, electronic, and catalytic applications. The processes used to prepare these materials variously lead to one-, two-, and three-dimensional structures. The phases are described as "guest and host," "infiltrant and matrix," and *in situ*. The common theme is that all of the materials are classified as hybrids and all of them are nanocomposites.

1. Definition of Nanocomposite

First, we use the term hybrid as the generic term for an inorganic–organic material. An accepted name for many of these materials is organically modified silicates (ormosils) (Schmidt and Wolter 1990) or, more generally, organically modified ceramics (ormocers) (Schmidt 1994). Another name is ceramic modified with polymer (ceramer) (Huang *et al.* 1985).

The second term we use commonly is nanocomposite to emphasize the nanometer level of mixing. Nanocomposites often refer to hybrids where organic and inorganic constituents are not covalently bonded, but it also applies to covalently bonded constituents. The forces acting between the constituents vary from weak to relatively strong.

Some notable attempts to classify hybrids have appeared. For example, Chujo and Saegusa (1992) have reviewed inorganic–organic materials prepared where the organic constituents are polymers, but not low molecular weight radicals or groupings. Sanchez and Ribot (1994) divide hybrids into two classes: Class I corresponds to hybrids where organic molecules are blended into the inorganic network, whereas Class II includes hybrids where inorganic and organic constituents are linked together via covalent bonds. Avnir *et al.* (1998) concentrate on inorganic–organic hybrids using organofunctional silicon alkoxides. Wen and Wilkes (1996) classify the resulting materials as networks. The dimensionality of hybrids has been reviewed by Lerner and Oriakhi (1997), principally in layered materials. We prefer the terms physical hybrids and chemical hybrids (Wojcik and Klein 1997). Overall these classifications organize hybrids into groups by looking at (i) the structure, (ii) methods of preparation, or (iii) the nature of links between organic and inorganic constituents.

The majority of processes treated in the following sections refer to the sol–gel process (Brinker and Scherer 1990). The sol–gel process is defined in this context as the hydrolytic process with a metal alkoxide such as tetraethylorthosilicate (TEOS). Upon

addition of water TEOS in a cosolvent hydrolyzes:

$$Si(OC_2H_5)_4 + 4H_2O \rightarrow Si(OH)_4 + 4C_2H_5OH \quad (3)$$

and polymerizes:

$$Si(OH)_4 + Si(OH)_4 \rightarrow (OH)_3Si - O - Si(OH)_3 + H_2O \quad (4)$$
to build a silicate network. In time, the system arrives at the sol–gel transition where an irreversible gel exists. In the single component system, it is known that the result is an oxide skeleton which is porous once the solvent is removed.

The sol–gel approach as described is a room-temperature process. Polymers that otherwise are destroyed at ceramic processing temperatures can be incorporated. The impetus for so many combinations of polymers and oxides is, in fact, the sol–gel process. The concept of modifying inorganic networks by using covalent bonding works when the M–C (M is the metal species: aluminum, silicon, titanium, zirconium, etc.) bond is stable and does not undergo hydrolysis under the conditions of the sol–gel process.

1.1 Physical Nanocomposites

(*a*) *Interpenetrating networks.* A major classification of hybrids is interpenetrating networks, characterized by a time factor, i.e., sequential or simultaneous. The terminology of interpenetrating polymer networks (IPNs) is borrowed from organic polymer technology (Sperling 1981). In some cases semisequential is used to reflect the linear structure of the organic polymer in which a cross-linked inorganic network is formed.

Some of the earliest inorganic–organic hybrids were prepared by monomer infiltration into a previously formed silica gel. This is an example of a sequential interpenetrating network where the inorganic is the matrix. Specifically, when a dried silica gel (xerogel) is filled with monomer, the monomer can be polymerized *in situ*. Interpenetration is achieved when the impregnating monomer polymerizes in the open pores of the rigid, fully cross-linked silica matrix. In the polymer-impregnated gels, some porosity typically remains. Although some copolymers of methyl methacrylate, butadiene, and styrene have been used as polymers to impregnate silica, the best-known system is silica impregnated with PMMA (Klein 1994). While this type of hybrid was important at first, it has been surpassed by other methods that are simpler.

Another type of sequential interpenetrating network uses silica precursors (TEOS or tetramethylorthosilicate (TMOS)), which are able to solvate some organic polymers (Beaudry and Klein 1996). The polymer solubility enables the silica precursor to polymerize in the environment of an organic polymer solution. This is an example of a sequential interpenetrating network where the organic phase is the

matrix. The number of polymers that form solutions with sol–gel formulations is, however, limited. Some initially soluble polymers tend to precipitate during gelation when a change in solvent composition leads to phase separation.

While only a few organic polymers are soluble in sol–gel formulations, many organic monomers are soluble in TEOS (Wojcik and Klein 1995a). These monomers can be introduced directly into sol–gel formulations. Both ring opening polymerizations and free radical polymerizations can be carried out simultaneously with the hydrolysis–condensation of TEOS. To reflect their synchronous polymerizations, the name is simultaneous inorganic–organic interpenetrating polymeric networks. This simultaneous route captures insoluble organic polymers within a sol–gel inorganic network. Generally, the resulting hybrids have no covalent linkages between the organic and inorganic components. The exception occurs when the organic monomer has hydroxyl or carboxyl groups that can lead to M–O–links.

In the preparation of simultaneous networks, it is important to control both polymerizations rates. On the one hand, systems with inorganic condensation rates much faster than the organic polymerization rates turn into brittle hybrids that shrink because the polymer content drops when unreacted monomer evaporates. On the other hand, systems with large organic polymerization rates usually show uncontrolled polymer precipitation. In practice, the kinetics of polymerization are difficult to control, so the success of the simultaneous approach rests on the careful selection of the monomers.

The idea of simultaneous interpenetrating networks has been advanced by Ellsworth and Novak (1993). Several monomers of acrylate type (free radical polymerization) or cyclic alkenes (ring opening metathesis) have been used. They include the acrylamide/N,N'-bisacrylamide monomer system, 2-hydroxyethyl or hydroxymethyl acrylate, and 7-oxanorbornene and its derivatives. In order to get nonshrinking hybrids, tetraacryloxyethoxysilane has been used instead of TEOS. The acrylate monomer liberated due to hydrolysis acts as a cosolvent to solvate the polymerizing silica network. The result is transparent hybrids with no shrinkage. Wojcik and Klein (1994) have studied the incorporation of silica with di- and triacrylate monomers, hexanediol diacrylate (HDDA), and glyceryl propoxy triacrylate (GPTA). These simultaneous IPNs are transparent hybrids with good mechanical strength.

For functional applications, inorganic gels can be doped with small quantities of organic molecules. Doped gels are prepared either by addition of organics into sol–gel solutions, or by infiltration of the dopant into previously formed xerogels. Although some interactions between the dopant molecules and the inorganic matrix take place, the optical properties or chemical functions of the organics are preserved in the solid state. A number of organics have been used, including organic dyes and chromophores, liquid crystals and active biomolecules, and enzymes and proteins, in order to produce specific optically active or bioactive devices for a broad range of optic and electro-optic applications. Suitably doped gels exhibit highly efficient luminescence, photochemical hole burning, photochromism, and tunable laser action (Avnir *et al.* 1994). In pure inorganic matrices, the activity of the dopant has been found to decrease because of thermodynamic incompatibility with the inorganic phase. Consequently, organic-doped inorganic gels have been replaced with organic-doped hybrid gels. A good example is PMMA–silica composites doped with organic laser dyes, where the hybrid has better properties as a laser host than either pure PMMA or pure silica.

(*b*) *Soluble polymers.* For those select polymers that are soluble in metal alkoxide solutions, the preparation of inorganic–organic hybrids is very simple. Taking again the example of silica, the polymerization of the silica precursor occurs around existing polymer chains or domains. Generally it is found that polymerization of TEOS in the presence of polymers under acidic conditions generates small, well-dispersed silica particles. Depending on the choice of polymer, highly transparent, lightweight materials can be obtained. Among the polymers used to form these sequential IPNs, those that give transparent hybrids are those capable of forming hydrogen bonds with hydroxylated silica particles (Landry *et al.* 1992a). Strong interactions between silanols, having the character of Brønsted acids, and specific groups on the polymer that are hydrogen acceptors are responsible for the high degree of two-phase mixing.

Linear polymers with hydrogen acceptor groups, amide, carbonyl, and carbinol, have been used in semisequential inorganic–organic IPNs. These polymers are poly(N,N-dimethacrylamide), poly(2-methyl-2-oxazoline), PMMA, poly(vinyl pyrrolidone) (PVP), poly(acrylic acid) (PAA) and its copolymers, PVAc, and poly(vinyl alcohol) (PVA) (Landry *et al.* 1992b).

In detail, the properties of the hybrids are functions of the relative fractions of the polymer and TEOS in the sol–gel formulation, along with the chemistry and length of the polymer chain. When TEOS is polymerized in the presence of the polymer, the glass transition temperature (T_g) of the polymer increases or becomes undetectable. The density of the hybrid does not follow a mixing rule for the inorganic and organic components, but is suppressed even with high inorganic contents. More or less porous structures can be formed with open or closed pores. We have studied the optical properties, mechanical properties, and phase separation in sol–gel formulations containing PVAc and poly(ethylene oxide) PEO. These are

useful model systems for understanding the behavior in physical nanocomposites (Klein *et al*. 1997).

1.2 Chemical Nanocomposites

(*a*) *Monomer systems*. The purely inorganic three-dimensional network in the conventional sol–gel process consists of M–O–M units in the general case, or Si–O–Si units for silica. The purely organic polymer consists of C–C covalent bonds, in the general case, between mers in a polymer backbone, along with weaker van der Waals bonds between polymer chains. However, in a sol–gel process carried out with a precursor containing direct inorganic–organic links, it is possible to form homogeneous materials with C–C, M–C, and M–O bonds. This class of hybrids constitutes inorganic–organic polymers. Undoubtedly, the largest class of true inorganic–organic hybrids is made up of hybrids linked via Si–C bonds that are stable and do not undergo hydrolysis under the sol–gel processing conditions.

There are several methods to link covalently polymers to silica. In an early example, silanol-terminated poly(dimethylsiloxane) (PDMS) was co-condensed with TEOS:

$$2Si(OH)_4 + HO-[-\underset{\underset{CH_3}{|}}{\overset{\overset{CH_3}{|}}{Si}}-O-\underset{\underset{CH_3}{|}}{\overset{\overset{CH_3}{|}}{Si}}-]-OH \rightarrow$$

$$-O-\underset{\underset{CH_3}{|}}{\overset{\overset{CH_3}{|}}{Si}}-O-[-\underset{\underset{CH_3}{|}}{\overset{\overset{CH_3}{|}}{Si}}-O-\underset{\underset{CH_3}{|}}{Si}-]-O-\underset{\underset{CH_3}{|}}{Si}-O-+2H_2O$$

$$(5)$$
to give inorganic–organic PDMS chains, containing nonbridging methyl groups and nonlinear Si–O–Si angles, which exhibited significant flexibility (Mackenzie *et al*. 1992). When the functionality of PDMS is increased to six (the number of alkoxysilyl groups per oligomeric chain) or PDMS is replaced by poly(tetramethylene oxide) (PTMO), the stiffness and mechanical strength improve considerably (Wang *et al*. 1991).

In a way similar to PDMS and TEOS, other organic polymers have been functionalized with alkoxysilyl groups and covalently bonded to silica. Polymers that have been coupled with silica are PTMO-based polyurethane oligomers, polyoxazolines, polyimide (Mascia and Kioul 1995), poly(arylene ether ketone), poly(arylene ether sulfone), polystyrene, polyoxopropylene (PPO), polyacrylonitrile, copolymers of methyl methacrylate and allyl methacrylate (Wei *et al*. 1990), and cyclophosphazenes (Guglielmi *et al*. 1994).

Naturally, the properties of inorganic–organic hybrids are governed by their microstructure. For example, cellular structures are observed in PDMS–silica gels when the sol–gel parameters (water, HCl concentration, and temperature) are adjusted to accelerate the gelation process. With high concentrations of the organic component, hybrids have low densities, indicating high free volumes characteristic of the organic polymers.

Another method leading to covalent linkage of organic polymer to silica is free radical polymerization. When an organic radical R′ in an organo-substituted silicoester of formula R′Si(OR)$_3$ contains olefinic moieties, it is possible to build a polymeric network by thermal or photochemical free radical polymerization of C=C bonds, for example:

$$R\bullet + CH_2 = CHX \rightarrow R-CH_2-CHX\bullet \qquad (6)$$

$$R-CH_2-CHX\bullet + CH_2=CHX \rightarrow R-\overset{\overset{H}{|}}{\underset{\underset{H}{|}}{C}}-\overset{\overset{H}{|}}{\underset{\underset{X}{|}}{C}}-\overset{\overset{H}{|}}{\underset{\underset{H}{|}}{C}}-\overset{\overset{H}{|}}{\underset{\underset{X}{|}}{C}}\bullet \qquad (6a)$$
where R$\bullet$ is a free radical and X is Cl, acetate, CH$_2$CCl$_2$, etc. An initiator to produce the free radical is often benzoyl peroxide, (C$_6$H$_5$)$_2$C$_2$O$_4$. Epoxide groups are also polymer-formers via cationic polymerization or via condensation with curing agents bearing groups such as amine or hydroxyl. Organic polymerization can be carried out simultaneously with condensation of hydrolyzed alkoxysilyl groups.

The commonly used organoalkoxysilanes bearing polymerizable C=C bonds are 3-methacryloxypropyl trimethoxysilane (MEMO) (CH$_2$=C(CH$_3$)COO(CH$_2$) Si(OCH$_3$)$_3$) and vinyl trimethoxysilane (VTMS) (CH$_2$=CH–Si(OCH$_3$)$_3$) or their ethoxy analog. Alkoxysilyl groups of these inorganic–organic monomers form Si–O–Si bonds upon condensation or co-condensation with another silica precursor such as TEOS. At the same time, (meth)acryl or vinyl groups are able to polymerize with inorganic–organic monomers or with (meth)acrylic or vinyl monomers. These processes lead to the formation of inorganic–organic polymers and copolymers.

Reportedly, inorganic polycondensations of inorganic–organic monomers by the sol–gel process from single monomer systems are difficult. For most of the inorganic–organic precursors, gelation times under acidic conditions are quite long. The reason for the long gelation time is the low concentration of alkoxysilyl groups and steric hindrance from organics in the system. However, the process can be accelerated by incorporation of TEOS.

An idealized structure of an inorganic–organic copolymer synthesis by co-condensation and copolymerization of the tri-monomer system TEOS–vinyl-triethoxysilane (VTES)–hydroxyethyl methacrylate

(HEMA) is shown below. To accelerate gelation and at the same time reduce shrinkage, inorganic oligomers are used instead of inorganic precursors.

$$(7)$$
Ellsworth and Novak (1993) used soluble oligomers of silicic acid instead of TEOS in a condensation with (meth)acryl trialkoxysilane to increase the silica content of inorganic–organic hybrids and reduce shrinkage. Hoebbel *et al.* (1994) used tetramethylammonium silicate $((N(CH_3)_4)_8Si_8O_{20} \cdot 69H_2O)$ converted by an ion-exchange process into double four-ring oligomers of silicic acid $(H_8Si_8O_{20})$. This oligomer can be stabilized by reaction with functional siloxanes containing polymerizable groups like vinyl, allyl, hydrido, or chloromethyl. The functionalized derivative can be polymerized while preserving silicic acid cages in the structure.

When the inorganic–organic monomer bears two or more olefinic moieties in its structure, the monomer becomes highly reactive, creating very favorable conditions for rapid cross-linking by photopolymerization. A series of diacrylate alkoxysilanes was synthesized by Wolter *et al.* (1992) by coupling mercapto-substituted alkoxysilanes to the triacrylate monomers or acrylate resins. The resulting inorganic–organic monomer can be co-condensed via its alkoxysilyl groups with TEOS, whereas its acrylic groups can be cured by UV light, or polymerized thermally. Likewise, diacrylotrialkoxy silane inorganic–organic monomer from aliphatic triacrylate-glycerol propoxy triacrylate (GPTA) and 3-mercaptopropyl triethoxysilane was used to synthesize UV-curable coatings for optical fibers (Wojcik *et al.* 1993).

A subgroup of hybrids containing a covalent link are those where the polymer exhibits specific electronic or electro-optic properties. Examples of these hybrids include nonlinear optics (NLO) polymer–silica gels, organic dye–silica gels, and conducting polymer–silica gels. For example, organic dye–silica gels of cyan, magenta, and yellow were synthesized at Kodak, where the chromophore was linked covalently to the polymeric component via the reaction of an amine, halogen, or isocyanate functionality, while the silica and polymeric components were covalently bonded via the action of 3-chloropropyltrimethoxysilane. Polymers with conducting properties like polypyrrole, polyaniline, or polythiophene have been covalently incorporated into silica, following their alkoxysilyl functionalization (Sanchez *et al.* 1994).

(*b*) *Monomer–polymer systems*. When the organic component is a low molecular weight group or radical and not a polymeric chain or network, the hybrid is an organically modified gel (ormogel) as distinct from an ormosil. Ormogels are formed from $R'Si(OR)_3$-type organosilanes where radical R has a network-modifying effect and is used to introduce new functionalities into the inorganic network. For example, hydrophobicity can be achieved by introducing a methyl, phenyl, or fluoroalkyl chain for R (Schmidt *et al.* 1986). Polymerization of $R'Si(OR)_3$ alone leads to formation of silsesquioxanes of general formula $(RSiO)_{1.5}$, a silicate framework where each silicon is linked covalently to an organic radical R. A new class of hybrids is emerging called polyhedral oligomeric silsesquioxanes (POSS) that can be blended into rubbers, resins, thermoplastics, and thermosets to enhance thermal stability (Lichtenhan *et al.* 1995).

Bifunctional silanes of formula $R'R''Si(OR)_2$ are used also to prepare ormogels. Upon polymerization, these organoalkoxysilanes form cyclic species or linear chains that are not able to cross-link and form networks themselves. They can be used with tetrafunctional silanes (TEOS) to incorporate desirable functionality into the hybrid network. There are also ormogels where radical R forms a bridge between two silicon atoms. Good examples of these are arylene or alkylene-bridged polysilsesquioxanes synthesized from bis(triethoxysilyl) or bis(trichlorosilyl) aryl or alkyl monomers (Shea *et al.* 1989). Various aliphatic or aromatic molecules have been used as the organic spacer between two silicon atoms.

(*c*) *Copolymers*. Copolymers are the products of addition polymerization between two different monomers. Some examples have been mentioned in the sections on physical nanocomposites, as well as chemical nanocomposites. Between two linear polymers such as PVC and PVAc, the units can be arranged in a random copolymer, block copolymer, or graft copolymer. The interesting aspect of copolymers is that the properties of the copolymer are often quite different from the properties of either homopolymer.

In the context of nanocomposites, the term copolymer is applied to polymers with organic and inorganic units. Here especially, the properties of the copolymer are different from the properties of either component. Systems with two or more monomers

open opportunities for designing properties, using surface treatments, coupling agents, and sophisticated manufacturing methods.

To recap on chemical nanocomposites, we find that covalently bonded hybrids combine the flexibility and mechanical properties of the organic polymer chains with the hardness and stiffness of the inorganic polymer. In detail, the properties of the hybrids are governed by the chemistry, presence of side chains or pendant groups, and length of polymeric chains. Especially important are the concentration and distribution of alkoxysilyl or equivalent groups, as they directly affect the rigidity or flexibility of the system.

2. Classes of Polymers in Nanocomposites

The five classes of polymers that have been incorporated into organic–inorganic hybrids, principally using the sol–gel process, are discussed.

2.1 Elastomers

An elastomer is a polymer with high elasticity due to its coiled structure. A typical elastomer is nonvulcanized rubber, where the chains are first unkinked when a stress is applied, followed by chain straightening and lengthening. Elastomers are poorly crystallized but become more crystalline as they are stretched. Some examples of elastomers include rubbers, polyurethane, and PDMS.

2.2 Partially Crystalline Polymers

Crystallization in polymers is often difficult, leading to glassy or partially crystalline polymers. In general, linear polymers are easier to crystallize than network polymers. Isotactic (the same stereostructure) polymers are easier to crystallize than atactic (random positions) or syndiotactic (alternating positions) polymers. Likewise, it is easier to crystallize polymers in the *trans* (unsaturated positions on opposite sides of the chain) than in the *cis* (unsaturated positions on same side of the chain) configuration. Condensation polymers such as poly(ethylene glycol terephthalate) (Dacron), polyimide, and nylon exhibit some crystallinity because of their moderately stiff chain structures.

2.3 Glassy Polymers

A common example of a glassy polymer is PMMA, where it is difficult to crystallize PMMA because of the atactic structure following addition polymerization. Glassy polymers exhibit a glass transition characterized by the temperature range where the polymer changes its behavior from glassy to rubbery.

2.4 Liquid-Crystalline Polymers

An example of a liquid-crystalline (LC) polymer is hydroxypropyl cellulose (HPC) or 4′-pentyl-4-biphenylcarbonitrile. The characteristic of LC polymers is that they align what are called nematogenic compounds in response to electric fields. LC polymers encapsulated in inorganic materials have been developed for displays. The inorganic encapsulation gives the liquid crystals thermal stability.

2.5 Thermosets

Thermosetting polymers are polymers that do not soften when heated. Instead, a thermoset polymerizes further with increasing temperature, resulting in a continuous network where polymer units cannot slip past each other. An example of a thermosetting polymer is phenol formaldehyde, where phenol (C_6H_6O) and formaldehyde (CH_2O) undergo condensation polymerization to generate phenol formaldehyde that is able to link at a minimum of three places and a maximum of five places.

3. Weak and Strong Bonding in Nanocomposites

3.1 Covalently Bonded Systems

The majority of hybrids investigated have covalent bonds between the organic and inorganic components. These bonds are formed before incorporation into a nanocomposite. A typical route involves a metal alkoxide that has been functionalized via a mercapto group (Wojcik and Klein 1995b):

$$H-S-(CH_2)_3-\underset{\underset{\displaystyle OCH_3}{|}}{\overset{\overset{\displaystyle OCH_3}{|}}{Si}}-OCH_3 \tag{8}$$
which is used during the creation of the nanocomposite when a reactive site, such as a vinyl group:

$$\underset{Si(OC_2H_5)_3}{\overset{CH=CH_2}{|}} \tag{9}$$

is available and covalently bonded to the silicon atom. The reason that forming direct linkages has been popular is, in large part, that it ensures strong bonds between the components.

3.2 Hydrogen-Bonded Systems

The minority of hybrids investigated have hydrogen bonds between the organic and inorganic components. These bonds are formed between hydroxyls on the inorganic gel and ether oxygens on the polymers

assuming a resonant hybrid pair for PEO:

$$[+CH_2-CH_2-O-/+O-CH_2-CH_2-] \rightarrow$$
$$-(O-CH_2-CH_2-)_{n-} \qquad (10)$$

or carbonyl groups on the polymers:

$$
\begin{array}{c}
-(CH_2-CH)_n- \\
\vert \\
O \\
\vert \\
C=O \\
\vert \\
CH_3
\end{array}
\qquad (11)
$$
as in the case of PVAc. The reason that there are few hydrogen-bonded hybrids is directly related to the small number of water-soluble monomers and the even smaller number of soluble polymers. Nevertheless, the technological importance of the hydrogen-bonded systems is evident in the development of organically modified electrolytes (ormolytes) (Charbouillot *et al.* 1988).

3.3 Phase Separation: Phenomena and Kinetics

As described above, physical hybrids depend on the polycondensation of an inorganic network in the presence of an organic polymer dissolved in the solution, or polymerization of organic monomers inside the porous inorganic network. To obtain homogeneous mixing, the degree of phase separation has to be controlled. There should be strong, attractive interactions between the organic and inorganic polymers to achieve good interfacial bonding. Polymers containing carbonyl groups, such as PVAc, can be incorporated into sol–gel processes because they are soluble in alcohol–water mixtures due to partial esterification of the side chains. Polymers containing ether oxygens, such as PEO, sometimes referred to as poly(ethylene glycol) (PEG), are soluble in water because the ether oxygens readily form hydrogen bonds.

Landry *et al.* (1992b) have demonstrated the simplicity of the approach with TEOS and a number of polymers. Depending on (a) the synthesis conditions and (b) the relative amounts of organic and inorganic polymer, the morphologies ranged from discrete silica particles within an organic matrix, to interpenetrating networks, to polymeric domains dispersed within a silica matrix. Under acidic conditions with TEOS it was possible to form optically transparent films with PMMA, PVAc, poly(vinyl pyrrolidone), and poly(*N,N*-dimethacrylamide). Hydrogen bonding between the silanols on the silica polymer and the carbonyl groups on the polymers prevented macroscopic phase separation. Phase separation, if any, occurred on such a small scale that transparent materials were formed without the need for covalent bonding. Fur-

thermore, there is no evidence for chemical reactions below 150 °C. Acetic acid was evolved from PVAc above 200 °C, but this is likely to be a decomposition product and not an indication of covalent bonding between TEOS and PVAc.

Polymerization of TEOS in the presence of a soluble polymer does not always lead to a homogeneous mixture. Kaji *et al.* (1993) have taken advantage of the incompatibility of PAA and silica and PEO and silica. Their studies have shown that the scale of the phase separation and its timing are dependent on (i) the amount of polymer, (ii) the molecular weight of the polymer, (iii) the solvent composition, and (iv) the pH. The gel morphologies are the results of a competition between phase separation and gelation, also referred to as "chemical quenching." The rate of gelation of the silica network is in opposition to the rate of phase separation, which is an indication of the segregation strength. When gelation is faster than phase separation, the system becomes rigid with a morphology reflecting the early structure of the gel. When phase separation is faster than gelation, the system becomes rigid with a variety of transient structures that are increasingly heterogeneous, with the extreme case being sedimentation.

4. Importance of Interfaces in Inorganic–Organic Nanocomposites

The interface between the organic and the inorganic constituents is the key issue in hybrids and nanocomposites. In our work we are measuring strengths, hardness, and skeletal densities of some representative systems. Mechanical behavior is at best an indirect measurement of interface behavior. However, by relating these properties to bonding and microstructure, we try to examine the nature of the interface and the scale on which it controls properties.

Other properties, such as optical, electronic, magnetic, catalytic, and chemical durability require further investigation. We need to understand what these properties tell us about the interfaces, so that we can better engineer the interfaces.

Finally, we should address the questions, what analytical techniques are available to probe the interface? Are indirect measurements more or less meaningful than direct measurements, considering that performance may be a reflection of averaged properties? Other articles in this encyclopedia should shed some light on these subjects.

Polymer-modified Ceramics

Ceramics are inorganic solid compounds that contain metallic and nonmetallic elements, such as silica glass, the cement of concrete, and most of high temperature superconductors. Polymers, such as polystyrene, polysiloxane, and proteins, are large molecules built up by the linking together of great numbers of much smaller molecules that contain nonmetallic elements. Polymer-modified ceramics are materials that contain both the polymer and ceramic components mixed homogeneously at the molecular or nanometer scales. There are two major families of polymer-modified ceramics: (i) polymer–ceramic hybrid materials, which have strong chemical interactions between the polymer and ceramic components such as extensive hydrogen-bonds and/or covalent bonds; and (ii) polymer–ceramic molecular composites (or nanocomposites), in which the polymer components are physically trapped in the ceramic networks with no or limited chemical interactions. Though all these terms (and many others) have been loosely used, one significant feature of the polymer-modified ceramics is that the polymer components are uniformly dispersed, with or without formation of chemical bonding, in the inorganic networks and, therefore, the macroscopic interfaces (e.g., $\geqslant 400$ nm—wavelength of visible light), that exist in traditional composite materials between the polymer and the inorganic components, are eliminated.

In this article, the major theme is the synthesis and characterization of polymer-modified ceramic materials in which the polymer is the dispersed phase for improving the properties of the host ceramic matrix. Discussion is focused mainly on the hybrid materials that have strong interactions, such as extensive hydrogen-bonding and/or covalent bonding, between the polymer (particularly vinyl plastics) and ceramic (particularly silica, alumina, and titania) components. Various synthetic routes are reviewed with emphasis on the chemically or photochemically catalyzed sol–gel reactions under controlled conditions, so that the polymer chains are uniformly incorporated into the ceramic networks without macroscopic phase separation. The chemical, physical and biological properties of the polymer-modified ceramics are described and their dependence on the structure and composition of the polymer and ceramic components is outlined. Examples are selected mostly from results, including some original data, from the author's laboratory. A number of potential applications are presented. Related information can be found in *Polymer–Ceramic Nanocomposites: Polymer Overview** and *Polymer–Ceramic Nanocomposites: Ceramic Phases**.

1. General Principles

Since the 1970s, the field of materials science has witnessed the emergence of a sol–gel process for the preparation of ceramic materials from precursor compounds in the presence of a catalyst at relatively low temperatures. For example, acid-catalyzed hydrolysis and polycondensation (i.e., the sol–gel reactions) of tetraethyl orthosilicate (TEOS) yield a silica glass at temperatures much lower than the conventional fusion process. Because most organic polymers (i.e., carbon-containing polymers) undergo thermal decomposition under the high-temperature conditions that are often required for processing ceramics, the sol–gel process opened a new door in materials science that allows for the synthesis of polymer-modified ceramics, i.e., the integration of polymers and ceramics, two major types of industrial materials in modern society.

From 1980 to 1990, silica sol–gel materials were covalently modified by small organic groups, i.e., organic-modified silica or Ormosils (e.g., Schmidt 1985), by polymers containing heteroatoms in the backbones such as polydimethylsiloxanes (e.g., Huang *et al*. 1985), polyethers (e.g., Huang and Wilkes 1987), and polyoxazolines (e.g., Chujo *et al*. 1990), and by vinyl polymers such as polymethacrylates (e.g., Wei *et al*. 1990). Modification of polymers by *in situ* precipitation of sol–gel silica was also achieved (e.g., Jang and Mark 1984). To date, many dozens of various types of polymers have been successfully incorporated into silica, titania, alumina, zirconia and other ceramic matrices via the sol–gel process. A number of excellent books and reviews have been published related to the polymer-modified ceramics (e.g., Mackenzie and Ulrich 1988, Brinker and Scherer 1990, Wilkes *et al*. 1990, Novak 1993, Mark *et al*. 1995, Laine *et al*. 1998, Klein *et al*. 1999).

Ceramics are generally known for their hardness and brittleness, along with their resistance to high temperatures and to severe environments. In addition, many ceramic materials such as silica glass have excellent optical properties such as transparency. For most applications, their brittleness (i.e., lack of impact strength) is the major, sometimes fatal, deficiency of ceramics. However, organic polymers are usually noted for their low density and high toughness (i.e., high impact strength). They can be tailor-made to have excellent elasticity (e.g., synthetic rubbers) or optical transparency (e.g., polymethacrylates or Plexiglas^{TM}). However, lack of hardness is one of most significant flaws of polymers in many applications. Associated with the lack of hardness are the problems of low wear and scratch resistance as well as dimensional stability. The development of conventional composite materials with ceramics as fillers and polymers as matrices have solved some of the above-mentioned problems to some extent. Because of organic–inorganic thermodynamic incompatibility, the presence of macroscopic interfaces between the inorganic fillers and organic matrices often leads to many undesired problems in the performance of materials. For example, mechanical failure often

occurs because of cracking of the interfaces. Treatment of the fillers with silane coupling agents strengthens the interfaces to a certain but limited extent. In addition, optical properties such as transparency of either silica or polymethacrylates cannot be maintained due to the existence of macroscopic phase separation in conventional composites.

Hence, among the motivations for developing polymer-modified ceramics has been toughening of ceramics by polymers or hardening of polymers by ceramics in a controllable manner without sacrificing the optical properties. By varying the structure and composition of polymer and ceramic components, the idea was that properties of the polymer-modified ceramics would be designable in a continuum between those of pure polymers and pure ceramics. Polymer–ceramic nanocomposites or molecular composites would achieve such a goal. If the polymer–ceramic phase separation is at the microscopic level (e.g., domain size of either the polymer or ceramic component <400 nm), the materials are transparent to visible light. However, again because of the thermodynamic incompatibility between the usually hydrophobic polymer chains and the usually hydrophilic ceramic matrices, the dimension of the phase separation cannot be controlled easily during the sol–gel processing and the interfaces, however small in scale, remain weak. In contrast, polymer–ceramic hybrid materials could fundamentally eliminate the interface problem because the thermodynamic repulsion can be compensated by the formation of strong chemical bonding between the polymer and ceramic components. In the case where the bonding is covalent, the materials can be considered as cross-linked copolymers that contain organic and inorganic building blocks.

2. Synthesis

There are a number of general strategies for the synthesis of polymer-modified ceramics based on sol–gel chemistry. (i) Ceramic matrix route: forming a porous inorganic sol–gel matrix first and impregnating the matrix with monomers followed by polymerization *in situ*. (ii) Polymer matrix route: forming a polymer matrix first and impregnating it with an inorganic precursor followed by the sol–gel reactions to deposit or precipitate a ceramic component in the polymer matrix. (iii) Polymer precursor route: forming a polymer precursor that bears sol–gel active functional groups first and mixing it with an inorganic precursor followed by the sol–gel reactions of both precursors. (iv) Simultaneous formation of ceramics and polymers: preparing a mixture or compound that contains both the sol–gel reactive preceramic and the polymerizable monomer components first and initiating both the sol–gel reactions and polymerization at nearly the same time.

It is noted that the ceramic materials prepared via the sol–gel process without densification at elevated temperatures are porous and, hence, often referred to as gels. For example, pure silica obtained by the sol–gel reactions of an inorganic precursor like TEOS under acid catalysis at ambient temperature is microporous, with internal pore diameter and surface area typically about 15–20 Å or smaller and about $100–200$ m^2 g^{-1} respectively, based on measurements of adsorption isotherms of gases such as N$_2$. The ceramic matrix route takes advantage of this porosity by impregnating monomers along with polymerization initiators or catalysts into the pores. Polymerization of the monomers inside the porous ceramic matrix yields a polymer-modified ceramic material, which can be considered as a polymer-ceramic semi-interpenetrating network or interpenetrating network (IPN) if the polymerization results in cross-linking of polymer chains. As an example, monolithic sol–gel silica was soaked with methyl methacrylate (MMA), which was then polymerized *in situ* with a free radical initiation system to afford the PMMA-modified silica (Pope *et al.* 1989). It is conceivable that further exploration of this route would lead to many interesting new materials, particularly if some polymerizable functional groups are present on the surface of the internal pores of ceramic matrices to form covalent bonds between the matrices and the polymer chains, and if the pore parameters, e.g., size and distribution of the internal pores in the matrices, can be controlled as in the cases of microporous and mesoporous molecular sieves.

In the polymer matrix route, a polymer with or without cross-linking is impregnated with an inorganic sol–gel precursor, which undergoes the sol–gel reactions *in situ* to form ceramic components in the polymer matrix. As examples, sol–gel silica was successfully introduced into plastics and elastomers (Jang and Mark 1984). As a possible generalization of this polymer matrix route, a polymer could be mixed with a sol–gel precursor to form a homogeneous solution and, after the sol–gel reactions, the polymer chains could be entrapped in the ceramic network, in principle, uniformly at the molecular level. However, among the difficulties in such a generalization is the thermodynamic incompatibility of organic polymers with inorganic networks that leads to macroscopic phase separation before and/or after the gelation (i.e., in sols and in gels, respectively), as often evidenced by the formation of translucent or opaque gel products. There are a few examples where highly hydrophilic polymers such as polyethers are encapsulated in inorganic sol–gel matrices without apparent macroscopic phase separation. To prevent the macroscopic phase separation, strong interactions between the polymer and ceramic components are required—this leads to the third and the fourth synthetic strategies, i.e., the polymer precursor route and the simultaneous formation of

polymers and ceramics, which are described below in detail.

2.1 Polymer Precursor Route

In the polymer precursor route, preformed polymers that contain a designed number of sol–gel active functionalities are employed as precursors to mix and react with inorganic sol–gel precursors. The active functionalities include those that can undergo the sol–gel reactions with the inorganic precursors, such as hydroxysilyl ($\equiv$Si-OH), alkoxysilyl ($\equiv$Si-OR), silane ($\equiv$Si-H), and halosilyl ($\equiv$Si-X; X = Cl, Br, etc.) groups. The cross-condensation of these functional groups with similar or identical groups in the inorganic precursor, e.g., $Si(OEt)_4$ and its hydrolysis product $Si(OH)_4$, would result in covalent bonding, e.g., siloxane $\equiv$Si-O-Si$\equiv$ bonds, between the polymer chains and the ceramic matrix, e.g., silicates formed by self-condensation of $Si(OEt)_4$ and/or $Si(OH)_4$. Since the formation of covalent bonds may kinetically pre-empt the thermodynamic repulsion, hydrophobic polymers like vinyl polymers could be homogeneously transfixed in hydrophilic ceramic matrices. A general methodology has been thus developed to prepare vinyl polymer-modified ceramic hybrid materials (Wei *et al.* 1990, 1995a).

The use of vinyl polymers to modify ceramics is of great importance because these polymers are among the most widely used organic materials in our daily life. To list just a few general categories of usage, polystyrene (PSt), poly(methyl methacrylate) (PMMA), poly(vinyl chloride) (PVC), and isotactic polypropylene can be used as plastics; polyacrylonitrile (PAn), poly(vinyl acetate) (PVAc), and linear polyethylene as fibers; and polybutadiene, polyisoprene, and poly(styrene-block-butadiene) (SBR) as elastomers or rubbers. As a basic strategy for the synthesis of the sol–gel active vinyl polymers such as poly[methyl methacrylate-co-3-(trimethoxysilyl)propyl methacrylate] [P(MMA-MSMA)], common vinyl monomers such as methyl methacrylates, acrylonitrile, and styrene are copolymerized with monomers such as 3-(trimethoxysilyl)propyl methacrylate (MSMA) that contain one or more sol–gel active functional groups, e.g., -SiOMe. The general equations for the preparation of vinyl polymer precursors and their subsequent sol–gel reactions with inorganic precursors are illustrated in Fig. 1.

The number (y) of the sol–gel active units in the polymer precursor can be designed and controlled by varying the co-monomer feed and other synthetic parameters. It is usually maintained low to yield the copolymers whose properties are closer to those of conventional vinyl polymers. However, if it is too low, macroscopic phase separation might occur during the sol–gel reactions. The distribution of the sol–gel active units along the copolymer chains can also be controlled by using proper copolymerization

Figure 1
Preparation of the sol–gel active polymer precursors and subsequent sol–gel reactions with inorganic precursors. X, Y and Z are various groups; R: alkyl groups; $m = 1$, 2 or 3 (with attachment of other groups to Si when $m \neq 3$); Si can be replaced by other metals such as Al, Ti, Zr, etc.; -OR can be replaced by other sol–gel active groups such as halogen, etc.

methods and conditions. These polymer precursors are then hydrolyzed and co-condensed with one or more inorganic precursors at ambient temperature to afford the vinyl polymer-modified hybrid ceramic materials. The generality of this strategy could in principle allow for incorporation of virtually any vinyl polymers into sol–gel ceramic matrices.

The alkoxysilyl-containing monomers that have been employed include 3-(trimethoxysilyl)propyl methacrylate, 3-(triethoxysilyl)propyl methacrylate (ESMA), styrylethyltrimethoxysilane (STMS), etc. It is interesting to note that many of these sol–gel active monomers have been extensively used as silane coupling agents in the manufacturing of traditional composite materials. Vinyl monomers include methyl methacrylate, ethyl methacrylate (EMA), sec-butyl methacrylate (SBMA), styrene (St), acrylonitrile (An), ethylene-propylene-diene elastomer (EPDM), etc. The inorganic precursors include TEOS, tetramethyl orthosilicate (TMOS), titanium tetraisopropoxide (TIPO), aluminum tri-sec-butoxide (ASBO), etc.

As part of the same strategy, the sol–gel active functionalities can also be introduced to the polymer precursors via chemical transformation of the groups in preformed polymers. For example, poly[methyl methacrylate-co-3-(triethoxysilyl)propyl methacrylate] [P(MMA-ESMA)] precursors with designed number of trialkoxysilyl groups and molecular weights were prepared by the living group-transfer copolymerization of allyl methacrylate with methyl methacrylate using trimethylsilyl ketene acetal as initiator and tris(dimethylamino)-sulfonium bifluoride

(TASHF$_2$) as catalyst, followed by hydro- silylation of the ester allyl groups in the polymer in the presence of the Speier's catalyst (H$_2$PtCl$_6$), as shown in Fig. 2 (Wei *et al.* 1990). Anhydride groups in vinyl polymers such as poly(styrene-co-maleic anhydride) can be converted to sol–gel active groups by treatment with 3-aminopropyltriethoxysilane (Zhou *et al.* 1998). Taking advantages of tremendous progress in the synthetic polymer chemistry, it is conceivable that polymer precursors with various architectures such as star and comb polymers, dendrimers, hyperbranched, and nanostructured polymers could be prepared to have sol–gel active functionalities along the main chains or as the end groups for ceramic modification.

Sol–gel active functional groups in polymer precursors also include those that can form extensive hydrogen bonds, ether (e.g., $\equiv$Si-O-C$\equiv$), ester (e.g., $\equiv$Si-O-CO-C$\equiv$) and other types of covalent bonds with ceramic sol–gel precursors. As examples, poly(methacrylic acid), poly(hydroxyethyl methacrylate), poly(vinyl alcohol), and poly(styrene sulfonic acid) can form hybrid materials with sol–gel ceramic matrices through ether, ester, and/or hydrogen bonding. The hydroxy groups in the sol–gel reaction intermediates and in the ceramic network (e.g., silanol group$\equiv$Si-O-H) may function as both the donor and acceptor of hydrogen bonds with a variety of functional groups such as hydroxyl, amine and carbonyl groups. Taking advantage of the acidity of the silanol proton, polymer–ceramic hybrid materials could also be obtained under proper conditions, based on ionic charge pairing between the ceramic component and ion-containing polymer chains.

(a) Group-transfer polymerization

PAMA ($x = 0$) or PA-MMA
(b) Hydrosilylation
Figure 2
Synthesis of polyacrylate precursors via group-transfer polymerization.

In addition to vinyl polymers, polymer precursors can be prepared via step-growth or ring-opening polymerizations or copolymerizations. Among the examples are polyamides, polyimides, polyethers, polysiloxanes, polyesters, and epoxy polymers. In fact, polydimethylsiloxanes with sol–gel active -SiMe$_2$-OH end groups were used as polymer precursors in some pioneering works of synthesizing polymer–ceramic hybrid materials (e.g., Huang *et al.* 1985). The polysiloxane chains are covalently bonded to sol–gel silica matrix by forming the silyl ether linkage (i.e., $\equiv$Si-O-SiMe$_2$-). Like their counterpart in the vinyl polymer precursors, sol–gel active functional groups can be introduced to step-growth or ring-opening polymers by using the monomers that bear the sol–gel active groups in the polymerization or by post-polymerization transformations. Many polymers prepared by step-growth and ring-opening reactions already contain sol–gel active functionalities such as -OH, -COOH, -COCl, $\equiv$Si-OH, $\equiv$Si-Cl, etc., along the main chain or as the end groups. These polymers can be used directly in the sol–gel reactions with inorganic precursors to afford polymer-modified ceramics. It is important to emphasize that in the designing of any polymer precursors, the number of the sol–gel active functionalities per polymer chain should be great enough to overcome or compensate the thermodynamic repulsion between usually hydrophobic polymer and hydrophilic sol–gel ceramic components, in order to avoid macroscopic phase separation.

2.2 Sol–Gel Reactions of Polymer Precursors

In general, all the techniques for preparing pure sol–gel ceramics can be adopted or modified for the synthesis of polymer–ceramic hybrid materials. Typically, the sol–gel reactions of both the polymer and inorganic precursors are carried out in the presence of an acid (e.g., aqueous HCl) or a base catalyst (e.g., NH$_3$·H$_2$O) in a medium containing water and organic solvent, e.g., alcohols, tetrahydrofuran (THF) and *N*-methylpyrrolidinone (NMP), at room or elevated temperatures (usually $<100\,^\circ$C). By optimizing reaction conditions, hybrid materials in a form of bulk objects or thin films can be made transparent, monolithic, and free of cracks. The polymer–ceramic composition of the hybrid materials is governed by the amounts of polymer and inorganic precursors in the reactants. The chief purpose for using organic solvents is to dissolve both the polymer and inorganic precursors. The organic solvents are selected based on the following criteria: (i) they can dissolve the precursors; (ii) they have reasonable solubility in water; (iii) they have no or limited undesired reactions with the components in the system; and (iv) preferably, they are volatile compounds and can be removed readily by evaporation during the drying

and aging of the gels. There is not much limitation in the choice of inorganic precursors, except for the consideration that the reactivity of the inorganic precursors should be comparable to that of the sol–gel active groups such as -Si(OMe)$_3$ in the polymer precursors. If the difference in reactivities is too high, there would be excessive self-condensation among either the polymer precursors or the inorganic precursors, leading to macroscopic phase separation. The high temperature densification or sintering of gels, as in the preparation of pure ceramics, is avoided to prevent thermal decomposition of the polymer component. It is known that acid-catalysis tends to yield more linear intermediates, while the base-catalysis tends to generate highly branched and, hence, globular intermediates in the sol–gel reactions before gelation. Therefore, the acid catalysts are often preferred, particularly when a product of excellent optical transparency is desired.

As an example, the synthesis of polymethacrylate–silica hybrid materials is achieved by the HCl-catalyzed sol–gel reactions of the trialkoxysilyl groups in the polymer precursor P(MMA–MSMA) with the inorganic precursor TEOS. The process consists of the following typical steps: (i) preparation of a solution (A) of the polymer precursor in an organic solvent (e.g., THF); (ii) HCl-catalyzed prehydrolysis of TEOS in a mixture of water and THF to give soln B; (iii) combining solutions A and B while stirring to afford a homogeneous solution (C); (iv) further reactions leading to gelation and formation of a homogeneous, transparent wet gel; and (v) aging and drying (by evaporating the solvents and byproducts, i.e., water and alcohol) to afford a homogeneous, transparent, and monolithic polymethacrylate–silica hybrid material. The purpose of the prehydrolysis is to form silanols and oligosilicates that can rapidly react with the polymer precursors before the occurrence of possible polymer–silicate phase separation in solution C. Various synthetic parameters, such as type and amount of catalysts and solvents, amounts of the polymers, inorganic precursors and water, reaction temperature, and rate of evaporation of the volatile, are optimized to assure optical transparency and integrity of the products.

A photochemically catalyzed sol–gel synthesis of polymer-modified ceramics was developed (Wei *et al.* 1994a). In this method, the catalyst for the sol–gel reactions is a photoacid, which is neutral in the dark and generates acid upon exposure to light. Among typical photoacids are diphenyliodonium chloride (DIC) and triphenylsulfonium hexafluoroantimonate (TSHF), both of which yield protonic acid under UV radiation. The acid thus generated catalyzes the sol–gel reactions. To prepare the polymethacrylate–silica hybrid materials, a mixture of the trialkoxysilyl-bearing polymer precursors, TEOS, THF, water, and a photoacid (e.g., DIC or TSHF) is exposed to UV radiation. After a certain time period, the initial

organic/water phase separation disappears because of hydrolysis of alkoxysilyl groups and the system becomes a homogeneous solution. Subsequent gelation, aging, and drying steps are the same as in HCl-catalyzed process to yield homogeneous, transparent hybrid materials. As controls, no sol–gel reaction was observed for the system without the photoacid after exposure to the UV radiation or for the system with the photoacid that was kept in darkness for over 24 hours. This photochemical method is very general and can be readily extended to the synthesis of any type of polymer-modified sol–gel ceramics. It should find interesting applications in lithography, and in the coating and dental materials industries. By choosing appropriate photoacids, various light sources could be employed including sunlight.

The kinetics of the sol–gel reactions of mixed polymer and inorganic precursors have been studied to some extent. The presence of polymer precursors usually shortens the time required for the system gelation. In the case of poly[methyl methacrylate-co-3-(trimethoxysilyl)propyl methacrylate] [P(MMA-MSMA)] precursors, the higher the polymer content the shorter the gelation time. Such a trend was interpreted based on the fact that the polymer chain bears more reactive alkoxysilyl functional groups per molecule and, therefore, reaches gelation (i.e., formation of cross-linked network) sooner than the inorganic precursor TEOS. For the same reason, the polymer precursors containing more MSMA units have shorter gelation time than those containing fewer MSMA units (Wei *et al.* 1995a). Many multicomponent ceramic systems have also been investigated. For example, ternary P(MMA-MSMA)–SiO_2–Al_2O_3 and P(MMA–MSMA)–SiO_2–TiO_2 hybrid materials were synthesized via the sol–gel reactions of P(MMA-MSMA) with TEOS, TIPO, and/or ASBO. Alkoxides of different metal elements are known to have a wide range of reactivities toward hydrolysis. The titanium and aluminum precursors, TIPO and ASBO, react with water much faster than does TEOS, often resulting in inhomogeneous sol–gel products. Among the solutions to this problem are (i) to introduce of a chelating organic ligand into the reaction to reduce the hydrolysis rate of the highly reactive metal alkoxides; and/or (ii) to change the in addition sequence of the reactants so that the less reactive precursors will have longer time to react before the more reactive precursors are added.

2.3 Simultaneous Formation of Ceramics and Polymers

Despite the many great advantages of the sol–gel process, there are several severe, sometimes detrimental, drawbacks in this process, which have limited its technological applications. One of the inherent problems in conventional sol–gel process is exceedingly large volume shrinkage resulting from the removal of solvents and small molecular by-products of hydrolysis and polycondensation such as water and alcohol. The volume shrinkage can easily reach 75% or more. For example, the theoretical shrinkage from TEOS to silica without any solvent is 55% based on their bulk densities. Thus, the preparation of monolithic sol–gel materials with predictable and controllable shape and dimension becomes very difficult and time-consuming because of the high internal stress induced by the volume shrinkage.

Among a few strategies developed to overcome the problem is the simultaneous formation of ceramics and polymers for the preparation of polyacrylate–silica composites. One elegant design is to make the alkoxy groups in the inorganic precursors polymerizable such as $Si(OR)_4$, where R is acrylate monomer moiety, CH_2=CMe–COO–. The sol–gel reactions of $Si(OR)_4$ proceed simultaneously with a free-radical polymerization of the acrylate sol–gel by-product so that no small ROH molecules will be released from the system and the volume shrinkage is reduced significantly or nearly eliminated (Ellsworth and Novak 1991). One of the limitations of this method is that only a fixed, low ceramic content in the composites can be obtained. To increase the silica content, poly(silicic acid) was introduced to the synthetic system as the major silica source (Novak and Ellsworth 1993), which, however, often has an adverse effect on optical transparency of the products.

Another strategy is based on removing most of the volatile molecules from the reaction systems just before gelation (Wei *et al.* 1996). In this method, the sol–gel precursors are commercially available alkoxides such as TEOS and vinyl monomers such as 2-hydroxyethyl methacrylate (HEMA), which contain sol–gel active functional groups (e.g., OH in HEMA). First, acid-catalyzed sol–gel reactions of TEOS are allowed to proceed, in the presence of the vinyl monomer HEMA, until the system becomes homogeneous. The silanol (SiOH) groups in the silicate colloids or hydrolyzed TEOS then react with the OH groups in HEMA to form covalent linkage between the monomer and the silicate component. At this stage, a polymerization initiator, such as the thermal radical initiator benzoyl peroxide (BPO) or photoinitiator benzoin methyl ether (BME), is dissolved in the solution and the reaction system is placed under a dynamic vacuum to remove large amount of solvent (i.e., THF) and by-products of the sol–gel reactions. After exhaustive pumping, the resultant nonvolatile fluid can be cast in molds of desired size and geometry. Then the free-radical polymerization of the vinyl monomers can be initiated either by increasing the temperature when the thermal initiator is used or by exposing the system to light when the photoinitiator is used. The vinyl polymerization proceeds simultaneously with further sol–gel reactions to afford the organic–inorganic hybrid materials. Since the

major portion of solvent and small molecular by-products are removed before the gelation, the volume shrinkage from the casting stage to the final hybrid product is significantly reduced to about 6–20% at silica contents up to 47%.

Because of the low volume shrinkage, the shrinkage-induced stress is lessened and the probability of crack formation in the hybrid materials is, therefore, greatly reduced. The sample preparation time is greatly shortened, from a few weeks to about 12 hours or less. Furthermore, vinyl monomers other than HEMA can be introduced into the system before the initiation of the vinyl polymerization so that the hybrid materials containing a variety of organic polymers can be designed and prepared. Other methods, such as differential solvent extraction, for removing the volatile molecules before the system gelation have also been investigated.

3. General Characterization Techniques

In general, the structures of polymer-modified ceramics can be characterized by most of the techniques that are commonly used for characterization of polymers and ceramics. Solid-state nuclear magnetic resonance (NMR) spectroscopy (particularly ^{29}Si NMR for silica) has proven informative. Conventional solution NMR can be employed in monitoring the sol–gel reactions up to gelation. Electronic absorption spectroscopy (UV–vis) can be performed on a monolithic disk or film of the polymer–ceramic sol–gel materials to yield information about the structure and optical properties including transparency. Infrared spectroscopy (IR) is suitable for identifying characteristic bands of the polymer and ceramic components in the final products. From intensities of the IR absorptions, polymer–ceramic composition can be estimated. Thermogravimetric analysis (TGA) is particularly useful for determining compositions in the materials by decomposing all the organic polymer contents at high temperatures (e.g., $> 700\,^{\circ}\text{C}$). For example, the silica contents in the vinyl polymer–silica hybrids measured from TGA generally agree well with the calculated values based on the stoichiometry of the starting materials. In addition, many other physical properties, such as bulk density, refractive index, and hardness, exhibit strong correlation with the polymer–ceramic compositions of the hybrid materials. Extraction of the materials with a good solvent for the polymer can be employed to access qualitatively if there is a strong, particularly a covalent, bonding between the polymer and ceramic components.

There have been many studies of morphology and microstructures of polymer-modified ceramics using techniques such as x-ray diffraction and transmission and scanning electron microscopy (TEM and SEM). Atomic force microscopy (AFM) has proven helpful in identifying polymer–ceramic phase separation, or lack of it, in the hybrid materials (Wei *et al.* 1998a). The internal porosity of the sol–gel materials is commonly measured by nitrogen adsorption–desorption isotherms (the BET method). Differential scanning calorimetry (DSC) serves as an important technique in characterizing the glass transition of the polymers in the ceramic matrices. Lack of a well-defined glass transition temperature (T_g) generally indicates that the polymer chains are uniformly distributed in the materials. Dynamic mechanical analysis (DMA) can be used not only to study the glass transition but also to evaluate mechanical properties of the materials. In principle, all the standardized tests (e.g., ASTM protocols) can be employed for evaluating the polymer-modified ceramics. The limitation for these tests is in the sample preparation. Because of the volume shrinkage and stress-induced cracking, as mentioned above, it is very difficult to prepare samples of large dimensions per specifications with good reproducibility. Therefore, a relatively small number of reports has been published on systematic evaluation of mechanical and other physical properties of the polymer–ceramic hybrid materials.

4. Properties and Potential Applications

Polymer-modified sol–gel ceramics are usually amorphous, transparent to visible light and, therefore, the scale of phase separation, if any, should be below the wavelengths of visible light (i.e., $< 400\,\text{nm}$). In general, physiochemical properties of the materials are between those of pure polymers and pure ceramics as anticipated and can be controlled by varying the polymer–ceramic compositions. Polymer–ceramic hybrid materials can be made harder than polymers and less brittle than ceramics. Typically, as the ceramic content is increased, the glass transition temperature of the polymer measured with DSC and DMA increases, becomes less pronounced and eventually disappears, because of the increasing restriction of large-scale, cooperative segmental motions of the polymer chains. The thermal stability of some polymer components (e.g., polyacrylates) is enhanced as indicated by the higher thermal decomposition temperatures compared to those of pure polymers. Optical properties such as index of refraction can be continuously tuned, e.g., from ~ 1.45 for sol–gel silica to 1.49 for PMMA or 1.60 for polystyrene (Wei *et al.* 1992, 1993a). This has prompted investigations of these hybrid materials for applications in optical waveguides and circuitry (Xu *et al.* 1996). Nonlinear optical (NLO) properties have also been explored by introducing vinyl polymer precursors that contain NLO moieties with either the second ($\chi2$) or third ($\chi3$) harmonic generation into a sol–gel silica matrix. Taking advantage of the restricted motion of polymer chains in the ceramic

matrices, thermal randomization of the $\chi 2$ moieties could conceivably be minimized if the formation of ceramic network occurs concurrently with poling under electric or magnetic field.

4.1 Mechanical and Surface Properties

Bulk density and hardness of polymer-modified ceramics increase with ceramic content. For example, Vickers hardness was found to increase drastically from $\sim 20\,\mathrm{kg\,mm^{-2}}$ for pure polystyrene to $\sim 120\,\mathrm{kg\,mm^{-2}}$ for polystyrene–silica hybrid materials at silica content of $\sim 80\%$ (Wei *et al*. 1993a). The value for pure sol–gel silica is $\sim 160\,\mathrm{kg\,mm^{-2}}$. The relationship between the hardness and the silica content becomes linear after the silica content reaches $\sim 20\%$ as dictated by percolation theory. Similarly, the hybrid materials exhibit superior scratch-resistance over polymers. There have been numerous studies of mechanical properties of polymer-modified ceramics by dynamic mechanical analysis (DMA) (e.g., Wei *et al*. 1998c). In general, the storage modulus (E') becomes higher and the loss factor ($\tan \delta$) is smaller as the ceramic content is increased. All the results suggest that polymers are stiffened and hardened by the introduction of ceramic components.

As a typical example of the standardized tests for mechanical properties, a comparative study using the standard compressive strength test (ASTM D695-91) was performed in the author's laboratory on P(MMA-MSMA)–silica hybrid materials prepared via the polymer precursor route and on conventional composites of PMMA with fused silica powder as filler (particle size: 8–17 µm). Figure 3 shows the stress–strain behavior of the hybrid materials (bottom) in comparison with that of conventional composites (top) at various silica contents (wt%) as indicated by the last number in the curve labels. Pure sol–gel (SG) silica and PMMA (Plexiglas[TM]) were also tested for comparison. It is clear that the behavior of the hybrids differs significantly from conventional composites. In the range of silica contents up to $\sim 50\%$, the curves for the PMMA–silica composites are very similar. In sharp contrast, the Young's modulus, yield and compressive strength of the hybrid materials increase rapidly as the silica content is increased. At silica contents of 32% and higher, the yield stress increases drastically and the hybrid materials exhibit strain hardening, which is not observed for PMMA–silica composites with up to 50% silica filler. It was also noticed that during compressive tests most of the hybrid samples maintained their excellent optical transparency even after the yielding points, until the moment of implosion. However, the composite samples crazed (see *Polymer Glasses, Fracture of: Crazing*[#]) after yielding. These results could be interpreted based on the picture that in the hybrid materials there is no macroscopic phase
Figure 3
Stress–strain curves of conventional PMMA–silica composite (top) and P(MMA-MSMA)–silica hybrid materials with 10% MSMA in P(MMA-MSMA) precursor (bottom). The silica content (wt.%) of each sample is indicated by the last number on the curve label.

separation. Similar linear correlations of modulus and silica content were observed with the standard flexural 3-point-bending test (ASTM C1161-90; C674-88) on poly(2-hydroxyethyl methacrylate) (PHEMA)–silica hybrid materials. The modulus increased from $\sim 1.6\,\mathrm{GPa}$ for pure PHEMA to $\sim 3.2\,\mathrm{GPa}$ for the hybrid samples with silica content of 34%.

Based on their controllable mechanical properties, polymer-modified sol–gel ceramics can be designed for many applications. As examples, P(MMA-MSMA)–silica hybrid materials have been explored as a new generation of dental materials, which have chemical components similar to those of conventional dental composites (i.e., silica as fillers and polyacrylates as matrices) but no undesired macroscopic interfaces that could lead to mechanical failure and microleakage in the oral environment (Wei and Jin 1997). By tuning the hardness of the hybrid materials, hard coatings or pressure-sensitive coatings/capsules could also be obtained.

The polymer modification improves the impact strength of sol–gel ceramics significantly, particularly when the polymers of high flexibility and low T_g such as polydimethylsiloxanes are employed. Relative

brittleness of vinyl polymer–ceramic hybrid materials was evaluated, however, qualitatively because of the difficulties in the preparation of samples for standardized tests. The brittleness of the PMMA–silica hybrid samples tends to decrease as the polymer content is increased. At the same polymer content, the materials prepared from the polymer precursors containing fewer sol–gel active trialkoxysilyl groups (i.e., $Y \ll X$ in Fig. 1) appear to be less brittle than those containing more trialkoxysilyl groups (e.g., $X = 0$). Such a trend can be rationalized by considering segmental motions of polymer chains that could absorb impact energy. The higher the trialkoxysilyl group content the greater the extent of cross-linking via the formation of Si–O bonds, which leads to lesser segmental motions through conformation changes of the polymer chains and, hence, more pronounced brittleness of the materials. For the same reason, the effect of molecular weight of the polymer components is usually less pronounced than that of extent of cross-linking on many mechanical properties. Though this article has emphasized the amorphous hybrid materials without macroscopic phase separation, it should be noted that for some applications the phase-separated materials are actually desired. For example, deformation or breakage of numerous small and weak interfaces could absorb externally applied energy or relax internal stress more uniformly to avoid catastrophic failure of the bulk material. Furthermore, polymer-modified ceramics with controllable degrees of crystallinity present interesting opportunities in the exploration of nanostructured materials.

Polymer-modified ceramics may exhibit designable surface properties because both polymers and ceramics, typically hydrophobic and hydrophilic, respectively, are exposed on the surface. For example, by controlling the compositions of PMMA–silica hybrid materials, the contact angles of water on the surface of the hybrid materials were found to be much greater than that of silica glass and to increase with the polymer content, approaching the value for pure PMMA. With consideration that the PMMA–silica hybrids should have better thermodynamic compatibility with polyacrylate resins, applications of the hybrid materials as filler to substitute for powdered silica in conventional dental composites have been investigated. Composites were prepared using both the PMMA–silica hybrid materials and the powdered silicas (with or without surface silane treatment) as fillers in a commercial 2,2-bis(*p*-2-hydroxy-3-methacryloxy-propoxyphenyl)propane (bis-GMA) resin system. The results of compressive tests showed that the samples with the hybrid fillers had elastic moduli and maximum strengths comparable to or higher than those with silane-treated silica fillers at the same silica content in the composites (Wei *et al* 1998b).

Introduction of sol–gel ceramic components to polymers can also significantly improve adhesion of polymers as coatings to inorganic substrates, which often contain surface hydroxy groups that can react with the sol–gel precursors. For example, polyaniline, an important electroactive polymer, could be employed as thin-film coatings in electrochromic, electrooptical, chemical/biological sensing, and electronic devices. However, the films exhibited poor adhesion to the substrates such as indium–tin oxide (ITO) and silica glasses, particularly in aqueous media, which severely limited the performance and lifetime of the devices. By modifying polyaniline solutions with relatively small amounts (e.g., 10 wt.%) of sol–gel precursors such as TEOS or trialkoxysilyl-containing polymethacrylates, adhesion of the solution-cast composite films to ITO and silica glasses was increased dramatically while the electrooptical properties of polyaniline remained satisfactory (Jang *et al*. 1996, Wei *et al*. 1995b).

4.2 Chemical Properties and Postsynthesis Modifications

Both polymer and ceramic components in polymer-modified sol–gel ceramics can undergo a variety of reactions to afford new materials of desired properties. As examples, the polyacrylonitrile component in hybrid silica materials was found to undergo pyrolysis in an inert atmosphere towards the formation of carbon fibers of micro- or nanostructures in the silica matrix (Wei *et al*. 1993b). Chemoselective hydrolysis of polyacrylonitrile component yields new water-soluble polyacrylic-modified silica materials via transformation of nitrile (-CN) groups to amide ($-CONH_2$) and carboxylate ($-COO^-$) groups (Wei *et al*. 1994b). Sulfonation of the polystyrene component in the polystyrene–silica hybrid materials resulted in new materials containing sulfonate groups with good cationic exchange properties (Wei *et al*. 1997). Similarly, chloromethylation can yield anionic exchange materials. Properly functionalized hybrid materials could also be used in chromatography, solid-phase protein synthesis, polyelectrolytes, catalysts, and membranes for bioseparations. The ceramic components can also undergo post-synthesis reactions. As examples, the Si-OH groups on the external or internal surfaces could be alkylated and silica content could be removed with reagents such as HF or strong bases.

The organic polymer content in polymer–ceramic hybrid materials could be removed by thermal or chemical decomposition to afford porous ceramic materials. For example, a PMMA–silica hybrid sample synthesized at room temperature was found to have a BET surface area of $\sim 0.1 \, m^2 \, g^{-1}$. After thermal treatment at $\sim 400 \, ^{\circ}C$ in nitrogen, the polymer content was completely removed leaving a porous silica with a dramatically increased surface area of $\sim 630 \, m^2 \, g^{-1}$ and an average pore diameter

of ∼28 Å. By tailoring the nature and the composition of the polymers, it is possible to control the size and volume of the pores and/or microchannels in the porous inorganic materials (Wei *et al*. 1995a). These materials could also be made to contain other metal oxides such as titanium, vanadium, zirconium, etc., via multicomponent sol–gel process. Polymers such as poly(ethylene oxide) (PEO) have been employed to form PEO–ceramic sol–gel composites. Upon removal of PEO, meso- or nanoporous molecular sieves were obtained. There are many potential applications for these porous ceramic materials including catalysts/catalyst supports, reaction templates, host matrices for fabricating capacitors, and as size-selective membranes for construction of biosensor devices.

Polymers can also include many bioactive substances such as proteins, DNAs, RNAs, polysaccharides, etc. In this sense, there has been a large body of work on encapsulation or immobilization of biomolecules in sol–gel ceramics (e.g., Avnir *et al*. 1994, Wei *et al*. 1999). These biopolymer-modified ceramics have tremendous potential for applications in biocatalysis, biosensor, medical, and pharmaceutical industries.

5. Concluding Remarks

Polymer-modified ceramics have become an important area of research in both polymer and ceramic sciences since the 1980s. There has been a great deal of fundamental research on the synthesis, characterization, and properties of this new class of materials, including polymer–ceramic hybrid materials and polymer–ceramic molecular composites or nanocomposites. Many major synthetic strategies have been derived and a variety of new materials prepared. Advances in synthetic polymer chemistry allow for designing and preparing various monomers and polymers that are suitable for ceramic modification. Better understanding of sol–gel chemistry and ever-developing processing methodology make it possible to incorporate almost any conceivable polymer, natural or synthetic, into inorganic matrices at the molecular or nanometer scales. Basically, polymer-modified ceramics can be viewed as conventional polymer–ceramic composites at much shrunken scales (i.e., molecular composites or nanocomposites) or as single-phase (i.e., hybrid) materials. In terms of properties, polymer-modified ceramics have lived up to the expectations of their designers. These materials have physical, chemical, and biological properties continuously tailorable between those of pure polymers and pure ceramics in most cases. Such a versatile tunability would provide a unique and powerful means for materials design. Because of the mixing at the molecular or nanometer scales, polymer-modified ceramics such as polyacrylate–silica hybrid materials could be made transparent to visible light.

With controlled conditions, polymer-modified sol–gel ceramics could be prepared as films, coatings, fibers, powders, beads, and bulk objects of various shapes and dimensions. Numerous applications for these materials have been proposed and explored. So far the initial results are very promising. With further research efforts and investment, there will be enormous opportunities for the development of commercial products in both civilian and defense use, particularly coatings, optical, electronic, biotechnology, and dental materials industries.

Polymer–Nonsilica Ceramic Nanocomposites

A nanocomposite comprises at least one phase with dimensions in the nanometer regime (1–100 nm) for its combination of two or more phases (Gonsalves and Chen 1996a, 1996b, Lerner and Oriakhi 1997). The form of the nanophase can be grains, clusters, or fibers with a nanoscale diameter, or layers with a thickness in the nanometer range (Dagani 1992). The high surface-to-volume ratio of the nanophase in nanocomposites has made them extraordinary materials with unusual properties including electrical, optical, magnetic, gas barrier, thermal, and mechanical properties. They have shown promise in important applications such as digital information storage, color imaging and printing, medical diagnostics, leak-free sealing, detection sensing devices, magnetic refrigeration (Dagani 1992), ferrofluids (Dagani 1992, Meldrum *et al.* 1992), lithium rechargeable batteries (Koene and Nazar 1996), light-emitting diodes (Alivisatos 1996), gas separation membranes (Hu *et al.* 1997), and structural materials (Wang and Mark 1987, Mark and Wang 1988). Although existing nanocomposites contain only two phases, those having more phases will emerge to satisfy other needs.

One class of nanocomposites with fascinating properties is polymer–ceramic nanocomposites. They often possess desirable combinations of properties from both polymer and ceramic components. Although the term 'polymer' has an exact definition, the term 'ceramic' has several approximate definitions. Based on these definitions (Brinker and Scherer 1990, Riedel and Dressler 1996, Calvert 1996, Zhang and Gonsalves 1994), metal or metalloid oxides, nitrides, carbides, borides, sulfides, silicides, phosphides, and carbonates may reasonably be considered as ceramics. However, ceramics are inorganic materials, both crystalline and noncrystalline in nature.

Properties of polymer–ceramic nanocomposites mainly depend on the size, size distribution, shape, and homogeneous dispersion of the nanophase, and morphology, relative amounts, orientation, and interactions of both polymer and ceramic phases. The design and preparation of a polymer–ceramic nanocomposite with desired properties are a challenge. Therefore, it is important to explore the synthesis routes of such nanocomposites and their resulting properties. This article addresses the synthesis and the properties of polymer–nonsilica ceramic nanocomposites.

1. Host–Guest Behavior

There are two main types of polymer–ceramic nanocomposite, based on their host–guest architecture. The first type of nanocomposite consists of nanoscale
Figure 1
Structures of polymer–ceramic nanocomposites in which (a) ceramic nanoparticles reside in a polymer host matrix and (b) polymeric guests are intercalated in nanoscale galleries between layered ceramic hosts.

ceramic guests in a polymer host matrix (Fig. 1(a)). In such an intimate environment, nanoparticles can benefit from the polymer host matrix or the polymer matrix can benefit from the nanoparticle guests, or both, to improve their properties. Nanoparticles themselves reveal exceptional mechanical, electrical, and optical properties. For instance, ceramic semiconductor nanoparticles such as CdS (Alivisatos 1996) exhibit remarkable optoelectronic properties that cannot be obtained either from individual molecules or bulk semiconductors. Such optoelectronic properties arise from the quantum confinement of electrons in the nanoparticles. In other words, electrons in semiconductor nanoparticles, or so-called quantum dots, occupy a small number of discrete energy levels as is the case with the ''particle in a box'' concept. These electrons can absorb energy from electricity or sunlight and emit energy as electricity or light. In order to take advantage of such nanoparticles, it is very important to overcome the main obstacles in obtaining unagglomerated nanoparticles with desired uniform sizes. One way to achieve this is to fabricate polymer–ceramic nanocomposites in which there is a homogeneous dispersion of unagglomerated uniform particles throughout a processable polymer matrix. The benefits from ceramic nanoparticle guests for their polymeric hosts in a polymer–ceramic nanocomposite include improved mechanical and gas permeability properties. By introducing an inorganic phase into a polymer, the mobility of polymer chain segments can be hindered and chain packing can be inhibited, resulting in an increase in gas separation capabilities (Hu *et al.* 1997). Also, ceramic nanoparticles in a polymer matrix can act as reinforcing fillers improving mechanical properties (Wang and Mark 1987, Mark and Wang 1988) (see *Elastomers: Ceramic-modified**). Furthermore, the electrochemical properties of polymer electrolytes can be improved by incorporating ceramic nanoparticles into the polymer phase (Krawiec *et al.* 1995).

The second type of polymer–ceramic nanocomposite consists of a ceramic host matrix having nanosize cavities and polymeric guests residing in these cavities (Fig. 1(b)). These polymeric guests benefit from the ceramic host. Conjugated polymers of this kind possess high electrical conductivity and large nonlinear susceptibility. Such important properties of conjugated polymers can be improved by enhancing the degree of chain orientation. Intercalation of a conjugated polymer in nanoscale spaces in ordered ceramic crystalline structures gives rise to an oriented polymer and thereby results in a nanocomposite having a conjugated polymer with improved electrical conductivity and nonlinear optical properties (Nazar *et al.* 1992).

2. Synthesis of Nanocomposites of Nonsilica Ceramic Guests and Polymeric Hosts

2.1 Blending

Agglomeration of nanoparticles during the preparation of polymer–ceramic nanocomposites is one of the main disadvantages of the conventional blending method. However, advances in synthesis of nanocomposites have not abandoned the blending process. Polyethylene oxide (PEO)/Al_2O_3 nanocomposites (Krawiec *et al.* 1995) have been prepared by using a homogeneous mixture of PEO, Al_2O_3 nanoparticles and Li_2F_4 in acetonitrile. The agglomeration of Al_2O_3 particles is prevented by agitating the mixture. Composite films prepared by casting the resulting mixture and evaporating the acetonitrile have shown homogeneously dispersed alumina nanoparticles in the polymer matrix. The ionic conductivity of the resulting composites is increased by an order of magnitude compared to the same composites having alumina microparticles, also at ambient temperature.

Polymethylmethacrylate/CdS nanocomposites having significantly high third-order optical nonlinearity have been prepared by uniformly dispersing phenyl–CdS nanoparticles with narrow size distributions in the PMMA matrix (Yanagida *et al.* 1990). Films of these composites have been formed by mixing a

solution of PMMA in pyridine and a solution of phenyl–CdS in pyridine and casting the resulting mixture. Surface modification of CdS with phenyl capping prevents particle agglomeration.

The use of polyimides in microelectronic applications is limited because of their low thermal conductivity and high thermal expansion coefficient. Incorporating aluminum nitride (AlN) nanoparticles into the polymer matrix can diminish such drawbacks with polyimide. In this process, the agglomeration of AlN particles is successfully prevented. Agglomerated AlN nanoparticles were first partially deagglomerated by suspending in *N*-methylpyrrolidone. A solution of polyimide precursor, polyamic acid (PAA), in *N*-methylpyrrolidone was then added to this suspension and the resulting mixture agitated for further deagglomeration. It is thought that the deagglomeration of AlN nanoparticles is due to several factors, such as electrostatic stabilization of particles by the polar organic solvent *N*-methylpyr5rolidone and the polyelectrolyte polymer PAA, interpenetration of polyamic acid chains into the loosened structure of agglomerates, and mechanical agitation. Polyimide/AlN nanocomposite samples have been prepared from the resulting homogeneous suspension by casting (Gonsalves and Chen 1994) followed by thermal imidization or rapid precipitation with triethylamine followed by thermal imidization and then hot pressing (Gonsalves and Chen 1995, Gonsalves *et al.* 1997). These composites were a homogeneous dispersion of nanosized AlN particles in the polymer matrix. Thermal conductivity and mechanical properties such as hardness and Young's modulus were increased and the thermal expansion coefficient was decreased for the hot-pressed composite samples with increasing amount of AlN present.

2.2 In Situ Precipitation

In situ precipitation is a very efficient method of distributing ceramic nanoparticles homogeneously throughout the polymer matrix without particle agglomeration. Another advantage of this method is its ability to control particle sizes. *In situ* generation of ceramic metal oxide particles in a polymer matrix is often achieved by the sol–gel process. Sol–gel technology (Brinker and Scherer 1990) offers an attractive alternate route to prepare ceramics at, or near, ambient temperatures unlike the traditional high-temperature sintering method. Using this process, the composition and the microstructure of the ceramic can be controlled at the molecular level and the desired shape of the material can be achieved. In addition, high purity of the sol–gel precursors yields higher ceramic purity relative to the ceramics traditionally made by melting minerals. The sol–gel process involves the hydrolysis of metal alkoxide precursors such as organosilicates, -titanates,

and -aluminates, followed by condensation of the multihydroxy compounds produced (see *Sol–Gel Reactions: Theory[#]*). These hydrolysis and condensation reactions can be catalyzed either by acids or bases (see *Polymer–Ceramic Nanocomposites: Catalysts**). Easy and proper mixing of polymer into liquid sol–gel precursors and the low processing temperatures which preserve the organic polymer from degradation are among the benefits of the sol–gel process in fabricating polymer–ceramic nanocomposites.

Although silica is used as an efficient reinforcing filler for polydimethylsiloxane (PDMS), it may cause an adverse effect on high-temperature stability of PDMS. In fact, the acidic SiOH groups on the silica particle surface can cleave the PDMS chain. Such an effect on PDMS has not been observed when titania is used as the reinforcing filler and the mechanical properties of the resulting composite have been improved. These elastomeric PDMS/TiO_2 nanocomposites (Wang and Mark 1987) have been prepared via the sol–gel process by first swelling the end-linked PDMS networks with the sol–gel precursor *n*-propyltitanate. Swelled networks are then immersed in an aqueous solution of the catalyst (HCl, NH_4OH, or $(C_2H_5)_2NH$) to precipitate the TiO_2 *in situ*. NH_4OH has proven to be the most efficient catalyst. Moduli of the resulting dried composites have shown an increase with increasing amount of TiO_2.

Similarly, alumina as a reinforcing filler has been *in situ* precipitated in end-linked PDMS networks employing aluminum tri-*sec*-butoxide as the sol–gel precursor and HCl or NH_4OH as the catalyst (Mark and Wang 1988). Modulus and the ultimate strength of the resulting elastomeric PDMS/Al_2O_3 composites were increased, while their ultimate elongation and toughness decreased with increasing amount of Al_2O_3.

Aromatic poly(amide-imide)s possess a combination of properties such as high thermal stability, chemical resistance, and gas permeability and permselectivity from polyimides and high mechanical properties from polyamides. In an attempt to improve the gas permeability properties of poly(amide-imide)s further, poly(amide-imide)/TiO_2 nanocomposites have been prepared by *in situ* precipitation of TiO_2 nanoparticles using sol–gel technology (Hu *et al.* 1997). First, a sol prepared by partially subjecting the precursor tetraethyltitanate to sol–gel reactions was mixed with a solution of the poly(amide-imide). Then the resulting homogeneous mixture was cast and the films formed upon drying were heat-treated for further condensation of the inorganic precursor. These composites have shown improved high permselectivities for selected gas pairs even at very low titania levels in the membrane. TiO_2 particles seem to have specific interactions with gases such as CO_2 and H_2.

In one study, a homogeneous dispersion of size-controlled TiO_2 nanoclusters (1–1.5 nm) in a polyimide matrix were obtained by sol–gel *in situ* precipitation

and chemically attaching the inorganic clusters to the specific sites on the polymer backbone (Nandi *et al.* 1991). Interestingly, this sol–gel precipitation has been supported by the chemical conversion of the polyimide precursor polyamic acid. During the preparation, first the polyamic acid is formed from a solution of dianhydride and diamine in the presence of the sol–gel precursor tetraethyltitanate. Carboxylic groups on the polyamic acid chains act as binding sites for the titania precursor. The films cast from the resulting solution are heat-treated, at which the imidization occurs. Water released from the imidization initiates the sol–gel processing of pre-bound titania precursor, giving rise to titania nanoclusters. The high glass-transition temperature of polyimides may also have been a factor in preventing the cluster agglomeration, since it decreases the cluster mobility inside the polymer matrix.

In situ precipitation of ceramic metal sulfide particles in a polymer host matrix is generally achieved by exposing a mixture of polymer and the ceramic precursor to H_2S gas. For instance, polystyrene phosphonate diethylester (PSP)/cellulose acetate (CA)/ CdS polymer–ceramic nanocomposites have been prepared by *in situ* precipitation of CdS semiconductor nanoparticles in PSP/CA membranes (Yuan *et al.* 1992). Initially, $Cd(NO_3)_2$ was incorporated into PSP/CA membranes either by floating PSP/CA membranes in a $Cd(NO_3)_2$ solution or casting followed by drying of a mixture of PSP, CA, and $Cd(NO_3)_2$ solutions. CdS particles have been generated subsequently by exposing the resulting films to H_2S gas.

In situ precipitation of ceramic nanoparticles accompanied by *in situ* copolymerization has been successfuly employed to obtain a narrow particle size distribution and a homogeneous dispersion of particles in methacrylate–styrene/PbS nanocomposites (Gao *et al.* 1994). Because of their contents, these composites have shown a significantly higher third-order nonlinear susceptibility. The first step in synthesizing methacrylate–styrene/PbS composites involves the formation of a lightly crosslinked microgel containing Pb^{2+} using a solution of lead methacrylate $(Pb(MA)_2)$ in the presence of the initiator azobisisobutyronitrile (AIBN). Subsequently, this microgel is dissolved in styrene and then treated with H_2S gas. Finally, the resulting styrene organosol is subjected to further polymerization using AIBN to obtain a transparent solid. In the copolymerization with styrene, $Pb(MA)_2$ acts as a crosslinking agent.

3. Synthesis of Nanocomposites of Polymeric Guests and Nonsilica Ceramic Hosts

3.1 In Situ *Intercalative Polymerization*

A ceramic structure in which polymer molecules reside is quite remarkable. It is difficult to insert polymer chains into the micro- or nanoscale cavities in ceramic structures by diffusion. Therefore, the direct insertion of polymer into the ceramic structure is not an effective method to fabricate nanocomposites with polymeric guests and ceramic hosts. One successful method to fabricate such composites is *in situ* intercalative polymerization. One strategy involved in this process is the insertion of small monomer molecules instead of polymer chains into those galleries or pores in the ceramic structure followed by *in situ* polymerization of inserted monomers. Some details are given in *Clay-based Polymer Nanocomposites**.

Ceramic hosts with oxidizing ability can initiate the polymerization of monomers such as aniline and pyrole and consequently the polymerization occurs simultaneously with the intercalation. In non-oxidizing hosts, *in situ* polymerization of these monomers is assisted by external oxidizing agents, such as oxygen, after the intercalation. In some cases, oxidizing cations have been incorporated into the ceramic structure prior to the monomer intercalation.

Polyaniline/$HMWO_6$ (M = Nb, Ta) nanocomposites have been prepared by *in situ* intercalative polymerization (Koene and Nazar 1996). Powdered $HMWO_6.nH_2O$ is stirred with aniline for several days at $100\,^\circ C$ in a sealed tube *in vacuo*. At this stage, the strong Brønsted acidity of these layered oxide hosts promotes the intercalation of the weakly basic aniline. The inserted monomer is then polymerized *in situ* at $130\,^\circ C$ in air for two days. The resulting composites have shown an increase in lithium ion mobility within their structure compared to $HMWO_6$. This is attributed to the fact that the presence of the conjugated polymer polyaniline reduces the interaction of lithium ion with the $HMWO_6$ structure. These results suggest that polyaniline/$HMWO_6$ nanocomposites are potential candidates for cathode materials in lithium rechargeable batteries in which the lithium ion mobility is an important issue.

Since $V_2O_5.nH_2O$ is an oxidizing host for aniline, it has to be reduced before the controlled polymerization is initiated in the preparation of polyaniline/ $V_2O_5.nH_2O$ nanocomposites (Liu *et al.* 1993). In this synthesis, V_2O_5 xerogel is mixed with a solution of anilium iodide in CH_2Cl_2. Oxidizing ability of the V_2O_5 ordered lamellar structure is diminished by the iodide, a better reducing agent than anilium. The intercalated aniline is then subjected to oxidative polymerization in air. The resulting composites have shown a slightly enhanced electrical conductivity.

3.2 *Simultaneous Insertion and Crystal Growth*

In another interesting approach, polymer–ceramic nanocomposite structures in which the polymers are molecularly run through the ceramic crystalline phases have been fabricated (Messersmith and Stupp 1992). In this process, inorganic ceramic crystals have

been nucleated and grown in homogeneous solutions containing polymers as co-solutes. Consequently, polymer chains have been entrapped in sites such as grain boundaries or other two-dimensional defects, nanopores, lattice channels, or interlamellar spaces of the ceramic structure. Synthesis of these architectures in which the ceramic phase is tetracalcium aluminate and the organic polymer is poly(vinyl alcohol), poly(dimethyldiallyl ammonium chloride), or poly(dibutyl ammonium iodide) has been reported.

3.3 Exfoliation–Adsorption

Layered ceramic structures can be disassembled in a suitable solvent and the resulting dispersed single layers can be restacked by applying the necessary chemical and physical conditions. This experience has been successfully exploited to intercalate polymer guests in layered ceramic hosts giving rise to polymer–ceramic layered nanocomposites. In this method, layers of the ceramic hosts are first exfoliated into a colloidal form. A solution of the polymer is then added to this colloid so that the polymer adsorbs on the dispersed single layers. The resulting layers are subjected to spontaneous or induced flocculation. Polyethylene oxide/MoS_2 layered nanocomposites have been prepared using this strategy (Lemmon and Lerner 1994), and X-ray diffraction results have suggested the presence of polymer double layers within the MoS_2 galleries.

3.4 Exfoliation–Adsorption Followed by In Situ Conversion

Some polymers are unable to dissolve in solvents that are compatible with the colloidal form of the desired layered ceramics. In addition, some may not be formed by oxidative polymerization. Accordingly, the polymer–ceramic nanocomposites associated with such polymers cannot be synthesized through exfoliation–adsorption or *in situ* intercalation polymerization methods. However, this has been accomplished by the use of soluble derivatives of these polymers as precursors. This synthesis route involves the intercalation of soluble precursor polymer into the layered ceramic host matrix by the exfoliation–adsorption method and subsequent thermal or chemical conversion of this precursor to form the desired polymer *in situ*. Examples of polymer–ceramic nanocomposites prepared through this process are poly(*p*-phenylenevinylene) (PPV)/MoO_3 composites (Nazar *et al.* 1992). In the preparation of PPV/MoO_3 composites, an ionomer, poly(*p*-xylene-α-dimethylsulfonium chloride), is used as the precursor to PPV and a solution of this ionomer is added to a colloidal dispersion of $[A(H_2O)_2]_{0.25}MoO_3$ ($A = Na$, Li) in water. At this stage, the high molecular weight ionomer has been inserted into the interlamellar gap

in the ceramic structure as linear chain molecules. Finally, the ionomer is converted to PPV by a thermal treatment. The opposite nature of the charges of the precursor polymer and the reduced molybdenum oxide plates can also facilitate the orientation of polymer chains in the host structure. The resulting composites show well-ordered stacks of polymer/ceramic layers. Although both PPV and MoO_3 are electrical insulators, PPV/MoO_3 thin films have shown increased electrical conductivity at room temperature. Thermally induced charge transport behavior of these materials suggests their suitability for semiconductor materials.

4. Biomimetic Approach

Nature has an incredible ability to design and biologically construct polymer–ceramic nanocomposites that are used to fulfill its needs. Such biocomposites include bones, teeth, and shells. They are formed by biomineralization in which the mineral guests are *in situ* precipitated within preorganized polymeric hosts. These hosts can be extracellular (intercellular) polymeric matrices, or self-assembled protein cages or lipid vesicles (Mann 1993). The well-ordered assembly of organic and inorganic constituents and their controlled sizes, shapes, spatial distributions, and chemical and physical properties are responsible for the remarkable properties of biocomposites.

Bone is a collagen polymer matrix reinforced by nanosized ribbon-shaped crystals of hydroxyapatite ceramics (Burdon *et al.* 1995). The mechanical properties of these biological composites are superior to those of synthetic nanocomposites. In fact, they can maintain a significant toughness with high modulus and tensile strength, unlike synthetic nanocomposites (Calvert 1996). Ferritin, which functions as an iron store in the liver, is a spherical-shaped shell (apoferritin) filled with a hydrated iron oxide ferrihydrate ($5Fe_2O_3.9H_2O$) core (Meldrum *et al.* 1992). External and internal diameters of the ferritin micelle are approximately 12 nm and 8 nm, respectively. Host–guest architecture of both bone and ferritin are formed by biomineralization (Mann 1993).

The mimicry of Nature's architectures and the mechanisms through which they are made can result in better synthetic polymer–ceramic nanocomposites. Several polymer–nonsilica ceramic nanocomposites have been prepared by following the guidelines of the formation of biocomposites with polymeric host matrices. The already mentioned *in situ* precipitated polymer–nonsilica ceramic nanocomposites can fall into this category. A nanocomposite containing polypropylene matrix and elongated titania particles has been prepared by extruding the melt blended mixture of polypropylene and titanium *n*-butoxide followed by sol–gel processing of the alkoxide (Burdon *et al.* 1995). Proper interfacial bonding

between the titania particles and polymer phase was achieved by using a titanate coupling agent (see *Polymer–Ceramic Nanocomposites: Interfacial Bonding Agents**). Although the resulting composites were stiff, their strength was poor. Calcium carbonate–chitosan nanocomposites prepared using the biomimetic approach have also been reported (Zhang and Gonsalves 1994).

There have been several successful attempts in which polymer–nonsilica ceramic nanocomposites were synthesized, mimicking the biomineralization in protein cages (Meldrum *et al.* 1992, Chan *et al.* 1995). The goal was to generate nanoscale magnetic particles. The usefulness of these protein cages is that they can act as reaction cages to control the nucleation and growth of these ceramic nanoparticles. In one study, ferrimagnetic iron oxide magnetite Fe_3O_4 nanoparticles were formed using horse spleen ferritin cages (Meldrum *et al.* 1992). The first step of this process involved the removal of existing iron core from ferritin to form apoferritin by dialysis. Reconstruction of the apoferritin was achieved by slow addition of iron(II) solution to the apoferritin solution under slow oxidative conditions. The resulting magnetic protein, ferrofluid or magnetoferritin, contained uniform sized (6 nm) spherical Fe_3O_4 single crystals as the core. In a similar approach, nanoscale iron(III) hydroxide clusters have been synthesized employing horse spleen ferritin cages (Chan *et al.* 1995).

5. Concluding Remarks

Polymer–nonsilica ceramic nanocomposites comprise a combination of optimal properties from both polymer and ceramic phases, or even exclusive properties that are not related to either of these phases (from quantum confinement effects). These properties are favored by the intimate host–guest relationship of the constituents and the elegant architectures of the nanocomposites. A number of new structural designs and synthesis strategies have been successfully employed to obtain novel polymer–nonsilica ceramic nanocomposites with desirable properties. The mimickry of the structures of natural polymer–ceramic nanocomposites and their synthesis routes cannot be underestimated in this regard. Important applications such as communications, computing, and biomedical devices will potentially be developed in the light of such polymer–nonsilica ceramic nanocomposites.

Polymer–Silica Nanocomposites

Organic/inorganic nanocomposites are a class of composite materials that have been developed and have attracted significant interest since the early 1980s. Unlike the traditional composite materials which have macroscale domain sizes of micrometer and even millimeter scales, polymer–silica nanocomposites are mostly nanoscopic, with a typical physical constraint of 1–100 nm. There is also intimate contact between different phases in these materials. Therefore, they have the potential for providing unique combinations of properties that cannot be achieved by conventional methods.

Of organic/inorganic nanocomposites, polymer–silica nanocomposites draw the most attention, and their synthesis and properties are the focus of this article. The pioneering work in this area includes that from research groups directed by Schmidt, Mark, and Wilkes. There are several very informative reviews of organic/inorganic nanocomposites available (Chujo and Saegusa 1992, Novak 1993, Schmidt 1994, Sanchez and Ribot 1994, Mark *et al.* 1995, Mascia 1995, Mark 1996, Wilkes and Wen 1996, Wen and Wilkes 1996, Sharp 1998).

1. General Synthetic Considerations

Although polymer–silica nanocomposites can be prepared by a variety of approaches, most are obtained through the sol–gel approach: sol–gel reactions of silicon alkoxides and related derivatives. Considering the important role of the sol–gel reaction, it is difficult to understand the preparation of these nanocomposites without a basic knowledge of the sol–gel process. The sol–gel reaction of silicon alkoxides is a method for preparing inorganic silicon oxides under mild conditions (Brinker and Scherer 1990). It involves the simultaneous hydrolysis and condensation of silicon alkoxides to form a three-dimensional SiO₂ network. The reactions are carried out typically in an acidic or alkaline medium with either an acid or a base as catalyst. The general scheme is represented in Scheme 1.

Despite the fact that tetraethoxysilane (TEOS) results in considerable volume shrinkage, it is the most-used precursor to generate silica because of its moderate hydrolysis and condensation rate compared to the fast-reacting tetramethoxysilane (TMOS). The nature of the catalyst and the pH of the reaction have a pronounced effect on the hydrolysis and condensation reactions and also on the structure of the SiO₂ formed. The hydrolysis rate is high under an acidic environment relative to that of condensation, while base catalysis results in a higher condensation rate. Therefore, the presence of acid tends to produce more linear or polymeric molecules in the initial stage which leads to the formation of high-density, low-fractal-dimension structures, while a basic environment tends to produce more of a cluster growth leading to dense, colloidal, particulate structures. Once formed, the cosolvent(s) such as alcohol and small molecular weight by-products such as ethanol and water must be removed from the gelled SiO₂ network during the gel drying. The removal of these cosolvent(s) and by-products contributes to the high shrinkage that occurs during the classical sol–gel process. (For a discussion of possible remedies see *Polymer–Ceramic Nanocomposites: Control of Shrinkage*.*)

Traditional sol–gel reactions of pure silicon alkoxides are very complicated, with many variables such as water-to-alkoxyl ratio, acid (base)-to-alkoxyl ratio, catalyst type, reaction medium, alkoxyl type, etc. The introduction of organic polymeric components adds additional variations. On the one hand this complexity makes the basic chemistry of the reactions even more difficult to understand, but on the other hand it opens the door for the development of many different synthetic approaches.

2. Synthetic Approaches

The unique low-temperature characteristic of sol–gel reactions provides opportunities to make polymer–silica hybrid materials at temperatures under which the polymeric species can survive. Numerous combinations of polymer–silica and different synthetic procedures have been tried in the attempt to create

Hydrolysis

$$Si(OR)_4 \; + \; H_2O \; \rightleftharpoons \; (HO)Si(OR)_3 \; + \; ROH$$
$$(OH)Si(OR)_3 \; + \; H_2O \; \rightleftharpoons \; (HO)_2 Si(OR)_2 \; + \; ROH$$
$$(OH)_2Si(OR)_2 \; + \; H_2O \; \rightleftharpoons \; (HO)_3Si(OR) \; + \; ROH$$

novel polymer–silica nanocomposites with vastly different properties. Therefore, a brief summary of different synthetic approaches is needed before the discussion of various polymer–silica nanocomposite systems.

2.1 Formation of Inorganic Silica Within a Swollen Polymer Network

An approach developed by Mark and Pan (1982) involves the *in situ* formation of inorganic silica within a swollen polymer network. In this approach, silica particles with a characteristic size of a few hundred angstroms can be generated within the polymer by first swelling a cross-linked polymeric host with a compatible solution containing a silicon alkoxide, usually TEOS, followed by the promotion of a base-catalyzed sol–gel reaction of the silicon alk-

oxide. This approach has been used successfully to reinforce many elastomers and plastics, such as poly(dimethylsiloxane) (PDMS), poly(methyl methacrylate) (PMMA), polyisobutylene, poly(vinyl acetate), polyurethane, etc. This approach has the most potential in the preparation of novel thin-film hybrid materials where the dispersion of water into the organic components is not a major concern. For a detailed review see *Elastomers, Ceramic-modified**.

2.2 Co-condensation of Functionalized Polymers with Silicon Alkoxides

Polymer–silica nanocomposites can be formed via co-condensation of functionalized polymers with silicon alkoxides in which chemical bonding is established between inorganic and organic phases. Scheme 2 shows this approach schematically with ethoxysilane

functionalized polymer as an example. This approach was developed in the early 1980s (Wilkes *et al.* 1985) and has been used widely in the preparation of polymer–silica hybrid materials because of its ability to incorporate various organic polymers or oligomers with a silica network through chemical bonding. The typical terminal functional groups for polymers or oligomers include alkoxysilane, amino, hydroxyl, etc. Theoretically, any functional groups that can participate in the sol–gel reaction can be used to functionalize polymers or oligomers. However, a difference in the reactivity of the functional groups from that of the silicon alkoxide (typically TEOS) can result in poor incorporation of the organic component. Triethoxysilane is the most-used end group because its reactivity is comparable to that of TEOS and hence favors the formation of hybrid systems with better component dispersion and network development.

2.3 Simultaneous Formation of Silica and Organic Phases

Another approach to produce polymer–silica nanocomposites is through interpenetrating networks and simultaneous formation of both silica and organic polymeric phases. By using triethoxysilane, $R'_n(OR)_{3-n}$, as the precursor with R' being a polymerizable group such as an epoxy group, an organic network can be formed within the SiO$_2$ network by either photochemical or thermal curing of such groups (Schmidt *et al.* 1984). In this approach, the chemical bonding between inorganic and organic components already exists. Novak and Grubbs (1988) developed another similar method to form inorganic/organic simultaneous interpenetrating networks (SPINs), where both inorganic glass and polymer formation occur at the same time through a synchronous application of the aqueous ring-opening metathesis polymerization (aqueous ROMP) of cyclic alkenyl monomers and the hydrolysis and condensation of metal alkoxides. The successful preparation of polymer–silica nanocomposites using this approach requires matching the polymerization rates of the two systems as well as noninterference between the two reactions.

2.4 Infiltration of Oxide Gels with Organic Monomers or Mixing Polymers with Silicon Alkoxides

Polymer–silica nanocomposites can be obtained by either the infiltration of previously formed oxide gels with polymerizable organic monomers or the mixing of polymers with silicon alkoxides in a common solvent. In the first approach, the impregnation of porous silica gels with organics is followed by an *in situ* polymerization initiated by thermal or irradiation methods (Pope and Mackenzie 1989). In the second approach, polymers can be trapped within the oxide gel network if the hydrolysis and condensation of silicon alkoxides are carried out in the presence of polymers (Landry and Coltrain 1991). If no coupling agent is used, the interaction between organic and inorganic phases is typically physical in nature. The application of these approaches is apparently limited by the solubility of the polymers in the solvents.

2.5 Other Synthetic Strategies Using the Sol–Gel Process

Other synthetic strategies making use of the sol–gel process have also been developed. Given here are two examples of such approaches. A significant drawback associated with the sol–gel process is the removal of the cosolvent, excess water, and liberated alcohol. Large volume shrinkage during the drying process will occur due to the high interfacial area of the solid–liquid interface coupled with the reduction in chemical potential. By employing polymerizable monomers as the cosolvent such that all mixture components contribute either to the silica network or to the organic polymer to avoid large-scale shrinkage, "nonshrinking" sol–gel composite materials can be obtained (Ellsworth and Novak 1991). A different kind of inorganic/organic nanocomposite material has been developed by exploiting the unique intercalation and self-assembling characteristics of layered ceramics, particularly those based on the 2:1 layered silicates (Giannelis 1992). These 2:1 layered silicates consist of two-dimensional layers formed by sandwiching two SiO$_2$ tetrahedral sheets to an edge-shared octahedral sheet. Single chains of the polymer alternately stacked with the layers of the host can be

obtained by intercalative polymerization of various monomers in the silicate galleries.

2.6 Synthesis Using Nanometer-size Silica Particles

Although the sol–gel approach is the dominant one, polymer–silica nanocomposites can also be obtained using nanometer-size silica particles. In this approach, silica particles are dispersed in either a polymer matrix or a monomer solution in which *in situ* polymerization of the monomer is carried out later. Silica particles are usually premodified so that a good dispersion of the particles in the matrix can be obtained. Polymer–silica nanocomposites such as polyamide 6–silica, PMMA–silica, nylon 11–silica, and polypyrrole–silica have been prepared using this approach.

3. Properties and Applications

Compared to the polymer–silica materials prepared by the conventional method (i.e., direct blending of silica with polymer), the polymer–silica nanocomposites discussed in this article often have superior properties and are expected to provide many different possibilities. The unique properties that these hybrid materials display arise mainly from three sources. (i) The reduction of the domain size to 100 nm or below (often much less, sometimes even at molecular level). A direct consequence of ultrasmall domain size (smaller than the wavelength of visible light) is optical clarity of the materials by virtual elimination of light scattering, although the refractive index of the two phases might be very different. As a result, polymer–silica nanocomposites find applications in many fields, such as optical devices, which are far beyond the scope of application of traditional composites. (ii) Generation of enormous interfacial areas due to the nanoscale domain size and intimate contact between the two phases. This can result in numerous covalent bonds or other interaction between the phases. Therefore, the formation of morphologies such as interpenetrating networks and even molecular-level mixing with no distinct phases that are essentially unknown for conventional composite materials become possible. (iii) The tremendous range of chemistry available to optimize specific properties and to produce materials with unique properties. It is possible to shift the morphology of these materials from that of a continuous flexible organic domain with separated inorganic phases to a continuous glassy inorganic phase with separated organic domains.

The sol–gel process makes possible the preparation of polymer–silica nanocomposites through numerous combinations of polymers and silicon alkoxides. The resulting hybrid materials could be vastly different in properties depending on the reaction conditions and the chemical structure of polymers and silicon alkoxides. Therefore, it is better to discuss the properties of individual polymer–silica systems (see Sect. 4). Generally speaking, polymer–silica nanocomposites usually show intermediate properties between those of organic polymers and inorganic silica glasses. Accordingly, they can be used to modify organic polymeric materials or to modify inorganic glassy silica. In terms of organic polymer modification, almost an infinite number of variations can be obtained while the flexibility is the focus in terms of inorganic glassy silica modification. Polymer–silica hybrid materials may also possess new properties that the original organic and inorganic components do not have because of their unique structural features, such as small domain size and intimate contact between the two phases. Besides the original role of enhancing mechanical properties, the applications for polymer–silica nanocomposites have expanded to many areas. Applications include reinforcement of elastomers and plastics, toughening of silica glasses, special coatings such as abrasion resistance coatings for plastics, electrical and nonlinear optical (NLO) materials for optical and optoelectronic devices, porous templates for catalysts and surfactants, and biomimic materials.

4. Examples of Polymer–Silica Nanocomposites

Many polymer–silica nanocomposites have been obtained successfully by different synthetic approaches. The resulting composites can vary from soft and flexible to brittle and hard materials depending on the chemical structure of the polymeric components and the overall organic-to-inorganic composition ratio. Some representative polymer systems, including some early classic systems, will now be presented individually. Other polymer–silica nanocomposite systems are discussed in Sanchez and Ribot (1994), Wilkes and Wen (1996), Wen and Wilkes (1996), Mark (1996), and Sharp (1998).

4.1 PDMS–Silica

One of the first successfully prepared polymer–silica nanocomposites was a PDMS–silica system developed first by Mark's group in the early 1980s. The use of PDMS is obvious considering the fact that the backbones of PDMS and silica possess the same nature of (Si–O–Si) chemical bonds which make the organic and inorganic components more compatible. In this approach, TEOS was the preferred precursor to generate the silica domain because of its good miscibility with PDMS and also its moderate hydrolysis and condensation rate compared to the fast-reacting TMOS. Three synthetic methods have been used to prepare polymer–silica nanocomposites. In the first approach, the already cross-linked PDMS elastomer is swollen with TEOS, and the sol–gel

reactions are carried out within the PDMS matrix to generate *in situ* small, well-dispersed silica particles with a diameter around a few hundred angstroms. The silica particle size can be controlled by the ratio of PDMS to TEOS and the pH of the solution. In most cases base catalysts were used to promote the formation of dense silica particles. In the second technique, hydroxyl-terminated PDMS chains are blended with enough TEOS to both end-link them and provide silica by the hydrolysis reaction. Thus, curing and filler generation takes place simultaneously. In the third approach, TEOS is blended into PDMS having end groups (e.g., vinyls) that are unreactive under the hydrolysis conditions. Therefore, PDMS curing takes place after the generation of silica in the usual manner. It has been demonstrated that extremely uniform silica particle sizes can be obtained. Since the PDMS–silica nanocomposites prepared in this way can also be viewed as reinforced elastomers, they are the ideal candidates for studies of fundamental reinforcement principles. The concept of such "*in situ*" filler precipitation within elastomers is also of practical importance because these particles provide the same highly desirable reinforcing effects obtained by the traditional blending technique, yet avoid the time-consuming, energy-intensive process associated with it. For further details see *Elastomers, Ceramic-modified**.

PDMS–silica systems prepared with acid catalysts were also synthesized and studied by Wilkes and other researchers. Low molecular weight (500–1700 g mol^{-1}) PDMS oligomers with silanol terminal groups and TEOS were used first as the reactants to form a chainlike organic/inorganic structure with hydrogen chloride (HCl) as catalyst. The studies were later expanded to the systems with high molecular weight PDMS, PDMS with higher functionality, and using other acid catalysts. Depending on the amount and molecular weight of PDMS, the final materials could be either flexible or brittle and all showed optical transparency indicating a phase (domain) size of smaller than the wavelength of visible light. The microstructure of these PDMS–silica hybrids was determined to be microphase-separated with PDMS- and silica-rich domains, using a variety of analytical techniques such as DSC, dynamic mechanical analysis (DMA), and small-angle x-ray scattering (SAXS). The structure and properties of PDMS–silica systems are found to be dependent mainly on the content of PDMS, the molecular weight of PDMS, and the content of the acid catalyst.

4.2 Acrylate Polymers–Silica

Acrylate polymers are another class of polymers that have attracted extensive research effort in the synthesis of polymer–silica nanocomposites. PMMA–silica nanocomposites have been synthesized using different approaches by different research groups. Schmidt synthesized PMMA–silica materials with improved mechanical properties through an *in situ* polymerization of methacrylate monomers, which were introduced by using monomers containing trialkoxysilyl functional groups, within the inorganic silica network. Through the infiltration of previously formed oxide gels with polymerizable organic monomers followed by an *in situ* polymerization initiated by thermal or irradiation methods, Pope and Mackenzie (1989) developed transparent optical PMMA–silica nanocomposites although there was no chemical bonding between the two phases without the use of a coupling agent. Extensive work has been done by Landry and Coltrain (1991) and Landry *et al*. (1992) toward synthesizing and studying PMMA–silica materials through first trapping PMMA within a silica gel and then carrying out the hydrolysis and condensation of a silicon alkoxide in the presence of PMMA. They found that there was no covalent bonding between organic and inorganic phases. The ability to produce well-dispersed nanocomposite materials was attributed to hydrogen bonding between the silanol groups in the inorganic phase and the carbonyl units in the PMMA.

Other acrylate–silica nanocomposites have also been produced and studied, including poly(methyl acrylate) (PMA), poly(butyl methacrylate) (PBMA), allyl methacrylate (AMA) and its copolymer with methyl methacrylate, and poly(methyl methacrylate-co-styrene). Based on their previous effort, Wei *et al*. (1998) have synthesized and studied a series of monolithic poly(methyl methacrylate-co-3-(trimethoxysilyl)propyl methacrylate)–silica hybrid materials through HCl-catalyzed sol–gel reactions of TEOS with polymethacrylates at various compositions. The structures of these hybrid materials were studied by atomic force microscopy (AFM) and other analytical techniques, and their applications as the filler for dental composite materials was also investigated. It was found that the polymethacrylate chains are uniformly distributed in, and covalently bonded to, the silica networks at a molecular level without macroscopic organic/inorganic phase separation.

4.3 Polyimides–Silica

Usually high-temperature polymers are very difficult to treat in the usual sol–gel technique. However, polyimides are synthesized from a precursor molecule, such as poly(amic acid), which is soluble in some organic solvents. This makes it possible to produce polyimide–silica hybrid materials through the sol–gel approach. Most of the research work has been aimed at improving the properties of polymers with respect to better thermal stability and mechanical strength. The synthetic procedure for the preparation of

polyimide–silica nanocomposites involves mixing varying amounts of the precursor for the polyimide, typically poly(amic acid), with TEOS and water in a common solvent, followed by imidization and simultaneous network formation. Nandi *et al.* (1991) reported the preparation of molecular level polyimide–silica composites by using a so-called "site isolation" method in which TEOS is maintained in isolated pockets in the polymeric matrix by prebinding it to the carboxylic sites of the poly(amic acid) formed initially. The authors suggested that the metal alkoxide can be bonded chemically with the precursor poly(amic acid) through cohydrolysis of carboxylic groups and the metal alkoxide, although the formation of chemical bonding was not confirmed. Both transmission electron microscopy (TEM) and scanning electron microscopy (SEM) observations indicate the formation of a homogeneous dispersion of SiO_2 nanoclusters with a size of about 1.5 nm within the polyimide matrix. As a result, transparent and flexible polyimide-containing organic/inorganic films can be obtained in this way. Morikawa *et al.* (1992) also reported the preparation of polyimide–silica hybrid films by the hydrolysis and condensation of TEOS in a poly(amic acid) solution, followed by heating of the resulting film at high temperature. TEOS and water were added to the N,N'-dimethylacetamide (DMAc) solution of poly(amic acid). The reaction between TEOS and water resulted in a homogeneous mixture which was then cast onto a glass plate. The polyimide–silica hybrid film was obtained after heating at about 270 °C. Hybrid films having a silica content up to 70 wt.% and a silica size of approximately 5 μm can be obtained. In subsequent work, ethoxysilyl groups were introduced as the diamine monomer into the polyimide matrix to connect the silica particles with the matrix. By using methanol as the solvent, hybrid films containing up to 50 wt.% silica with much smaller size (about 0.2–0.08 μm in diameter) have been obtained. In contrast to the other preparation method given above, the hybrid films made in this way show a higher storage modulus, a reduction in the decrease of the glass transition temperature, and low tanδ maximum.

The preparation and properties of other polyimide–silica hybrid systems have been investigated by several other research groups. One focus of the research is to improve the compatibility between the two phases. Kioul and Mascia (1994) improved the compatibility of polyimide–silica ceramers by adding a small amount of γ-glycidyloxypropyltrimethoxysilane (GOTMS) as a coupling agent. The morphology of the hybrid films was dependent strongly on the molecular weight of the poly(amic acid), the alkoxysilane solution composition, the reaction time, and the type of coupling agent and catalyst. The tensile strength and ductility of the hybrid materials were found to increase with the addition of the low functionality alkoxysilane and GOTMS coupling agent.

Using an organically substituted alkoxysilane, (aminophenyl)trimethoxysilane (APTMOS), to provide bonding sites between the polyimide and the silica-like phase, Wang *et al.* (1994) studied the morphology, thermal stability, and mechanical properties of polyimide–silica composites and found that small amounts of APTMOS can improve the modulus and strength of the resulting hybrid materials, and that the transparency also increased with an increase of APTMOS. In order to better control the structure, Hedrick *et al.* (1997) developed an alternative route to polyimide–silica hybrid materials based on poly(amic acid ethyl ester) precursors to the polyimide. Poly(amic acid ethyl ester) precursors are hydrolytically stable, allowing isolation, characterization, and copolymerization in a variety of solvents and cosolvents. The high cure temperature of poly(amic acid ethyl ester) precursors allows significant vitrification of the gel prior to imidization, providing a kinetic means of controlling the morphology. Compared to bulk silica, these polyimide–silica hybrids show enhanced resistance to cracking.

4.4 Poly(Tetramethylene Oxide) (PTMO)–Silica

Following their work on PDMS–silica nanocomposites, Wilkes and co-workers (Huang 1990) turned their attention to PTMO–silica systems and conducted systematic investigations on the preparation, structure, and properties of PTMO–silica hybrid materials. PDMS–silica nanocomposites did not display high tensile strength and elongation, which was attributed to the inherently poor mechanical properties of pure PDMS and the network defects such as remaining loose or dangling PDMS chain ends and the molecular weight redistribution of PDMS chains. Therefore, PTMS–silica, which can offer much better mechanical properties, was made to overcome these problems. However, the lack of the siloxane backbone to make the organic polymer and inorganic silica compatible was a concern. To improve the compatibility of PTMO with silica, isocyanatopropyltriethoxysilane (instead of hydroxyl) functionalized PTMO oligomers were used. Depending on the reaction conditions and composition ratio of PTMO to TEOS, these resulting hybrid materials can vary from soft and flexible to brittle and hard materials and still maintain optical transparency. Compared to PDMS–silica systems, the acid-catalyzed PTMO-containing hybrid materials generally provide an enhanced mechanical response (30 MPa in tensile strength and 100% in elongation compared to 6 MPa and 20%) for an equivalent oligomer content due to higher functionality (6 compared to 2) and the nature of PTMO oligomers.

The structure and morphology of PTMO–silica nanocomposites were investigated extensively using SAXS and dynamic mechanical spectroscopy (DMS)

techniques. The high transparency, given the large difference in refractive index between the two components, clearly demonstrated that no macroscale phase separation occurred. However, SAXS results showed that they tend to undergo some microphase separation similar to segmented or block polymers. The observed correlation distance is of the order of about 10 nm for the PTMO–silica systems. The high angular tail of the scattering curve also suggested that some level of mixing of the inorganic phase occurs within the oligomeric phase. This partial phase mixing was also supported by DMS data.

Systematic work has also been done on the variables of oligomer molecular weight and functionality, ratio of PTMO to TEOS, acid concentration and type, processing temperatures and methods, gel aging, and solvent type by using characterization techniques such as SAXS, DMS, IR spectroscopy, NMR, and mechanical testing. Besides mineral and low molecular weight organic acids the use of the polymeric acid catalyst poly(styrene sulfonic acid) (PSS), which is readily available in various molecular weights and degrees of sulfonation, has also been investigated. An advantage of a polymeric acid catalyst is that it can be used as a rheological modifier to enhance processability yet minimize fugitive acid moieties that are prominent in a low molecular weight catalyst. SAXS studies also showed that when using a *N*,*N*-dimethylformamide (DMF)–IPA cosolvent system as the reaction medium, instead of using pure IPA as solvent, the SAXS profiles became much sharper as the DMF content increased, indicating a narrower distribution of either domain sizes or interdomain spacings or both. This was believed to be attributable to the less acidic nature of the mixture when DMF was used as cosolvent because it promoted less mixing between the two components.

Other studies in Wilkes' program include the chemical stability of PTMO–silica hybrid materials in neutral and alkaline aqueous solutions, the aging effect, and the microwave curing process. It was found that because of the solubility of silicon oxide in highly basic solutions a better-defined two-phase microstructure can be obtained if PTMO–silica hybrids were aged in 1 M NaOH for 24 h. If the films cast at ambient temperature are later heated to a higher temperature ($\sim 100\,^\circ$C), the extent of the reaction can be increased. This so-called "aging" can also take place in the time period between gelation and vitrification of the "hard" regions and this aging effect can be easily interpreted by using the concept of the time–temperature transformation (TTT) cure diagram established by Gillham. Microwave curing processing has also been used to promote the sol–gel reaction of PTMO–silica systems. Microwave processing has the ability to promote potentially a higher rate of reaction due to specific interactions with the dipoles of the appropriate functionalized reacting groups. It was found that gelation and near

final properties of the PTMO–silica hybrid systems can be achieved in a matter of minutes. The higher intensity and flat "tail region" from the SAXS curve of microwave-processed PTMO–silica hybrid networks also indicated a higher extent of reaction and higher level of phase separation compared to ambient-temperature casting or even conventional thermal (convection) cured systems.

4.5 Polyoxazoline (POZO)–Silica

By using a comparable synthetic approach, Chujo *et al.* (1991) synthesized POZO–silica nanocomposites using triethoxysilane-terminated POZO with a molecular weight of 500–2000 g mol^{-1} for the acid-catalyzed cohydrolysis and condensation with TEOS. The resulting materials are homogeneous, transparent, and glassy inorganic/organic nanocomposites with chemical bonding between the two phases. Similar POZO–silica hybrid materials which have no chemical bonding between the organic and inorganic phases have also been prepared by using the hydrogen bond interactions between the silanol group and the POZO amide carbonyl group. The latter material has been used as the precursor for porous silica glass of controllable pore size and very large surface area by calcination of the materials at temperatures between 600 and 800 °C. Poly(ethyl oxazoline) and poly(methyl oxazoline) have also been dispersed into a silica matrix to make POZO–silica hybrid materials (David and Scherer 1995). The authors claim that the dispersion is at the molecular level because only a single phase was observed as evidenced by SAXS and TEM results.

4.6 Poly(Ether Ketone) (PEK)–Silica

PEK–silica hybrids were prepared with a similar synthetic approach to that of the PTMO–silica systems, using triethoxysilane-functionalized PEK oligomers ($M_n = 3900$ g mol^{-1}) and TEOS (Noell *et al.* 1990). PEK is an amorphous thermoplastic material with good mechanical properties, thermal stability, and a relatively high glass transition temperature compared to PDMS or PTMO systems. Although this material is transparent, SAXS experiments confirmed the presence of local microphase separation, as is the case with other hybrid materials. However, the high glass transition temperature of PEK can limit further the extent of cure caused by vitrification as gelation and network buildup occur. Again, thermal postcure treatments at elevated temperature can promote further network development.

4.7 Nonshrinking Polymer–Silica

It is well known that in the sol–gel process there is significant gel shrinkage and cracking during drying
Scheme 3

due to the removal of excess water, cosolvent(s), and the liberated alcohol. This shrinkage is caused mainly by the large capillary forces generated in the nano-porous structure. As a consequence, films with a thickness larger than 1 μm are difficult to dry and usually crack extensively. One way to alleviate the shrinkage problem is to incorporate organic polymers into the inorganic silica network. However, shrinkage still remains a problem for the preparation of polymer–silica nanocomposites. Novak and Davis (1991) and Ellsworth and Novak (1991) developed a way to synthesize so-called ''nonshrinking'' polymer–silica hybrid materials. They synthesized a series of tetra-alkyl orthosilicate derivatives possessing polymerizable alkoxide groups. These siloxane derivatives liberate four equivalents of polymerizable alcohol during the sol–gel process. By employing polymerizable monomers as cosolvent, all components contribute either to the silica network or to the organic polymer. Therefore, gel drying is unnecessary and large-scale shrinkage is avoided. Scheme 3 shows a typical example of this approach. The mechanical properties of these materials can be improved greatly through the incorporation of an organic phase. The glass content of these nonshrinking hybrid materials can be increased further by using soluble poly(silicic acid ester) oligomers possessing the same polymerizable alkoxides as the staring materials.

4.8 Poly(ε-Caprolactone) (PCL)–Silica

This is a typical example of a polyester–silica system. Tian *et al.* (1997, 1999) reported the synthesis and characterization, and particularly the property–structure–morphology characteristics, of biodegradable and biocompatible PCL–silica hybrid materials. PCL is well known for biocompatibility, permeability, and biodegradability. Transparent hybrid materials have been prepared from both linear and three-arm star-shaped triethoxysilane-, hydroxyl-,or

vinyl-terminated PCL and TEOS by the acid-catalyzed sol–gel process. The organic PCL components and inorganic silica components can be associated either by covalent bonding (in the case of triethoxysilane-terminated PCL) or by hydrogen bonding between the carbonyl groups of PCL and the residual OH groups on the silica. The incorporation of PCL into the silica network, and consequently the morphology and structure of the resulting PCL–silica materials, has been investigated by TEM, SAXS, DMA, AFM, SEM-EDAX, IR analysis, and solid-state NMR, and was found to be dependent on the PCL content and molecular weight, the reactivity of the PCL end-groups and their number per chain, and the acid and water content. For example, lower PCL content, higher PCL molecular weight, higher acidity, more functional groups per chain, and triethoxysilane end groups are favorable to PCL incorporation. The analysis of the Porod region of the SAXS profiles show that the PCL–silica interface is mass fractal, in agreement with a co-continuous two-phase morphology. A more open structure can be formed at lower acid content and higher water content. Similar to PTMO–silica and PEK–silica systems, the extent of the sol–gel reaction is limited by the early vitrification of the reactive system, and thermal post-treatment can overcome these diffusional and/or kinetic limitations. *In vitro* cell culture and biodegradation tests show that PCL–silica systems are biomaterials with biodegradable and biocompatible properties. Another application of these materials is that they can be used to produce porous silicas by pyrolysis to remove the organic components. The silica microporosity can be tailored by the content, molecular weight, and molecular weight distribution of PCL as well as by the reactivity and number of the PCL end groups.

4.9 Partially Deacetylated Chitin (CHI)–Silica

CHI is a biopolymer structurally similar to cellulose, but containing predominantly amino groups at the C-2 position. CHI–silica hybrid materials were made by a controlled acid-catalyzed hydrolysis of TEOS via the sol–gel process in the presence of CHI (Retuert *et al.* 1997). The resulting hybrids were homogeneous, transparent, glassy materials with a wide composition range. The hydrogen bonding between the amino functional groups of CHI and the silanol groups on the silica could be attributed to some degree to the compatibility between CHI and silica. It was also suggested that the homogeneity of the hybrids could be due to the dispersion of CHI at the molecular level in the silica network.

4.10 Fluoropolymers–Silica

Generally speaking, fluoropolymers are not good candidates for preparing polymer–silica nanocomposites

because most of them only dissolve in perfluorinated solvents that are profoundly incompatible with water. Work has been done to conduct the sol–gel reactions in such highly inhospitable solvents by using poly-fluoroalkoxysilanes with trifluoroacetic acid as the gelling agent (Sharp 1998). For example, *in situ* generation of silica by the sol–gel process was carried out in the presence of the soluble fluoropolymer Teflon AF which is a copolymer of tetrafluoroethylene and bis-2,2-(trifluoromethyl)-4,5-difluoro-1,3-dioxole. Optically clear coatings can be obtained after casting the solution on glass or metal substrates. These hybrid materials show improved adhesion to glass and better abrasion resistance than the pure fluoropolymer counterpart. SAXS and TEM results showed that the largest particles observed in a hybrid containing 17 wt.% silicate in Teflon AF were about 15 nm. Therefore, the extremely high transparency of the fluoropolymer was not compromised by the presence of moderate amounts of silicate.

Polymers in Constrained Ceramic Environments

There is a great deal of interest in the preparation and characterization of organic–inorganic nanocomposites, particularly in those materials in which an organic phase is ceramic constrained in such a way as to produce novel structures, frequently at the molecular level. Such ceramic-constrained environments include zeolites, clay galleries, and mesoporous silica. In some cases, a polymer is directly introduced into a constraining structure (clay galleries), while in others a constrained monomer is polymerized subsequently, for example in pores, to obtain the final composite material. This review focuses on some specific aspects of the morphology of organic–inorganic nanocomposites and how the confinement affects the properties of the polymer.

1. Simple Mixture of a Polymer and a Zeolite

In the simplest study of this type, Al-Ghamdi and Mark (1988) studied reinforcement of poly(dimethylsiloxane) (PDMS) by two zeolites having different pore sizes. The zeolites were simply blended into hydroxyl-terminated chains of PDMS, which were subsequently end-linked with tetraethoxysilane to form an elastomeric network. Stress–strain isotherms measured in elongation showed that both types of zeolites increased the ultimate properties of the elastomer and were thus effective reinforcing fillers, the one having the larger pore size giving a larger increase in the ultimate strength of the elastomers.

Further characterization of the mechanical properties and structure of such zeolite-reinforced PDMS elastomers by Wen and Mark (1994) also utilized small-angle neutron scattering (SANS) and transmission electron microscopy (TEM). The neutron-scattering profiles of the pure and zeolite-filled PDMS networks were identical, which indicates negligible penetration of the polymer into the zeolite pores. The TEM pictures showed that the zeolite with the larger pore size (zeolite 13X) had a smaller particle size, and this is probably the origin of its superior reinforcing ability.

2. Polymerizing Monomer within Zeolite Cavities

A different approach was initiated by Frisch and Xue (1995) to introduce polymer into the internal pores of the zeolite 13X. As will be seen in the following section, the approach is very similar to that used by Wu and Bein (1994a,b) to form molecular-scale wires of polyaniline within nanometer-sized channels.

In the first application of this approach, Frisch and Xue added (liquid) monomeric styrene in various ratios to a weighed amount of zeolite. A desired amount of benzoyl peroxide was then added to the mixture for subsequent generation of free radicals by thermolysis, producing polymerization of the styrene. The polymerization was carried out at 70 °C, either directly in this form or in the presence of the cross-linker ethylene glycol dimethacrylate (EGDM; 0.017 mol/mol of monomer). In the absence of the cross-linker, the linear PS chains and the zeolite were considered to form a hybrid inorganic/organic "pseudo-interpenetrating polymer network" (PIPN) or "semi-interpenetrating network," while the cross-linked polystyrene (PS) and zeolite composite was considered to have formed a full interpenetrating polymer network (IPN).

Subsequently, Frisch *et al.* (1996a, c) were also able to form both PIPNs and IPNs from poly(ethylene acrylate) (PEA) and zeolite 13X. At room temperature the PEA is a rubbery polymer while PS is glassy. In this case, the polymerization was carried out at 40 °C using liquid ethyl acrylate monomer in the zeolite mixtures, with benzoyl peroxide initiator, either in the absence or presence of EGDM cross-linker.

These studies provided substantial confirmation that the polymer grows within the internal pores. Specifically:

(i) Removal of about half of the linear polymer by solvent extraction (determined gravimetrically) left individual zeolite crystals containing the remaining polymer. The SEM micrographs showed that there was essentially no polymer between or on the zeolite surface (which was present before the extraction), and resembled micrographs of the pure zeolite. All linear polymer could be removed on extended solvent extraction (Soxhlet extraction for one week in suitable solvents).

(ii) Solid-state ^{13}C nuclear magnetic resonance (NMR) showed significant line-width broadening of the quaternary aromatic, methine, and methylene carbons in the linear PS. The effect was strongest in the partially solvent-extracted samples. This is consistent with the speculation that the "internal" PS chains in the pores of the zeolite are more confined by their environment than in the pure PS (without any zeolite).

(iii) The small-angle x-ray scattering (SAXS) curve of the PIPN of the PEA/zeolite exhibited two maxima, as shown in Fig. 1. The first rather sharp peak was the same as in the pure zeolite 13X and corresponds to a Bragg's law distance of 14.3 Å (the periodic interpore distance in zeolite 13X). The second (weaker and broader) peak disappears completely in the scattering curve for the fully extracted PIPN (containing no residual PEA polymer). This weaker peak has a maximum which corresponds to the doubled distance (~ 28.6 Å) which is interpreted to be due to the presence of PEA-filled pores in an arrangement showing some type of imperfect regularity.

(iv) Of greatest relevance were the differential scanning calorimetry (DSC) curves for IPNs and PIPNs of PS/zeolite or PEA/zeolite containing 50–60 wt.% polymer (where the zeolite crystals were present during the polymerizations, with some of them being threaded in a matrix of cross-linked or linear polymer). These materials exhibited a glass transition temperature T_g, which was approximately the same as that of the corresponding pure polymer. Partially extracted samples of the PIPNs in which essentially all the interparticle and surface polymer has been removed exhibited no T_g at all, despite gravimetric weight measurements indicating that a considerable amount of PS (26.6 wt.% PS) was still present. Presumably, the internal linear polymer

chains in the pores of the zeolite 13X adopt a conformation more extended in one dimension and thus exhibit no bulk T_g. In qualitative terms, the constraints prevent the long-range motions that would otherwise occur at the normal glass transition. The same results were found with partially extracted PEA in zeolite 13X. The root mean square radii of gyration of polystyrene and polyethylacrylate of viscosity average molecular weight of 3.0×10^5 for PS and 4.2×10^5 for PEA which were used are 71 Å and 99 Å, respectively. In the zeolite 13X the pores have a diameter of 10 Å, considerably smaller than the root mean square radii of gyration of these polymers.

3. Polymers Constrained in Clay Galleries

A polymer–clay hybrid is defined as a molecular composite of polymer and silicate layers of clay minerals, such as montmorillonite, saponite, hectrite, and synthetic mica. Two main methods of synthesis have been proposed. One is the *in situ* polymerization of metal alkoxides in organic matrices via the sol–gel process. The second is the utilization of intercalation reactions of clay minerals. This article reviews the research in the latter field in which polymers have been introduced into suitably modified interlayer spaces (galleries) of clays.

Figure 1
Excess scattering intensities for a poly(ethyl acrylate)/zeolite pseudointerpenetrating polymer network (PIPN).

In general, two types of hybrids are possible: intercalated, in which a single, extended polymer chain is intercalated between the host layers resulting in a well ordered multilayer with alternating polymer/inorganic host layers and repeat distance of a few nanometers; and delaminated, in which the silicate layers (1 nm thick) are exfoliated and dispersed in a continuous polymer matrix.

In an early study in this area, Vaia *et al.* (1993) reported on the properties of the intercalated polymers by concentrating on the polystyrene–organosilicate hybrid. The gallery height increased by 0.7 nm in the hybrid. The intercalated polystyrene chains adopted a collapsed, two-dimensional conformation and did not show the characteristic bulk glass transition. This behavior is qualitatively different from that exhibited by the bulk polymer and is attributed to the confinement of the polymer chains between the host layers.

Kojima *et al.* (1993b,c) synthesized nylon 6–clay hybrid, in which layered clay minerals are uniformly dispersed in nylon 6 matrix. The features of this polymer are high strength, high modulus, high distortion temperature, and low gas permeability. It was suggested that the ionic interaction between the host and the polymer was one of the reasons why these hybrid materials had superior mechanical properties.

Kojima *et al.* (1993a) also synthesized rubber–clay hybrid (RCH). The mechanical properties of RCH were superior to those of vulcanized acrylonitrile butadiene rubber. The permeabilities of hydrogen and water vapor in RCH were measured and it was found that the RCH has an improved gas barrier property. The same result was found by Yano *et al.* (1993) in synthesizing the polyimide–clay hybrid. Furthermore, this hybrid also had a low thermal expansion coefficient.

Okada and Usuki (1995) prepared several polymer–clay hybrids, in which the polymers are nylon 6, nitrile rubber, and others. These, when molded, have excellent mechanical, thermal, and chemical properties as compared with the unfilled polymers and/or conventional composites. The mechanism of reinforcement was explained using the results of ^{15}N CP-MAS and proton pulsed NMR studies. The results revealed that all polymers in the interlayer space of minerals are partially ionized. It is suggested that the chemical bond between the inorganic silicate and the organic polymers at the molecular level causes an improvement in the macroscopic mechanical properties of materials.

In the work of Krishnamoorti *et al.* (1996), the static and dynamic properties of polymer-layered silicate nanocomposites are discussed in the context of polymers in confined media. Despite the topological constraints imposed by the host lattice, mass transport of the polymer into the silicate layers (at least in the case of essentially non-polar polystyrene) appears to be unhindered and exhibits mobility similar to that of the pure polymer. However, both the local and global dynamics of the polymer in the hybrids are dramatically different from those in the bulk. On a local scale, intercalated polymer chains exhibit higher flexibility along their backbone along with a marked suppression (or even absence) of cooperative dynamics typically associated with the glass transition. On a global scale, relaxation of polymer chains either tethered to or in close proximity (<1 nm as in intercalated hybrids) to the host surface are dramatically altered and parallel those of other intrinsically anisotropic materials such as block copolymers and liquid crystals.

Lee and Jang (1996) prepared a polymethylmethacrylate (PMMA)–clay hybrid, and the differential scanning calorimetry (DSC) traces corroborate the confinement of the polymer in the inorganic layer by exhibiting no observable transition in the thermogram. Both the thermal stability and tensile properties of the products appear to be substantially enhanced.

Later, the relaxation behavior of poly(ethylene oxide) (PEO), intercalated in montmorillonite, was studied by Vaia *et al.* (1997). The motions of the intercalated PEO chains are inherently noncooperative relative to the cooperative T_g motions in the amorphous portion of the bulk polymer. This is presumably due to the strong confining effect of the silicate layers on the relaxation of the intercalated polymer. Additional details are given in *Clay-based Polymer Nanocomposites** in this Encyclopedia.

The layered silicate–epoxy nanocomposites have also been investigated by Messersmith and Giannelis (1994). The nanocomposite exhibits a broadened T_g at slightly higher temperature than the unmodified epoxy. Furthermore, the dynamic storage modulus of the nanocomposite containing 4 vol.% silicate was approximately 58% higher in the glassy region and 450% higher in the rubbery plateau region compared to the unmodified epoxy.

4. Polymerization of Monomer within Porous Silica

After the study of the zeolite/polymer composites, Frisch *et al.* (1996b) also investigated the polystyrene (PS) constrained in two porous silicas, one of which was an amorphous silica composed of silica gel nanotubes with pore sizes of 200–8000 Å, and the other a novel crystalline mesoporous hexagonal silica with uniform holes of 28 Å in diameter.

Because of the large ratio of the silica pore diameter to the PS root mean square radius of gyration, the interpenetrating network (IPN) and pseudointerpenetrating network (PIPN) of the nanotube silica material displayed normal glass transitions, which differed little from the pure cross-linked PS and linear PS transitions. The small difference can be attributed to molecular weight differences, with lower molecular

weights corresponding to lower glass transition temperatures. The extracted PS PIPN material in the nanotubes retained the bulk glass transition, unlike the PS confined in the smaller diameter zeolite 13X in which it disappeared. However, the pore size of the nanosilica was one to three orders of magnitude larger, with a diameter of 200–8000 Å compared to the zeolite 13X diameter of 10 Å. The morphology of the chains in the nanotubes may be similar to bulk PS and thus exhibit a bulk T_g.

The PS PIPN material made with the mesoporous silica was very similar in physical appearance to the nanosilica PIPN. The unextracted material had a normal glass transition curve and a T_g close to the bulk PS T_g. However, upon extraction of the polymer in the PIPN composite as the wt.% of organic polymer to inorganic material dropped from 70:30 to 22:78, when the external PS was removed there was no bulk glass transition observed in the temperature range 25–160 °C. This suggests that no bulk glass transition exists for linear PS chains (root mean square radius of gyration of about 100 Å) confined to pores of less than 30 Å.

Further work on the mechanical properties of films of such hybrid inorganic/organic IPNs is in progress (Maaref *et al.* 1999). The authors' group have investigated the conductive polyaniline complex/zeolite hybrids at high polyaniline contents which exhibit an apppreciable antiferromagnetic component as well as paramagnetic component to their electron paramagnetic resonance spectra (Frisch *et al.* 2001).

5. Concluding Remarks

The effect on the mechanical properties of the polymer (e.g., reinforcement) from forming a polymer–ceramic mixture can be quite variable and depend strongly on the particle size, etc. The mechanical properties of polymers confined to clay galleries are generally superior. This may be due, at least in part, to the fact that in certain clay systems there are ionic forces between the clay gallery and the polymer. When the distances between the walls of the clay gallery are sufficiently small then the polymer morphology in this constrained structure changes and no bulk T_g is observed. In general, when polymers are confined in pores whose diameter is smaller than the root mean square radius of gyration of the polymers no bulk T_g is observed. When the diameter of the pore is larger than the root mean square radius of gyration, as in the silica nanotubes, a bulklike T_g is observed. Clearly confinement in these cases also changes the polymer morphology with consequences for the glass transition.

Porous Ceramic Processing

There are numerous applications in which it is necessary or useful to introduce porosity into a ceramic material. For example, in filtration applications, materials need to be permeable and the processing emphasis is often focused on controlling the size of the pore channels. Applications include the removal of particles or large molecules from liquids (for concentration or purification) and gas separation. Similarly, many sensors, catalytic systems, and gas burners require materials to be permeable as well as providing other functions. Porosity can also be used as a second phase to design materials with tailored properties, and in this case it is necessary to control both porosity volume fraction and its size. For example, porosity can be used to decrease thermal conductivity, which is important in refractory and thermal insulation materials. The presence of porosity can decrease the dielectric constant of a ceramic, which is a property sought in substrates used for microelectronics. The void space in porous ceramics can also be used as a storage medium for the later release of the second phase. For example, this idea has been exploited for medication delivery devices or as diffusion sources in the semiconductor industry. Porous ceramics are also being used as bone implants and the porous structure has been shown to promote bone growth. The decrease of density with the addition of porosity can be used in some structures to produce materials of a given stiffness or strength with minimum weight. The sandwich panel structure, in which a porous (core) material is bonded to strong, stiff faceplates, is an example of this design methodology. The primary function of porous ceramics is, however, not often structural and the presence of porosity usually degrades strength. As many applications require a high degree of mechanical reliability, there is often a need to ensure a compromise between strength and the other properties required for the given application. Porous ceramics are often attractive in applications that involve high temperature or corrosive environments.

The processing techniques required for porous ceramics depend critically on the volume fraction and size of the required porosity. For example, ceramics with porosity levels greater than 70 vol.% can be produced with a (hollow) cellular structure. The processing of cellular ceramics often involves a foaming process and the pore size is typically greater than 100 μm. High-porosity ceramics can also be produced by the bonding or sintering of ceramic fibers. These are termed fibrous ceramics and such materials are commonly used as high-temperature thermal insulation. For example, the thermal protection system of the NASA space shuttle is based on fibrous tiles that use bonded silica or aluminosilicate fibers. An example of the microstructure of this material is given in Fig. 1. Another approach for processing high-porosity materials is to use sol–gel technology and the pore size in these materials is typically less than 1 μm. To produce ceramics with lower levels of porosity, conventional ceramic powder processing is often used but modified to ensure control of the pore volume and size. The main aspects of these various established processing approaches are discussed below. Porous ceramics can also be produced by the oxidation of metals, gas dissolution during solidification, or removal of a (continuous) second phase, e.g., by leaching. An example of the third approach is the production of "thirsty" glass (Vycor), in which one phase is leached from a phase-separated glass. This approach has also been applied to glass ceramics. It is anticipated that porous materials will also be produced by solid freeform processing or by the deposition/etching techniques that are employed in the microelectronics industry.

Figure 1
Fibrous structure of the high-porosity tiles used in the thermal protection system of the space shuttles.

1. Cellular Ceramics

Cellular materials are generally classified into two broad groups, honeycombs and foams. In honeycombs, the cells form a two-dimensional array whereas foams are comprised of a three-dimensional array of hollow polygons. Ceramic honeycombs have found a substantial market as catalytic converters, heat exchangers, and combustors. Foams are usually divided into two further categories depending on whether or not the individual cells possess solid faces. If the solid is contained only in cell edges, the material is termed open cell (or reticulated) and the material is permeable. These materials are often used as filters for molten metals or as kiln furniture. An example of an open-cell ceramic is shown in Fig. 2. If the cell faces are present, the foam is termed closed cell and the individual cells are isolated from each other. Closed-cell glass foams are commercially available as thermal insulation or as abrasives.

Ceramic honeycombs are usually formed by extrusion and this structure then undergoes a conventional binder burn-out and sintering process. The die used in the extrusion process can be designed to produce a wide variety of cell geometric structures, e.g., square, triangular, hexagonal, etc. The extrusion process requires moldable raw materials, the rheological behavior of which can be adjusted by water-soluble additives. In this process, a balance is needed in this rheology to ensure stability of the cellular structure without excessive die wear.

A common processing approach for open-cell ceramics is to coat open-cell polymer foams, usually with a ceramic powder dispersed in a liquid (slurry). This approach approximately replicates the polymer and gives a rather distinct structure in that the cell struts

Figure 2
Structure of an open-cell ceramic produced by the sponge replication technique. This material shows the presence of longitudinal strut cracks that probably result from nonuniform coating.

are hollow after the process is complete. The central hole represents the original shape and position of the polymer, which is removed by pyrolysis during the firing process. Various open-cell polymers have been used as substrates for the coating process including polyurethane, poly(vinyl chloride), polystyrene, and latex. The composition of the ceramic slurry used to coat the polymer depends on the final application but has included a wide variety of oxide and nonoxide ceramics. The ceramic slurry often contains various additives to act as binders, rheological control agents, or setting compounds to facilitate the coating process. It is critical that the slurry produces a uniform coating, especially as the polymer foam can often contain sharp corners at the strut edges. The presence of longitudinal strut cracks in Fig. 2 is probably a result of poor coating at the strut corners. In the processing, the polymer "sponge" is immersed in the ceramic slurry. The excess slurry is then removed by mechanical compression or centrifugation. The ceramic foam is dried and fired in a typical manner, except for a pyrolysis step in which the organic additives and polymer foam are removed. During heating, the expansion and gas evolution behavior of the polymer can lead to significant stresses that can damage the ceramic coating if not carefully controlled. For these materials, the pore size in the final product is determined primarily by the cell size of the polymer foam.

An alternative approach for producing open-cell ceramics is to use a physical deposition process on an open-cell substrate. For example, open-cell vitreous carbon foams can be produced by pyrolysis of thermosetting polymer foams. The carbon foam can then be coated with a dense ceramic material, e.g., by chemical vapor deposition. This process has been used to produce a variety of oxide, boride, nitride, and carbide foams. Replication has also been performed on biological materials. For example, a lost wax process has been used to replicate coral and sols have been absorbed into wood to produce a porous structure after the firing process.

In contrast to the above replication methods, there are direct techniques to foam a liquid in which a ceramic powder or a precursor to a ceramic is dispersed. The liquid also contains a constituent which, when treated appropriately, will lead to gas evolution causing bubbles to form in the liquid. The gas evolution process is usually initiated by heat or chemical reaction and a wide variety of processes have been devised. For example, organic compounds can be mixed to produce carbon dioxide or hydrogen in an ambient temperature reaction. Other additives to the liquid are used to stabilize and harden the cellular structure once it is produced. The hardening may occur by a chemical reaction or gelation and is used to "set" the foamed structure. The foam is dried and sintered by conventional means. The final structure of a foamed material often exhibits some morphological

anisotropy associated with the "rise" direction of the foam. Glass foams are produced by a high-temperature version of this process in which additives such as hydroxides, carbonates, and sulfates are mixed with glass powder. On heating, the glass becomes fluid and the decomposition of the salts leads to bubble formation. The direct foaming approaches give rise to a closed-cell structure, but if sintering is used the cell faces often perforate and produce an open-cell ceramic. As an alternative to direct foaming, the sintering or bonding of hollow spheres has been used to produce closed-cell ceramics.

2. Fibrous Ceramics

Fibers in a blanket or felt form have been used extensively as thermal insulation but fibers can also be "rigidized" by bonding processes to produce fibrous ceramic monoliths (tiles or boards). These materials are used for a wide variety of thermal insulation applications and are attractive as a result of their low thermal mass, which allows fuel savings. These bodies are usually classified in terms of the refractoriness of the fibers. They may range from low- to high-purity silica glasses or from low- to high-purity alumina fibers, depending on the alumina/silica ratio in the latter fibers. The low-alumina fibers are usually produced by a melt blowing process. One of the processing concerns in blown fibers is the amount of "shot" (solidified particles that escape the fiber-shaping process) that is present in the final product. High-alumina fibers (ICI's Saffil alumina or 3M Corporation's Nextel mullite) are produced by a sol–gel route and can be used at temperatures up to 1600 °C.

Fibrous ceramics are often formed by a uniaxial pressing operation and this can lead to significant anisotropy in the physical properties. In this process, conditioned fibers are mixed with a liquid that contains the appropriate binders and dispersants. This slurry is then mechanically pressed or molded into the required shape and gelation is used to set the structure. The green body is dried and fired by conventional means, although the low thermal conductivity of these materials can lead to longer processing times being required to reach thermal equilibrium.

3. Porous Sol–Gel-derived Ceramics

Sol–gel chemistry can be used to produce porous ceramics either as monoliths or as thin films. The latter are termed ceramic membranes and are used for filtration. The pore size in these sol–gel-derived materials can be controlled from approximately 1 nm to 1 μm. The sol–gel process can be accomplished using a wide variety of techniques. For example, alkoxides such as tetraethyl orthosilicate can be mixed with water to initiate the gelation. Subsequently, hydro-

lysis, condensation, and polymerization take place to form an alcogel, which is an oxide network that has condensed with liquid (alcohol) filling the porous network. The liquid is then removed by evaporation (xerogels) or by hypercritical drying (aerogels) to produce high-porosity silica. The pore structure can then be further modified by a heat treatment. Alumina, zirconia, and titiania ceramics can be produced by similar sol–gel processes. An alternative sol–gel process is one in which a colloidal suspension of hydroxide or hydrated oxide particles is peptized. Gel formation is induced by increasing particle concentration or by manipulating the zeta potential. The process is controlled by pH, the nature/concentration of the electrolyte, and particle size.

Zeolites are materials in which porosity is available at the molecular level and sol–gel technology has extended this behavior to larger pore sizes. An interesting development of these ideas is the production of porous silica-based material, in which the pores are ordered at the nanoscale. For example, Kresge *et al.* (1992) produced silica-based materials in which the pores are in hexagonal arrays and the pore sizes are in the range 1.6–10 nm. This has proved to be a very active research area and scientists have worked to extend the pore size range and choice of materials. These materials use organic "templates," such as surfactant arrays or emulsion droplets that allow the porous materials to be self-assembled. Latex spheres and block copolymers can also be used to introduce submicrometer pores into sol–gel-derived materials, and it has been demonstrated that three-dimensional ordered structures can be produced by such means.

4. Partially Densified Ceramics

Many ceramics are produced by the (high-temperature) firing of powder compacts. The level of porosity in these materials can be controlled by either firing at a temperature at which densification is incomplete (see Fig. 3) or by controlling the particle size distribution. This latter approach is used extensively in the refractories industry. The microstructure of refractories usually consists of grain and bond phases. The large refractory grains are often derived from the raw materials with a minimum of preprocessing. The bonding phase is usually fine-grained, such as the glassy or silicate bonding derived from clays, carbon bonding derived from resin or pitch, or calcium aluminate cements. During the powder processing, the fractions of the coarse, intermediate, and fine-sized particles are carefully controlled as this defines not only the green density but also the amount of shrinkage that occurs during firing. Unlike other engineering ceramics, refractories may only have limited shrinkage during firing. The firing process is, however, important in controlling the bonding process,
Figure 3

such as carbonates or hydoxides, which decompose by gas evolution, can be employed. If porosity of well-defined shape is required, polymeric fibers or particles can be used. For example, Fig. 4 shows a porous ceramic in which the pores are produced by the pyrolysis of polymeric fibers. Some ceramic materials are available in the form of hollow spheres, and incorporation of these materials into a powder mix can produce well-defined porosity. In the cement industry, hollow flyash spheres (cenospheres) are sometimes used to produce a lightweight cement or concrete.

which leads to strength development. As refractories can contain several phases, there is the possibility of residual stress development from thermal expansion mismatch and the molar volume changes that arise from the various chemical reactions. Clearly, these stresses must be controlled so that any microcracking does not have an impact on the desired properties in the final product.

Porosity can also be introduced into powder-processed ceramics by adding a fugitive phase to the powder mix. For example, inexpensive raw materials, such as sawdust or starch, are employed. These organic materials are "burnt off" by the firing process leaving the additional void space. Alternatively salts,

Porous Silica Xerogel

Scaling of integrated circuit (IC) feature sizes has brought tremendous performance improvement and miniaturization. The primary contribution to IC performance improvement has been from the device gate level. However, metal interconnects become the limiting factors for continued IC performance improvement when the feature size scales down to the deep-submicrometer region and below. The gain in device speed at the gate level is offset by propagation delays at metal interconnects owing to the increased RC time constant. The RC time delay can be reduced by the incorporation of low dielectric constant (k) materials and/or high conductivity metals. The use of low-k dielectric materials also lowers power consumption and reduces crosstalk (Jeng *et al*. 1994).

There are numerous low-k dielectric candidates available with dielectric constants roughly in the range 2.4–4.0 (Lee and Ho 1997). As predicted by the Semiconductor Industry Association (1998), continued scaling of devices will require ultralow-k materials with dielectric constants as low as 1.5. One of the ways to obtain a lower dielectric constant is fluorination of either inorganic or organic dielectric materials. However, the lowest dielectric constant available for fluorinated dense materials is $k \sim 1.9$ (Teflon) and none of the approaches using dense materials is expected to achieve k values lower than this. Air practically has the lowest dielectric constant possible, $k \sim 1$. Incorporation of air into dense materials to make them porous is another attractive method to obtain ultralow-k materials. The ultralow dielectric constant results from the incorporation of pores. For a porous material, the dielectric constant is a combination of air and that of the dense phase, and it has the potential to drive the dielectric constant significantly below 2. To meet performance goals, future technology nodes will require materials with progressively lower dielectric constant. A change in dielectric material for each technology node increases process and equipment complexity and development costs. It is desirable to have one kind of material that can meet the requirements for multiple future technology nodes. Porous dielectric materials offer the extendibility to multiple technology nodes because they have a tunable dielectric constant. The dielectric constant variation with respect to porosity (volume fraction of pores) of porous silica xerogel is shown in Fig. 1. The figure includes predictions from the parallel model as well as bulk sample measurements (Hrubesh *et al*. 1993). Clearly, a dielectric constant of interest can be achieved by tuning the porosity to a proper level. Besides the tunable k value, porous silica xerogel also has the advantage of using SiO_2 as the base material. It offers some of the advantages SiO_2 has in process integration such as high thermal stability, etc.
Figure 1
Dielectric constant of porous silica xerogel as a function of porosity based on a parallel model and experiments on bulk samples.

1. Porous Silica Xerogel Processing

Porous silica xerogel is produced using sol–gel processes through hydrolysis and polycondensation of an alkoxide, such as tetraethoxysilane (TEOS), followed by drying of the gel to form a porous silica network (Iler 1979, Brinker and Scherer 1990). Porous silica xerogel films for semiconductor applications are deposited using spin coating. Figure 2 depicts an overall process block diagram (Jin *et al*. 1996, Ramos *et al*. 1996).

In precursor preparation, the hydrolysis and condensation reactions are controlled to obtain solutions suitable for spin coating. The precursor is then dispensed onto a substrate and spin-coated to produce a uniform film. If the precursor is dispensed and coated in an open environment typical of most spin-on-dielectric (SOD) processes, polycondensation, gelation, and solvent evaporation stages can overlap during spin coating. Ethanol is usually used as the common solvent for water and TEOS in the sol–gel process. Severe solvent evaporation can occur during spin coating owing to the high vapor pressure of ethanol. It causes premature drying and shrinkage of the gel. To control the solvent evaporation, a sealed chamber saturated with ethanol vapor is necessary for precursor dispense and coating, making the process neither safe nor practical for manufacturing. To solve this problem, alternative low vapor pressure solvents are used to reduce the solvent evaporation during coating. The precursor now can be dispensed and coated without ambient control on regular commercial SOD process equipment.

After spin coating, the wafer is aged in a controlled environment with NH_4OH vapor. Aging of the silica gel is necessary to increase its mechanical strength and prevent unnecessary shrinkage in a subsequent drying step. Again, solvent evaporation from the film
Figure 2
Porous silica xerogel film deposition steps using sol–gel processes by spin coating.

is minimized during aging. After aging, the original solvent is exchanged with a low surface tension solvent to reduce the capillary pressure in micropores during drying. Because of the high porosity and small pore sizes, silica xerogel has a large surface area, typically in the range 500–1000 $m^2 g^{-1}$. Hydroxyl groups usually terminate the surface silicon atoms. The average coverage is around 4.9 OH nm^{-2} and is largely independent of process conditions. These surface hydroxyl groups are the primary sites for moisture adsorption, which increases the dielectric constant and causes integration problems. The surface silanol groups also form Si–O–Si bonds through condensation reactions during drying, resulting permanent shrinkage of the film. To reduce moisture adsorption and film shrinkage during drying, surface hydroxyl groups in xerogel films are replaced with noncondensing organic groups such as methyl in a surface passivation step. Since no permanent Si–O–Si bonds are formed, the film can ''spring-back'' after drying. Surface passivation is typically conducted during the solvent exchange step. The xerogel film is then dried on a series of hot plates and sometimes thermally annealed in a furnace.

The dielectric constant of porous silica xerogel films can be tuned by adjusting the solid content in the precursor. The aging and surface passivation steps are critical in controlling xerogel film properties. The dielectric constant can easily vary by more than 20% for the same chemical precursor under different aging and/or surface passivation process conditions.

2. Porous Silica Xerogel Film Characterization and Properties

Porous silica xerogel films have been partially characterized for semiconductor applications (Jin *et al.* 1996). The dielectric constant measured using the metal–insulation–semiconductor capacitor method is $k \sim 1.8$–2.5 depending on porosity and process conditions. Porous silica xerogel films display good dielectric strength with a breakdown field in excess of 2 MVcm^{-1}. Because the pore sizes of porous silica xerogel films are typically less than 10 nm and are much smaller than the mean free path (~ 60 nm) of ambient air, the film dielectric strength is much greater than that of ambient air. Porosity of the films is measured using spectroscopic ellipsometry and Rutherford backscattering spectroscopy (RBS). Ellipsometry data fit very well with a uniform SiO$_2$ and air mixture model. RBS measures the area density of the film, and the porosity is calculated based on the film thickness from ellipsometry measurements and the SiO$_2$ density of 2.22 g cm^{-3}. Porosities obtained from RBS and ellipsometry agree with each other. Porosity can also be measured using specular x-ray reflectivity (SXR). In SXR, electron density is directly determined from the critical angle where an x-ray beam is no longer totally reflected from the film surface. If chemical composition of the material is known, the mass density can be calculated. The porosity can then be derived in the same way as for RBS. Adhesion of porous silica xerogel films to silicon and plasma enhanced TEOS-based CVD oxide (PETEOS) substrates are analyzed using Scotch tape and stud pull tests. In both cases, no delamination occurs between the porous silica xerogel films and the substrates. Porous silica xerogel films exhibit good adhesion to both silicon and PETEOS substrates. However, cohesive failures can occur if the xerogel films themselves are not strong enough. As expected for highly porous materials, porous silica xerogel films display very low stress in the temperature range 20–500 °C. FTIR spectra of the films show an absence of moisture peaks after the surface passivation step. The surface contact angle can reach nearly 90° in water drop contact angle measurements, confirming the hydrophobicity of the xerogel films.

One of the major drawbacks of porous materials is their mechanical strength. Just as the dielectric constant of a porous material is between that of its dense phase and that of air, mechanical properties such as Young's modulus also fall between that of its dense phase and of air. Young's modulus of a porous material depends strongly on its density and usually exhibits a power law relationship, $K \sim (\rho/\rho_0)^m$, where

K is Young's modulus, ρ and ρ_0 are the porous material density and a reference density, respectively, and $m = 3$–4. Changing the density, and therefore the porosity, will have a significant impact on the mechanical properties of a porous material. In addition, process conditions also play an important role in determining the mechanical properties. An order of magnitude change in modulus can be obtained by varying process conditions.

3. Integration of Porous Silica Xerogel Films

The feasibility of integrating porous silica xerogel films into IC test structures has been studied for both aluminum and copper metallization processes (Zielinski *et al.* 1997, Jin *et al.* 1996). In conventional non-damascene aluminum metallization processes, gapfill capability is an important factor for intermetal dielectrics. Because low vapor pressure solvent is used in the xerogel chemical precursor, the film remains wet and flowable after spin coating giving sufficient time for it to fill complex gap structures. However, shrinkage during aging and drying may cause the porous silica xerogel film to crack and pull back from narrow gaps between metal lines. With proper process control and without resorting to an elaborate process setup and/or supercritical drying, shrinkage can be minimized such that narrow gaps with high aspect ratios can be filled.

A dense capping layer on top of porous silica xerogel films is needed for chemical mechanical polish (CMP) and etch processes. Various CVD dielectric films are deposited on top of porous silica xerogel films without deeply penetrating into the pores and changing the porosity of the underlining films. However, because xerogel pore surfaces are passivated with organic groups such as methyl, they are susceptible to oxidizing plasma damage. The removal of the organic passivation groups such as methyl will result in high silanol content and increase moisture adsorption. Optimized capping layer deposition, etching, photoresist ashing, and cleaning processes are needed to minimize the damage. FTIR is usually used as a quick way to monitor damages to low-k films. One can also measure other parameters such as dielectric constant, moisture adsorption, etc. A reducing atmosphere instead of the conventional O_2 plasma may be used in photoresist ashing. C_2F_6-type chemistry has been tested in a plasma reactor to etch porous silica xerogel films. Porous silica xerogel films etch much faster than dense CVD oxides under the same conditions although the etch rate is controllable. Vias and trenches etched through these porous films have reasonably vertical profiles.

Concerns over their mechanical strength require compatibility studies of porous silica xerogel films with processes that generate high mechanical stress such as CMP and CVD tungsten plug deposition. To integrate xerogel films with the CMP process, they are capped with a dense CVD oxide film. To prevent plasma damage and ensure mechanical integrity of the film stack, a buffer layer between the xerogel film and the CVD cap oxide may be incorporated. The CVD oxide film is successfully polished, indicating the feasibility of the CMP process for such a film stack. The xerogel film maintains its porosity and thickness after CMP. CVD tungsten is also deposited on such a film stack without delamination.

List *et al.* (1997) have successfully integrated porous silica xerogel films into double-level metal (DLM) test structures using aluminum metallization processes. High-density plasma (HDP) CVD oxide and spin-on hydrogen silsesquioxane (HSQ) are used as controls. Both of these materials are used in semiconductor manufacturing. Metal lines with 0.3 μm width/spacing are patterned and etched. Part of the wafers receives an HDP oxide deposition. For the rest of the wafers, a 50 nm CVD oxide layer with about 50% sidewall coverage is deposited as a liner to cover the aluminum metal lines before the coating of xerogel and HSQ. After deposition, xerogel and HSQ films are capped with a CVD oxide film. A buffer layer is used between the xerogel and the CVD oxide cap. All wafers are then planarized using CMP. Splits are run to fill vias with aluminum and tungsten plugs, respectively, after via pattern and etch. All wafers receive a final 450 °C sinter.

Electrical measurements and analysis are performed to determine total capacitance, leakage current, via resistance, and electromigration lifetimes in structures with xerogel, HSQ, and HDP oxide dielectric materials. 0.3 μm line/space interdigited comb structures are used for the total capacitance distribution measurements. The xerogel wafers demonstrate a total capacitance reduction of 35% compared to HDP oxide and 14% reduction compared to HSQ. Raphael modeling of these structures gives a fitted xerogel dielectric constant of 2.0. None of the materials shows any frequency dependence in capacitance between 1 kHz and 1 MHz. All the structures have very low leakage currents and via resistance. As shown in Fig. 3, reliability measurements on bow tie metal leads indicate that aluminum/xerogel structures have similar electromigration lifetime as those of aluminum/HSQ structures.

Porous silica xerogel has also been integrated into copper damascene structures (Zielinski *et al.* 1997). In the copper/xerogel damascene process flow, xerogel films are coated on substrates followed by the deposition of a buffer layer and a CVD oxide cap. The buffer layer serves the purpose of improving film stack integrity. 0.3 μm trenches are patterned and etched. After deposition of PVD barrier and copper seed layers, the trenches are filled with electroplated copper. Copper lines are formed by CMP removal of copper on the field with a minimal amount of oxide loss and copper dishing in wide
Figure 3
Distribution of electromigration failures for porous silica xerogel and HSQ in aluminum gapfill structures measured on bow tie metal leads.
Figure 4
Cross-sectional SEM image of copper lines embedded in porous silica xerogel trenches.

lines. Copper is then capped with a silicon nitride/oxide/silicon nitride stack and bond pads are opened followed by electrical measurements. Figure 4 shows a cross-sectional scanning electron microscopy (SEM) image of copper lines embedded in xerogel trenches. In comparison with a standard aluminum/oxide structure, the copper/xerogel structure shows advantages both in measured total capacitance and metal line resistance.

4. Conclusions

It is generally believed that to drive the dielectric constant below 2 while satisfying integration requirements, incorporation of porosity into dielectric materials is necessary. Porous silica xerogel is the first porous material being proposed as an ultralow-*k* dielectric and is the most studied. Numerous porous dielectrics based on different materials and obtained through various approaches are becoming available. One of these approaches is to deposit a composite of thermally labile organic polymers with thermally stable materials. Upon thermal treatment under various process conditions, the labile components are removed leaving pores in the stable material. Porous materials that have been produced this way include surfactant templated porous silica, block polymers, and organic/inorganic composite materials (Bruinsma *et al.* 1996, Miller *et al.* 1997). Although there are many material, processing, metrology, and integration issues to be resolved, preliminary studies have shown the feasibility of incorporating porous materials into ULSI test structures.

Portland Cements

Cement is the binder used to make concrete mortars, stuccos and grouts for all types of building and construction. Although cement is a generic term and can be applied to many inorganic and organic materials, by far the most widely used and most versatile cement is Portland cement. This article is primarily concerned with Portland cement, but a brief description of other inorganic cements is also given. Unlike gypsum plaster, Portland cement is a hydraulic cement; i.e., it sets and hardens under water and hence can be used safely in all structures in contact with water. This article describes the manufacture and chemical composition of Portland cements used by the construction industry. It also summarizes the chemistry and microstructure of hydrated cement paste which is the binder in concrete and masonary construction.

The ancestry of Portland cement can be traced back to Greek and Roman times, but the year 1824 is generally considered to mark the origin of modern Portland cements when the name "Portland" was used in a patent by Joseph Aspdin to emphasize the similarity of concrete made with his cement to Portland limestone, which was a favored building material at the time. By the 1860s the Portland-cement industry was flourishing in the UK and Europe, but the first patent in the US was not taken out until 1870 by David Saylor. Today about 90 Mt are produced annually in the US.

1. Manufacture

Portland cement is commonly made from limestone and clay, two of the most widespread and abundant materials. The principal constituents are thus lime (CaO) and silica (SiO_2) which, when subjected to high temperatures ($\sim 1450\,°C$), form the hydraulic calcium silicates that are the active compounds in cement. Other calcareous materials (such as muds, marls, and shell deposits) or argillaceous materials (such as slates, shales, and coal ashes) are used in some cases.

The overall manufacturing process is shown schematically in Fig. 1. The various steps are: (i) quarrying and crushing the raw materials, (ii) proportioning and fine grinding of the crushed materials, (iii) burning in a rotary kiln at high temperature, and (iv) grinding the resulting clinker to a fine powder with the addition of a small amount of gypsum. Although wet milling and proportioning with the aid of slurries (the *wet process*) is traditional and is found in older plants in the US, modern plants all use dry grinding and proportioning (the *dry process*). Although it was made possible by improvements in grinding mills, in particle-size classification, and in dust collection, the adoption of the dry process has been motivated largely by energy efficiency.
Figure 1
Schematic layout of a modern dry-process cement plant.

In the wet process, large amounts of energy are required to evaporate the water, and the long kilns, which must be used to attain large throughputs of materials (Fig. 2), have high heat losses. In addition, the dry process lends itself to the use of more efficient heat exchangers, such as the suspension preheater, in which the incoming kiln feed draws heat from the exit gases in a series of cyclones. As a result, dry-process rotary kilns are much shorter than those used in the wet process (Fig. 2), heat losses are much reduced, and throughputs are higher. Further savings can be realized by precalcining the hot feed in a flash furnace (precalciner) before it enters the kiln.

Typical energy consumptions in cement manufacture are given in Table 1. Average overall energy consumptions ($MJ\,kg^{-1}$) for countries with cement industries employing various processes are as follows; Japan, 4.5; FRG, 4.2; and US, 5.7. Theoretically a value of $1.7\,MJ\,kg^{-1}$ is calculated from the basic chemical processes involved; in practice, modern plants now have energy consumptions approaching $3.5\,MJ\,kg^{-1}$. The average figure for the US is relatively high because of a preponderance of older plants built when energy was inexpensive.

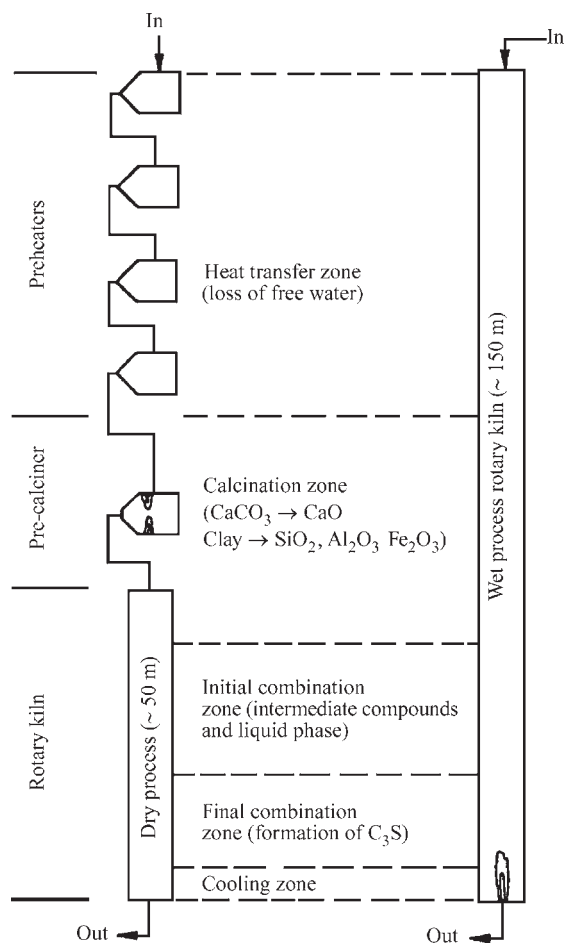
As calcination of the raw materials progresses, chemical combination takes place in the hotter zones of the rotary kiln (see Fig. 2). Formation of intermediate compounds by sintering occurs first, until at $1335\,°C$ a quarternary liquid phase appears with a composition close to that predicted from the C-S-A-F phase diagram. (C = CaO, S = SiO_2, A = Al_2O_3, and F = Fe_2O_2 in conventional cement chemists' notation; other symbols employed include $\bar{S}$ = SO_2, H = H_2O, and K = K_2O.) The amount of liquid formed depends on the amount of A and F present in the raw feed and on the kiln temperature.


Figure 2
Comparison of kiln reactions in the wet and dry processes.

Table 1
Average energy consumption in cement manufacture ($MJ \, kg^{-1}$).

Kiln operation	Wet process	Dry process
Fuel consumption	6.5	4.7
Electrical energy	0.5	0.6

Generally, about 25% of the total mix is liquid and hence the process is neither a complete fusion or a pure solid-state sintering; it is called *clinkering*. The liquid phase allows chemical combination to go to completion in a relatively short time. Much C_2S has formed by solid-state reactions before the liquid appears but its formation is completed in the liquid. The final reaction between C_2S and lime to form C_2S

takes place wholly within the liquid at 1450–1500 °C. The rate of combination depends on the rate of dissolution of lime in the clinker liquid, which is dependent on both particle size and temperature.

On leaving the hottest zone, the clinker cools to about 1100–1200 °C. Then it is air-quenched as it exits the kiln. However, cooling is usually too rapid to allow true equilibrium to be maintained. The rate of cooling also controls the crystal growth of the calcium silicates and the crystallization of liquid phase to form C_3A, C_4AF, and additional C_2S ($C_3A = 3CaO.Al_2O_3$, etc.), slow cooling results in the formation of larger and less-reactive crystals. The structure of a clinker can be studied by optical microscopy and used to predict clinker performance. After cooling, the clinker may be stored for future grinding or it may be ground immediately. Finish grinding takes place in ball mills equipped with particle-size classifiers that avoid over-grinding. At this time, small quantities of gypsum are added to control the early hydration reactions of C_3A and thus optimize cement performance.

2. Composition

Portland cement consists of four major clinker compounds, C_3S, C_2S, C_3A, and C_4AF together with the gypsum added during grinding. The relative portions of these compounds can be changed to optimize specific properties of the cement (discussed in more detail below). Table 2 shows typical compound compositions, which are calculated assuming (incorrectly) ideal stoichiometries and chemical equilibrium in the kiln (the Bogue calculation).

All the clinker compounds form solid solutions with small amounts of every element that is in a clinker. In addition to the four major oxides, MgO, K_2O, and Na_2O are ubiquitous impurities in most raw materials. Impure C_3S is called *alite*: it reacts more rapidly with water than does pure C_2S. C_2S exists as four major polymorphs: γ, β, α', and α. At ambient temperatures, the nonhydraulic γ polymorph is thermodynamically stable but, in cement, impurities stabilize the hydraulic β polymorph. Impure C_3A contains considerable quantities ($\sim 10 \, mol.\%$) of iron, which may make it less reactive than the pure compound. High levels of sodium substitution modify its crystal structure from orthorhombic to cubic with a corresponding decrease in reactivity.

C_4AF does not have an exact stoichiometry; continuous solid solution between A and F allows its composition to vary from about C_6A_2F to C_6AF_2. For this reason C_4AF is usually called the ferrite phase. Although in many cements the composition of the ferrite phase is close to C_4AF, in those that have very low C_3A contents, the composition is closer to C_6AF_2. As the iron content increases, the reactivity of the ferrite phase decreases. It is the ferrite phase that

Table 2
Average compound composition of Portland cement (wt.%).

ASTM type	Description	C_3S	C_2S	C_3A	C_4AF	$C\bar{S}_2$
I	General purpose	55	17	10	7	6
II	Moderate sulfate resistant	55	20	6	10	5
III	High early strength*	55	17	9	8	7
IV	Low heat of hydration	35	40	4	12	4
V	Sulfate resistant	55	20	4	12	4

Note: *This cement is usually ground more finely: $\sim 550 \, \mathrm{m^2 \, kg^{-1}}$ compared to $380 \, \mathrm{m^2 \, kg^{-1}}$.

Table 3
Hydration of clinker compounds.

Compound	Hydration reactions	Heat of reaction $(\mathrm{kJ \, mol^{-1}})$	$\mathrm{J \, g^{-1}}$
Alit	$2C_3S + 11H \rightarrow C_3S_2H_8 + 3CH$	-114	-500
Belite	$2C_2S + 9H \rightarrow C_3S_2H_8 + CH$	-43	-250
C_3A	$C_3A + 3C\bar{S}H_2 + 26H \rightarrow C_6A\bar{S}_3H_{32}$	-365	-1350
	$2C_3A + C_6A\bar{S}_3H_{32} + 4H \rightarrow 3C_4A\bar{S}H_{12}$		
Ferrite	$C_4AF + 15H \rightarrow C_4(A_3F)\bar{S}H_{12} + (A,F)H_3$	-403	-200

gives cement its color: when MgO is present in the ferrite phase, it becomes black and the cement gray.

If the MgO content is low, or if the ferrite phase contains appreciable ferrous iron (due to a reducing atmosphere in the kiln), the cement is browner. In addition, crystalline MgO (periclase) is present in most clinkers, typically in the range 2–4 wt.%. There are limits placed on the amount of MgO, because its slow hydration can cause disruptive expansions in the hardened paste. In clinkers that are produced using high sulfur coal as a fuel, alkali sulfates, such as $K\bar{S}$ or $C_2K\bar{S}_3$ sometimes occur; these compounds may affect setting behavior and can lower the 28-day strength.

Cements can be classified according to the ASTM types given in Table 2. These classifications are based mostly on performance, not composition, although in general cements of the same type have broadly similar compositions. Over 90% of all Portland cement made in the USA is type I. When higher strength is required at early ages (1–3 days) a type III can be used. This is more finely ground so that its overall hydration is faster. Type IV cement can be used to avoid thermal cracking in mass concrete, by lowering the heat of hydration and hence the internal temperature of the mass but are no longer manufactured in the US. In the presence of high concentrations of sulfates in ground waters or soils, the hydration products of C_3A may undergo further reactions that result in disruptive expansion. The resistance of concrete to sulfate attack can be improved by lowering the C_3A content in a type V cement. Type II cement has

properties intermediate between those of type I and type V.

Aside from the five ASTM types of Portland cement, other special cements are available. Blended cements, containing reactive siliceous materials (pozzolans), or hydraulic slags mixed with type I, are used in most countries as alternatives to types IV and V. On hydration, they form more C–S–H and less calcium hydroxide. Expansive cements are modified Portland cements that counteract the effects of drying shrinkage by forming large amounts of ettringite to generate restrained expansion. Some special cements use ettringite to provide high early strength. Masonry cements and oil-well cements are Portland cements, modified to optimize the special requirements of these applications. Calcium aluminates (high-alumina cements) are used principally for refractory concretes. They cannot be used for structural purposes because of potential strength loss during service. Magnesium oxychloride (Sorel) cements can be used only for interior applications because they do not resist moisture.

3. Hydration

The setting and hardening of concrete is the result of complex chemical reactions between cement and water (hydration) in the cement paste binder. The overall reactions are summarized in Table 3. Both alite and belite form the same hydration products: an amorphous calcium silicate hydrate $(C_3S_2H_8)$
Figure 3
Rate of hydration of the clinker compounds.

and crystalline calcium hydroxide (CH). (The designated stoichiometry of the calcium silicate hydrate is only an approximation, since its composition is variable. It is usually referred to as C–S–H, which implies no definite stoichiometry or regular crystal structure.) The rate of hydration (Fig. 3) and the heat of hydration of the two silicates are quite different. The silicates are the components responsible for the strength of cement pastes, but in the first seven days the alite content controls the development of strength. The hydration of alite has an initial induction period that keeps concrete fluid for 1–2 hours and allows it to be handled and placed conveniently.

In the presence of gypsum, C_3A and the ferrite phase form calcium sulfoaluminate hydrates. The first product is the trisulfate form, ettringite, but when all gypsum has been consumed ettringite converts to the monosulfate form. Although C_3A and the ferrite phase contribute little to strength, they are still important components. When $C_4A\bar{S}H_{12}$ is exposed to an external source of sulfate ions, it will convert back to ettringite with concomitant expansion.

Interactions occur between the clinker compounds when they are hydrating in cement. For example, belite hydrates faster in the presence of alite, C_3A and the ferrite phase compete for the gypsum during their hydration, and gypsum accelerates the hydration of alite. During its formation, C–S–H can incorporate considerable quantities of alumina, sulfate, and Fe_2O_3 into solid solution. Thus less sulfoaluminates are formed during hydration than theory predicts; perhaps as little as half the expected amount.

It is important to know the effect of temperature on the hydration process because often concretes are cured at elevated temperatures. During the first 24 hours, the hydration of cement is very sensitive to temperature; apparent activation energies of $40 \, kJ \, mol^{-1}$ have been reported for cement or alite. Thus, at low temperatures the rate of hydration, and hence of strength development, is very much reduced, while at high temperatures the reaction is accelerated.
Figure 4
Microstructure of hardened cement paste revealed by scanning electron micrographs. (Courtesy of Dr. Paul Stutzman, National Institute of Standards and Technology).
Upper panel: fracture surface of a 7-day old paste. Ettringite needles are growing into waterfilled pores and monolithic $Ca(OH)_2$ on the right-hand side. ($\times 2500$)
Lower panel: polished epoxy-impregnated 28-day old cement paste. Bright particles of unreacted cement are surrounded by dark grey C–S–H. The matrix between the particles is an intimate mixture of C–S–H (dark grey) and $Ca(OH)_2$ (light grey) ($\times 1000$).

The calcium sulfoaluminate hydrates become unstable at 70–90 °C, while above 100 °C, C–S–H will convert to crystalline compounds. In the temperature range of autoclaved concrete products (150–200 °C under pressurized steam), C–S–H rapidly transforms to α-C_2SH. This results in low strength because the transformation increases porosity, but when finely divided silica is added, C–S–H converts to 1.1 nm tobermorite ($C_5S_6H_5$), which has good cementing properties.

Table 4
Composition of hardened paste (water–cement weight ratio, w/c = 0.5)

Volume component	Percent	Remarks
C–S–H	55	Continuous matrix: high intrinsic porosity; amorphous
CH	20	Large crystals (0.01–1 mm)
Calcium sulfoaluminate hydrates	10	Small crystals (1–10 μm)
Capillary porosity	∼15	Depends on the amount of water used

Table 5
Influence of paste porosity on concrete properties.

Pore component	Size	Effect on properties
Capillary pores		
Macropores	>0.1 μm (100 nm)	Permeability coefficient; Ionic diffusivities Strength (also total porosity)
Large mesopores	10–100 nm	Permeability coefficient; Ionic diffusivities Drying shrinkage
Gel pores		
Small mesopores	2.5–10 nm	Drying shrinkage; Creep
Micropores	<2.5 nm	Drying shrinkage; Creep

4. Structure of Hardened Cement Paste

The transition of a hydrating cement paste from a fluid to a rigid material is a continuous process resulting from progressive hydration of the calcium silicates. Ettringite may control rheological properties, but does not form a continuous matrix because C_3A and the ferrite phase are minor components. Ettringite crystallizes mostly at the surface of the cement grains but also grows in the pore space (Fig. 4). Under special conditions crystallization of larger amounts of ettringite can cause premature stiffening because of physical interlocking of the needle-like crystals. The continuous matrix of hardened paste is formed as C–S–H coatings at the surface of calcium silicate particles merge as hydration proceeds. Calcium hydroxide grows in the water-filled voids between the hydrating particles. The approximate composition of the paste is given in Table 4.

C–S–H is amorphous colloidal material with high surface area and small particle size; these features can be seen only with an electron microscope. It has a large volume of intrinsic microporosity (∼25 vol.%), which lowers its intrinsic strength and causes volume instability on drying. To a large extent, the material properties of concrete reflect the properties of C–S–H. In contrast, massive crystals of calcium hydroxide can be readily seen, even by optical microscopy. Calcium hydroxide contributes to strength because it
Figure 5
Accessibility of the pore volume of hydrated cement paste as measured by mercury intrusion porosimetry.

fills voids, but it is highly soluble. The presence of soluble alkali salts makes the concrete pore solution very alkaline, and this can reduce the durability of concrete in certain circumstances. The calcium sulfoaluminate hydrates play a relatively minor role in

Table 6
Mineral admixtures used in concrete.

| Admixture	Form of reactive silica	Reaction
Fly ash– Class F	Aluminosilicate glass	Pozzolanic
Class F	Calcium aluminosilicate glass	Pozzolanic (cementitious)
Silica fume	Amorphous silica ($\sim 20\,\mathrm{m^2\,g^{-1}}$)	Pozzolanic
Granulated blast furnace slag	Calcium aluminiosilicate glass	Cementitious + pozzolanic
Calcined clay	Amorphous silica (and alumina) ($\sim 10\,\mathrm{m^2\,g^{-1}}$)	Pozzolanic
Rice husk ash	Amorphous silica ($\sim 60\,\mathrm{m^2\,g^{-1}}$)	Pozzolanic

the behavior of hardened pastes, except when sulfates are present.

All properties of concrete are affected by the volume of capillary pores in the hardened cement paste. The pores are interconnected, allowing water and dissolved species to penetrate the concrete, with potential adverse consequences for service life (i.e., durability). Transport properties such as water permeability and ionic diffusivity are controlled by the size and volume of pores. A pore size distribution can be obtained using mercury intrusion porosimetry (Fig. 5). The volume of pore space accessible through a pore diameter $> 0.1\,\mu\mathrm{m}$, and the pore diameter corresponding to the maximum rate of intrusion are the main parameters controlling transport. The capillary pore volume is controlled by the water–cement ratio and the extent of hydration during curing. Capillary pores also affect other properties as well (see Table 5).

4.1 Modification of Microstructure

The microstructure can also be modified by the use of reactive aluminosilicate (mineral admixtures), such as fly ash, silica fume, or granulated blast furnace slag. These compounds contain amorphous silica and react chemically to convert calcium hydroxide to C–S–H (see Table 6). This the so-called *pozzolanic reaction*. In addition, slag will react cementitiously to form C–S–H directly. The C–S–H formed by mineral admixtures has a lower C/S molar ratio than that formed by direct hydration.

Increasing the volume factor of C–S–H in the microstructure reduces the overall porosity because C–S–H has a lower specific gravity than $Ca(OH)_2$. The proportion of micropores and small mesopores also increases. As a result such pastes have enhanced resistance to the transport of water and dissolved species, thereby creating more durable concrete. The reduction of the volume fraction of leachable $Ca(OH)_2$ and of the pore solution also enhances durability.

5. Concluding Remarks

Portland cement is a calcium silicate cement formed by high temperature reactions between limestone and clay. The reaction of calcium silicates with water (hydration) are responsible for the strength and durability of concrete. Small quantities of alumina and iron oxide which act as fluxing agents during manufacture form calcium aluminates, which also react with water. The hydration products are arranged physically to form a solid structure with a network of small pores. Hydration chemistry and the resulting microstructure can be modified by the addition of reactive aluminosilicates.

Powders, Solution Synthesis of

The purpose of this article is to describe solution-based technologies for controlling powder characteristics of a spectrum of oxide and nonoxide ceramic materials. It will also highlight the advantages and drawbacks that each solution-based method offers in terms of the powder characteristics that can and cannot be controlled. For further information on vapor phase methods see *Vapor Synthesis*[#].

Ceramics, whether they are single phase or composite materials, are typically based on multicomponent chemistries where more than one cation and/or anion must be incorporated, e.g., barium titanate and silicon oxynitride. For the processing of typical polycrystalline ceramics, desirable physicochemical characteristics of a ceramic powder include submicron particle size, controlled particle size distribution, uniform and equiaxed shape, minimum degree of agglomeration, high degree of chemical purity, controlled chemical and phase homogeneity, low intraparticle density, minimum weight loss upon heating, and controlled surface chemistry.

Conventional powder synthesis technology, discussed in detail in *Calcination and Phase Transformations*[#], requires the three consecutive steps of mixing, solid-state reaction, and milling. This overall process produces undesirable characteristics, which include phase and stoichiometric heterogeneities and poor control of morphology, particle size distribution, and aggregate population (chemically bound agglomerates). In many cases, remedial processing is required to improve the characteristics of conventional powders, such as repeated calcination and milling steps. The limitations of conventional technology drive the research, development, and commercialization of chemical (solution- and vapor-phase) synthesis methods for making powders.

Solution-based powder synthesis technologies utilize a broad base of technologies. The technologies discussed in this article all use a liquid phase to solubilize one or more components in the process. These technologies will be categorized by identifying where the chemical supersaturation takes place that produces the particulate phase. This review encompasses technologies that use chemistry in the bulk liquid phase, chemistry between heterogeneous phases, and chemistry in a droplet.

1. Chemistry in the Bulk Liquid Phase

Chemistry in the bulk liquid phase is an approach in which the physical characteristics of a ceramic powder are controlled by nucleation, growth, and aging processes in solution. In these systems, precipitation is driven by chemical supersaturation using one of the following synthetic methods: direct strike precipitation, solvent removal, nonsolvent addition, or precipitation from homogeneous solution.

1.1 Direct Strike Precipitation

Direct strike precipitation, commonly employed for a range of materials, involves the addition of a precipitating agent to a solution of soluble metal salts to form a sparingly soluble salt. When the soluble salts are added to a solution containing the precipitating agent, the procedure is referred to as a reverse strike process.

In direct strike precipitation, copious precipitation ensues at a rate faster than the timescale required for mixing of the reagents. For example, in the preparation of lanthanum-modified lead zirconate titanate, lead and lanthanum nitrates, zirconium oxychloride, titanium tetrachloride, and hydrogen peroxide are dissolved in water at $40\,^{\circ}\mathrm{C}$. Precipitation is induced by the addition of ammonium hydroxide to this solution to maintain a pH of ~ 9. The precipitate, most likely a mixture of various hydroxides, is filtered from suspension, washed free of soluble species with hot distilled water and dried at $100\,^{\circ}\mathrm{C}$. Calcination at a temperature of $650\,^{\circ}\mathrm{C}$ is necessary to form the oxide, followed by subsequent milling to break up aggregates formed during precipitation and calcination.

Nonoxides can be prepared by direct strike precipitation. Aluminum hydride can be reacted with ammonia at room temperature in tetrahydrofuran to yield a precipitate ($Al(NH)NH_2$) that can be calcined at $1100\,^{\circ}\mathrm{C}$ to form aluminum nitride. Silicon diimide ($[-Si(NH)_2-]_x$) can be prepared as follows:

$$SiCl_4 + 18NH_3 \rightarrow [-Si(NH)_2-]_x + 4NH_4Cl \cdot 3NH_3 \quad (1)$$
Submicron silicon nitride (95% α-Si_3N_4/5% β-Si_3N_4) has been prepared by pyrolysis of silicon diimide at temperatures of 1200–$1700\,^{\circ}\mathrm{C}$. Ammonium salts that coprecipitate with the desired product must be eliminated via washing prior to pyrolysis of the precipitate.

The common ion effect can cause solution homogeneity problems in multicomponent precursor solutions when one of the soluble salts has an anion that renders one or more of the cation components insoluble. Such a heterogeneous precursor system is unlikely to produce a physically and chemically uniform powder. Thus, the solubility of all salts that can form in the system should be examined to avoid this problem.

Differential solubilities of the various precipitating phases also affect the precipitation kinetics of each component, causing the stoichiometry of the precipitate to vary with reaction time. The copious nature of a direct strike precipitation creates concentration gradients in solution that can further accentuate this effect. Differential solubility problems can be

minimized by introducing a mixture of anions that renders all cations highly insoluble. For instance, manganese–zinc ferrite can be prepared by addition of ammonium hydroxide (NH_4OH) and ammonium bicarbonate (NH_4HCO_3) to metal sulfate solutions to prepare a hydroxide–carbonate coprecipitate.

To minimize segregation during direct strike precipitation and to optimize control of the stoichiometry, multicomponent salts of fixed stoichiometry can be precipitated. $BaTiO_3$ with a Ba:Ti molar ratio of 0.995 ± 0.005 has been prepared by calcination of $BaTi(C_6H_6O_7)_3 \cdot 6H_2O$. In order to prepare this salt, titanium tetrabutoxide, citric acid, and barium carbonate are mixed in aqueous solution in a pH range of 0.5 to 2.6. At a pH of 3.2, a $Ba_2Ti(C_6H_6O_7)_2 \cdot 7H_2O$ salt forms instead.

Other undesirable effects such as coprecipitated anion impurities (e.g., chlorides and sulfates) plague direct strike precipitation. These impurities can be incorporated into the particles as lattice defects or can adsorb onto powder surfaces. In addition, soluble species in solution can become occluded within agglomerates of particles.

Proper choice of the soluble anions in solution is important in order to minimize the above problems. Anions such as nitrates, which decompose at low temperatures, are more desirable since they can be eliminated from the powder during calcination. Anion contamination problems can be avoided with the use of "anion-less" precursors such as metal alkoxides. Metal alkoxides react with water to precipitate ceramic polymers by hydrolysis:

$$M(OR)_4 + H_2O \rightarrow (OR)_3M{-}OH + ROH \qquad (2)$$

and polymerization:

$$(RO)_3M{-}OH + HO{-}M(OR)_3$$
$$\rightarrow (RO)_3M{-}O{-}M(OR)_3 + H_2O \qquad (3)$$

$$(RO)_3M{-}OH + RO{-}M(OR)_3$$
$$\rightarrow (RO)_3M{-}O{-}M(OR)_3 + ROH \qquad (4)$$

In many cases, a nearly fully cross-linked oxide powder (e.g., silica) can result, subsequently forming a hydrous oxide. However, the formation of various types of hydrates, such as $AlO(OH)$ or $Sr(OH)_2$ that cannot fully or even partially polymerize according to Eqns. (3) and (4), is also possible.

Metal alkoxides are useful for preparing uniform multicomponent solutions since most exhibit excellent solubility in organic solvents such as alcohol, toluene, or tetrahydrofuran. Multicomponent alkoxide formation can enhance solution solubility further. For instance, solutions of $MgAl_2(O\text{-}i\text{-}Pr)_8$ can be prepared from reactions between magnesium and al-

uminum alkoxides. The complex can be hydrolytically decomposed to form a coprecipitate of hydroxides and calcined at 800 °C to prepare submicron spinel ($MgAl_2O_4$). When a multiphase coprecipitate is undesirable, condensation complexes can be prepared by partial hydrolysis routes:

$$M(OR)_4 + H_2O \rightarrow (RO)_3M{-}OH + ROH \qquad (5)$$

$$(RO)_3M{-}OH + RO{-}M'(OR)_3$$
$$\rightarrow (RO)_3M{-}O{-}M'(OR)_3 + ROH \qquad (6)$$
This approach has been utilized in the preparation of multicomponent ceramic powders such as cordierite ($2MgO \cdot 2Al_2O_3 \cdot 5SiO_2$) with no evidence of segregation.

Alkoxides can be complexed with other metal organic compounds or inorganic salts to prepare useful precursors for powders. For instance, barium hydroxide can be reacted with titanium isopropoxide in methanol to prepare a soluble complex as a precursor for barium titanate, and lead acetate and titanium isopropoxide can be reacted in methoxymethanol as a precursor for lead titanate.

1.2 Solvent Removal and Nonsolvent Addition

Sol–gel methods are generally useful for preparing powders since the gels can be broken up into granules during the drying step or ground in the dry state to produce granules of high surface area material. Supercritical CO_2 extraction, in which an overpressure of supercritical CO_2 is applied to extract the solvent from the gel, is another route for powder preparation. A constant flow of supercritical CO_2 is maintained until alcohol can no longer be seen separating from the CO_2 leaving the autoclave. Solvent is removed from the autoclave by depressurizing the gel at the rate required to maintain a temperature above the critical temperature of the fluid while drying the gel. Highly microporous single-component (silica, titania, etc.) and multicomponent powders (aluminum titanates, aluminosilicates, etc.) have been prepared with surface areas as high as $950 \, m^2 \, g^{-1}$ and disbursed particle sizes of less than 1 μm.

In addition to solvent removal techniques, there are also direct precipitation methods based on addition of a nonsolvent. In this case, an aqueous solution is prepared and precipitation is induced by dilution of this solution with a hydrophilic nonsolvent. Soluble salts employed include sulfates, citrates, and nitrates, depending on the assortment of cations desired. Alcohol (ethanol, isopropanol, etc.) or acetone typically is employed as the nonsolvent. Proper choice of the salt concentration, solution environment (pH, addition of complexing agents) and nonsolvent is essential

to achieve the proper stoichiometry and satisfactory homogeneity. Materials such as barium titanate, lead zirconate, magnesium aluminate, and manganese ferrites can be prepared. This method and other approaches such as freeze drying and evaporation are commonly employed in chemistry in a droplet approach, discussed later in this article.

1.3 Drawbacks of the Above Technologies

In most liquid-phase approaches (including all of the cases described above), the precipitation product must be calcined to form the oxide and thus is subjected to the same types of problems inherent in conventional processing. Reduced particle size and greater homogeneity accelerate the reaction kinetics, as mentioned earlier, resulting in lower calcination temperatures. However, the precipitate also becomes a great deal more aggregated (Fig. 1). Thus, in many cases, a milling step is required, allowing impurities to be introduced into the powder.

In a few cases, direct strike precipitation can result in the direct formation of oxides. Titanium alkoxides can be hydrolyzed with an aqueous solution of barium hydroxide, producing submicron agglomerates of $\sim 10\,nm\,BaTiO_3$. The same result can be accomplished by hydrolyzing a barium–titanium double alkoxide dissolved in benzene or toluene. The use of anions such as tungstate, chromate, or molybdate is useful for the preparation of oxides directly from solution. For instance, barium chromate can be precipitated from a solution of potassium chromate and barium chloride. Oxides also can be precipitated directly from solution via oxidation reactions. Basic aqueous solutions of iron nitrates or sulfates can be reacted with oxygen to prepare polymorphs of Fe_2O_3 and other multicomponent ferrites (Mn, Zn, or Co) at temperatures as low as 70 °C.

Despite advances in direct strike precipitation technology, the inability to avoid nonuniformities in solution hinders control of the physical characteristics of the powder. For example, high particle number densities and high electrolyte concentrations encountered during direct strike precipitation lead to a low degree of colloid stability and a concomitant high degree of agglomeration. As growth and aging proceed, aggregates (hard agglomerates) are formed. The presence of dispersants during precipitation can reduce aggregation. Polyethylene glycol has been used as an *in situ* dispersant for the preparation of 10 nm yttrium-stabilized zirconia.

1.4 Precipitation from Homogeneous Solution

Precise control of physical powder characteristics requires uniform supersaturation in solution. When this is achieved, nucleation precedes growth and aging, and these processes occur uniformly through-

out the reaction medium. Controlled precipitation is best accomplished using a precipitation from homogeneous solution (PFHS) technique. This approach utilizes chemical reactions whose kinetics somehow limit the rate of release of supersaturating species.

In order to control particle size, size distribution, and morphology, special attention must be given to concentration, pH, heating rate, temperature, corresponding anion of the soluble metal salt, choice of precipitating reaction, and aging conditions. For monodisperse powders (Fig. 2), precipitation must occur at concentrations typically less than 0.05 M and at a pH near the solubility limit of the precipitate. At higher concentrations morphology nonuniformity and aggregation result.

A detailed understanding of the interplay between solution processing variables and physical powder characteristics is lacking. Thus, the appropriate precipitation conditions for each system must be investigated empirically. For instance, the use of chloride vs. nitrate solutions to precipitate α-Fe_2O_3 under otherwise identical conditions yields elliptical vs. star-shaped particles.

The most commonly used PFHS technique uses a soluble salt codissolved with a precursor that decomposes upon heating, releasing an anion that quantitatively precipitates the dissolved cation. Zinc oxalate dihydrate also can be precipitated from an aqueous oxalic acid–zinc nitrate solution via anion release by hydrolyzing diethyl oxalate in 15 vol.% water in a nonaqueous acetic acid solution:

$$Et_2C_2O_4 + 2H_2O \rightarrow 2EtOH + 2H^+ + [C_2O_4]^{2-} \quad (7)$$

The release of the oxalate dianion is being regulated by the rate of diethyl oxalate decomposition in a solution of dissociated Zn^{2+} to precipitate $ZnC_2O_4 \cdot 2H_2O$ as shown below:

$$Zn^{2+} + [C_2O_4]^{2-} + 2H_2O \rightarrow ZnC_2O_4 \cdot 2H_2O(s) \quad (8)$$
This PFHS system precipitates $\sim 10\,\mu m$ (~ 7 aspect ratio) needle-like $ZnC_2O_4 \cdot 2H_2O$ particles.

PFHS techniques can also be used to prepare multicomponent powders with controlled stoichiometry and phase homogeneity. In order to obtain a phase-homogeneous powder with the intended cation stoichiometry, careful attention must be paid to preparation of the homogeneous solution and the types of multicomponent complexes that form. Problems such as stoichiometry control that are associated with multicomponent monodisperse syntheses can be avoided when multilayer structures are prepared, since each component is added in a separate processing step. A magnetic material was prepared by precipitating Fe_2O_3-based compositions via oxidation of Fe^{2+} solutions on a porous silica carrier in suspension.
Figure 1
Lead oxalate: (a) as-precipitated from solution; (b) calcined at 600 °C in air for 2 h to form lead oxide.

In nonaqueous media, controlled hydrolysis of metal alkoxides with dilute alcoholic solutions provides the simplest means of preparing spherical monodisperse powders and composite powders. At times, alcohol solvents produce inorganic gels instead of precipitate, necessitating the use of other water-soluble solvents such as acetonitrile. Single and multicomponent oxides such as hydrous titania, hydrous silica, strontium–titanium hydrous oxides, and yttria-doped zirconium hydrous oxide can be prepared by

hydrolysis of metal alkoxide solutions. Composite particles such as alumina coated with hydrous titania have been prepared for alumina–titania composites. *In situ* dispersants such as hydroxyl propyl cellulose have been used in nonaqueous PFHS systems for monodisperse titanium hydrous oxide.

Nonoxide powder preparation is possible via a small number of PFHS techniques. Submicron diborides of titanium, zirconium, and hafnium are prepared by refluxing metal borohydrides in
Figure 2
Monodisperse lead hydroxycarbonate prepared by a precipitation from homogeneous solution method.

xylene at 140 °C:

$$Zr(BH_4)_4 \rightarrow ZrB_2 + B_2H_6 + 5H_2 \qquad (9)$$

The powders are amorphous as precipitated but crystallized when annealed. $SiCl_4$ was dehalogenated and carburized at 130 °C in *n*-heptane to form 1–5 μm $(70\,m^2\,g^{-1})$ amorphous silicon carbide:

$$SiCl_4 + CCl_4 + 8Na \rightarrow SiC + 8NaCl. \qquad (10)$$
By using the chloride pairs $TiCl_4$ and BCl_3, $TiCl_4$ and CCl_4, or BCl_3 and CCl_4, the nonoxides TiB_2, TiC or B_4C, respectively, were obtained.

2. Chemistry Between Heterogeneous Phases

Chemistry between heterogeneous phases is an approach in which the physical powder characteristics are controlled by interaction of a discrete solid phase with a continuous one. Synthetic methods falling into this category include hydrothermal synthesis, molten salt synthesis, pyrolysis, and spark erosion.

2.1 Hydrothermal Synthesis

Hydrothermal synthesis utilizes solutions, gels, and/or suspensions as precursors to precipitate anhydrous oxides in a single step at elevated pressures (e.g., ~14–160 atm) and metric temperatures (e.g., 100–350 °C). The low reaction temperatures, relative to those of synthesis methods based on solid-state reaction, are due to a solution-phase mass transport instead of solid-state diffusion. The combined effect of pressure and temperature can also reduce free energies for various equilibria. This serves to stabilize phases that might not be stable at atmospheric conditions. There are many instances where anhydrous phases are unstable in aqueous solutions. In these cases, solvothermal synthesis is employed where

nonaqueous liquids such as 1,4-butanediol, ammonia, or isopropanol are used as alternative precipitation media. In addition, efforts are under way to develop processes that operate above the critical point of water (374 °C, 22.4 MPa); however, reactor safety and cost present significant technological barriers.

Hydrothermal reactions are sometimes referred to as high-temperature PFHS systems since uniform solutions of aqueous complexes prepared under atmospheric conditions are reacted at elevated temperature and pressure instead. For instance, 200 °C thermal decomposition of calcium EDTA (ethylenediaminetetraacetate) complexes in pH 7.5 phosphate solution has been used to prepare 100 μm hexagonal rods of carbonate-substituted hydroxyl apatite.

Ceramic powders can be prepared from suspensions or gels via an *in situ* transformation and/or a dissolution–reprecipitation. The former can be effected in a dispersion when suspended particles undergo a polymorphic or chemical phase transformation. The control of particle morphology and size is a function of the characteristics of the suspended solid phase precursor. For instance, narrow size distribution spherical submicron titanium hydrous oxide can be chemically transformed into polycrystalline anhydrous anatase spheres (TiO_2) of the same size by refluxing the powder for 12 h in a pH 10 ammonium hydroxide–water suspension at atmospheric pressure and a temperature of 100 °C.

Dissolution–reprecipitation of suspensions or gels can be effected when suspended particles dissolve into solution, supersaturate the solution phase, and subsequently precipitate particles (Fig. 3). In many cases, the suspended solids are not very soluble in water, and solubilizing components (mineralizers) such as acids, bases, or other complex-forming substances must be added. For example, in the preparation of zirconia powder from a suspension of hydrous zirconium oxide, a hydrothermal reaction at low pH (<3.5) dissolves the zirconium hydrous oxide precursor in soluble species that subsequently reprecipitate the oxide. Additives play a significant role in controlling particle size, morphology, and chemical reaction rate in a manner very similar to that observed in PFHS systems. For instance, a fraction of a pH unit change in the hydrothermal solution determines whether $PbTiO_3$ forms as a platelet- or cube-shaped particle.

Hydrothermal oxidation of metals is another interesting route for preparing ceramic powders. Metals such as iron, zirconium, aluminum, or hafnium can be reacted with water at temperatures as low as 500 °C and 100 MPa:

$$mM + nH_2O \rightarrow M_mO_n + nH_2 \qquad (11)$$

Multicomponent oxides such as alumina–zirconia composite powders can be prepared from a Zr–Al
Figure 3
Cube-shaped lead zirconate titanate prepared via hydrothermal methods.

metal alloy. Metals such as titanium or zirconium can be reacted with ammonium chloride in an ammoniacal medium (rather than water) to form nitrides at rather high temperatures (500–600 °C) and pressures (1 MPa).

2.2 Molten Salt Synthesis

Molten (fused) salt synthesis is similar in many ways to a dissolution–reprecipitation hydrothermal synthesis. An inert molten ceramic material in which the ceramic powders are somewhat soluble acts as a solvent medium. The single-component oxides dissolve, react in solution to form multicomponent species and precipitate from solution. For example, lead zirconate titanate can be prepared by first mixing together TiO_2, ZrO_2, PbO, and any desired dopants to form an aqueous slurry. A KCl–NaCl molten salt eutectic is mixed into the slurry, causing the system to gel. Upon drying, the mixture is heated to ~ 980 °C for 1 h to form the lead zirconate titanate, which subsequently is rinsed free of the molten salts and any excess unreacted ions. In some systems, the solvent can react with the other components to yield multicomponent powders:

$$TiO_2 + 2MgCl_2 + 2SiO_2 \rightarrow TiCl_4 + 2MgSiO_3 \quad (12)$$
Since $TiCl_4$ is highly volatile, purification of the precipitated powder is easily accomplished. Materials such as spinel, cordierite, and magnesium titanate have been prepared in this manner.

Particle formation in molten salt synthesis has been observed to depend upon the dissolution characteristics of the individual components. When a slowly dissolving component is in the presence of a rapidly dissolving one, the multicomponent reaction product precipitates on the surface of the less soluble component. Unidirectional diffusion of the more soluble component through the product layer carries the process to completion, resulting in a powder with a morphology reflective of the more slowly dissolving component. Both needle-like barium titanate and plate-like zinc ferrite have been prepared in this manner. On the other hand, feedstocks with somewhat equivalent dissolution characteristics precipitate
Figure 4
Nanostructured aluminum nitride prepared by pyrolyzing aluminum-based Pechini polymers in nitrogen at 1500 °C for 4 h.

in bulk solution, producing more equiaxed morphologies. Oxides such as Bi_2WO_6 and $PbNb_2O_6$ are believed to form in this manner.

2.3 Pyrolysis

Pyrolysis processes form a ceramic powder by solid-state decomposition of a solid or molten precursor (typically a molecular or polymeric compound) in the presence of an inert (e.g., vacuum, argon) or reactive (e.g., oxygen, nitrogen) atmosphere. This method is distinguishable from a solution precipitation/calcination method because it is the pyrolysis rather than the chemical synthesis that influences the physical characteristics of the powder. For instance, agglomeration and excessive crystallite growth can be caused by excessive exothermic decomposition. Decomposition residue (e.g., carbon) can result from factors such as poor choice of pyrolysis atmosphere and control, improper gas flow rates, and furnace choice. Mechanistic studies of the decomposition and its interaction with the processing variables are essential for control of the powder characteristics of the pyrolysis product.

Metal–organic molecular compounds such as carboxylates are useful materials for preparing oxides and nonoxides. These compounds can be derived in-house from starting reagents such as metal alkoxides, nitrates, or chlorides using simple procedures. Neodecanoate salts of various metals form uniform solutions in xylene. These solutions can be pyrolyzed to form submicron powders. For instance, $PbTiO_3$ can be prepared from a solution of dimethoxytitanium dineodecanoate $((MeO)_2Ti(OCOC_9H_{19})_2)$ and lead dineodecanoate $(Pb(OCOC_9H_{19})_2)$ by pyrolyzing at temperatures of ~ 600 °C. Molecular metal–organic precursors are useful for the preparation of nonoxide ceramics such as boron nitride using nitrogen-bearing molecular precursors such as $B(N(C_2H_4O)_3)_3$. Pyrolysis in a nitrogen-bearing atmosphere such as nitrogen or ammonia is critical. In general, most pyrolysis processes can be modified to produce nonoxides by paying careful attention to the pyrolysis atmosphere. Thermodynamic approaches used for engineering conventional solid state reactions, such as halogenation for halides, carbothermal nitridation for nitrides, and carbothermal reduction for carbides, provide the necessary insight for proper choice of

atmosphere and firing schedule to make the chosen nonoxide material.

Choice of ligand in the molecular precursor is an important processing variable since it controls pyrolysis behavior. Crystalline solids such as the hydrazinium metal hydrazinecarboxylate hydrates, easily prepared from aqueous metal sulfate solutions, autocatalytically decompose at low temperatures to form oxide powders. For example, a compound such as $N_2H_5Mn_{1/3}Fe_{2/3}(OCONHNH_2)_3 \cdot H_2O$ decomposes in a single step in a temperature range of 75–120 °C to form agglomerates of nanometer-sized $MnFe_2O_4$. Inorganic nitrates (oxidizers) can be combined with organics such as urea (fuel) in stoichiometric compositions using principles of propellant chemistry to produce 4–5 μm agglomerates of submicron particles at temperatures as low as 500 °C. A diverse number of oxides, including spinel ($MgAl_2O_4$), $Y_3Al_5O_{12}$ (YAG), ZrO_2–Al_2O_3 composites and α-Al_2O_3, have been prepared with this method.

Polymeric metal organic precursors prepared from water-soluble metallic salts of polyfunctional acids are useful for the preparation of multicomponent oxides. Typically, α-hydroxy acids (e.g., hydroxybutyric acid, citric acid) and/or α,β-unsaturated acids (maleic acid, acrylic acid) are mixed with metal salts to form a uniform solution of metal cation complexes. The solution subsequently is evaporated until a viscous mass is obtained, followed by a drying step at ~120 °C. During the dissolution and solvent removal stages, it is essential that none of the components crystallizes, so that powder homogeneity is ensured. Finally, the precursor powder is calcined (>600 °C). Materials such as $BaFe_{12}O_{19}$, $LaCrO_3$, and $Y_3Fe_{4.9}Al_{0.1}O_{12}$ have been prepared with this method. A variant of the above process is the liquid mix process, where a polyfunctional alcohol such as ethylene glycol is added to the acid to make a polyester polymeric residue that can complex practically any metal ion in the periodic table. Many ceramic compositions, including aluminates ($LaAlO_3$), silicates (Zn_2SiO_4), zirconates ($CaZrO_3$), and titanates ($Pb(Zr,Ti)O_3$), and nitrides (AlN) have been prepared by this method.

Organometallic polymers are considered desirable for nonoxide materials free of oxygen contamination since the metal center is bonded to carbon rather than oxygen. However, the synthesis of organometallic compounds requires air-sensitive procedures that can be complex. Many problems must be overcome with this approach, such as obtaining the desired phase assemblage, controlling chemical purity, diminishing the loss of volatile species that belong in the final ceramic product (e.g., Si, C, or N), minimizing the weight loss of organic species, and controlling the physical characteristics of the powder. Various nonoxide powders such as silicon nitride and silicon carbide have been prepared by decomposing polymeric precursors, sometimes producing a powder and other

times yielding a porous monolithic form. The decomposition of the materials to produce a desired phase requires a combination of skill and art. For instance, silazane polymer obtained by KH treatment of $[MeSiHNH]_x$ cyclics in diethyl ether pyrolyzes in nitrogen to form α-silicon nitride at 1420 °C. When the synthesis is conducted in tetrahydrofuran, silicon nitride/silicon carbide composite powders form instead. Composite powder mixtures of silicon nitride and aluminum nitride can be made by pyrolyzing a mixture of polycarbosilane and diisobutylaluminum amide.

2.4 Spark Erosion

Another method that uses reactions between heterogeneous phases for preparing submicron ceramic powders is spark erosion. In this technique two electrodes are immersed in a dielectric liquid (organic or cryogenic) with a charge of large granules of the electrode material between the electrodes. A field strength of $\sim 10^5 \, V \, cm^{-1}$ is applied in a pulsed mode (230–610 kHz) to generate a spark discharge that takes place at the asperities of the electrode and granular charge. Since the material is heated in localized regions well above its melting point via plasma channel transient pressure zones, molten droplets or vapor species are produced. When the species leave the localized region they either freeze or condense to form particles. Subsequent reaction between the dielectric fluid or decomposition products and the powder (either as molten droplets or vapor) produces a ceramic powder. Spherical narrow-size distribution $\sim 34 \, \mu m$ titanium carbide has been prepared in a dodecane fluid using a titanium metal electrode, a graphite electrode, and a granular charge of titanium metal. Spark erosion of aluminum electrodes and charge in water produces submicron acicular aluminum hydroxide. This product is considered to form from condensed aluminum vapor species instead of molten droplets.

3. Chemistry in a Droplet

Chemistry in a droplet is an approach in which one of the earlier described synthetic methods occurs within the confines of a solvent droplet. The droplet not only controls the physical powder characteristics but also limits chemical segregation to the scale of the droplet diameter. Synthetic methods falling into this category involve the use of either liquid phase systems such as emulsions or microemulsions or liquid–gas phase systems such as aerosols.

3.1 Emulsions

An emulsion is a mixture of two immiscible liquids in which one liquid is dispersed in the other with the aid

of a surfactant. The surfactant stabilizes the emulsion by reducing interfacial tension, reinforcing the interfacial film, and preventing coalescence of the droplets. Mixing conditions and surfactant variables control the size of the droplet. High shear rates and surfactant levels promote smaller droplet sizes, which can range from one to 50 μm. A single surfactant such as sorbitan monooleate can be employed for water-in-2-ethylhexanol emulsions. In some cases, a mixture of surfactants is employed. Sorbitan monostearate and polyoxyethylene sorbitan monolaurate mixtures are useful for water-in-toluene emulsions.

The water-in-oil emulsion has been the most widely used type of emulsion for the preparation of single-component oxides such as titania, multicomponent oxides as complex as synroc (a mixture of $BaAl_2Ti_6O_{16}$, $CaZrTi_2O_7$, and $CaTiO_3$), and nonoxides such as the carbides of thorium or uranium. In this type of emulsion, a stable colloidal sol consisting of one or more metal complexes is prepared and emulsified in an oil medium to form spherical droplets. Gelation of the spheres is induced in one of two ways. First, a liquid removal technique such as dehydration or evaporation can be used. For example, large volumes of an organic phase such as a long-chain alcohol (2-ethylhexanol) can be used to concentrate the sol by dehydrating the droplets. Upon sufficient dehydration, van der Waals forces predominate and flocculate the sol within the droplet. It is conceivable that a precipitation reaction occurs inside the droplet as well. Evaporation methods such as the "hot kerosene method," in which either an emulsion is added to a hot oil phase or the water is distilled from the emulsion using a Dean Stark moisture trap, also have been employed to remove the liquid phase from the droplet and flocculate the sol.

The second technique induces gelation internally by changing the pH inside the sol droplet. This reduces electrostatic attraction between colloidal species and/or initiates a chemical reaction inside the droplet. For example, urea (H_2NCONH_2) added to a stable sol decomposes and releases ammonia in the aqueous phase during heating of the emulsion. For droplets smaller than 50 μm, amines can be added that diffuse into the droplet and effect an internal pH change. Organic primary amines (R_3CNH_2) added to the sol remain in the organic phase while extracting protons and anions from the droplet, whereas bubbling ammonia diffuses into the droplet to raise the pH. The organic amine route is preferable to the use of bubbling ammonia or dehydration of sol droplets because it minimizes anion contamination in the powder. This is particularly important when the anions present are difficult to eliminate during calcination. In addition, the amine route requires less solvent than the dehydration route, with a 10:1 ratio of gelation solvent to sol for the primary amine route, compared with a 200:1 ratio for dehydration.

"Gel sphere" particles can also be prepared by delivering metal organic monomers to the droplet. First, a hydrochloric acid solution is emulsified in an oil phase (mineral oil and heptane). Silicon tetraethoxide-in-heptane solution is then added to the emulsion to facilitate transport of alkoxide monomers to the acidified droplets where they undergo hydrolysis and polymerization to effect a sol–gel transition within the droplet. This method produces silica gel spheres in the submicron-to-micron range.

Emulsions of nonpolar nonaqueous phases in polar nonaqueous phases can be used to make ceramic powders. Droplets of nonpolar metal alkoxides (or alkoxides dissolved in hexane) can be dispersed and diffusively hydrolyzed and polymerized by the water-soluble polar continuous phase to form spherical powder. Continuous phases such as acetonitrile or propylene carbonate have been employed successfully for insoluble alkoxides such as titanium tetra-*n*-butoxide or aluminum tri-*sec*-butoxide. Systems using propylene carbonate as a continuous phase do not require a surfactant to stabilize the emulsion, whereas those using acetonitrile do. Single- and multicomponent hydrous oxides yield spherical submicron atomically homogeneous oxide powders such as titania, aluminum titanate, or alumina–zirconia. Unlike other emulsion powders synthesized with inorganic salts, these powders are free of anions such as nitrates and chlorides.

3.2 Microemulsions

Unlike emulsions, which are kinetically stable, microemulsions are thermodynamically stable. In addition, the dispersed phase of a microemulsion is on a size scale of less than 0.15 μm and therefore is transparent, while emulsions, having a droplet size greater than 1 μm, appear turbid. The reduction in size provides a means of forming finer particles than are possible with emulsions. Both nonoxides and oxides have been prepared from microemulsions. Water-in-oil microemulsions utilizing lyotropic liquid crystals or normal or inverse micelles are usually the systems of interest.

Ultrafine ($\sim 4\,nm$) narrow size distribution magnetite (Fe_3O_4) has been prepared using inverse micelles. The first step is to mix the following two microemulsions: (i) $FeCl_3$ aqueous droplets stabilized with the bisoctyl ester of sodium sulfosuccinic acid in a continuous phase of cyclohexane; and (ii) ammonium hydroxide droplets (microemulsified similarly). Upon the addition of aqueous $FeCl_2$ to the vigorously stirred microemulsion, Fe_2O_3 is formed in the aqueous droplet phase. Precipitation is effected both by diffusion of $FeCl_2$ species and by communication between microemulsion droplets, a process in which two droplets coalesce, exchange contents, and separate, reforming two droplets each with a new

composition. Communication allows chemical species (e.g., NH_4OH, $FeCl_2$, and $FeCl_3$) to be exchanged, activating chemical and precipitation reactions in a manner analogous to a titration process. However, not all microemulsion systems rely on communication mechanisms to initiate precipitation. Like emulsions, microemulsion systems can rely on diffusion of reactants through the continuous phase to make a variety of materials which include oxides (SiO_2), carbonates ($CaCO_3$), and borides (Ni_2B).

Reverse microemulsions can also be prepared using supercritical fluids. Submicron aluminum hydroxide particles have been formed by introducing ammonia into a microemulsion of supercritical aqueous aluminum nitrate in propane stabilized by sodium bis(2-ethylhexyl)sulfosuccinate at $100\,°C$ and $\sim 20\,MPa$.

Research has been directed to the preparation of ceramic powders using lyotropic liquid crystals. Monodisperse basic copper sulfate ($[Cu_4(OH)_6]SO_4$) has been prepared from a hexagonal liquid crystal formed by using a mixture of sorbitan monooleate with 20 ethylene oxide groups and aqueous copper sulfate ($CuSO_4$) solution. In this system, precipitation occurs in the interstitial zones between the columns of surfactant molecules arranged in hexagonal arrays. This compartmentalization approach (templating) has also been used to mimic the way nature precipitates ceramic materials such as bone or teeth. For instance, aluminum oxide in the nanometer size range (10–30 nm) has been prepared using single-compartment unilamellar vesicles. A unilamellar vesicle is a hollow sphere with an internal diameter in the range of tens of nanometers. The thin walls facilitate small anion transport but minimize cation diffusion. Vesicles containing aluminum ions are formed by mixing egg yolk phosphatidylcholine ultrasonically with an aqueous solution of aluminum nitrate. After removing all aluminum ions outside the vesicle wall by ion exchange, an aqueous sodium hydroxide solution is mixed with the vesicle suspension. Hydroxyl ions preferentially permeate the vesicle wall to effect a precipitation reaction. A porous synthetic polymer (e.g., poly(dimethylsiloxane) or poly(methylmethacrylate)) can also be used as an alternative to self-assembling surfactants as a template for controlling particle size and morphology. Using a two-stage infiltration process, a hydrolytically sensitive precursor such as a metal alkoxide is introduced into the polymer followed by the addition of a hydrolysis solution. Submicron powders of silica, titania, and barium titanate of sizes with anisotropic and equiaxed morphologies have been produced.

3.3 Aerosols

Aerosols or sprays are liquids dispersed in the gas phase. As with micelle-based systems, particle size control is directly related to the droplet size, which can be controlled by the selection of both the precursor system and the method of aerosol generation.

Submicron aerosols can be generated by vapor condensation. This approach has been used primarily in low-temperature reactions in which particles form within the precursor droplets as they react with the species in the vapor phase. For instance, narrow size distribution $0.2\,\mu m$ powders can be precipitated from monodisperse $0.4\,\mu m$ aerosols of alkoxides ($Ti(OR)_4$, $Al(O\text{-}sec\text{-}Bu)_3$) or metal tetrachlorides ($SiCl_4$, $TiCl_4$) by seeding the vapor phase with silver chloride and subsequently hydrolyzing the droplets with water vapor in one or more successive stages at temperatures greater than $0\,°C$. The hydrolysis is completed by elevating the temperature of the aerosol to $100\,°C$ or more.

Multicomponent systems such as titania–silica powders have been prepared by diffusing $SiCl_4$ vapor into monodisperse $Ti(OEt)_4$ droplets and subsequently hydrolyzing the multicomponent droplet. However, silver chloride contamination and chlorine contamination from the precursor may present problems for ceramics processing applications. Purity problems can be avoided by using a two-stage reaction. First, alkoxide vapor is hydrolytically decomposed to form hydrous oxide seed particles to nucleate an aerosol. This aerosol subsequently can be hydrolyzed to form spherical hydrous oxide particles.

Using mechanical rather than vapor condensation methods for generating droplets, sols have been sprayed into immiscible liquids to form "gel microspheres" by a subsequent dehydration or pH change step as described for emulsions. This technique usually produces particles with sizes in the order of tens of microns. Mechanically generated aerosols have also been used with other types of precipitation chemistries. For instance, an ultrasonic spray atomizer has been used to react aqueous zirconium nitrate with ammonia gas to precipitate a hydrous oxide. Electrostatic aerosols of aqueous solutions of zirconium acetate and polyethylene oxide yielded 0.1–$5\,\mu m$ diameter acetate particles, which were subsequently calcined at $1100\,°C$ to form zirconia. In this system, varying concentrations of polyethylene oxide ($<0.06\,wt.\%$) served as a means to control the particle size. Salts can be spray-dried as well; however, significantly larger particle sizes result. Iron oxides spray dried as various salts typically have particle sizes of 3–$20\,\mu m$.

Because of their unique solvating properties, supercritical fluids have been used to generate aerosols. With this method, a solute soluble in a supercritical fluid produces supersaturated species by an abrupt loss of solvency as the fluid expands into a low-pressure environment. Selection of the proper pressure and temperature of the pre-expansion and postexpansion conditions produces either one-phase (vapor) or two-phase (liquid–vapor) systems.

Two-phase aqueous systems have been used to precipitate silica, germanium oxide, and uniform mixtures of the two components, while nonaqueous systems have been used to prepare zirconium oxynitrate and polycarbosilane, useful precursors for zirconium oxide and silicon carbide, respectively.

Ceramic powders have been prepared by freeze drying, in which multicomponent liquid solutions are sprayed into a cold liquid to freeze the droplets which are then separated from the liquid and subsequently sublimed. Spherical alumina, magnesium oxide, and spinel powders with submillimeter particle sizes have been prepared from calcined sulfate salts by pneumatically spraying aluminum sulfate solutions into hexane solutions chilled with a dry ice–acetone bath. Acidic barium–yttrium–copper formate solutions have been ultrasonically sprayed into liquid nitrogen ($-196\,^{\circ}\mathrm{C}$) to prepare 10–90 μm spheres that calcine as $Ba_2YCu_3O_7$. The results of these two examples demonstrate the importance of the method of aerosol generation in controlling the particle size. Other variables affecting size and the related chemical and physical particle homogeneity, such as spray height distance above the bath and cooling bath temperature, have been examined. In general, it is desirable to spray at a distance that minimizes droplet evaporation and at a temperature that minimizes rejection of the solute as the ice front propagates towards the center of the droplet. In a homogeneous powder, the freezing process imparts a porous, high surface area microstructure to the droplet.

Powders can also be precipitated in spray droplets by solvent replacement. This technique involves the addition of an aerosol of an aqueous solution of metal salts to a nonsolvent that solubilizes water but not the dissolved salts. Various factors, such as the choice of aerosol generator and nonsolvent, control the size distribution and morphology of yttria-stabilized zirconia powder derived from sulfate salts. For instance, acetone produces fused masses, whereas with isopropanol spheres are formed almost exclusively. In ethanol, dropwise addition with a pipette yields a precipitate with a diameter (214 nm) five times that produced by atomization (42 nm).

In spray pyrolysis liquid droplets are sprayed into a reactor that has a low-temperature chamber for precipitating salts and a high-temperature chamber for subsequent pyrolysis. Powders range from micrometer-sized shell-like aggregates to narrow size distribution submicron solid spheres. A broad range of oxide, nonoxide, and composite powders (e.g., WC/Co) are prepared using this approach.

The problems inherent in spray pyrolysis are magnified due to the fact that reactor and precursor systems must incorporate the ideal attributes of both spray-drying and calcination processes. During drying, the kinetics of both solvent evaporation and salt precipitation propagating inwards from the surface of the droplet should be optimized while maintaining the spherical morphology. During pyrolysis, attention must be paid to the large amounts of volatile products that are associated with rate-limiting processes such as heat transfer, diffusion through a product layer, and crust formation. In addition, in each case it must be determined whether or not spray pyrolysis is a liquid–gas phase reaction or a vapor-phase process using a liquid precursor (see *Vapor Synthesis*[#]). If the latter process is occurring, particle size will not be controlled by droplet size.

4. Summary

Ideal physicochemical characteristics of a ceramic powder include submicron particle size, controlled particle size distribution, uniform and equiaxed shape, minimum degree of agglomeration, high degree of chemical purity, controlled chemical and phase homogeneity, low intraparticle porosity, minimum weight loss upon heating, and controlled surface chemistry. Present technology offers the investigator many alternative approaches for preparing powders with ideal or near-ideal characteristics. There are many technologies to choose from, which enables engineers to make virtually any ceramic composition with the desired physical and chemical characteristics. This article has presented three primary categories of technologies: (i) chemistry in the bulk liquid phase; (ii) chemistry between heterogeneous phases; and (iii) chemistry in a droplet. These technologies center around the site where the chemical reaction to form particles takes place.

Processing Flexible Polymers to High Performance Fibers

In the 1970s, significant progress was made in exploiting the intrinsic properties of the macromolecular chain, especially in the field of 1D objects such as fibers. Two major routes can be discerned which are completely different in respect to the starting (base) materials, namely rigid as opposed to flexible macromolecules (Lemstra *et al.* 2000). The prime examples of rigid chain polymers are the aromatic polyamides (aramids), notably poly(*p*-phenylene terephthalamide) (PPTA), currently produced under the trade names Kevlar (Du Pont) and Twaron (Akzo Nobel). More recent developments include the PBO fiber from Toyobo, Zylon, and the experimental fiber M-5 from Akzo Nobel based on poly-diimidazo pyridynylene dihydroxy phenylene (Lammers *et al.* 1998). The *primus inter pares* of a high-performance fiber based on flexible macromolecules is polyethylene (PE) which is currently produced by DSM (Dyneema) and its licensee Allied Signal (Spectra). The main difference between rigid and flexible chains is the necessity to force chain extension in the case of flexible polymer molecules in order to exploit the intrinsic possibilities of the chain concerning ultimate mechanical properties, while for rigid rod polymers chain-extension has been built in by synthesis. Figure 1 shows the specific, based on performance by weight, strength versus specific modulus of the various fibers.

1. Ultimate Properties

1.1 Tensile Modulus

The ultimate tensile moduli of PE and other polymer systems, can be calculated or obtained experimentally from x ray diffraction measurements on oriented fibers during mechanical loading (Nakamae and Nishino 1992). All the literature data show that the Young's modulus E of PE in the chain direction is extremely high, $\geqslant 200\,GPa$, due to the small cross-sectional area of the chain, the absence of side groups, and the planar zigzag chain conformation in the orthorhombic crystal lattice. PE is not unique and other linear polymers with similar crystal structures possess similar theoretical moduli, e.g., poly(vinyl
Figure 1
Specific strength versus specific modulus of various fibers. HPPE = high-performance PE fibers.

alcohol). In contrast, isotactic polypropylene has a lower ultimate modulus (60 GPa) in the chain direction due to its 3_1 helix conformation of the chain in the crystal lattice.

1.2 Ultimate Tensile Strength

In the past, a variety of studies have been devoted to the theoretical tensile strength of oriented and chain extended structures, i.e., the breaking of chains upon loading (He 1986). The theoretical tensile strength of a single, extended polymer chain can be calculated directly from the C–C bond energy. These calculations show that the theoretical tensile strengths are extremely high, in the order of 20–60 GPa (at 0 K). This requires a defect-free, chain-extended structure and *infinite* polymer chains. In practice, however, we are dealing with *finite* chains and a completely different situation is encountered as will be addressed in sect. 2.3.

1.3 Infinite Versus Finite Chains

Upon loading an array of perfectly aligned and extended finite polymer chains, the stress transfer in the system occurs via secondary, intermolecular bonds. Chain overlap is needed in order to be able to transfer the load through the system. Qualitatively, it could be envisaged that the bonds in the main chains are only activated when the sum of the small secondary interactions, $\Sigma\varepsilon_i$, approaches the bond energy, E_i, in the main chain. Intuitively, one expects that in order to obtain high-strength structures in the case of PE, a high molar mass is needed, in combination with a high degree of chain-extension, to build up sufficient

intermolecular interactions along the chains. Termonia and Smith (1987) used a kinetic model to simulate the fracture behavior of an array of aligned and extended *finite* polymer chains. It was found that the molecular weight (or number of chain ends) has a profound influence both on the fracture mechanism and on the theoretical tensile strength of these hypothetical structures. In order to obtain a strength level of 5 GPa, a molar mass of $> 1 \times 10^5$ Dalton is needed for PE whereas 5×10^3 Dalton is sufficient for PPTA. The conclusion is that polymers possessing strong secondary bonds require a smaller overlap length to obtain a high tenacity.

2. Melt-spinning/Drawing

Chain orientation and extension is generated in melt- and solution-spun fibers by: (i) applying a draw-down to the fibers during or immediately after spinning (in the molten state or super-cooled melt) and (ii) drawing of fibers at temperatures close to, but below, the melting or dissolution temperature. Drawing in the (semi-)solid state, i.e., below the melting and/or dissolution temperature is usually much more effective. Relaxation processes are restricted since the chains are trapped into crystals which act as physical network junctions. In the 1970s, Capaccio and Ward (1974) started systematic studies concerning the drawability of linear PEs in the solid state and they developed a technological route. By optimizing the polymer composition and process conditions, PE fibers could be produced possessing tensile (Young) moduli up to 75 GPa and a strength level up to 1.5 GPa. A well-known observation made by Capaccio and Ward (1974) based on numerous *isothermal* drawing experiments, is that with increasing molar mass the maximum draw ratio decreases towards a limiting value of 4–5 at MW values over 1×10^6 Dalton. A limited drawability in the solid state is not unique for PEs. Many other polymers demonstrate a limited drawability, for example polyamides, which are often referred to as the natural draw ratio.

To understand the drawing behavior of PEs in the solid-state, one automatically focuses on the role of crystallites, viz the folded-chain crystals which are organized in more or less well-developed spherulites in melt-crystallized samples. There is, however, no direct correlation between crystal size/crystallinity, or morphology in general, versus the maximum draw ratio. Depending on the crystallization conditions, the drawability can change dramatically for one specific sample. For example, slow cooling from the melt can promote the drawability in the solid state Capaccio and Ward (1974) but also can cause identical PE samples to become brittle in the case of very slow cooling from the melt. In conclusion, melt-spinning/drawing is limited with respect to the molar mass of the PEs. With increasing molar mass, both the

spinnability (a strong increase of melt viscosity) and the drawability in the solid-state decrease, which sets an upper limit to melt-spinning of PEs of typically $500 \, \text{kg} \, \text{mol}^{-1}$.

3. Solution-processing and Solution(gel)-spinning

An obvious route to increase the spinnability of high molar mass PEs is to use solvents to lower the viscosity. In retrospect, the early attempts in the 1960s to employ solution-spinning of high molar mass PEs (Juergenleit 1956), to produce high-strength/high-modulus fibers failed since no proper understanding was available at that time concerning optimized drawing of solution-spun fibers. At the end of the 1970s, solution (gel)-spinning of UHMW-PE was discovered at DSM (DSM/Stamicarbon 1979, Smith and Lemstra 1979). In the solution (gel)-spinning technique, semi-dilute solutions are employed during spinning but the elongation of chains is performed by drawing in the semi-solid state, i.e., below the melting (dissolution) temperature. A solution of UHMW-PE with a low polymer concentration, typically of 1–2%, was spun into water.

Upon cooling a gel-like filament is obtained consisting of a physical network, obtained by thermoreversible gelation, containing a large amount of solvent. The as-spun/quenched filaments are mechanically sufficiently strong (gel-fibers) to be transported into an oven in which drawing is performed. The ultra-drawability of these gel-fibers seems not too surprising in view of the large amount of solvent which could act as a plasticizer during the draw. The remarkable feature, however, is that ultra-drawing is still possible after complete removal of the solvent prior to the drawing process. The solvent is necessary to facilitate processing of the rather intractable polymer UHMW-PE and induces a favorable structure/morphology for ultra-drawing but the solvent is not essential during the drawing process.

4. The Entanglement Concept

A very simple model for the enhanced drawability of solution-spun/cast UHMW-PE was put forward by Smith *et al.* (1982) based on a network approach, ignoring completely the morphology and crystal structure. In this model it is assumed that entanglements are trapped in PE upon crystallization and act as semi-permanent cross-links in a physical network upon solid state drawing. The crystals as such do not resist deformation in the temperature domain, close to but below the melting temperature, which is employed for (ultra-) drawing. The maximum draw ratio $\lambda_{\max}$ scales with the ratio between a fully stretched strand, scaling with M_e, between two entanglement points, and the average unperturbed end-to-end distance which scales with the square root of M_e, hence

λ_{max} scales with $M_e^{0.5}$. Upon dissolution, the entanglement density decreases and the molar mass between entanglement loci increases, in good solvents about proportional to the inverse of the volume fraction of polymer in solution: M_e (solid) $= M_e$ (melt)$/\varphi$. The maximum draw ratio of solution-cast/spun PEs is consequently given by: $\lambda_{max} \propto \varphi^{-0.5}$. For example, as-spun fibers from a 1% solution have an increased drawability with a factor of 10.

The entanglement model is remarkably versatile and can explain various phenomena such as the limited drawability of melt-crystallized UHMW-PE, λ_{max} 4–5, the dependence of the maximum draw ratio of solution-cast/spun UHMW-PE on the initial polymer concentration in solution, $\lambda_{max} \propto \varphi^{-0.5}$, and the increase of the drawability in the solid state upon isothermal crystallization at low supercoolings of UHMW-PE solutions, or from the melt in general, due to the fact that the chains are reeled in, viz pulled out their entanglement network. It is very important to note that the proposed "entanglement network" model is not universally valid. It can be applied to apolar polymers such as PEs and polypropylenes, but not to polymers possessing relatively strong secondary interactions, such as hydrogen bonds. In the case of polyamides, the folded chain crystal resist deformation and unfolding (Postma *et al.* 1990).

5. Solvent-free Processing of UHMW-PE; Nascent Reactor Powders

For solution(gel)-spinning of UHMW-PE a lot of solvent is needed for disentangling which has to be fully recovered in view of increased environmental legislation. Consequently, the challenge is to find "solvent-free" routes starting from disentangled precursors. The rationale behind this approach is that once disentangled UHMW-PE structures are obtained via some route, subsequent melt-processing should become feasible. One would at least expect a time-temperature window in which disentangled UHMW-PE should possess a lower initial melt-viscosity in comparison with a standard equilibrium melt. This is in accordance with the long relaxation (reptation) times $(1 \times 10^4$ seconds per $200\,^\circ C)$ of UHMW-PE, viz complete re-entangling is a time consuming process. To prepare (completely) disentangled UHMW-PE structures is feasible and rather straightforward using modern catalysts. Polymerization conditions are known, viz low temperature and rather low catalyst activity, which promote the formation of folded-chain crystals directly on the surface of the (supported) catalyst (Lemstra *et al.* 2000). In the limit of a low concentration of active sites on the catalyst (surface), one could expect that the individual growing chain would form its own *monomolecular* crystal. Despite all efforts made to prepare specific disentangled UHMW-PE precursors

for subsequent melt-spinning, the ultimate conclusion at this point in time is that processing disentangled UHMW-PE with the aim to benefit from an initial lower melt-viscosity and to preserve the disentangled state to some extent during processing and prior to drawing, is not feasible at all. The salient feature is that disentangled UHMW-PE, either obtained by collecting precipitated single crystals or via specific low-temperature polymerizations, shows (Engelen and Lemstra 1991) the same high melt viscosity (in shear) upon heating above the melting temperature as standard "equilibrium" UHMW-PE melts. No memory effect from any previous polymerization/crystallization history can be depicted, and moreover, upon re-crystallization from the melt, the favorable drawing characteristics of disentangled UHMW-PE are lost completely and the drawing behavior is indistinguishable from a standard melt-crystallized UHMW-PE sample.

This intriguing problem of no memory effect and immediate loss of drawability upon re-crystallization has been addressed by Sadler and Barham (1990) following the fate of a PE chain using neutron scattering upon melting. They showed that the radius of gyration, R_g, which is rather low in solution-crystallized samples due to chain folding, immediately jumps to its "equilibrium" random coil dimensions upon surpassing the melting temperature (*chain explosion*). The experiments concerning the fast decay in drawability upon re-crystallization, related to the phenomenon of "*coil explosion*," point out that rather local changes, involving chain segments rather than complete chain motion/diffusion (reptation), can dominate the drawing behavior and these results prompted us to modify the "entanglement model" to some extent (Lemstra *et al.* 2000). Upon crystallization from solution, the molecules fold usually along the {110} plane and the stems of a test chain (heavy dots) are shown in Fig. 2 without indicating the folds. For the sake of simplicity, we assume that adjacent re-entry occurs during crystallization and that the chain is located within one crystal plane. Shearing and unfolding in the direction perpendicular to the chain and along the {110} plane is rather easy in view of the low shear moduli. Upon melting these crystals the chains will immediately adopt a random coil conformation and stems of different molecules will interpenetrate in the "coil explosion" process. Upon re-crystallization, the stems of the test chain become crystallized in a more random order within the crystal and shearing (slip) is more difficult since the chains cannot cross mutually during deformation (Fig. 2).

The instantaneous loss in drawability upon melting and re-crystallization is due to re-arrangement and intermixing of stems involving only local chain motions rather than movement of the complete chains chain as proposed for self-diffusion in polymer melts. The driving force for the mixing of stems and coil-explosion upon melting is the gain in entropy (the

(a)

(b)

entropy of fusion which is absent in the diffusion/reptation processes in quiescent polymer melts.)

6. Solid-state Processing

From sect.5, it may be concluded that all attempts to prepare disentangled UHMW-PE structures by specific polymerizations are in vain since no advantage could be obtained in the subsequent melt-processing. This conclusion is, in fact, not true. The only lesson to be learned is that the disentangled UHMW-PE precursors should never be heated above the melting temperature. Below the melting temperature, the disentangled UHMW-PE reactor powders, the so-called nascent or virgin powders, are remarkably ductile and can be processed via calandering or
Figure 3
P–T diagram of PE.

hot-compacting and subsequently drawn into tapes or fibrillated structures. The draw ratio of well-prepared nascent UHMW-PE powders is similar to solution-crystallized UHMW-PE samples. Processing of UHMW-PE reactor powders has been partly successful for making oriented tapes by sintering/compacting between rollers and subsequent drawing. Kanamoto *et al.* (1987) developed a two-stage drawing process for reactor powders and they obtained Young's moduli of over 100 GPa. Nippon Oil Company developed and patented several solid-state processing routes for making strong UHMW-PE tapes. The only problem with solid-state processing is the handling and limited flow of powders. It is not possible to produce fine denier filaments. To enhance the flowability processing via the hexagonal phase might be a future option.

7. Processing via the Hexagonal Phase

The hexagonal phase of (isotropic) PEs is usually observed at elevated pressure and temperature. The (equilibrium) triple point *Q* is located at 5.2 kbar and 250 °C (see Fig. 3). It was shown by Rastogi *et al.* (1998b) that this triple point is dependent on the crystal size/dimensions and can be lowered to approximately 1 kbar in the case of nascent UHMW-PE reactor powders which possess very small dimensions (<10 nm). This opens the possibility for processing via the (mobile) hexagonal phase. In the hexagonal phase, the chains are mobile but only in the chain direction via chain-sliding, $\langle c \rangle$, or diffusion. Upon annealing in the hexagonal phase ultimately complete chain extension will be obtained and extended-chain crystals will be obtained. Since there is no motion perpendicular to the chains, the drawability is not lost based on our revised model for drawing (see Fig. 2). In fact, the drawability can even be enhanced in the hexagonal phase as shown by Maxwell *et al.* (1996)

since additional "disentangling" will occur as a consequence of extended-chain crystal formation. To date no processing routes via the hexagonal phase for making PE fibers are known. However, processing via the hexagonal phase for making hip joints based on UHMW-PE have been discussed in the literature (Rastogi *et al.* 1998b).

8. Drawing Behavior of Other Flexible Polymer Systems

The success of melt-spinning/drawing in general, and of solution(gel)-spinning in the particular case of ultra-high molecular weight PE, to produce oriented PE structures possessing high tensile moduli, stimulated research activities concerning the drawing behavior of other linear polymers, notably polypropylene, polyoxymethylene, and the aliphatic polyamides, nylon 6 and nylon 66. The high melting temperatures, $225\,°C$ (nylon 6) to $310\,°C$ (nylon 46) compared with PE ($\sim 150\,°C$), and the presence of hydrogen bonds, which could reduce the creep make the polyamides attractive candidates. Extensive research effort to produce high modulus and strength fibers based on aliphatic polyamides have failed, however, despite major efforts in industry to perform solution(gel)-spinning based on high molar mass polyamides. The reason for this failure was demonstrated by Postma *et al.* (1990) who showed that the hydrogen bonds in lamellar, solution(gel)-crystallized polyamides, are essentially static up to the melting temperature and act as barriers, thus prohibiting draw. Solution(gel)-spinning promotes the formation of rather well-developed polyamide (single) crystals and, consequently, unfolding into extended-chain structures becomes more difficult.

9. Properties of PE Fibers

9.1 Tensile Strength (1D)

Currently, UHMW-PE fibers possessing tensile strengths of 3–4 GPa are produced commercially, e.g., Dyneema by DSM and Spectra by its licensee Allied Signal (see Fig. 1). Due to its low density, the specific values for the stiffness and strength of PE fibers are currently superior, at least at *ambient* temperatures.

9.2 Melting Temperature

The melting temperature is given by $T_m = \Delta H/\Delta S$ and the chains in the fiber can not melt when the fiber is constrained, because the chains cannot adopt a random coil conformation. Consequently, ΔS is low and the melting temperature increases. In the case of UHMW-PE fibers, this enhanced melting temperature by external constraints is not possible due to the

onset of the hexagonal phase at $155\,°C$. Above this temperature, the orthorhombic crystals in the fiber transform into the hexagonal structure. In the hexagonal phase the chain mobility is high and the fiber cannot sustain any load and fails (Lemstra *et al.* 2000).

9.3 3D Properties

PE fibers are highly anisotropic structures. The favorable characteristics in the fiber (chain) direction in terms of stiffness and strength are not matched at all in off-axis properties. The low transverse and shear moduli of PE are due to the absence of specific interactions perpendicular to the chain (only weak van der Waals bonding). The absence of strong interactions between adjacent chains causes the strength of the fibers to also be highly anisotropic. This is a major drawback in structural composite applications. It was shown by Peijs (1994) that the low interlaminar shear strength (ILLS) obtained from a three point bending test of unidirectional composites containing UHMW-PE fibers (Table 1) is inherently due to the poor shear and compressive properties of PE fibers. Consequently, UHMW-PE fibers cannot be used in structural composite applications.

9.4 Long-term Mechanical Properties: Creep

Soon after the gel-spun fibers were produced, it became apparent that the exceptionally good short-term mechanical properties were not matched by equally good long-term properties. In tensile tests at low strain rates, the UHMW-PE fibers exhibit a drop in Young's modulus and they exhibit a yield stress which is highly dependent on the strain rate. In fact, it is shown that the tensile strength (yield stress) drops by at least an order of magnitude at prolonged time scales. Some representative creep data of UHMW-PE fibers, in this case of a Dyneema fiber (SK66) possessing a tensile modulus of ~ 100 GPa are shown in Fig. 4. Figure 4 shows that initially the elongation increases proportionally to the logarithm of time.

The creep becomes important at longer loading times. This pronounced, irreversible creep is not too

Table 1

Interlaminar shear strength (ILSS) of unidirectional composites; 50/50 fiber/epoxy composites.

Fiber	ILSS (MPa)
UHMW-PE (untreated)	13

Fish farms	Ballistic blankets	Speaker cones
Parapent lines	Containment shields	Cryogenic composites

surprising when we take into account that UHMW-PE fibers are made by ultra-drawing and in the drawing process folded-chain crystals are transformed into chain-extended structures. In order to avoid fiber breakage in the drawing operation, the fibers are never drawn to their maximum draw ratio λ_{max} and, since there is no "lock-in" mechanism, the fibers can de drawn further in any subsequent tensile loading experiment, such as a creep test. Consequently, there is no basic difference between the drawing operation and a creep test, especially at elevated temperatures. All known methods for improving the creep resistance such as cross-linking (e.g., electron beam and UV) and chemical modification, require the presence of a certain degree of imperfection in the fiber in order to bring the chains together to form a covalent bond. Creep improvement, therefore, implies a compromise between short-term and long-term mechanical properties (Lemstra *et al.* 2000).

10. Major Applications of PE Fibers

In the previous sections the properties of solution-spun, ultra-drawn UHMW-PE fibers were discussed in terms of their tensile (Young) modulus and tensile strength which show impressive values at short loading times but rather extensive creep at prolonged loading times. These properties are, of course, relevant in a large number of applications such as fishing nets and/or lines, ropes, and composites. Such fibers also possess a number of favorable properties such as a high-impact resistance, high-cutting resistance, low dielectric constant, low dielectric loss, low stretch, high heat conductivity in the fiber direction, and a high sonic modulus. These "secondary" properties are particularly important in applications such as ballistic applications (bulletproof vests), helmets (impact), hybrid composites (impact), gloves (cutting

resistance), fishing lines (low stretch), loudspeaker cones (sonic modulus), and radomes/sonar domes (dielectric properties). The properties which motivate the use of highly oriented gel-spun UHMW-PE fibers are high (specific) strength and modulus (all applications), low density, high energy absorption capability (ballistic protection and composites), high sound speed (ballistic protection and speaker cones), flexibility, (ropes and nets), good dielectric properties (radomes), and good chemical resistance (Table 2).

Processing Rigid Polymers to High Performance Fibers

Fiber materials obtained from natural sources have been used through the ages for reinforcement and other structural applications. Well-known examples include the use of straw as reinforcement of clay and plaster, and the use of flax and hemp for cables and ropes. Although such natural fibers are still used extensively, high performance man-made fibers take a steadily increasing share of the market. This is due to the fact that they allow the production of continuous fibers with exceptional mechanical properties, for instance specific tensile strengths that are 5–10 times

higher than that of steel. In addition to the purely synthetic materials, also natural sources for man-made fibers are of major importance, e.g., regenerated cellulose. To obtain fiber materials with high performance properties requires processing methods that yield extremely high molecular orientation of the polymer chains along the fiber axis. For the processing of rigid polymers various techniques are possible. With the first method the required high level of molecular orientation is obtained by the processing of rigid polymer chains from liquid-crystalline (LC) nematic solution, using the dry-jet, wet-spinning technique. Alternatively, rigid polymers can be spun from isotropic solutions. In this case a relatively low degree of orientation is induced during the spinning process. The high orientation, which is required for a high tenacity and modulus is imposed in a hot drawing after-treatment. Kevlar (DuPont), Twaron (Acordis), and Zylon (Toyobo) are representatives of the first category, Technora (Teijin), Armos, and Rusar of the second. Because, from an industrial point of view the dry-jet, wet-spinning of nematic solutions is the most important one, this article will concentrate on this process route. Nematic LC spinning solutions are liquids where the polymer chains show spontaneous alignment along a locally defined axis of orientation $\tilde{n}$, the director (see *Liquid Crystalline Polymers: An Introduction*[#]). Figure 1 shows the molecular arrangement in a nematic polymer solution.

1. History

The first observation of a LC rigid polymer solution was reported by Conmar-Robinson for poly(benzyl-*L*-glutamate) or PBLG in m-cresol, subsequently also p-aramids were found to show such behavior in concentrated sulfuric acid solution. The latter solutions were found to be suitable for the spinning of high performance aramid fibers, presently known as Kevlar (DuPont) and Twaron (Teijin Twaron). Inspired by this success, alternatives to aramid spinning were developed: PBO and PBT fibers, and more

recently PIPD (or M5) and a new cellulose yarn. The last example refers to a spinning process that makes use of nematic cellulose solutions and is an excellent example of a high performance man-made fiber from natural sources.

2. Chemical Structures

The global requirements for polymer chains that are suitable for fiber spinning from nematic solution are rigid chains, a small molecular cross-section, and strong lateral interactions. Some examples of molecular structures that fit this description are shown in Fig. 2, together with the solvent of choice.

Clearly it is necessary to identify solvents suitable for use in a dry-jet wet-spinning process, where the solvents are preferably cheap and not highly toxic. Contrary to common belief strong acids such as sulfuric acid and phosphoric acid while being corrosive are not particularly toxic or volatile, and, therefore, can be used on an industrial scale without putting the operating personnel at any undue risk. For this reason other known solvents, such as hydrofluoric acid for aramids and trifluoroacetic acid for cellulose-acetate, are not generally considered to be serious options for commercial spinning processes.

3. Liquid-crystalline Order

The remarkable mechanical properties of fibers, made from the above polymers, can be understood from the occurrence of LC order in the spinning solution (see Fig. 1). Due to the stiffness of the polymer chains in these materials there is a tendency for them to pack together in a uniform fashion. This so-called LC order manifests itself in the fact that at a given temperature and for sufficient polymer concentration the polymer solutions show distinctly anisotropic properties. The anisotropy relates to many observable physical properties, such as the optical (birefringence) and the rheological properties, where the collective molecular alignment causes a dependence on the orientation of the sample with respect to the external fields. Many LC phases are known, with varying degrees of orientational and positional order. For reasons of simplicity this article will be confined to the simplest case of the nematic phase. This is a fluid phase where the molecules show collective orientation but without the positional order commonly associated with true crystalline materials. The LC structure shown by these polymer solutions does strongly depend on the polymer concentration and the temperature. For a given polymer concentration, at high temperatures the polymer solution will be isotropic, i.e., without orientation, whereas at low temperatures the molecules will show the collective nematic order described above.
At a well-defined temperature the material will show a phase transition from the nematic to the isotropic phase, which is similar in nature to better known phase transitions like the freezing and boiling point. Figure 3 shows this so-called clearing temperature for three polymer solutions.

In addition to this, the degree of molecular orientation in the nematic phase will depend on temperature, at low temperatures the orientational order will be more perfect than at higher temperatures. This is obvious when the thermal motion of the polymer chains is taken into account. The degree of orientation can be expressed as a number, the orientational order parameter, which by definition is zero for an isotropic phase and is one for a material with perfect molecular alignment. It should be clear that the order parameter will increase with increasing polymer concentration and will decrease with increasing temperature. This can be made more quantitative using a variety of theoretical models such as the Maier-Saupe model and the Onsager model.

Figure 2
Structures of some rigid main chain LC polymers.
Figure 3
Clearing temperature from the nematic to the isotropic phase of PPTA in sulfuric acid, and PIPD and cellulose in phosphoric acid.

4. Spinning of Liquid-crystalline Polymer Solutions

Poly(p-phenylene terephthalamide) (PPTA), poly-*p*-phenylenebenzobisoxazole (PBO), poly{2,6-diimidazo[4,5-b:4′,5′-e]pyridinylene-1,4-(2,5-dihydroxy)phenylene} (PIPD), and cellulose are all spun from LC (nematic) solutions. After being filtered and heated, the LC solutions are extruded through gold/platinum spinnerets containing approximately 1000 capillaries with a diameter of 50–200 µm. Figure 4 gives a schematic view of the dry–jet wet-spinning processes.

Rheology of the LC phase plays an important role in processing and structure formation. Shear flow occurs during the melting of the solution, in the pipes of the machine, and in the capillaries of the spinneret. A well-known phenomenon, which was first observed by Kwolek (DuPont) on solutions of aromatic polyamides, is the fact that at low shear rates the shear viscosity exhibits a maximum as a function of the polymer concentration. This maximum in the viscosity versus concentration corresponds to the onset of the nematic phase as is also explained by the Doi theory. When the shear rate increases, the maximum becomes smaller and can even disappear. This is due to flow-induced orientation of the isotropic phase, which diminishes the difference in flow characteristics between the isotropic and the nematic phase. Main-chain LC phase solutions are strongly shear-thinning, especially in the region of the phase transition. Elongational flow fields occur in the entrance zone of the spinneret capillaries and in the air gap, where a draw ratio of approximately 10 is imposed. The elongational viscosity is much less dependent on the deformation rate than is the case for the shear viscosity. For example, with cellulose solutions in phosphoric acid the velocity profile in the air gap has an exponential shape, indicating a constant elongational viscosity. PPTA solutions show similar behavior. The elongational viscosity of PPTA solutions is in the order of 1 kPa, while for cellulose solutions in phosphoric acid it is about 20 kPa.

For some polymers, e.g., PBO, it can be useful to cool the filaments in the air gap by blowing air onto them. This method is also used in melt spinning of cellulose fibers from NMMO solutions (Tencel, Acordis and Lyocel, Lenzing) and can reduce the occurrence of draw resonance.

Compared to solutions or melts of flexible polymers, the die swell for LC solutions of rigid polymers is rather small. The birefringence in the die swell area is very low, but once the velocity in the air gap passes the extrusion velocity the level of birefringence is close to saturation. Additional further drawing slightly improves the orientation of the nematic phase according to the affine deformation model. In this model the orientation of the director field is calculated by assuming that the strain in the liquid-crystal solution is uniform and equal to the externally applied strain. This allows the calculation of the director orientation in terms of a "director order parameter" that is a function of the externally applied strain only. This director order parameter can be used together with the local orientational order parameter, of the molecules with respect to the director, to calculate the mechanical properties of spun fibers as a function of temperature, concentration, and draw-ratio.

The high level of orientation, which is created during the dry-jet spinning, should be maintained in subsequent washing and drying steps. This is achieved by keeping the yarn under tension in these process steps.

5. Structure of Main Chain Liquid-crystalline Phase Spun Fibers

In general the rigid rod polymeric chains of the LC phase fibers bring about a highly crystalline and oriented structure, which is borne out by the results of x ray diffraction, electron diffraction, and in particular by the lattice imaging technique. The chains in cellulose II, PPTA, and PIPD are packed in a 3D order extending in transverse direction over 5–8 nm and in longitudinal direction over more than 40 nm. In the PBO structure the 3D order is disturbed by random translations parallel to the chain axis. In cellulose II and PIPD the chains are laterally bonded by hydrogen bonds in two directions, whereas the crystalline structure of PPTA the hydrogen bonding between the chains extends in a single direction. Different kinds of lateral textures, depending on the coagulation conditions, have been observed in cellulose II and PPTA fibers. In addition, the LC phase fibers can display a pleated sheet morphology with a period of about 250 nm. Typical for the wet-spinning process are the finely distributed and highly elongated voids in the fiber, which give it a fibrillar morphology.
Figure 4
Schematic view of the dry-jet wet-spinning process, the solvent is removed in the coagulation bath containing the coagulant (e.g., H$_2$O or dilute sulfuric acid for PPTA-spinning).

6. Mechanical Properties

The mechanical properties of LC phase solution spun fibers can be fully understood on the basis of a single-phase crystalline structure. Numerous experiments show that the continuous chain model provides a good interpretation of the mechanical properties. In this model the fiber properties are determined by the chain modulus (e_c), the shear modulus between adjacent chains (g), the corresponding critical shear stress (τ_c), the orientation distribution of the chain axes ($\langle \sin^2\Theta \rangle$), and the molecular weight distribution (MW). The fiber is modeled as a series arrangement of crystalline domains consisting of perfectly oriented chains. The fiber strain is brought about by elastic chain extension and by elastic shear of the chain axes towards the fiber axis. Both contributions form the equation for the initial modulus of the fiber (E) given by:

$$\frac{1}{E} = \frac{1}{e_c} + \frac{\langle \sin^2\theta \rangle}{2g}$$

where θ is the angle between the chain axis and the fiber axis. For a crack-free fiber the internal shear modulus is about equal to the torsion modulus of the filament.

High draw ratios in the spinning process improve the chain orientation resulting in a higher modulus. Other process conditions, such as hot drawing, can influence the molecular interactions to some degree, e.g., by improving the crystalline order, and hence may increase the shear modulus. Table 1 presents the significant data and the types of interchain bonds. Depending on the degree of chain orientation the tensile curves of polymer fibers below their glass transition temperature are characterized by a more or less pronounced yield at about 0.005–0.025 strain. This yield can be modeled using a critical resolved shear stress, τ_c, at which local loosening of the intermolecular bonds occurs, resulting in a permanent rotation and displacement of adjacent chains and, thus, in a permanent shear deformation of the domains. Hence, above the yield strain the tensile extension of the fiber is accompanied by plastic deformation. It has been shown that the compressive strength of polymer fibers is determined by the same critical shear stress leading to yielding in compression occurring at the same strain as in tensile deformation. Generally, the compressive strength of a crack free

Table 1

Summary of the basic elastic constants g and e_c for various organic polymer fibers, together with the highest filament values reached for the modulus (E) and the tensile strength (σ_b). Also shown are the average values for the creep compliance (CC) at 20 °C, which is the ratio of creep rate and load stress, and the character of the lateral interchain bonds.

Fiber	e_c (GPa)	g (GPa)	E (GPa)	σ_b (GPa)	CC (%/dec/GPa)	Interchain bond

[a] New cellulose yarn from phosphoric acid solutions.

polymer fiber is about 0.3 times the shear modulus (this is supported by the yield model and experimental results). The highest experimental value for compressive strength of 1.7 GPa obtained so far is for the PIPD fiber, which is due to the network of hydrogen bonds that extends in two different directions normal to the chain. The hydrogen bond networks of cellulose II and PIPD are rather similar, which causes high shear moduli for both fibers. The intermolecular bonding also to a large extent determines the viscoelastic properties like the creep compliance of the polymer fibers as shown in Table 1. Strong LC phase-based fibers are obtained for large values of MW, τ_c, and a high degree of chain orientation, i.e., for high values of E and a more uniform structure of the fiber. The highly rigid nature of the polymer chain in PBO and PIPD, and the relatively strong interchain bonding, in particular in PIPD, ensure excellent thermal properties such as a low creep rate and long lifetimes at relatively high temperatures. It is noted that the creep rates for LC phase spun fibers (PPTA, PBO, and PIPD) are much lower than those for UHMW-PE and PET due to the stronger lateral interactions.

7. Applications

Due to their impressive mechanical and thermal properties, polymer fibers spun from LC solutions are extensively used for various reinforcement and structural applications. In general the advantage of such polymer fibers is that they have a high modulus and strength and are not brittle and have relatively good damage tolerance compared to, for example, carbon fiber and glass fiber. One of the largest applications of PPTA fibers is in the making of brake linings as a replacement of asbestos. Also PPTA aramid fibers are used for ballistics as the main component of bullet proof vests. Some additional applications are listed in Table 2. The various materials each have their own niche in the market and the estimated annual production is shown in Table 3.

Pulp and Paper: Nonfibrous Components

Paper and paperboard consist of mainly of cellulosic fibers. In order to increase the quality and properties of these products, nonfibrous components are added. The types of materials and steps in the process are discussed in this article.

1. Wet End Addition

This addition or loading occurs when there is at least 60% fiber and before the formation of the paper or paperboard. Loading, a traditional term, means the incorporation of inorganic materials in the fibrous web to improve quality. The word ''load'' is used because a constant basis weight of the paper product is maintained during the addition of 1–40% inorganic material that has a higher density (2600–4500 $kg\,m^{-3}$) with a similar reduction of the less dense cellulose fibers (1500 $kg\,m^{-3}$). A web consisting of only fibrous materials will often have a discontinuous surface with minute hills, valleys, and randomly distributed voids. The objective is to close or plug the spaces between the fibers in the web of the paper product with nonfibrous materials. Another term used for the inorganic additives is fillers, essentially inorganic materials also called pigments. Different types of clay, calcium carbonate, titanium dioxide, talc, and specially made proprietary materials are examples of wet end fillers.

1.1 Clay

Kaolin is the most important clay material to improve surface smoothness for better print quality. Clay materials are natural, earthy, fine-grained, and plate-like materials, and the terms clay and kaolin are used interchangeably. Chemically, clays are hydrous aluminum silicates with an approximate composition of Al_2O_3–$2SiO_2$–$2H_2O$. At least 12 different classes of clays are available, which can be supplied in either a dry powder or a dispersed slurry water solution. In order to obtain maximum efficiency of clay, each particle must be completely separate or dispersed to ensure optimum flow properties. In its natural state, clay is acid and particles are attracted to each other (flocculated).

1.2 Calcium Carbonate

This additive increases brightness, ash, and opacity. Calcium carbonate can be divided into two general classifications: naturally occurring products such as limestone, granite, and chalk processed by wet or dry grinding; and those chemically produced by precipitation. Within these two groups are a wide variety of subgroups based on particle size, shape, and distribution. Lime is converted to calcium hydroxide which is reacted with carbon dioxide to form calcium carbonate and water. A number of on-site calcium carbonate plants have been constructed.

1.3 Titanium Dioxide

Titanium dioxide pigments are finely divided white powders which are chemically inert or unreactive, in contrast to all commonly used materials for paper filling or coating systems, and are used to increase opacity. Titanium dioxide is classified based on its crystalline arrangement as either anatase or rutile. The high light reflectivity, low light absorption and small particle size make this pigment ideal for obtaining high opacity. In their finely divided form, these pigments are very intensely white. With this characteristic, even at low concentration levels, titanium dioxide pigments are a major contributor to the optical performance of brightness and opacity of paper. If only brightness is needed, calcium carbonate is a more cost-effective pigment.

1.4 Talc

Talc is a silica combined with magnesium salts, being mined and processed similarly to clay, and used to decrease the amount of ''pitch'' in pulp.

1.5 Retention Aids

Another series of chemicals called retention aids are added at the wet end to ensure efficient capture of pigments during the paper-forming process. These materials are pigment specific and have a very complex chemistry.

2. Surface Treatment

Surface treatment of paper or paperboard is a general term used to describe the application of adhesives, functional products, pigments, and their combinations to the already formed fibrous web. Surface sizing and coating are designations that are frequently chosen to separate arbitrarily certain processes in surface treating.

3. Surface Sizing

Sizing occurs on the paper machine using specially designed equipment. The application of the treatment may consist of one material, usually a starch solution, or a combination of adhesives, pigments, and functional products. Again, the objective is to improve the appearance and print properties of the paper product. An example of a similar process would be the priming of bare wood.

4. Coating

This process can be accomplished either on or off the paper machine A coating formula or recipe contains three major components.

4.1 Coating Pigments

These are similar to the pigments previously described. Pigments are 70–80% of the coating formula. Properties affected by adding pigments are color, brightness, opacity, paper and ink gloss, smoothness, and holdout.

4.2 Adhesives

Also termed binders, adhesives are necessary to bond the coating to the paper/board and to the pigments. Normally, a coating formula contains 10–20% adhesives. There are two classifications of adhesives, natural and synthetic.

Protein and starch are examples of natural adhesives. Several types of industrial-grade soy protein are available. These are classified as unmodified (unhydrolyzed) and modified (hydrolyzed) types of high-, medium-, low-, and extra-low viscosity grades. The source of soy protein is defatted soybean flakes. Starch is a high molecular weight polymer, with many sources, including corn, wheat, potato, and waxy maize. Starches can be chemically modified for specific uses in coatings, surface sizing, or at the wet end of a paper machine. Starch must be gelatinized to be an adhesive, which is accomplished by cooking a starch–water mixture.

Synthetic coating adhesives are latexes or poly(vinyl alcohol). Latex is a synthetic resin emulsion, a dispersion of very small (0.1 μm) water-insoluble particles held in a water suspension by a balance of surface-active agents (surfactants or soaps). Poly(vinyl alcohol) is an unusually strong resin and provides excellent adhesive strength in binding pigments, cellulose, and other change particles. Poly(vinyl alcohol) is sold commercially as a powder or granular material that is white to cream in color. When dissolved in water, cast, and dried, a tough clear colorless film is formed. Poly(vinyl alcohol) is supplied in a variety of grades, which are dependent on the size and weight of the monomer. The type and level of adhesives affect not only the final strength but also brightness, opacity, paper and ink gloss, smoothness, ink and water absorption, flow properties, ease of drying, and coater runnability. The major pigment binding adhesives for the paper industry are polystyrene, a hard, inflexible thermoplastic polymer, and butadiene, a soft, flexible elastomer.

4.3 Additives

There are a number of materials in this classification which give specific properties to the coating formula. The amount added is usually 0.2–2% based on total pigment. Discussed below are some of the major additives.

(*a*) *Biocides*. Deterioration or spoilage of paper coating formulations and ingredients is a problem. Spoilage may show up as a loss in viscosity, change in pH, development of odor, or change in color. These conditions result in production problems, coating loss, and/or excessive losses to the sewer. Even though bacteria and fungi involved in spoilage are microscopic, their activities are readily visible in the final product.

(*b*) *Dispersants*. These chemicals are used to overcome the natural mutual attraction of pigment particles. If the particles are not separated, poor coater runnability develops. The separation is done through mechanical agitation or by chemical means. Slurry pigments have dispersants added by the suppliers. When using dry pigments in a formula, additional dispersant is required under high agitation conditions. Too much or too little dispersant will affect the coating viscosity.

(*c*) *Dyes*. Color changes are made through these additives, including fluorescent dyes. The addition of fluorescents improves the whiteness and blue-white hue of coated paper.

(*d*) *Flow modifiers*. Either natural or synthetic chemicals are used to modify the viscosity of coatings during the make-down, pumping, and application processes. A knowledge of the types of flow modifiers and how and where to add them to a coating mix is critical to the final quality of the coated sheet. Some examples of flow modifier problems include excessive dispersant in pigments or coating mix, not enough defoamer to minimize air entrapment (foam), and excessive caustic that causes pigment shock.

(*e*) *Lubricants*. There is no simple definition for the numerous properties and a function of a lubricant, the need of which is still debated. To impart lubrication to the wet coating, the following compounds may be used: soluble soaps (ammonium stearate and sodium sterate) to increase the viscosity of starch coatings; insoluble soaps (aluminum stearate and calcium stearate), which have a small effect on starch coating viscosity; polyethylene emulsion; or emulsion of various animal fats.

(*f*) *Insolubilizers*. Water resistance of paper coatings is very important in the printing process and the addition of an insolublizer imparts this property. The need for water resistance is determined by using a mixture of water and alcohol (fountain solution) in the printing process.

(*g*) *pH controls*. Materials can be acidic, neutral, or alkaline, of which pH is a measure. pH shock occurs when a strong acid or alkaline material is added to a coating mix in the wrong sequence. The result is a thick, lumpy coating similar to cottage cheese.

(*h*) *Plastic pigments*. A variety of synthetic polymers can be used as plastic pigments in place of minerals. The main criteria are that the plastic pigment particles be non-film-forming and remain discrete under conditions of application, drying, and finishing. They also should be insoluble in the binders used. Since plastic pigments are completely synthetic, their size, shape, mass, electrical charge, surface activity, compatibility, and fusion temperature can be well controlled.

(*i*) *Others*. Other materials can be added in small amounts. The types and amounts are proprietary and provide distinctive coated paper properties.

5. Summary

Paper and paperboard consist mainly of cellulosic fibers. In order to enhance the quality and properties of these products, nonfibrous components are added.

Nonfibrous materials that are added to paper, paperboard, and coatings are dynamic as a result of ongoing research, specific applications, and customer demands. This article only identifies the major components relating to paper and paperboard coating surface and printing improvement.

Radiation Effects in Carbon–Carbon Composites

Carbon–carbon (C/C) composite materials are a class of high-temperature materials that consist of a carbon or graphite matrix, reinforced with carbon or graphite fibers (see *Carbon–Carbon Composites**, where this class of material is reviewed in detail). C/C materials that are used in nuclear environments are typically manufactured from graphitic fibers, and exhibit graphitic matrices by virtue of the matrix precursors and high heat treatment temperatures employed in their manufacture. Potential nuclear applications for C/C composites include high-temperature control rods for advanced, high-temperature, gas-cooled reactors (Burchell 1999), and the plasma-facing components of a fusion reactor (Snead 1999). Owing to its use as a moderator in nuclear fission reactors, much is known about the irradiation behavior of graphite (see *Nuclear Graphite and Radiation Effects#*). In contrast, comparatively little is known about irradiation damage effects in C/C composites (Burchell 1997).

1. Carbon–Carbon Composites as Fusion Reactor Plasma-facing Materials

In a fusion reactor, light elements are brought together at enormous temperatures and "fuse" to form a heavier element, energy being released in the process. There are many reactions that could be utilized in a fusion reactor. However, the fusion reaction that has been most widely studied is the deuterium–tritium reaction, which involves two isotopes of hydrogen:

$$_1\mathrm{H}^2 +_1 \mathrm{H}^3 \rightarrow _2\mathrm{He}^4 + \text{neutron} + \text{energy}$$
In a fusion reactor, the hot plasma (ionized gas) is magnetically confined within a toroidal-shaped vacuum vessel. The plasma temperature required to sustain the fusion reaction is $> 50 \times 10^6$ K (> 10 keV). If the plasma were allowed to contact the vacuum vessel structural material, the high atomic number elements vaporized by the intense heat of the plasma would enter the plasma and create plasma instability. Consequently, it is necessary to protect or "armor" the inner walls of the vessel with a material of low atomic number, or a highly refractory material. The vessel armor is often referred to as a "plasma-facing component" (PFC) and the materials used are called "plasma-facing materials." The tokamak concept is one of the more popular of the highly specialized designs of fusion reactors (see *Fusion Reactors (Magnetically Confined)—Tokamaks: Materials#*).

A tokamak utilizes a toroidal magnetic field confinement system in which the plasma ions are confined within, and coupled to, continuous magnetic field lines that travel helically through the toroidal vacuum vessel. Carbon–carbon composites have been widely used as tokamak plasma-facing materials, and are under consideration for use in "next-generation" tokamaks such as ITER (Barabash *et al.* 1998). The interactions that occur between the plasma-facing material and the plasma are particularly severe, and can result in failure due to high thermal stress, melting, sublimation, excessive surface erosion, and neutron damage. The effect of this latter phenomenon on C/C composites is the subject of this article.

2. Neutron Irradiation Damage Mechanism

In the graphite crystal, carbon atoms are covalently bound in a hexagonal array with a binding energy in the crystal lattice of about 7 eV. The lattice basal planes are stacked upon one another in an ABAB … stacking sequence with an optimal separation of 0.335 nm. The bonding between the basal planes is of the weak attractive type (Van der Waals). McEnaney (1999) gives a full account of the structure and bonding in carbon materials. Energetic particles, such as electron, ions, or fast neutrons, can displace carbon atoms from their equilibrium lattice positions. The energy required to displace a carbon atom is in the range 24–60 eV (Kelly 1981, Burchell 1996a). The displaced carbon atoms, referred to as primary knock-on carbon atoms (PKAs), may displace further carbon atoms themselves, through secondary collisions with the carbon atoms in the graphite lattice in a cascade effect. The cascade carbon atoms are referred to as secondary knock-on carbon atoms (SKAs). The displaced SKAs tend to be clustered in small groups of 5–10 atoms and are generally treated as if they occur randomly. The total number of displaced carbon atoms produced depends upon the energy of the PKA, which in turn is a function of the neutron energy spectrum and the neutron flux. Displaced carbon atoms recoil through the crystal lattice, displacing other carbon atoms and creating vacant lattice sites. A significant fraction of the PKAs and SKAs do not remain displaced, but diffuse between the graphite crystal layer planes and recombine with lattice vacancies. Others will coalesce to form C_2, C_3, or C_4 linear molecules that in turn form the nucleus of a dislocation loop—essentially a new graphite plane. Adjacent lattice vacancies in the same graphitic layer are believed to collapse parallel to the layers, thus forming sinks for other vacancies, and can no longer recombine and annihilate interstitial defects.
Figure 1
The radiation damage mechanism in graphite showing the induced crystal strains.

Figure 1 is a schematic representation of the neutron damage mechanism in graphite.

3. Irradiation Induced Dimensional Changes

Dimensional changes occur in the graphite crystallites because of the carbon atom displacements described above. Interstitial defects will cause the crystallites to expand perpendicularly to the basal planes (**c**-direction in Fig. 1), and relaxation in the plane due to the coalescence of vacancies will cause shrinkage parallel to the basal planes (**a**-direction in Fig. 1). The dimensional changes can be very large, as demonstrated in studies on well-ordered graphite materials, such as pyrolytic graphite (Price 1974). Typically, the dimensional change (**a**-axis shrinkage and **c**-axis growth) in pyrolytic graphite and graphite single crystals increases linearly with dose, but decreases with increasing graphitization temperature. The effect of graphitization temperature can be attributed to thermally induced improvements in crystal perfection, which reduces the number of vacancy trapping sites in the lattice.

Radiation damage in C/C composites has been recently reviewed and materials property data for fusion reactor plasma-facing C/C composites reported (Burchell 1996a, Burchell and Oku 1994). Two-directional (2D) C/C composites have been reported to exhibit excessive swelling perpendicular to the fabric layers (22–37% growth), and shrinkage in directions parallel to the fabric layers (typically 3–19%), on irradiation at 400 °C and to a dose of approximately 4 displacements per atom (dpa) (Burchell *et al.* 1991). C/C composites are an infinitely variable family of materials, and processing and design variables influence their properties and behavior. In order to select a C/C composite for a PFC application in which neutron damage will be significant, we must understand the effect of processing variables on neutron irradiation-induced structure and property changes. Burchell *et al.* (1992) irradiated 1D, 2D, and 3D C/C

composites at 600 °C and to damage doses up to 1.5 dpa. Three-directional C/C composites were shown to exhibit more isotropic dimensional changes than either 1D or 2D C/C composite materials. Pitch fiber composites were shown to be more dimensionally stable than polyacrylonitrile (PAN) fiber composites, and high final heat-treatment (graphitization) temperatures were found to be beneficial. Similar trends were reported by Bonal and Wu (1996).

Burchell *et al.* (1996b) reported dimensional, strength, and thermal conductivity changes for so-called 1D, 2D, and 3D C/C composites irradiated to a peak neutron dose of 4.7 dpa at an irradiation temperature of 600 °C. Neutron irradiation-induced dimensional changes for three of the PAN fiber composite materials are summarized in Fig. 2. Specimen length and diameter changes are shown for a unidirectional fiber composite (UFC), a random fiber composite (RFC), and a 3D composite (223). The 1D composite exhibited extremely anisotropic dimensional changes, undergoing rapid shrinkage in the fiber-axis direction (length). In the direction perpendicular to the fiber axis (diameter), the composite shrank at a dose <1 dpa, followed by a reversal to expansion, returning to zero-dimensional change at approximately 2.5 dpa and continuing to expand at an increasing rate. A similar trend was observed for the 2D composites, as typified by the RFC material (Fig. 2), where the fiber axis is in the specimen diameter direction. In the off-axis direction (length), the composite exhibited a slight contraction followed by expansion, returning to the original length at approximately 2 dpa. The diameter (fiber-axis) directions of the RFC specimens exhibited shrinkage, although the magnitude of the shrinkage was much less for the same damage dose than in the case of the 1D composite. In contrast to the 1D and 2D composites, the 3D PAN fiber composite exhibited isotropic behavior at damage doses up to approximately 2 dpa. At doses exceeding 2 dpa, the composite **z**-direction (specimen length) continued to display shrinkage, whereas the fiber **x-y** (specimen
Figure 2
Neutron irradiation-induced dimensional changes of carbon/carbon composites irradiated at 600 °C.

diameter) direction exhibited reversal and slight growth. Irradiation-induced dimensional changes in C/C composites has recently been explained in terms of the following (Burchell 1996b):

(i) an understanding of the graphite single crystal dimensional changes;

(ii) a microstructure model of the carbon fibers used in the composite (PAN fibers in all three materials in Fig. 2); and

(iii) a knowledge of the composite architecture and the interactions of the fiber, fiber bundle, matrix, and porosity in the composite.

4. The Effects of Neutron Irradiation on Thermal Conductivity

Carbon and graphite are phonon conductors of heat. The thermal conductivity increases with increasing temperature from absolute zero, and peaks at a temperature typically close to room temperature, due to the opposing effects of the increasing specific heat
Figure 3
The temperature dependence of thermal conductivity for non-irradiated, irradiated, and annealed carbon/carbon composite material, AO-5.

and decreasing phonon mean free path – resulting from thermally induced phonon self-scattering (Umklapp scattering). The thermal conductivity decreases with further increases in temperature due to the dominating effect Umklapp scattering (Fig. 3). Phonon scattering also occurs from microstructural defects in the materials. Therefore, more graphitic materials exhibit greater thermal conductivity, and the peak in the thermal conductivity–temperature plot is sharper and shifts to lower temperatures. The mechanism of neutron irradiation-induced degradation of thermal conductivity in graphite has been extensively studied and reviewed (Burchell 1996a; Kelly 1981), and data for several C/C composites have been reported by Snead and Burchell (1995), Wu *et al.* (1994) and Eto *et al.* (1998).

The thermal conductivity is rapidly reduced with increasing neutron damage dose, due to the introduction of additional lattice defects, such as interstitial clusters, vacant lattice sites (singles, pairs or small groups of carbon atoms), and basal plane vacancy loops. Figure 3 illustrates the reduction of thermal conductivity with neutron damage dose. The lower curve in Fig. 3 illustrates the temperature dependence of the thermal conductivity of C/C composite A05 after neutron irradiation at 600 °C to ~1 dpa. At the irradiation temperature the thermal conductivity was reduced from >80 $Wm^{-1}K^{-1}$ to ~40 $Wm^{-1}K^{-1}$. Some fraction of the thermal conductivity may be recovered by thermally annealing the irradiation-induced defects, by heating the material above its irradiation temperature. This phenomenon may be seen in the "cooling" curve of Fig. 3. On cooling from the annealing temperature of 1200 °C to the

irradiation temperature (600 °C), the thermal conductivity recovers to $67\,\mathrm{Wm^{-1}\,K^{-1}}$. A greater recovery of thermal conductivity can be expected with increasing annealing temperature. The reduction in thermal conductivity due to irradiation damage is sensitive to dose and temperature. At any given dose and temperature, a saturation limit will be reached that is not exceeded until the composite undergoes gross structural changes at high damage doses. The saturation level of thermal conductivity will be lower, and will be attained more rapidly, at low irradiation temperatures.

5. Conclusions

Carbon–carbon composites are currently used in experimental fusion reactors, and are being considered for specialized high temperature gas-cooled fission reactors. In these nuclear applications, the material will be subjected to fast neutrons which result in structural damage and physical property degradation. Although relatively little work has been done to elucidate the effects of neutron damage in C/C composites, a vast body of literature exists for neutron damage in graphite. The data from the earlier studies on graphite has been used successfully to interpret new data on the effects of neutron damage in C/C composites.

Reaction Forming

The shrinkage upon firing of a porous ceramic-bearing preform can be reduced by increasing the solid volume within the preform prior to or during sintering. This may be accomplished by infiltrating a fluid (liquid or gas) into the porous preform and then converting the fluid into a solid by solidification, condensation, and/or chemical reaction with the preform. Approaches based on solidification or condensation will not be reviewed here. The purpose of the present contribution is to describe recent developments in processes that utilize oxidation reactions between an infiltrant (gas or liquid) and a shaped preform to produce near net-shaped, ceramic-bearing components. Two of these approaches yield all-ceramic bodies by the reactive infiltration of $O_2(g)$ into shaped metal-bearing preforms: the reaction bonded aluminum oxide (RBAO) and volume identical metal oxidation (VIMOX) methods. In two other processes, ceramic/metal (intermetallic) composites are fabricated by the reactive infiltration of molten metals into porous, oxide-bearing preforms: the infiltration alumina aluminide alloy (i-3A) and displacive compensation of porosity (DCP) methods. In these processes the oxygen source is a solid oxide within the solid preform.

1. Near Net-shaped Ceramics from Formable, Metal-bearing Preforms: The RBAO and VIMOX Methods

Oxidation-induced changes in volume are utilized in the patented RBAO (Claussen 1992) and VIMOX (Sandhage 1997) methods to convert shaped metal-bearing precursors into ceramic bodies of similar shape and dimensions. The ratio of the volume of oxide produced to the volume of metal consumed is often referred to as the Pilling–Bedworth ratio (PBR). PBR values for several metals are shown in Table 1.

For most metals, the PBR is in excess of unity. The increase in solid volume associated with the oxidation of such metals within a porous body can be used to offset the contraction associated with postoxidation sintering. Hence, porous shaped preforms comprising intimate mixtures of metal and ceramic can be converted into dense all-ceramic bodies that retain the preform shape and dimensions. For example, the oxidation of a porous mixture of $Al + Al_2O_3 + ZrO_2$ followed by sintering can yield Al_2O_3/ZrO_2 composites with relatively low net shrinkage (Wu *et al.* 1993, Holz *et al.* 1994). This is the basic premise for near net-shape processing by the RBAO method.

Unlike most metals, the alkali and alkaline earth metals tend to possess PBR values less than unity (see the right half of Table 1). Such oxidation-induced reductions in solid volume can be used to offset volume expansions associated with the oxidation of other elements and/or the formation of ceramic compounds. That is, a preform composed of an appropriate mixture of alkali or alkaline earth elements with other metallic and/or ceramic constituents can be converted by oxidation and further reaction into a near net-shaped monolithic ceramic or ceramic composite. For example, a dense, shaped mixture of $Ba + Sr + Al + Al_2O_3 + SiO_2$ can be oxidized and annealed to produce a dense body of celsian, $(Ba,Sr)Al_2Si_2O_8$, with little or no change in shape and dimensions (Sandhage *et al.* 2000, Viers and Sandhage 1999). This is the basic premise for near net-shape fabrication by the VIMOX process.

Table 1
Pilling–Bedworth ratio (PBR) for several elements.

Metal/oxide	PBR	Metal/oxide	PBR
Al/Al_2O_3	1.28	Mg/MgO	0.804
Si/SiO_2	2.14	Ca/CaO	0.638
Cr/Cr_2O_3	2.01	Sr/SrO	0.611
Ni/NiO	1.66	Ba/BaO	0.670
Ti/TiO_2	1.77	Li/Li_2O	0.567
Zr/ZrO_2	1.51	Na/Na_2O	0.541
Nb/Nb_2O_5	2.69	K/K_2O	0.474

For both the RBAO and VIMOX methods, preforms composed of fine, intimate mixtures of metal and ceramic are required in order to obtain desired oxidation and reaction kinetics, and to produce near net-shaped bodies without macrocracking or distortion (Wu *et al.* 1993, Holz *et al.* 1994, Sandhage *et al.* 2000, Viers and Sandhage 1999, Schmutzler *et al.* 1994). High-energy milling can be an effective means of producing such mixtures. However, proper selection of the milling intensity (e.g., rotation speed during attrition milling), milling time, ball-to-charge ratio, and milling liquid are required to produce high yields of fine, intimate metal/oxide mixtures (Wu *et al.* 1993, Holz *et al.* 1994, Sandhage *et al.* 2000, Viers and Sandhage 1999, Schmutzler *et al.* 1994, 1996). Incomplete milling will yield coarse, nonuniform mixtures, whereas excessive milling may result in undesired mechanochemical reactions (e.g., the formation of brittle intermetallic compounds). Excessive mechanochemical reaction and oxidation of the metal-bearing powder mixture must be avoided during milling, so that a sufficient amount of ductile metal is retained to allow for: (i) uniform compaction and forming into a green body of desired shape; and (ii) small net volume changes upon conversion of the green body into the desired ceramic phase(s) (Holz *et al.* 1994, Sandhage *et al.* 2000, Viers and Sandhage 1999). Excessive hydration of the ceramic constituents during milling must also be avoided in order to reduce the risk of bloating during subsequent firing (Holz *et al.* 1994). Finally, owing to the inevitable wear that occurs during high-energy milling, the compositions of the milling media and milling vessel must be properly chosen to avoid degradation of the performance of the final fired components (Wu *et al.* 1993, Holz *et al.* 1994, Sandhage *et al.* 2000, Schmutzler *et al.* 1994).

Due to the presence of appreciable ductile metal in the milled powders (usually > 30 vol.%), the green strengths of compacted RBAO and VIMOX mixtures can be appreciably higher than for conventional ceramic green bodies; that is, green strengths of 20–50 MPa are typically achieved in pressed metal-bearing RBAO and VIMOX preforms (Wu *et al.* 1993, Holz *et al.* 1994, Sandhage *et al.* 2000). In the RBAO process, compaction pressures of up to 500 MPa are commonly used to produce $Al–Al_2O_3$-bearing preforms with a sufficient amount of porosity (usually $\geqslant 25$ vol.%) so as to allow for a relatively high oxygen infiltration rate during oxidation and a good match between the oxidation-induced volume increase and the sintering-induced contraction. In the VIMOX process, preforms with densities of up to 93% have been produced using uniaxial compaction stresses as high as 1200 MPa. (Open porosity is not required in VIMOX preforms for near net-shape processing.) After compaction, the robust metal-bearing RBAO and VIMOX preforms can be readily machined into more complicated shapes (Wu *et al.*

1993, Viers and Sandhage 1999). Dense, metal-rich VIMOX preforms have also been formed into wires and tapes by drawing and rolling (Sandhage *et al.* 2000, Schmutzler *et al.* 1994, 1996).

Shaped metal-bearing VIMOX preforms can also be produced by melt infiltration. For example, dense Mg–Al$_2$O$_3$-bearing precursors to spinel (MgAl$_2$O$_4$) have been produced by the pressureless infiltration of molten magnesium into porous Al$_2$O$_3$ preforms followed by solidification (Sandhage *et al.* 2000, Kumar and Sandhage 1998). With careful tailoring of the porosity of the Al$_2$O$_3$ preform, the desired magnesium content for producing stoichiometric spinel can be achieved. The ductile, interconnected magnesium endows the infiltrated preform with a relatively high green strength (70–100 MPa). As for the milled, powder-derived preforms discussed above, melt-infiltrated preforms can be readily machined into more complex shapes (Kumar and Sandhage 1998).

Shaped, robust VIMOX and RBAO precursors can be converted into dense all-ceramic bodies with the use of appropriate oxidation and postoxidation heat treatments. The porous, nonprotective nature of the oxide scales formed on alkali or alkaline earth metals results in relatively rapid oxidation of VIMOX preforms at $\leqslant 500\,^{\circ}$C (Sandhage *et al.* 2000, Schmutzler *et al.* 1994, 1996). Although a dense, slow-growing layer of alumina tends to form on aluminum, a relatively high rate of oxidation of porous RBAO preforms can be achieved if the aluminum is in the form of fine (submicron) particles (Wu *et al.* 1993, Holz *et al.* 1994). (The protective nature of an alumina scale can also be reduced if the scale is allowed to react with other oxides, such as silica or baria, present in a preform (Sandhage *et al.* 2000, Viers and Sandhage 1999, Scheppokat *et al.* 1999)). During the oxidation of RBAO and VIMOX preforms, the following phenomena are of particular concern: (i) the formation of appreciable molten metal due to incomplete oxidation at subsolidus temperatures; and (ii) significant nonuniform thermal excursions (runaway oxidation) resulting from the exothermic nature of the oxidation reaction(s) (Holz *et al.* 1994, Sandhage *et al.* 2000, Schmutzler *et al.* 1994, Gaus *et al.* 1999). The generation of molten metal can lead to appreciable agglomeration and phase coarsening or to the loss of such metal from the preforms due to poor wetting (Holz *et al.* 1994, Sandhage *et al.* 2000, Schmutzler *et al.* 1994, Gaus *et al.* 1999). In order to maximize the extent of oxidation at temperatures where the metallic constituents remain solid, oxidation is conducted with modest rates of heating up to, and/or with isothermal anneals below, subsolidus temperatures. For example, 30–32.5 mm diameter × 35 mm tall Al–Al$_2$O$_3$-bearing cylinders have been completely oxidized by heating at 1–2 $^{\circ}$C min^{-1} to 1100 $^{\circ}$C in air, in some cases with prolonged isothermal anneals at 400–475 $^{\circ}$C (Wu *et al.* 1993, Gaus *et al.* 1999), and 10–16 mm lengths of sheathed

Ba–Ce-bearing and Ba–Ti-bearing tapes have been completely oxidized (via oxygen migration from the exposed ends inward) within 4–10 h at 300 $^{\circ}$C in oxygen (Sandhage *et al.* 2000, Schmutzler *et al.* 1994, 1996). Such modest rates of heating and low-temperature annealing also help to reduce the occurrence of thermal excursions within the preforms that lead to extensive macrocracking (Sandhage *et al.* 2000, Schmutzler *et al.* 1994, Gaus *et al.* 1999). Reductions in the oxygen partial pressure, and the use of gas mixtures containing helium (i.e., to enhance the rate of heat transfer through gas-filled pores), have also been effective means of reducing thermal excursions and associated macrocracking (Viers and Sandhage 1999, Gaus *et al.* 1999).

The oxide grains formed within RBAO and VIMOX preforms upon oxidation at modest subsolidus temperatures tend to be submicron in size (Wu *et al.* 1993, Sandhage *et al.* 2000). Such an intimate mixture of fine-grained oxides can undergo further reaction and sintering under modest annealing conditions (Sandhage *et al.* 2000, Schmutzler *et al.* 1996, Scheppokat *et al* .1999). For example, tapes of BaTiO$_3$ and Ba(Ce,Nd)O$_3$ with densities of $\geqslant 98\%$ have been produced from well-milled and oxidized preforms at peak temperatures of $\leqslant 1085\,^{\circ}$C. Intentionally porous bodies of Ca$_{10}$(PO$_4$)$_6$(OH)$_2$ and (Ba,Pb)TiO$_3$ have been produced from well-milled and oxidized VIMOX preforms within times of only 1 h and 10 min, respectively, at peak temperatures of 1120–1150 $^{\circ}$C. Dense ($\geqslant 95\%$) Al$_2$O$_3$/ZrO$_2$ composites have also been synthesized by firing fully-oxidized RBAO preforms for only 20 min at 1550 $^{\circ}$C. Some care has to be taken, however, with such fast firing to avoid bloating. Bloating can occur if sintering at a specimen surface precedes complete removal of chemically-bound water (e.g., in the form of hydroxides) located deeper within the specimen. Preforms prepared with high compaction stresses from powders milled for extended times in water-bearing lubricants are particularly susceptible to such bloating (Holz *et al.* 1994).

With proper tailoring of the preform composition, phase content, and microstructure and with appropriate heat treatment conditions, easily-formed RBAO and VIMOX green bodies can be oxidized and converted into near net-shaped ceramics and ceramic composites with attractive properties. For example, dense (pressureless sintered) RBAO-derived Al$_2$O$_3$–ZrO$_2$ composites have been produced with fracture strengths and toughnesses of 700–800 MPa and 5–6 MPa m^{-2}, respectively. By incorporating metal or ceramic additives with larger oxidation-induced volume changes than for aluminum (e.g., Si, SiC, Zr, Cr), nearly zero shrinkage has been achieved by the reaction bonding process (Wu *et al.* 1993, Scheppokat *et al.* 1999). For example, porous preforms of Al–Al$_2$O$_3$–SiC–ZrO$_2$ have been converted into 93–99% dense composites of Al$_6$Si$_2$O$_{13}$ (mullite)

and ZrO_2 with net linear shrinkages of $\leqslant 1\%$ by slow heating in air (in some cases with several intermediate isothermal anneals) up to 1150–1200 °C, holding at this temperature for 15 h, and then sintering at 1550 °C (Scheppokat *et al.* 1999). Incomplete oxidation of the SiC has yielded $Al_6Si_2O_{13}/SiC/ZrO_2$-bearing composites with modest net shrinkages (e.g., $\leqslant 7\%$). The latter composites have exhibited fracture strength and toughness values of up to 610 MPa and 4.9 MPa m^{-2}, respectively.
A variety of functional, near net-shaped ceramics and ceramic composites have been fabricated by the VIMOX process for chemical, electronic, magnetic, gas-sensing, and biomedical applications. Such ceramics include refractory aluminates (e.g., $MgAl_2O_4$, $BaAl_2O_4$, $Ba(Sr)Al_2Si_2O_8$), dielectric or semiconducting titanates (e.g., $BaTiO_3$, $(Ba,Pb)TiO_3$), superconducting cuprates (e.g., $Bi_2Sr_2Ca_1Cu_2O_8$), magnetic ferrites (e.g., $BaFe_{12}O_{19}$), proton-conducting cerates (e.g., Nd_2O_3-doped $BaCeO_3$), water-sensitive chromates (e.g., TiO_2-doped $MgCr_2O_4$), and biocompatible phosphates (e.g., $Ca_{10}(PO_4)_6(OH)_2$). For example, machinable Ba(Sr)–Al–Al_2O_3–SiO_2-bearing preforms have been fully oxidized and converted into $Ba(Sr)Al_2Si_2O_8$ (celsian, a radome ceramic) bodies that retained the preform shapes with dimensional changes well under 1% (Sandhage *et al.* 2000, Viers and Sandhage 1999). Dense, machined Mg–Al_2O_3-bearing preforms have been fully oxidized and converted into dense bodies of spinel ($MgAl_2O_4$, a refractory ceramic) with dimensional changes of $\leqslant 0.6\%$ (Sandhage *et al.* 2000, Kumar and Sandhage 1998). Optical images of green-machined RBAO and VIMOX preforms, and corresponding fully-converted all-ceramic bodies, are shown in Fig. 1.

2. Net-shaped Ceramic/Metal(Intermetallic) Composites from Porous Oxide-bearing Preforms: The i-3A and DCP Methods

In the RBAO and VIMOX processes, a fluid oxidant (gaseous oxygen) is allowed to infiltrate into and react with shaped, metal-bearing preforms. A converse approach is to allow a fluid metal to infiltrate into and react with a shaped oxidant-bearing preform. The latter approach is the basis of two more recently developed, reactive infiltration techniques for fabricating dense, near net-shaped ceramic/intermetallic or ceramic/metal composites: the infiltration alumina aluminide alloy (i-3A) process and the displacive compensation of porosity (DCP) process.

A variety of high-melting, alumina–aluminide alloy composites can be fabricated at modest temperatures using the i-3A pressure infiltration process (Wagner *et al.* 1999, Schen *et al.* 1998). In this approach, a shaped, porous preform is first prepared by milling a mixture of a solid oxidant (e.g., TiO_2, Fe_2O_3, Nb_2O_5, ZrO_2) with a quantity of Al_2O_3. The

powder mixture is compacted and formed into a shaped green body that is then partially sintered under modest firing conditions (e.g., 30 min at 1250°C). Such sintering produces a rigid (inert) Al_2O_3 network that endows the green body with reasonable mechanical stability during infiltration and reaction. The mechanical stability may be further enhanced by adding water glass or ductile metals to the oxide-rich preform. The partial sintering treatment is also used to adjust the pore fraction of the preform to a predetermined value. By carefully controlling the preform porosity along with the volume fractions of solid oxidant and alumina, it is possible to produce dense, near net-shaped composites composed of tailored amounts of alumina and an intermetallic compound (Wagner *et al.* 1999, Schen *et al.* 1998). Consider the fabrication of dense $Al_2O_3/TiAl_3$ and $Al_2O_3/TiAl$ composites via the following displacement reactions:

$$3TiO_2(s) + 13Al(l) \rightarrow 2Al_2O_3(s) + 3TiAl_3(s) \quad (1)$$

$$3TiO_2(s) + 7Al(l) \rightarrow 2Al_2O_3(s) + 3TiAl(s) \quad (2)$$

The product of Eqn. (1) consists of 30.8 vol.% Al_2O_3 with 69.2 vol.% $TiAl_3$. In order to convert a preform undergoing this reaction into a $TiAl_3$-bearing composite with a higher alumina content, the preform should contain excess (inert) alumina. For example, a 60 vol.% Al_2O_3–40 vol.% $TiAl_3$ composite can be produced by the infiltration and reaction of molten aluminum with a 54.2% dense preform comprising 68.3 vol.% Al_2O_3 and 31.7 vol.% TiO_2 (rutile). (This calculation assumes that infiltration is conducted at 850°C, where the density of Al(l) is 2.332 g cm^{-3}, and that the reaction proceeds along with the infiltration.) If the preform density and alumina phase content are chosen to be 46.8% and 61.3 vol.%, respectively, then Al(l) infiltration and reaction should yield a dense composite of 60 vol.% Al_2O_3–40 vol.% TiAl (via Eqn. (2)). Similar calculations can be conducted for the fabrication of other well-defined 3A composites.

To enhance the rate of Al(l) infiltration, elevated gas pressure and direct squeeze casting have been used in the i-3A process (Wagner *et al.* 1999). With gas pressure infiltration, a porous specimen is immersed under a molten aluminum bath and the pressure of an inert gas (e.g., argon) over the bath is then gradually increased to a modest value for a short time (e.g., 12 MPa for 10–20 min). After infiltration, the preform is raised out of the melt and cooled to room temperature. With squeeze casting, the preform is preheated (e.g., to 600 °C) and then quickly placed into a heated die (e.g., at 300–600 °C). Molten aluminum is then poured into the die and a ram is used to squeeze Al(l) into the porous preform. After solidification of the aluminum, the infiltrated preform and excess solid aluminum are removed from the die.
Figure 1
Optical images of: (a) a machined Al–Al$_2$O$_3$–ZrO$_2$-bearing green body; (b) a similar body after full conversion into a low-shrinkage Al$_2$O$_3$/ZrO$_2$ composite (RBAO process); (c) a Mg–Al$_2$O$_3$-bearing green body; and (d) the resulting MgAl$_2$O$_4$ body (VIMOX process (Kumar and Sandhage 1998)). Dimensional changes at the positions A, B, and C in Figs. (c) and (d) were ⩽0.6%.

Although squeeze casting results in particularly rapid infiltration (i.e., 6 mm thick preforms can be completely infiltrated within a fraction of a second (Beyer *et al.* 2000)), additional processing must be undertaken to remove the excess solidified aluminum surrounding the specimen and possibly to complete the displacement reaction.

Displacement reactions between molten aluminum and solid oxidants tend to be relatively exothermic (e.g., the standard enthalpy per mole of reaction in Eqn. (1) is 1120 kJ at 850 °C). Such evolved heat can dramatically enhance the rate of reaction at modest applied temperatures. Indeed, dense, fully-reacted Al$_2$O$_3$–TiAl$_3$-bearing and Al$_2$O$_3$–NbAl$_3$–Nb$_2$Al-bearing composites have been produced by gas pressure infiltration of Al(l) into Al$_2$O$_3$/TiO$_2$ and Al$_2$O$_3$/ Nb$_2$O$_5$/NbAlO$_4$ preforms, respectively, at peak pressures of 12 MPa for ⩽20 min at ⩽850 °C (Wagner *et al.* 1999, Schen *et al.* 1998). In the case of squeeze casting, where the residence time of molten aluminum in the preform can be very short (≪1 s), a secondary heat treatment at a modest temperature may be required to complete the reaction (e.g., 640 °C for 4 h to produces an Al$_2$O$_3$–TiAl$_3$-bearing composite (Wagner *et al.* 1999)). Because the net volume change upon completion of the i-3A displacement reaction is negative (e.g., −19.6% for the reaction in Eqn. (1) above), some internal porosity can develop if such a secondary heat treatment is conducted in the absence of excess aluminum surrounding the preform. Alumina-bearing composites reinforced with a variety of interpenetrating intermetallic compounds

(e.g., TiAl$_3$, FeAl, NbAl$_3$, Nb$_2$Al) have been produced by the i-3A process.

The DCP process also involves the conversion of porous ceramic-bearing preforms into dense composites by the reactive infiltration of molten metals. However, unlike the i-3A method, the ceramic products of DCP-type reactions possess larger volumes than the ceramic reactants (Kumar and Sandhage 1999, Rogers *et al.* 1999). Such reaction-induced increases in ceramic volume can be used to fill the prior pore spaces (i.e., reaction-induced densification of the ceramic preform). The infiltration of shaped, rigid, partially-sintered preforms, followed by complete reaction at internal solid/liquid interfaces, can yield dense ceramic-rich composites that retain the shape and external dimensions of the starting preforms. Examples of two DCP-like reactions are:

$$3Mg(l) + Al_2O_3(s) \rightarrow 3MgO(s) + 2Al(l) \qquad (3)$$

$$3Mg(l) + 4Al_2O_3(s) \rightarrow 3MgAl_2O_4(s) + 2Al \qquad (4)$$

The reactions in Eqns.(3) and (4) are thermodynamically favored for Al–Mg melts containing more than about 0.3 at.% Mg and about 7.1 at.% Mg, respectively, at 1000 °C. Hence, as for the i-3A approach, these DCP reactions can be conducted with Al-rich melts. The volume of 3 moles of MgO is 31.9% larger than the volume of 1 mole of Al$_2$O$_3$, whereas the volume of 3 moles of MgAl$_2$O$_4$ is 16.6% larger than the volume of 4 moles of Al$_2$O$_3$. Consequently, a porous Al$_2$O$_3$-bearing preform can be converted into a MgO-bearing or MgAl$_2$O$_4$-bearing composite with a higher ceramic content than in the starting preform. Indeed, by adjusting the porosity and phase content of the DCP preforms along with the melt composition, fully-reacted ceramic/metal composites with a wide range of phase contents (i.e., from discontinuous to continuous metal reinforcements) and compositions can be directly produced. For example, 71%-dense Al$_2$O$_3$ preforms have been pressureless-infiltrated and reacted with pure Mg(l) at 1000 °C to produce composites of 86 vol.% MgO + 14 vol.% Mg–Al alloy; in this case, the metal phase was discontinuous, as demonstrated by electrical conductivity measurements (Kumar and Sandhage 1999, Rogers *et al.* 1999). Cocontinuous MgAl$_2$O$_4$/Fe–Ni–Al alloy-bearing composites (with 42–59 vol.% oxide) were fabricated by the pressureless infiltration and reaction of Mg–Al liquid at 900 °C with porous preforms comprising mixtures of Fe and NiAl$_2$O$_4$ (Rogers *et al.* 1999). Such DCP-derived composites were dense and retained the shapes and dimensions of the starting porous preforms to within a few percent (Kumar and Sandhage 1999, Rogers *et al.* 1999).

Near net-shaped oxide/metal and oxide/intermetallic composites with attractive, tailorable properties can be produced by the i-3A and DCP methods using low-temperature, low-cost casting technology. Lightweight Al$_2$O$_3$/TiAl$_3$ composites produced by the i-3A method have exhibited average strength and toughness values of 540 MPa and 8.6 MPa m^{-2}, respectively (Wagner *et al.* 1999, Schen *et al.* 1998). MgAl$_2$O$_4$/Fe–Ni–Al alloy-bearing composites produced by the DCP method have exhibited average strength and toughness values of 380 MPa and 11.3 MPa m^{-2}, respectively (Rogers *et al.* 1999). Composites that are electrically conductive (i.e., with a continuous metal or intermetallic phase) or electrically insulating (i.e., with a discontinuous metal phase) have also been fabricated (Wagner *et al.* 1999, Kumar and Sandhage 1999, Rogers *et al.* 1999).

Reactive Ceramic Nanocomposites with Organic and Bio-organic Phases

Ceramics and glasses can be modified into useful functional materials by doping with organic molecules, including proteins, via the sol–gel process. Taking into account the vastness of organic chemistry with its 23 million molecules and endless reactions, it becomes obvious that this new trend in materials chemistry ensures plenty of applications. This article provides some representative studies, mainly since the early 1980s, which marked the emergence of this field from obscurity into a self-contained domain of research and development (Avnir *et al.* 1998).

1. General Aspects of Doping of Sol–Gel Materials with Organic and Bioorganic Molecules

The inherent difficulty in combining organic chemistry with glass and ceramic chemistry which the ambient-temperature sol–gel process has successfully solved, is the temperature barrier. Organic compounds rarely survive temperatures higher than $200\,^{\circ}C$ and biomolecules far less. It is for this reason that over the millennia of the history of ceramics and glass production, one finds that the only additives, e.g., colorants, which could withstand the high temperatures were inorganic salts and other oxides. The sol–gel process has thus closed the ceramics–organic gap by utilizing it up to the porous xerogel stage.

Most of the inorganic oxides, MO_n (where M is a metal or semimetal, and n is not necessarily an integer) as well as many mixed oxides, have been used for this purpose (Brinker and Scherer 1990). Many studies concentrated on SiO_2 as a convenient model, although for most applications described below this need not be the optimal matrix, and one may also consider other oxides such as TiO_2, ZrO_2, Al_2O_3,

composites such as SiO_2–ZrO_2, and organically modified matrices obtainable by either inorganic–organic copolymerizations or by the use of organic substituents on the inorganic precursor. The formation of the sol–gel materials is through the hydrolysis–polycondensation of monomers such as tetramethoxyorthosilicate (TMOS), but many other alkoxides, aryl oxides, and esters, chlorides and metal–nitrogen compounds can be used. The resulting materials—$(SiO_nH_m)_p$ in the case of, e.g., TMOS—are highly porous with pore size distributions centered typically around several tens of angstroms with surface areas of several hundreds of square meters per gram in most cases. The doping procedure is simple: the guest molecule is added to the polymerizing mixture either to the solution of monomers, or to a sol obtained by partial prehydrolysis and condensation. When the polycondensation is completed, the dopant molecules are entangled in the inorganic polymeric network. Intensive studies (Avnir 1995) of organic molecules thus entrapped in sol–gel matrices have provided the following generalizations.

- Practically any desired molecule can be entrapped in sol–gel matrices.
- The entrapped molecule usually retains its characteristic physical properties. Of the many consequent applications, optical applications are the most developed.
- The entrapped molecule usually retains its chemical properties. Chemical reactions and interactions are thus possible.

Since this article focuses on applications of *reactive* organically doped sol–gel silicas, it is in order to mention some of the other properties which have contributed to the attractiveness and versatility of this approach. These include chemical, photochemical, and electrochemical inertness, thermal stability of the matrix, the ability to induce electrical conductivity (Tsionsky *et al.* 1994), the controllability of matrix structural properties and the many ways available to modify chemically the matrix and its surface, the enhanced stabilization of the entrapped molecule (Negishi *et al.* 1994), the ability to employ the chromatographic properties of the matrix for enhanced selectivity and sensitivity of reactions with the dopant, the simplicity of the entrapment procedure which does not require chemical modification of the dopant, and the ability to obtain the doped sol–gel materials in any desired form, including powders, monoliths, films, fibers, stable sols and more.

Within the family of reactive doped sol–gel materials, this article concentrates on three major areas: organometallic catalysis, enzymatic reactivity, and sensing processes. Several other important classes, e.g., photochromic isomerizations (Levy *et al.* 1989) are not included for lack of space. The huge field of organically doped sol–gel optics (Klein 1994, Jorgensen and Reisfeld 1996) is also omitted, which

includes useful materials such as light filters, luminescent materials, light guides, light collectors, dye-laser components, photochromic materials, hole-burning materials, optical memory materials, nonlinear optical materials, and liquid crystal displays (Levy *et al.* 1997). Information on such systems is given in *Ceramic Nanocomposites with Organic Phases, Optics of* *.

2. Catalysis with Entrapped Organic Complexes

Sol–gel materials have a long history in serving catalysis. Celebrated examples are the pioneering studies of Teichner *et al.* (Bianchini *et al.* 1981) who used as catalysts the pure oxides (e.g., alumina), the use of mixed oxides, such as NiO–alumina–silica (Monaco and Ko 1998, Livage 1998), the use of sol–gel supports such as silica, alumina, and titania for the preparation and entrapment of dispersed metals (Gonzales *et al.* 1997), and the copolymerization of pure metal–alkoxides with metal alkoxide derivatives which carry as a substituent an organic metal ligand (Lorenz *et al.* 1997). This section concentrates on the direct physical entrapment approach, in contrast to catalysts which carry covalently bound organic moieties. Physical entrapment has enabled the conversion of a variety of soluble metal compounds into leach-proof recyclable catalysts that usually proved to be more stable under ambient conditions than their homogeneous analogues. These heterogeneous catalysts are highly selective, but are limited to reactions with substrates which can penetrate the small pore network of the sol–gel matrix to reach the catalyst.

A wide range of organometallic catalysts of differing natures can be entrapped in sol–gel materials. Representative examples include $RhCl_3–[(C_4H_9)_4N]Cl$, $RhCl_3–[(C_7H_{15})_4N]Br$, $RhCl_3–[(C_8H_{17})_3NMe]Cl$, $RhCl_3–[(C_{16}H_{33})P(C_4H_9)_3]Br$, $PtCl_4–[(C_8H_{17})_3NMe]Cl$ (Blum *et al.* 1996, Rosenfeld *et al.* 1996), $RuCl_2(PPh_3)_3$, $RhCl(PPh_3)_3$, $IrCl(CO)(PPh_3)_2$, η^5-$C_5H_5Rh(CO)_2$, η^5-$C_5H_5Rh(cod)$, $[Rh(CO)_2(\mu\text{-}Cl)]_2$, $[Rh(CO)PPh_3(\mu\text{-}Cl)]_2$, $[Rh(CO)(PPh_3)(\mu\text{-pyrazolate})]_2$ (Sertchook *et al.* 1996, Schumann *et al.* 1998), heterodinuclear complexes such as $Co_2Rh_2(CO)_{12}$ (Labroue and Poilblanc 1977), hydrophilic catalysts such as $RuCl_2[Ph_2P(3{-}C_6H_4SO_3Na)]_2 \cdot 4H_2O$, $RuCl[Ph_2P(3{-}C_6H_4SO_3Na)]_2 \cdot 4H_2O$ and $IrCl(CO)[Ph_2P(3{-}C_6H_4SO_3Na)]_2$, and more.

Representative examples for the applications of these catalysts are the hydrogen transfer processes. The first case is the disproportionation reaction of *vic*-dihydroarenes. In a typical application of the sol–gel methodology, the entrapped ion pair $[(C_8H_{17})_3NMe]^+[RhCl_4 \cdot nH_2O]^-$ affected a series of 1,4-dihydroarenes, yielding exclusively the expected disproportionation products in equimolar quantities, whereas under similar conditions, the nonimmobi-

lized ion pair proved practically inactive (Rosenfeld *et al.* 1996). The rate of disproportionation by the sol–gel encapsulated ion pair was found to depend on the sizes and steric constraints of the starting materials. For instance, under comparable conditions the respective conversions of 1,3-cyclohexadiene, 1,2-dihydronaphthalene, 1,2-dihydro-4-methylnaphthalene, 1,2-dihydro-4-ethylnaphthalene, 1,2-dihydro-8-methoxynaphthalene, 1,2-dihydrophenanthrene, 3,4-dihydrophenanthrene, and 10,11-dihydrobenz[*a*]anthracene were 96, 99, 41, 17, 87, 73, 50, and 23%. This set of experiments emphasizes the difference between catalysis by zeolites and sol–gel catalysis. Zeolites are usually limited to a single substrate, whereas sol–gel catalysts can be utilized for a family of substrates, albeit with different efficiencies and rates. There are advantages and specific applications to each of these types of catalysts. The sol–gel entrapped $[(C_8H_{17})_3NMe]^+[RhCl_4 \cdot nH_2O]^-$ was found to be perfectly leach-proof during the disproportionation processes (amount of leached metal $\ll 1\,\mathrm{ppm}$) and could be recycled for 10–20 runs.

The second case for catalytic hydrogen transfer is double bond migration (Parshall and Ittel 1992). An example is 1-octen-3-ol which can be catalytically isomerized by sol–gel-entrapped $RhCl(PPh_3)_3$ to 3-octenone. Entrapment in a silica sol–gel matrix increases the catalytic activity. The catalytic properties of the encapsulated catalyst were found to depend on the structural features of the sol–gel matrix, and a rough correlation exists between the catalytic activity and the surface area. Thus, when the components of $[(C_8H_{17})_3NMe]^+[RhCl_4 \cdot nH_2O]^-$, $(RhCl_3 \cdot 3H_2O$ and $[(C_8H_{17})_3NMe]Cl)$ have been entrapped in sol–gel matrices prepared from tetramethoxy-, tetraethoxy-, tetrapropoxy- and tetrabutoxysilane (TMOS, TEOS, TPOS, and TBOS, respectively), under identical conditions, the N_2-Langmuir surface areas of the corresponding immobilized catalysts were 722, 539, 975, and $603\,\mathrm{m^2 g^{-1}}$ (the average pore diameter was 14–15 Å in the four matrices), and the respective initial rates of allylbenzene isomerization by these catalysts were found to be 1.00, 0.23, 2.10, and $1.40\,\mathrm{mmol \cdot min^{-1} \, ml^{-1}} \times 10^{-2}$.

Catalytic hydrogenations and hydrogenolyses by sol–gel entrapped ion-pairs are further examples, and these are described in Blum *et al.* (1996). Since the sol–gel entrapped catalysts, e.g., $[(C_8H_{17})_3NMe]^+[RhCl_4 \cdot nH_2O]^-$, withstand temperatures as high as 130 °C and hydrogen pressures as high as 60 atm, conditions under which the catalyst decomposes in solution, one can hydrogenate unsaturated substrates that are not affected by the nonencapsulated catalyst, a typical example being benzonitrile (Blum *et al.* 1996). Of environmental importance are the dehalogenation reactions. Thus, fluoro- and chloroarenes undergo hydrogenolysis with the catalyst at 16.5 atm hydrogen to give halogen-free cyclohexane derivatives.

Sol–gel entrapped chiral catalysts that include (*R*)-(+)- and (*S*)-(−)-2,2′-[bis(diphenylphosphino)-1,1′-binaphthyl]chloro(*p*-cymene)ruthenium chloride (Ru-BINAP), [(4*S*,5*S*)-(+)- and [(4*R*,5*R*)-(−)-[4,5-bis(diphenylphosphinomethyl)-2,2′-dimethyl-1,3-dioxalene]chlororhodium (Rh-DIOP), and [(2*S*,4*S*)-(−)-1-*tert*-butoxycarbonyl-4-diph enylphosphino-2-(diphenylphosphinomethyl)pyrrolidine]chlororhodium, (Rh-BPPM) (Gelman *et al*. 1999) have been used for asymmetric hydrogenation of the prochiral itaconic acid (Kawano *et al*. 1987). Thus, enantioselective hydrogenation of itaconic acid with Rh-BPPM entrapped in silica sol–gel resulted in leach-proof material which catalyzed quantitatively itaconic acid into (−)-2-methylsuccinic acid of 78% optical purity, the value reported for the same reaction using the nonimmobilized Rh-BPPM catalyst (Ojima and Kogure 1978). The ability to employ the heterogenized complexes in an aqueous medium should be noticed here, since their nonentrapped, water-insoluble analogues are completely inactive in this environmentally friendly solvent.

The transparency of silica sol–gel material makes them particularly suitable for photocatalysis. Remaining in the organometallic catalysis domain, a representative case is the photocatalyzed reduction of protons to hydrogen, using ruthenium and iridium bipyridyl complexes coentrapped as an isolated donor–acceptor pair in a silica sol–gel matrix (Slama-Schwok *et al*. 1991). For a summary of representative sol–gel photocatalyses see Castelano and Meyer (1997).

3. Biochemical Reactivity with Entrapped Proteins

One of the fastest growing fields within doped sol–gel materials is the entrapment of purified enzymes, cell extracts, whole-cells, antibodies, and other proteins (Livage 1996). Various applications of these novel bioreactive materials have been developed including biosensors (see Sect. 4), immunoadsorbents, optical components, environmentally-related materials, and biotechnology-related materials. Some of the properties that have contributed to the attractiveness of this immobilization methodology are the enhanced stability of the encapsulated molecules (Zheng *et al*. 1998), the absolute prevention of leaching of the proteins due to the effective caging, the ability to immobilize without resorting to covalent modification of the protein, and protection against enzymatic autodigestion. One of the most studied enzymes in this context has been glucose oxidase, reviewed elsewhere (Avnir *et al*. 1994a) (see also Sect. 4). Many other enzymes have been studied; some representative examples which demonstrate the scope and potential of this field are given below. (For additional examples see Avnir and Braun 1996, Dunn *et al*. 1998.)

3.1 Alkaline Phosphatase

This was an early case of enzyme entrapment by the direct use at TMDS (Braun *et al*. 1990) which triggered many enzyme entrapments to come. When entrapped in SiO_2 sol–gel and dried, its dose–response curve as determined by the phosphate bond cleavage of *p*-nitrophenyl phosphate did not fit a Michaelis–Menten model, but reflected a distribution of activity efficiencies of the individually trapped molecules. These variations in activity may be the result of different accessibilities of the individual active sites to the pore network in which the substrate resides, or the result of various degrees of denaturation caused by the sol–gel process. However, it was later found in many studies that when the gel was kept wet, the linear Michaelis–Menten behavior was retained. In any event, even in its dried entrapped form, alkaline phosphatase was proven to gain stability, and it retained its full activity for at least two months. One may attribute this enhanced stability to the protective nature of the cage itself and to the rigidity of the SiO_2 matrix which reduces the freedom of peptide-chain refolding molecular motions which occur in denaturation processes. For other representative studies of this group, particularly on trypsin see, e.g., Shtelzer *et al*. (1992).

3.2 Cytochrome c

Cytochrome *c* entrapped in silica sol–gel materials was studied in detail by Dunn *et al*. (Miller *et al*. 1996). The effects of several key parameters was studied (pH, alcohol/alkoxide ratio, buffer type) and it was found that the behavior of the protein encapsulated in silica gels mirrored their behavior in solution. This suggests that the stability limiting factor for encapsulating these biological molecules is determined by the solution stability of the protein. Entrapped cytochrome *c* was capable of undergoing redox processes exhibiting reversible changes in the oxidation state of iron upon addition of either hydrogen peroxide or sodium dithionate. Again, an important advantage of the sol–gel methodology was revealed: the thermal stability of cytochrome *c* was significantly improved by immobilization in a porous silica network (Lan *et al*. 1999).

3.3 Invertase

Invertase entrapment was used to demonstrate the usefulness of sol–gel materials beyond silica (Kurokawa 1996). Thus, gel fibers were formed from cellulose acetate and titanium as well as zirconium alkoxides. These proved to be stable in common solvents, phosphate solution, and electrolyte solution over a wide range of pH, from 4 to 10. The immobilized enzyme was found to be stable for long

periods and was used in a packed column. The pH maximum of activity became more alkaline compared with the native enzyme, reflecting the amphoteric property of the metal oxide.

3.4 Calcium-binding Protein Oncomodulin

This was studied by Brennan and co-workers, providing a methodology for improving further the thermal stability of entrapped proteins (Zheng *et al.* 1998). These authors showed that the performance of the sol–gel-entrapped protein can be improved substantially by maximizing the protein's thermodynamic stability so that it can withstand the harsh conditions associated with entrapment. Two mutants of the protein were entrapped, and the thermodynamic stability of both proteins could be manipulated by adjusting the level of calcium ions present during entrapment.

3.5 Lipase

Lipase entrapment, studied by Reetz *et al.*, demonstrated that sol–gel matrices can greatly enhance the activity of the sol–gel immobilized enzyme, as compared with its solution activity (Reetz *et al.* 1996). The enhancement of activity was achieved by entrapping lipases in hydrophobic organic/inorganic hybrid silica gels, prepared by hydrolysis of alkyl-substituted silanes in the presence of the enzyme. The method is applicable for a wide variety of lipases, yielding immobilized lipases with esterification activities enhanced by a factor of up to 88 compared with the commercial enzyme powders under identical conditions. Studies of the stability of sol–gel immobilized lipases under reaction conditions or storage (dry or in aqueous or organic medium) revealed an excellent retention of enzymatic activity. "Magnetic lipase" was prepared by mixing lipose with a paste of ferrite powder, tetramethoxysilane, 3-aminopropyltriethoxysilane, and propyltrimethoxysilane (Kuncová and Sivel 1997).

3.6 Bacteriorhodopsin

Bacteriorhodopsin was used to demonstrate the advantages of entrapping a photoreactive protein (Weetall 1996). From it, purple membrane fragments were isolated and entrapped in dried sol–gel glass. Samples showing constant activity when stored at 4 °C lost further activity at room temperature, eventually reaching a level where the activity remained constant.

3.7 Alcohol Dehydrogenase

Alcohol dehydrogenase entrapped in silica sol–gel was shown to withstand harsh nonaqueous and gas-phase environments (Williams and Hupp 1998).

Furthermore, it was demonstrated that cofactors can be used with entrapped enzyme—specifically, the pairs ADH/NAD$^+$ or ADH/NADH. The utilization of changes in fluorescence from the soluble, reduced cofactor NADH upon exposure to alcohols or aldehydes allows for semiquantitative determination of both substrates.

3.8 General Enzyme Entrapment

A general enzyme entrapment methodology has been described by Gill and Ballesteros (1998). The paper describes a class of sol–gel precursors based on polyol silicates and polyol siloxanes. In particular, poly(glyceryl silicate) provided high biocompatibility and mild encapsulation conditions, and enabled the reproducible and efficient confinement of a wide variety of proteins and cells inside silica. The methodology was extended to metallosilicate, alkylsiloxane, functionalized siloxane, and composite sol–gels, thereby allowing the fabrication of a physicochemically diverse range of bio-doped polymers. The hybrid materials displayed activities approaching those of the free enzymes and proteins, together with the high stabilities and robustness that characterize sol–gel bioceramics.

3.9 Cells and Whole Cell Extracts

These have been entrapped successfully in sol–gel matrices. An example is the silica sol–gel entrapment of parathion hydrolase extracted from *Pseudomonas* spp. (Dozorets *et al.* 1996). Another example is the study of Kaufmann and Mandelbaum (1998) in which atrazine chlorohydrolase from cell extracts of *Pseudomonas* was immobilized successfully in hydrophobic sol–gel matrices, and used for detoxification of this hazardous environmental pollutant. Carturan *et al.* (Inama *et al.* 1993) studied the sol–gel encapsulation of whole yeast cells (*Saccharomyces cerevisiae* as spores) using SiO$_2$ sols. This prehydrolysis approach, also used for enzyme entrapment, e.g., by Johnson (Johnson and Whateley 1971), predated the advent of the sol–gel metal alkoxide polymerization procedures.

3.10 Antibodies

Antibodies entrapped in sol–gel materials comprise our last but very interesting case (Aharonson *et al.* 1994). An application as an immunochromatographic material was demonstrated by Knopp *et al.* (Fröschl *et al.* 1998) who constructed a polyclonal-based 1-nitropyrene enzyme-linked immunosorbent assay (ELISA) methodology for environmental analytical chemistry for screening purposes. A different configuration was demonstrated by Roux *et al.* (1997). These authors succeeded in the encapsulation of

antigens, and showed that the pores of the sol–gel matrix are large enough to allow the diffusion of antibodies through the gel. They successfully performed ELISA immunoassays using hydatid cyst fluid as the source of antigens and sera from human patients as the source of antibodies. Finally, Shabat *et al.* (1997) demonstrated the first successful entrapment of catalytic antibodies. These materials, which in this case were used for the continuous-flow column synthesis of optically pure enantiomers, carry great potential for many other syntheses.

4. Sol–Gel Sensors

A chemical sensor is a small device comprising a molecular recognition system embedded within or on a supporting matrix and equipped with a signal translation and quantitation capability. Extensive sol–gel research efforts have been devoted to the optimization of each of these elements for different end applications and for improving the synergism between the inorganic and organic ingredients of the hybrid sensors (Collinson 1998). Sol–gel doping provides opportunities to benefit from the very large number of organic and biochemical molecular recognition reagents, including high selectivity, and still benefit from the favorable physical properties of silicates and Ormosils (organically modified silicas) as detailed earlier.

4.1 Molecular Recognition

The first series of reports on sol–gel sensing demonstrated the ability to incorporate molecular recognition elements in sol–gel-derived silicate monoliths by sol–gel doping (Zusman *et al.* 1990, Braun *et al.* 1990, Ellerby *et al.* 1992, Rottman *et al.* 1992, Lev 1992, Iosefzon *et al.* 1992, Dave *et al.* 1994). Colorimetric reagents were encapsulated in sol–gel-derived silicates, and color evolution was monitored after exposure of the doped monolith to liquid or gaseous environments. These reports illuminated two fundamental properties of doped sol–gel materials, which make them suitable candidates for sensing applications. They allow penetration of foreign molecules from the surrounding gas or liquid phase into the gel and further enable the participation of the diffusing compounds in molecular recognition interactions within the glass network. Proton transfer reactions (e.g., with pH indicators), reversible or irreversible redox reactions, complex formation, and enzymatic reactions involving diffusing analytes and organic dopants were demonstrated in the porous solid phase. The first reports on sol–gel sensing also made an important distinction between continuous and disposable sensors, which can both be realized by sol–gel doping technology (Lev 1992). Later, successful entrapment of immunoglobulins in

sol–gel matrices opened the door for optical and electrochemical immunoassay—ELISA-type—detection (Roux *et al.* 1997, Turniansky *et al.* 1996, Fröschl *et al.* 1998, Wang *et al.* 1998).

It was soon found that the porous sol–gel matrix provides sufficient connectivity to enable communication between different functionalities that are not necessarily embedded in the same pore. Multiligand chelate formation and multistep reactions within the glass phase exemplify this property. For example, iron(II) forms red, three-ligand chelates with 1,10-phenanthroline. This is a convenient analytical method for the determination of iron in aqueous environments. Electron spectroscopy shows that the very same chelate is formed within the glass phase when 1,10-phenanthroline-doped sol–gel glasses are immersed in aqueous solution containing ferrous cations (Iosefzon-Kuyavskaya *et al.* 1992). The ability to carry out multiple reactions employing different catalysts or biocatalysts within the sol–gel matrix is another attractive feature. This is used in integrated sol–gel sensors, where different dopants participate or catalyze different reactions (Lev *et al.* 1992, Wolfbeis *et al.* 1996, Avnir 1995). For example, optical (Avnir *et al.* 1994b) and amperometric (CocheGuerente *et al.* 1997) glucose sensing can be carried out by sol–gel materials doped with glucose oxidase, horseradish peroxidase, and a chromophore or charge mediator. Glucose is oxidized by the flavin prosthetic group of the glucose oxidase, which is then regenerated by oxygen to give hydrogen peroxide. The hydrogen peroxide is further biocatalytically reduced by a dye-forming reaction or by a charge mediator that shuttles the electrons to a conductive part of the electrode. Multienzyme catalysis is now routinely used for sensing applications (Avnir *et al.* 1994a).

4.2 Tailoring Sol–gel Composition for Specific End Applications

It was soon found that specific preparation protocols and different composition of the Ormosils should be tailored in order to meet the specifications of target end applications. This can be exemplified by the innovative remedies devised for a major problem that was raised in sol–gel infancy—the leaching of the dopants from sol–gel sensors during prolonged operation. Altering the dopant or the supporting matrix, and the interaction between the two solved this problem in many cases. It is relatively simple to construct leak-free sol–gel films and monoliths for high molecular weight proteins and synthetic polymer dopants. This approach was used to construct an electrochemical sensor for glucose using glucose oxidase-bound ferrocene (Sampath *et al.* 1996a). Osmium redox polymer was also embedded in sol–gelderived electrochemical biosensors for hydrogen

peroxide (Park *et al.* 1996). Zero leaching of the ferrocene and osmium mediators was reported even after prolonged operation periods.

Altering the silicate matrix was another successful approach. Carrying out the sol–gel polymerization under low pH gives rise to extremely small pore-size gels, which prevent leakage of the pH indicators (Aharonson *et al.* 1994). This approach is successful only for low-molecular weight analytes. McDonagh *et al.* (1998a) devised an innovative solution to prevent leakage of ruthenium complex dyes from their oxygen sensors. Quenching of the ruthenium fluorescence by oxygen was used to quantify the dissolved oxygen level. The ruthenium complex was embedded in hydrophobic methyltriethoxysilane-derived matrix. The hydrophobic matrix enhanced penetration of the uncharged oxygen analyte, whereas water was excluded from the sensing element.

Another approach to prevent leaching is to increase the affinity between the dopant and the silicate network. This can be accomplished by designing Ormosil networks containing functional groups that bind the dopant by electrostatic or hydrophobic interactions (e.g., Kraus *et al.* 1993, Lobnik and Wolfbeis 1998). Covalent bonding of reagents to pre-prepared sol–gel materials or to silyl monomers is increasingly used to prevent leaching from optical (Aharonson *et al.* 1994) and electrochemical sensors (Gun and Lev 1996).

4.3 Optical Sensing

Optical sol–gel sensing has matured since the first colorimetric feasibility studies were demonstrated in the early 1990s. Practically all major types of photometric sensing, including absorbance, plasmon resonance, fluorescence, room-temperature phosphorescence, and chemiluminescence spectroscopies, have been successfully carried out in doped sol–gel silicates (e.g., Wolfbies *et al.* 1996, Avnir 1995, Lev *et al.* 1995). Several examples depicted in Fig. 1 demonstrate the versatility in tailoring optical sensors of various configurations.

(*a*) *Fiber optic sensors*. Three modes of fiber optic photometric sensors have been proposed. In the simplest mode, optical fibers are used only to guide the light from the doped sol–gel sensor (Fig. 1(a)). This approach was used for pH sensing (Rottman *et al.* 1992). Grattan *et al.* (1991) used a similar approach for fluorescence pH detection with fluorescein isothiocyanate indicator (Fig. 1(b)). A related technique based on the modification of the optical fiber itself has also been developed. An unclad section of a home-made, porous optical fiber was infiltrated with the sol–gel precursors and pH indicators. This configuration (Fig. 1(c)) benefits from a long optical pathway, short analyte diffusion length, and simple
Figure 1
Configuration of reagent-doped sol–gel waveguides (after Lev *et al.* 1995, with permission). (a) Direct mode transmission sensor (Rottman *et al.* 1992); (b) fluorescence- or reflection-mode sensor (Grattan *et al.* 1991); (c) sol–gel-modified porous optical sensor (Shariari *et al.* 1994); (d) evanescent optical fiber sensor (McDonagh *et al.* 1998a); (e) planar waveguide evanescent sensor (Yang *et al.* 1994); (f) capillary flow-through evanescent sensor (Weigl and Wolfbeis 1994). 1: Sample; 2: optical fiber; 2a: core; 2b: cladding; 2c: uncladded section; 3: source; 4: photodetector, 5: auxiliary coupling; 6: sol–gel sensor; 7: optical mirror; 8: doped sol–gel glass; 9: doped sol–gel film; 10: planar glass support; 11: glass capillary.

optical coupling auxiliaries. A third approach, developed by McDonagh *et al.* (1998a, 1998b) is based on evanescent wave fluorescence excitation and involves pH sensitive sensors made by dip-coating unclad, fused-silica optical fiber with a fluorescein-doped sol–gel film (Fig. 1(d)). Such evanescent wave sensors benefit from a long optical path length, relatively low dye bleaching in laser-irradiated fiber optic sensors, and the large contact area between the film and the examined environment.

 (*b*) *Other waveguide configurations.* Sensing applications often require irregular sensor configurations; for example, planar and capillary tube waveguide configurations are useful in flow-cell detectors. Yang *et al.* (1994) devised a planar waveguide pH sensor made from a microscope slide coated with a bromophenol blue-doped thin silica film (Fig. 1(e)). In this configuration the microscope slide operates as a waveguide and the doped film as a sensing cladding. In another application Weigl and Wolfbeis (1994) proposed a sol–gel-coated capillary sensor in which the capillary tube acts as a core, as a reagent-doped coating, and as a cladding (Fig. 1(f)). This configuration can be used for flow-through detectors and also as disposable capillary suction detectors that provide accurate sampling volumes.

 (*c*) *Near-field optical sensors.* A demonstration of a way to push miniaturization of doped sol–gel sensors to the limit is the near-field optical sensor. Samuel *et al.* (1994) polymerized a pyranine-doped silicate microdot on the tip of a drawn glass capillary. A light beam was directed through the capillary with the sensing tip inducing pH-dependent fluorescence that was detected by a stationary photodetector. This device exhibited a response time of less than one second and reversible pH detection. Near-field microscopy opens the door to intracellular sensing and micron-resolution spatial pH mapping.

4.4 Electrochemical Sensing

The rapid development of optical doped sol–gel applications was soon followed by a parallel development of electroanalytical applications. Several reviews discuss the progress in this field (Lev *et al.* 1997, Walcarius 1998, Tess and Cox 1999, Collinson 1998, Alber and Cox 1997). Despite the fact that the diffusion coefficients of organic compounds in the silicate films are very low, the feasibility of sol–gel electrochemistry and bioelectrochemistry with doped silicates was soon proven. Dvorak and Armond (1993) made use of the favorable optical transparency of silicate films to demonstrate the photoelectrochemical activity of tris(2,2′-bipyridyl)ruthenium. The observed quantum yield was low and the electrochemical response was rather sluggish but feasibility was indeed demonstrated. Tatsu *et al.* (1992) constructed the first sol–gel glucose flow-injection

analyzer using glucose oxidase-doped inorganic silicate powder which was attached to an oxygen electrode by an external cellulose membrane. Oxygen depletion was used for quantification of the converted glucose.

Since these initial feasibility studies, electroanalytical studies have shifted towards doped Ormosils and composite materials which seem to provide higher diffusion rates and less sluggish electrochemistry. Indeed, within a relatively short period of time several potentiometric (e.g., Kim *et al.* 1997, Kimura *et al.* 1996), amperometric (e.g., Hsueh and Collinson 1997, Hu *et al.* 1998), and bioelectrochemical (e.g., Audebert *et al.* 1993, Narang *et al.* 1994, Pandey *et al.* 1999) applications where demonstrated for sol–gel-derived electrodes. Moreover, several reports of permselectivity of native and doped silicate and Ormosil modified electrodes were published (e.g., Collinson 1998).

4.5 Composite Materials Employing More Than One Phase

Increasing attention is also being devoted to composite materials employing more than one phase. For example, carbon ceramic composite electrodes (CCEs) and related sol–gel composites are attracting increased interest due to their versatility and improved electrochemical performance (e.g., Tsionsky *et al.* 1994, Gun *et al.* 1994a, 1994b, Wang *et al.* 1996). The basic ingredients of CCEs are graphite or carbon black powders dispersed in an Ormosil (e.g., methylsilicate) sol–gel network. The carbon or graphite powder provides electrical conductivity by an electron percolation mechanism, and the porous silicate matrix contributes rigid and brittle construction. The hydrophobicity of the methyl modifiers prevents water penetration into the electrode, and thus only the outermost section of the electrode remains in contact with the electrolyte. These electrodes showed an improvement of up to three orders of magnitude in Faradaic signal/background (capacitive) noise ratios compared with glassy carbon electrodes (Gun *et al.* 1994a, 1994b). The electrodes can be molded in diverse configurations, including supported or unsupported thick films, rods, disks, and even in the form of microelectrodes ($\sim 20\,\mu m$ in diameter). Graphite exhibits poor electrocatalytic activity, but addition of trace-metal or organometallic catalysts improves this activity. CCEs containing organometallic catalysts, such as cobalt phthalocyanine or cobalt porphyrin, showed pronounced electrocatalytic activity toward the reduction of dioxygen (Tsionsky and Lev 1995a, 1995b, Wang *et al.* 1997a). Since the electrodes are porous, the inert metal and organometallic-modified CCEs can act as electrodes for gases such as oxygen, carbon monoxide, and sulfur dioxide (Tsionsky *et al.* 1995a).

Since CCEs are molded at room temperature, it is possible to incorporate enzymes within the silicate material (Pankratov and Lev 1995, Tsionsky *et al*. 1994, Wang *et al*. 1996). The simplest form of enzyme electrode comprises a glucose oxidase–methyl silicate (or silica)–graphite composite. Dissolved oxygen serves as an electron acceptor, and the resulting hydrogen peroxide is electro-oxidized on the electrode. In order to account for the over-voltage for hydrogen peroxide oxidation, a palladium catalyst was added to the above construction. Electrodes for lactate (with lactate oxidase) and amino acids (amino acid oxidase) were prepared in a similar manner (Sampath and Lev 1996b). Reduction of the signal dependence on the level of oxygen was achieved by incorporating a mediator into the sol–gel starting solution. Tetra-thiafulvalene and glucose oxidase-doped CCE was found to show an oxygen-independent response (Pankratov and Lev 1995). In other modifications the ferrocenyl groups were covalently bound to the glucose oxidase enzyme, to the carbon powder, or bonded to the sol–gel precursor (Gun *et al*. 1995). The CCE biosensors were then molded by the usual protocol. In all cases zero leaching and good stability were observed. Wang *et al*. (1996) showed that CCEs can be produced by thick-film ink-jet technology. This technology enables highly reproducible mass production of biosensors. Wang and Pamidi (1997b) have also successfully replaced the graphite powder by noble metal particles, and our group has devised ways to replace the graphite by noble metal nanoparticles that are stabilized by aminosilane capping shells (Bharathi and Lev 1998, 1999).

Reinforced Concrete

This article deals with reinforced structural concrete in its most general meaning. It addresses reinforced and prestressed concrete, as well as ferrocement, thin reinforced concrete composites, fiber-reinforced concrete, and hybrid combinations of these. A number of books and references are given in the Bibliography and should be consulted for any in-depth coverage. The Bibliography represents only a limited selection of US titles of the 1980s and 1990s and is not in any way complete or comprehensive. Its purpose is to provide the reader with a first link to additional information on any of the subjects discussed.

1. *Definition: Concrete Matrix and Reinforcement*

Concrete is a cement-based composite generally obtained by mixing a Portland cement binder, water,

aggregates, and other additives. The aggregates may or may not be used; they generally comprise sand and gravel. Examples of additives include pozzolanic materials such as fly ash and silica fume, or simply very fine sand or clay. Additives may be inert or active. Depending on the aggregate content, different terms are used for concrete: a paste is made without aggregates; a mortar contains sand but no coarse aggregate (or gravel); a cement slurry is a very fluid paste containing a larger amount of water and/or some chemical additives to increase fluidity. For detailed coverage of concrete see *Portland Cements** and *Concrete as a Building Material**, and Mehta (1986) and Mindess and Young (1981). In this article the term concrete is used in the most general way to represent any one of the above-mentioned matrices.

Concrete is a durable construction material and has all the attributes suitable for constructed facilities.

From a mechanical viewpoint, all concrete matrices share a common property, i.e., they are weak in tension in comparison to their compressive strength and they have a low tensile strain prior to cracking. While formulas exists to estimate tensile strength based on compressive strength, as a first approximation the tensile strength of concrete ranges from about 7% to 10% of its compressive strength. Although very high strength concretes can be obtained, in most applications the compressive strength of concrete ranges from about 20 MPa to 60 MPa.

Since, in addition, concrete has a very low tensile strain capacity to failure it is brittle and it cracks. For all practical purposes in design, the tensile strength of concrete is ignored or assumed null.

To overcome the shortcoming of poor tensile resistance, reinforcement is added in concrete primarily in regions where tension is expected such as at the bottom of beams. However, in seismic regions where load reversals are expected, tension will occur at practically every portion of a section depending on the loading. So the reinforcement may be distributed along the section depth, as well as in two or three directions.

By its very definition and purpose, the reinforcement should have a tensile strength significantly higher than that of concrete. Also, when the reinforcement is not prestressed, a better performance or a more serviceable structural concrete is obtained when the modulus of elasticity of the reinforcement, E_r, is significantly larger than that of concrete, i.e., $E_r \gg E_c$.

When the reinforcement is embedded in concrete, both are generally assumed to be perfectly bonded to form a composite; this assumption has proved to be very effective in modeling the behavior of reinforced concrete members. In prestressed concrete the prestressed reinforcement may be bonded or intentionally unbonded; in the latter case, the reinforcement is anchored at the ends of the member.

2. Types of Reinforcement

The reinforcement in concrete structures can be either continuous or discontinuous or a combination of both (Fig. 1). The term "continuous" implies that the length of the reinforcement is of the same order as the length of the structural member, and generally larger than its least dimension. The term "discontinuous" generally implies a reinforcement significantly smaller than the length of the member and, except in thin reinforced sheets, also smaller that its least dimension; discontinuous reinforcement is described as fiber reinforcement.

2.1 Continuous Reinforcement

(*a*) *Steel reinforcing bars and prestressing tendons*. The most common form of reinforcement for concrete consists of round, surface-deformed steel reinforcing bars. However, welded wire fabric or grids can also be used. In the USA standard reinforcing bars are available in diameters ranging from about 9 mm to 57 mm and minimum specified yield strengths of either 276 MPa or 414 MPa. Wires are also available with minimum yield strengths of 483 MPa. Three types of steel tendons are used in prestressed concrete: wires, strands made with several wires, and bars. The most commonly used strands are made of seven wires (Fig. 2) and range in diameter from about 6.3 mm to 15.2 mm. They have a minimum specified tensile strength of 1860 MPa, and a yield strength of at least 85% of ultimate for normal relaxation and 90% of ultimate for low relaxation strand. Most common bars for prestressed concrete are deformed and range in diameter from about 19 mm to 35 mm. Their minimum specified tensile strengths are either 1000 MPa or 1104 MPa, and the minimum specified yield strength is 80% of tensile strength. Wires for prestressed concrete are generally less than 9 mm in diameter, and they can be used either individually, or as part of a cable assembly, or to make strands. Several strands can be assembled together to form cables for use in prestressing. Minimum properties of wires are similar to those of strands.

Reinforcing steel bars generally have an elastic plastic behavior in tension with a definite yield plateau (Fig. 3). Unlike reinforcing steels, prestressing steels do not show a definite yielding point; the onset of yielding is arbitrarily defined by standards. The yield strain of prestressing strands and wires is arbitrarily set by ASTM at 1%, while that of prestressing bars is set at 0.7%.

The modulus of elasticity of steel is almost independent of its strength. In lieu of information from the manufacturer, the following values can be used in design: 200 GPa for prestressing wires, 193 GPa for prestressing bars, and 186 GPa for prestressing strands.

Steel is the most common reinforcing material used with concrete. It has the advantages of being strong,

Cross-section of typical reinforcing elements.

Figure 3
Typical stress–strain curves in tension of reinforcement materials.

ductile, and with a relatively high modulus of elasticity in comparison to concrete. However, it is prone to corrosion and is relatively heavy to handle in the field. These drawbacks can be overcome by using fiber-reinforced polymeric or plastic (FRP) reinforcements using high-performance fibers.

(*b*) *FRP reinforcements.* FRP reinforcements, made from carbon, glass, aramid, or other high-performance fibers embedded in polymeric matrices, in the form of bars, tendons, strands, and two- or three-dimensional meshes, are produced and tested by various institutes around the world especially in Japan, the USA, and Western Europe (ACI 1997). Examples of FRP reinforcements include tendons with trade names like Parafil, Arapree, CFCC, Polystal, Fibra, Leadline, and numerous others.

The use of FRP reinforcements is seen primarily as a means to avoid corrosion problems otherwise encountered in concrete structures when using conventional steel reinforcing bars or prestressing tendons. Moreover, their nonmagnetic properties make them ideal for special applications, such as radar stations and structures for magnetic levitation (mag-lev) trains. FRP reinforcements are suitable for use in new structures, as well as for repair or strengthening of existing structures, where their properties can be most advantageous. In the latter case, FRP sheets are adhesively bonded to the concrete surface to provide strengthening in bending, or shear, or both; they are also used to confine reinforced concrete columns to improve their seismic resistance.

Other advantages of FRP reinforcements, particularly in prestressing applications, include lower unit weight, ease in coiling and handling, good damping and fatigue behavior, and low relaxation losses. However, FRP materials are not without drawbacks which include high cost, low shear (transverse) strength, susceptibility to stress-rupture effects, and, most importantly, low ductility (i.e., no yielding). Indeed they show a linear elastic response in tension up to failure (that is considered a brittle failure) which leads to poor sectional and member ductility. Also, they have an elastic modulus lower than that of steel, and generally ranging from about twice (glass FRP) to about five times (carbon FRP) that of normal strength concrete. The reader is strongly advised to consult technical papers or texts on the subject prior to designing concrete structures with FRP reinforcements. The design suggestions made in this chapter are applicable to concrete structures with steel reinforcements, and cannot be applied to FRP reinforcements without special limitations.

2.2 Discontinuous Fiber Reinforcement

Short fibers used in concrete can be characterized in different ways. First, according to the fiber material: natural organic (such as cellulose, sisal, jute, bamboo, etc.); natural mineral (such as asbestos, rock-wool, etc.); and synthetic (such as steel, titanium, glass, carbon, polymers, synthetics, etc.). Second, according to their physical/chemical properties: density, surface roughness, chemical stability, nonreactivity with the cement matrix, fire resistance or flammability, etc. Third, according to their mechanical properties: tensile strength, elastic modulus, stiffness, ductility, elongation to failure, surface adhesion, etc.

Fibers are differentiated by a number of other important geometric characteristics related to their cross-sectional shape, length, diameter or equivalent diameter, and surface deformation. The cross-section of the fiber can be circular, rectangular, diamond, square, triangular, flat, polygonal, or any substantially polygonal shape. To develop a better bond between the fiber and the matrix the fiber can be modified along its length by roughening its surface or by inducing mechanical deformations. Thus fibers can be smooth, deformed, crimped, coiled, twisted, with end hooks, paddles, buttons, or other anchorages. Typical examples of steel fibers are shown in Fig. 4.

Most common steel fibers are round, have a diameter ranging from 0.4 mm to 0.8 mm, and a length ranging from 25 mm to 50 mm. Their aspect ratio, i.e., the ratio of length to diameter or equivalent diameter, is generally less than 100, with a common range from 40 to 80. The length and diameter of synthetic fibers vary greatly. Single-filament fibers can be as little as 10 μm in diameter such as for Kevlar, and as large as 0.8 mm such as with some polypropylene or poly(vinyl alcohol) (PVA) fibers. Generally, the aspect ratio of very fine fibers exceeds 100 while that of courser fibers is less than 100.

Due to the formulation of the mechanics of the composite, the fiber content in cement matrices is

smooth round, flat, or of any section

twisted (polygonal section)

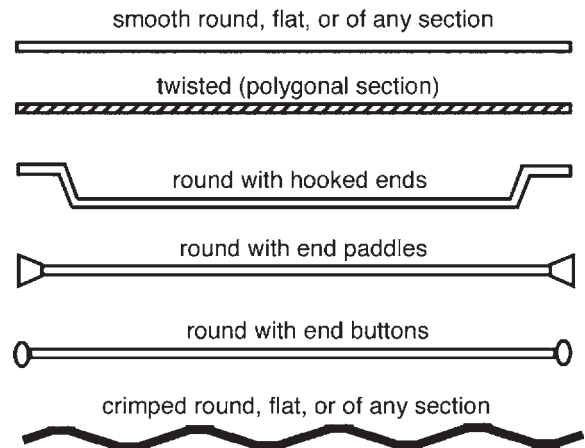
crimped round, flat, or of any section


Figure 4
Typical profiles of steel fibers used in concrete.

specified by volume fraction of the total composite. The fiber volume content of a typical fiber-reinforced concrete is less than about 2%. High-performance fiber-reinforced cement composites generally use fiber contents ranging from 2% to up to 15%, with a most common range between 2% and 6%. Because of fiber materials of different densities, the same volume fraction of fibers of different materials leads to different weight fractions of fibers. Fibers are purchased by weight. Typically a 1% volume fraction of steel fibers in normal-weight concrete amounts to about $80 \, \mathrm{kg \, m^{-3}}$ of concrete, whereas a 1% volume fraction of polypropylene fibers amounts to about only $9.2 \, \mathrm{kg \, m^{-3}}$.

To be effective, fibers must have the following properties: (i) a tensile strength significantly higher than that of concrete (2–3 orders of magnitude higher); (ii) a bond strength with the concrete matrix preferably of the same order as or higher than the tensile strength of the matrix; and (iii) an elastic modulus in tension significantly higher than that of the concrete matrix, unless self-stressing is used through fiber reinforcement.

The mechanics of fiber reinforcement of concrete and other information on the applications of fiber-reinforced concrete can be found in Balaguru and Shah (1992), Bentur and Mindess (1990)), Naaman and Reinhardt (1996), Naaman (2000), and Reinhardt and Naaman (1992, 1999).

3. Methods of Reinforcement of Concrete Structures

Generally all concrete structures are reinforced with some type of reinforcement. Nonreinforced concrete members are assumed to carry only small gravity loads or perform a noncritical, non-life-threatening load-carrying function. Examples include a slab on grade, a walkway, a low-height retaining wall, etc. All other applications belong to structural concrete where some type of reinforcement is used. It would be unsafe, for example, to use a nonreinforced concrete beam to sustain any external load including its own weight. Figure 5 illustrates the response of such a beam under service load and how reinforcement is placed to prevent its collapse. In reinforced concrete, bars are placed where tension and cracking are expected. In prestressed concrete, the tendons are stressed to apply a compressive force balancing tensile stresses and preventing cracking.

In concrete structures the reinforcement may be considered passive such as in reinforced concrete or ferrocement, or active such as in prestressed concrete. Active reinforcement implies that the reinforcement is stressed prior to application of external load to the structure.

Figure 6 illustrates the effects of prestressing for a concrete member subjected to tension. The reinforced
Figure 5
Response of plain, reinforced, and prestressed concrete to service loading.

concrete member will crack under load. When prestressing is used, the prestressed concrete member will not crack under load. This is because the uniform precompression stress induced by prestressing balances the tensile stress induced by external loads; the resulting stress remains a compressive stress throughout the member.

In reinforced concrete the bond is assumed to be perfect between the steel and the concrete. In prestressed concrete the prestressing tendons may be bonded or unbonded. In unbonded construction the prestressing force is transmitted to the concrete member at the end anchorages of the tendon only, as if it were an externally applied force. Unbonded prestressing tendons may be placed inside or outside the concrete section. In the latter case they are described as external tendons leading to external prestressing (Fig. 10). In its simplest definition, partially prestressed concrete is a combination of reinforced and prestressed concrete, i.e., a concrete member containing simultaneously reinforcing bars and stressed, prestressing tendons.

3.1 Various Types of Structural Concrete

Figure 7 schematically compares plain concrete with different forms of structural concrete beams
Figure 6
Internal stresses designed to balance external stresses in prestressing.
Figure 8
Typical sections of ferrocement and thin-sheet reinforced concrete products.

and provides the terminology used to designate each type of reinforcing system.

Reinforced and prestressed concrete structures can be built of practically any thickness. Nuclear power vessels can be more than 3 m thick, and dams can be as thick as a road is wide. However, it is not practical to build conventional concrete structures with a thickness of less than about 100 mm. Other forms of structural concrete such as ferrocement, fiber-reinforced concrete, or hybrid composites must be used (Balaguru and Shah 1992, Bentur and Mindess 1990, Naaman 2000).

Ferrocement is a type of thin-wall reinforced concrete commonly constructed of hydraulic cement mortar reinforced with closely spaced layers of continuous and relatively small size wire mesh (Fig. 8). The mesh may be made of metallic or other suitable materials. The fineness of the mortar matrix and its composition should be compatible with the mesh and armature systems it is meant to encapsulate. The matrix may contain discontinuous fibers or microfibers. The thickness of ferrocement is generally less than 50 mm, and in most applications less than 25 mm. The principles governing the design and analysis of ferrocement are similar to those used for reinforced concrete; however, a number of differentiating factors exists between them and should be evaluated prior to embarking on design and construction with ferrocement composites (Naaman 2000).

Figure 7
Various forms of structural concrete.

In the above paragraphs, it is assumed that continuous reinforcement is used. Short, strong, preferably stiff and ductile discontinuous reinforcing fibers can also be used with concrete matrices. The fibers can be added to the concrete matrix similarly to adding sand or other components; they are premixed with the concrete to lead to fiber-reinforced concrete. However, several forms of fiber-reinforced concrete exist where the fibers are not premixed. In some shotcreting operations, the fiber (such as glass fiber) is fed separately to the nozzle where the matrix is projected under pressure. In slurry-infiltrated fiber concrete (SIFCON), the fibers are preplaced in the mold to form a three-dimensional network then infiltrated by a cement slurry. In slurry-infiltrated mat concrete (SIMCON), the fibers are first used to produce a three-dimensional porous mat which is then infiltrated by a cement slurry in a manner similar to SIFCON (Naaman and Reinhardt 1996, Reinhardt and Naaman 1992, 1999).

Fibers or microfibers can be added to the concrete matrix used in conventional reinforced concrete, prestressed concrete, or ferrocement. In this case a hybrid system or a hybrid composite is obtained. While fibers generally tend to improve a number of material and structural properties of concrete, the most predominant improvement is in the energy absorption capacity of the matrix or its fracture energy. Moreover, when used in the right proportion, their presence may improve the tensile and shear resistance of concrete, the bond between reinforcing bars and concrete, and the cyclic response (Balaguru and Shah 1992, Bentur and Mindess 1990).

4. Prestressing

4.1 Definition

Prestressing is the deliberate creation of permanent internal stresses in a structure or system in order to improve its performance. Such stresses are designed to counteract those induced by external loadings. Prestressed concrete is a mature structural material with a proven technology; a number of textbooks have been written about it (Collins and Mitchell 1991, Gerwick 1993, Libby 1984, Lin and Burns 1981, Naaman 1982, Nawy 1995a, 1995b, Nilson 1987).

The application of prestressing to concrete is in a way a natural result. Concrete is strong in compression and weak in tension. For design purposes its tensile resistance is discounted. Prestressing the concrete would produce compressive stresses, either uniform or nonuniform, which will counteract tensile stresses induced by external loading (Fig. 6). The original concept, initially developed by Eugene Freyssinet, attempted to counteract tensile stresses entirely, thus producing a crack-free material during service. However, it has since evolved to counteract only in part externally induced tensile stresses, thus

allowing tension and controlled cracking in a way similar to reinforced concrete. This has led to what is called partial prestressing.

Partially prestressed concrete occupies the whole spectrum of the reinforcing range between fully reinforced and fully prestressed concrete. It can be considered a combination of both.

4.2 Prestressing Methods

Several methods and techniques of prestressing are available. However, except for chemical prestressing, most can be classified within two major groups: pretensioning and post-tensioning.

(*a*) *Pretensioning*. In pretensioning the prestressing tendons (wires, strands) are stretched to a predetermined tension and anchored to fixed bulkheads or molds (Fig. 9). The concrete is poured around the tendons, cured, and, upon hardening, the tendons are released. As the bond between the tendons and the concrete resists the shortening of the tendons, the concrete gets compressed. The prefix "pre" in pretensioning refers to the fact that the tendons are put in tension *prior* to hardening of the concrete.

Depending on the pretensioned structural elements produced, the profile of the tendons is either straight (Fig. 9), such as in hollow-cored slabs, or has one or two deflected points (also called draping or hold-down points) such as in bridge girders.

Pretensioning is the method mostly used for the production of precast prestressed concrete elements in the USA because it offers great potential for mechanization. Efficient long-line production techniques with casting bed lengths of up to 600 ft (182 m) where individual elements are cast end to end are preferred, as they require a single tensioning operation. Elements of standardized cross-sections are mass produced, yet customized by varying the length of each element and by placing inserts, holes, or blockouts for the mechanical or electrical distribution systems. Accelerated curing often permits early removal of the elements and daily reuse of the forms (24-hour production cycle). Excellent quality control and optimum use of labor and materials are achieved.

In order to stretch the tendons, hydraulic jacks are generally used. Another technique for stretching the
Figure 9
Typical pretensioning bed showing beams with straight tendons.

tendons is electrothermal prestressing. Here, high-strength deformed bars are heated by means of an electric current to between 250°C and 450°C, then placed and anchored at the ends of the molds or a pretensioning bed. Electrothermal prestressing is not used in the USA but has been used in the former Soviet Union and Eastern Europe. Its applications are limited.

(*b*) *Post-tensioning*. In post-tensioning the tendons are stressed and anchored at the ends of the concrete member *after* the member has been cast and has attained sufficient strength.

Commonly, a mortar-tight metal pipe or duct (also called sheath) is placed along the member before concrete casting. The tendons may have been pre-placed loosely inside the sheath prior to casting or could be placed after hardening of the concrete. After stressing and anchoring, the void between each tendon and its duct is filled with a mortar grout which subsequently hardens. Grouting ensures bonding of the tendon to the surrounding concrete, improves the resistance of the member to cracking, and reduces the risks of corrosion of the steel tendons.

This post-tensioning technique implies using what are commonly called "bonded tendons." If the duct is filled with grease instead of grout, bonding is prevented throughout the length of the tendon and the tendon force is transferred to the concrete member only at the anchorages. This leads to "unbonded tendons." Unbonded tendons are generally coated with grease or bituminous material and wrapped with waterproof paper or placed inside a flexible plastic hose; they are placed in the forms prior to concrete casting. When the concrete reaches sufficient strength, the tendons are stressed and anchored. They remain unbonded throughout their length and during service of the structure. Unbonded tendons can also be placed outside the concrete section leading to what is termed "external prestressing" (Fig. 10).

Although post-tensioning can be used in precast prestressed operations, it is most useful in cast-in-place

Figure 10
Illustration of external prestressing.

construction where large building and bridge girders cannot be transported, and for customized structures which need tensioning on the job site. Its application in slabs (unbonded tendons) or unusual projects, such as nuclear power vessels, TV towers, long-span bridges, and offshore structures has become a must and will certainly continue to expand.

(*c*) *Chemical prestressing and self-stressing*. Pretensioning and post-tensioning represent two general methodologies to which most prestressing techniques belong. It was mentioned above that electrothermal prestressing is in effect a pretensioning method. Chemical prestressing, however, does not belong to any of the above. In chemical prestressing the tendons are placed untensioned in the forms and the concrete is poured. Due to the special expansive cement used, the concrete, instead of shrinking, expands after curing and during hardening. As the steel is bonded to the concrete, it stretches with it, thus undergoing tension and inducing compression in the concrete. Because stresses due to chemical prestressing are generally low, this technique has not been widely used.

There are "smart" materials that allow us to envision self-stressing with effective prestress levels that can be controlled much more accurately, and can be of much larger magnitude than is achieved with expansive cement matrices or electrical prestressing. Shape memory alloys (SMAs) and some special polymeric fibers possess the unique property of being able to be frozen temporarily in a particular state, then, with proper heat or radiation treatment, go back to their previous equilibrium state. Compared to electrical prestressing these materials do not need costly specialized electric equipment and do not create safety problems in the field. The treatment (heat or radiation) can be applied any time after hardening of the matrix instead of during its curing and hardening. The special reinforcement needed, such as SMA, can be factory produced, stored, shelved, placed in the composite, and triggered to recover its deformation (inducing prestressing) at any appropriate time.

Finally, it is conceivable to combine the previous two methods, i.e., to have a matrix that expands and a reinforcement that shrinks in order to produce the proper amount of self-stressing. The technique of self-stressing using shape memory materials was still at the basic research stage at the end of the 1990s (Naaman 2000, Reinhardt and Naaman 1999).
5. Typical Behavior of Structural Concrete Beams Under Load

When a reinforced concrete beam is loaded in bending it undergoes several stages of behavior. These
Figure 11
Typical moment vs. deflection response of a typical reinforced concrete beam.

Figure 12
Typical model of a structural concrete section at nominal bending resistance.

help explain the basis for the different analysis and design approaches followed for reinforced concrete.

Consider the load (or moment) vs. deflection response of a typical beam (Fig. 11). Several portions of the curve can be identified.

(i) An initial portion (OA) where structural cracking does not occur.

(ii) A cracking region (AB) where cracks develop over a relatively short load range; their width increases thereafter with increasing load.

(iii) An almost linear portion (BC) where the concrete is cracked and both the concrete and the steel can be considered in their linear elastic range of behavior. The slope of this portion is smaller than that of the initial portion.

(iv) A region where the response of the concrete is nonlinear (CD) and/or where gradual yielding of the steel reinforcement occurs. This nonlinear region eventually leads to a maximum load (represented by point D) considered to be the nominal bending resistance.

(v) A post-peak portion (DE) at the end of which failure occurs either due to concrete failure in compression or due to failure of the extreme layer of reinforcement.

The analysis of stresses along each portion of the curve for the cases of reinforced concrete, prestressed concrete, and partially prestressed concrete is beyond the scope of this article since each commends a different procedure and a different set of equations. However, in predicting the nominal bending resistance (i.e., the maximum load for design purposes), a unified procedure can be followed for all reinforced and prestressed concrete members.

Indeed when a structural concrete section is subjected to bending in the cracked state, an internal couple develops with the compression force in the concrete and the tensile force in the steel reinforcement. The forces must remain equal. The compression force in the concrete balances the tensile force, whether it is resisted by reinforcing bars, prestressing tendons, or their combination. Since all steel reinforcements are assumed to yield, the initial prestress, if present, does not influence ultimate resistance. Figure 12 illustrates the section forces at nominal resistance. The corresponding detailed solution is given in Sect. 7.1.

6. Design Philosophy

The design philosophy generally adopted for concrete structures is based on satisfying a number of limit states where a limit state is defined as the boundary between acceptable and unacceptable performance. Limit states are generally classified in two categories, namely serviceability limit states and ultimate strength limit states. An allowable stress, a maximum crack width, or a limit value of deflection belong to the category of serviceability limit states. Collapse of the structure due to excessive bending or shear belongs to the category of ultimate strength limit states.

In the following formulation, the subscript u such as in M_u refers to ultimate and the subscript n such as in M_n refers to nominal. M_u is the required ultimate moment or the factored moment and M_n is the nominal moment resistance of the member, i.e., its maximum bending resistance. The factor ϕ is the capacity reduction factor or resistance factor and is defined below.

6.1 General Design Approaches

Design approaches applicable to all structural materials commonly use the following terminology:

USD: ultimate strength design
LSD: limit state design
LRFD: load and resistance factor design
WSD: working stress design
ASD: allowable stress design

Reinforced Concrete

WSD or ASD, also sometimes called the permissible stress design, are different terminologies for the same approach, in which maximum stress criteria are specified; i.e., an allowable stress is not to be exceeded. The USD, the LSD, and the LRFD imply essentially the same philosophy wherein collapse is considered under factored loads.

Note that WSD and USD may result in the same member design, but USD or LRFD generally allows for a more rational distribution of safety reserve.

6.2 USD, LSD, or LRFD

When the USD, LSD, or LRFD approach is applied, the general format is given by the formula:

$$U = \sum \gamma_i Q_i \leqslant \phi R_n$$

where i = type of load, i.e., dead load, live load, wind load, etc.; Q_i = nominal load effect; γ_i = load factor corresponding to Q_i; U = required or specified ultimate strength; $\sum \gamma_i Q_i$ = factored loads = required or specified ultimate strength U; R_n = nominal strength or nominal resistance; ϕ = resistance factor (or capacity reduction factor) corresponding to R_n; and ϕR_n = design strength or design nominal resistance.

The left-hand side of Eqn. (1) represents the required resistance which is computed from structural analysis based on assumed loads, and the right-hand side of Eqn. (1) represents a limiting structural capacity provided by the selected members. In USD or LRFD, the designer compares the effect of factored loads to the strength actually provided. The term design strength refers to the resistance or strength, ϕR_n, that must be provided by the selected member. The load factors, γ_i, and the resistance factor, ϕ, reflect the fact that loads, load effects (the computed forces and moments in the structural elements), and the resistances can be determined only to imperfect degrees of accuracy.

The required strength for design, $U = \sum \gamma_i Q_i$, is defined as the maximum (absolute value) of force obtained from the specified load combinations. The load factors and load combinations recognize that when several loads act in combination with the dead load, only one load takes on its maximum lifetime value at a time, while the other loads are at arbitrary point-in-time values. Examples of load combinations specified by the American Concrete Institute (ACI) Building Code Requirements for Reinforced Concrete (ACI 1995) are as follows:

$$1.4D + 1.7L$$
$$0.75(1.4D + 1.7L + 1.7W)$$
$$0.75(1.4D + 1.7W) \tag{2}$$
$$0.9D + 1.3W$$

where D, L, and W represent either the loads themselves (dead load, live load, wind load) or the load effects (i.e., the forces or moments caused by the loads). The coefficients are the applicable load factors, γ_i.

Values of resistance (or capacity reduction) factor, ϕ, given by ACI 318 (ACI 1995) for reinforced concrete are:

$\phi = 0.9$ for bending

$\phi = 0.9$ for axial load in tension

$\phi = 0.85$ for shear

$\phi = 0.75$ for axial load in compression, $\qquad$ (3)

assuming spiral confinement

$\phi = 0.70$ for axial load in compression,

assuming tie confinement

The factor ϕ accounts for uncertainties in materials properties, analysis approximation, etc.

When the USD approach is applied to bending, direct axial tension, or shear in reinforced concrete, the following formulation is obtained:

$$M_u = \gamma_D M_D + \gamma_L M_L \leqslant \phi M_n \tag{4}$$
$$N_u = \gamma_D N_D + \gamma_L N_L \leqslant \phi N_n \tag{5}$$
$$V_u = \gamma_D V_D + \gamma_L V_L \leqslant \phi V_n \tag{6}$$

where M is the bending moment, N the tensile axial load, V the shear force, and other notation is as above.

Note that the load and resistance factors are obtained from calibration using reliability analysis. Load factors are higher for loads with a higher degree of uncertainty. This is why the live load factor for reinforced concrete is higher than the dead load factor. However, resistance factors are lower for types of members or materials with a higher degree of uncertainty. This is why the capacity reduction factor, ϕ, for axial load is smaller than that for bending.

6.3 WSD or ASD

When the WSD or ASD approach is used, the following general formula applies:

$$\text{Actual stress} \leqslant \text{Allowable stress} \tag{7}$$

where absolute values of stresses are considered. The allowable stress can be obtained from:

$$\text{Allowable stress} = \frac{\text{Strength}}{\text{Safety factor}} \tag{8}$$

For bending, axial tensile load, or shear the actual stress induced by loading in an uncracked section is

directly proportional to the applied load:

Actual stress $= N/A_c$ for axial tensile load, N (9)

Actual stress $= M/S$ for a bending moment, M (10)

Actual stress $= VK/Ib$ for a shear force, V (11)

where S is the section modulus, K is the moment of area above the shear plane, and b is the width of the shear plane. Other notation is standard. Tensile and bending stresses in the cracked section in the linear elastic range of behavior can be similarly computed as described in Sects. 3 and 4.

Thus the allowable stress design criterion can be generally written as follows:

$$\sum \sigma_i \leqslant \left(\frac{1}{\text{SF}}\right)\sigma_n \quad (12)$$

where σ_i is the stress due to loading i, σ_n is the equivalent elastic stress at nominal resistance, and SF is a safety factor larger than one. The summation is done over the applied load combination of interest. Assuming, for instance, a combination of dead load and live load (often termed service load ($D+L$)) leads to:

$$\sigma_D + \sigma_L \leqslant \left(\frac{1}{\text{SF}}\right)\sigma_n \quad (13)$$

where σ_D is the stress due to dead load and σ_L is the stress due to live load.

Since, under elastic bending, stresses and moments are directly proportional, Eqn. (13) can be rewritten as:

$$M_D + M_L \leqslant \left(\frac{1}{\text{SF}}\right)M_n \quad (14)$$

where M_n is the nominal bending resistance. The safety factor is often taken equal to 2.5 in the WSD–ASD approach.

In comparing Eqns. (4)–(6) with Eqns. (13) and (14), it can be observed that in the USD–LRFD approach the effects of loads are multiplied by a factor (different for each load) and compared to the nominal resistance, while in the WSD–ASD approach the load effects are used without modification and the resistance is divided by a factor. The difference, however, lies in the fact that in the USD–LRFD approach each load has a different load factor, while in the WSD–ASD approach the same safety factor is applied to the effects of all loads. Figure 13 graphically illustrates the two approaches assuming a bending member.

7. Analysis of Structural Concrete Sections at Ultimate: Nominal Bending Resistance M_n

The purpose of the analysis at ultimate or maximum load is generally to determine the nominal moment

Figure 13
Illustrating the WSD and USD approach for a bending member.

resistance in bending (moment at ultimate behavior) of the section, assuming that cross-sectional dimensions, materials properties, and amounts of reinforcement are given. As pointed out earlier, the stress in the steel and in the concrete at ultimate are well outside their linear range of behavior. Although very accurate methods of analysis exists, a most efficient method used for everyday design is followed in the ACI Building Code (ACI 1995) where a rectangular stress block for the concrete is assumed and the reinforcing steel is considered to be at yield. Widely accepted assumptions for most codes are as follows:

(i) Plane sections remain plane under loading. Consequently it is assumed that a linear strain distribution exists along the concrete section up to ultimate load.

(ii) A perfect bond exists between steel and concrete. A direct result of this assumption is that any strain change in the steel due to an applied load is equal to the strain change in the concrete at the level of the steel due to the same load.

(iii) The tensile strength of concrete is neglected. Thus the point of zero stress represents the boundary between the cracked and the uncracked part of the section.

The ACI Building Code (ACI 1995) proposes the following additional assumptions (Fig. 14).

(iv) The limiting compressive strain of the concrete, ε_{cu}, is equal to 0.003, regardless of the strength of the concrete, the shape of the section, and the amount of reinforcement. It is also considered the same for normal weight and structural lightweight concrete.

(v) The maximum total force in the concrete compressive zone can be well approximated by considering

**C = 0.85 f'$_c$ b a = T = A$_{r1}$σ$_{ry1}$ + A$_{r2}$σ$_{ry2}$**

Figure 14
Internal resisting moment of the section at ultimate (or nominal bending resistance) assuming a concrete rectangular stress block in accordance with the ACI Building Code.

a uniform stress of magnitude $0.85f_c'$ over a rectangular block of width b and depth $a = \beta_1 c$, where c represents the depth of the neutral axis and β_1 is a factor defined by the ACI Code as follows (see Fig. 14):

$$\beta_1 = 0.85 \text{ for } f_c' \leqslant 4000 \text{ psi (28 MPa)}$$
$$\beta_1 = 0.65 \text{ for } f_c' \geqslant 8000 \text{ psi (56 MPa)} \quad (15)$$
$$\beta_1 = 0.85 - 5 \times 10^{-5}(f_c' - 4000) \quad \text{for } 4000 \leqslant f_c' \leqslant 8000 \text{ psi}$$
$$\beta_1 = 0.85 - 5 \times 10^{-2}(f_c' - 28)/7 \text{ for } 28 \leqslant f_c' \leqslant 56 \text{ MPa}$$

While other shapes of compression stress block have been used in the technical literature, the rectangular stress block described above leads to the simplest prediction equations of bending resistance with little loss in accuracy.

7.1 Rectangular Section (or Rectangular Section Behavior)

Specialized texts treat in detail various cases of reinforcement such as the case of reinforced, prestressed, or partially prestressed concrete rectangular or flanged sections (T-sections) with and without reinforcement in the compression zone. Here only the case of a reinforced concrete rectangular section is illustrated and some simplifying assumptions are made to accommodate prestressed and partially prestressed concrete as well.

The following notation is used:
a = depth of rectangular stress block as per the ACI Building Code $a \times b$ = area of rectangular stress block for a rectangular section of width b
A_r = area of tensile reinforcement considered (if only one type)
A_{ri} = area of a particular type of reinforcement such as of reinforcing steel or prestressing steel, or both, or two types of reinforcing steel having different yield strengths
b = width of concrete section
c = distance from extreme compression fiber to neutral axis at ultimate

d_{r_i} = distance from extreme compression fiber to centroid of reinforcing material i
f_c' = specified design compressive strength of concrete or mortar
f_r = modulus of rupture or stress range in reinforcement
i = the type of reinforcement such as reinforcing steel, prestressing steel, or a reinforcing steel with different yield strength; in Fig. 14 the value of i is taken as 1 for the reinforcing steel and 2 for the prestressing steel; in many textbooks the subscript s is used for the reinforcing steel and p for the prestressing steel. The proposed notation allows for several layers of different steel reinforcements such as for ferrocement. It is assumed that all reinforcements are in the tensile zone
M_n = nominal bending resistance or ultimate moment
β_1 = factor defined in Eqn. (15)
ε_{mu} = ultimate strain of concrete matrix in compression (usually assumed to be 0.003 for mortar or concrete)
σ_{ryi} = specified yield strength of tensile reinforcement of type i

Referring to Figs. 12 and 14, the force equilibrium equation (of the internal couple) can be set by writing that the compressive force in the concrete compression block is equal to the total tensile force in the steel reinforcement, thus:

$$C = T \quad (16)$$

or

$$0.85f_c'ba = \sum A_{ri}\sigma_{ryi} \quad i = 1, 2, 3... \quad (17)$$

Thus, for instance, if we had a reinforced concrete section containing only one type of reinforcing steel in the tensile zone, Eqn. (17) would read:

$$0.85f_c'ba = A_{r1}\sigma_{ry1} \quad (18)$$

For a section containing reinforcing steel and prestressed steel, Eqn. (17) would read:

$$0.85f_c'ba = A_{r1}\sigma_{ry1} + A_{r2}\sigma_{ry2} \quad (19)$$

where the subscript 1 refers to reinforcing steel and 2 to prestressing steel.

Equation (17) allows us to compute the value of the depth of the stress block at nominal bending resistance:

$$a = \frac{\sum A_{ri}\sigma_{ryi}}{0.85f_c'b} \quad i = 1, 2, 3... \quad (20)$$

where the summation is taken for all different reinforcements, provided they have yielding behavior such as typical reinforcing steel or prestressing steel.

Generally in prestressed and partially prestressed concrete members with bonded tendons, the prestressed steel has a stress at nominal bending resistance somewhere between its yield strength and its ultimate strength. Since the yield strength of most prestressing steels exceeds 85% of their ultimate strength, assuming the stress to be at yield introduces a relatively small error. This is suggested by the author in Eqns. (17) and (19); however, various codes such as the ACI Building Code (ACI 1995) and the AASHTO bridge code (AASHTO 1994) recommend computing the stress in the prestressing steel using a prediction equation or a strain compatibility approach. The author believes that the approximation suggested above is sufficient in many cases of design and is generally on the safe side.

Once a is determined from Eqn. (20) the nominal bending resistance (i.e., the moment of the internal couple of Fig. 14) can be estimated from the equation of equilibrium of moments:

$$M_n = \sum A_{ri}\sigma_{ryi}\left(d_{ri} - \frac{a}{2}\right) \quad i = 1, 2, 3\ldots \quad (21)$$

which, for a section containing only reinforcing steel, leads to:

$$M_n = A_{r1}\sigma_{ry1}\left(d_{r1} - \frac{a}{2}\right) \quad (22)$$

For a section containing reinforcing steel and bonded prestressed steel Eqn. (21) gives:

$$M_n = A_{r1}\sigma_{ry1}\left(d_{r1} - \frac{a}{2}\right) + A_{r2}\sigma_{ry2}\left(d_{r2} - \frac{a}{2}\right) \quad (23)$$

According to assumptions given in the ACI Building Code (ACI 1995), the depth of the equivalent concrete rectangular stress block, a, is related to the depth of the neutral axis at nominal bending resistance, c, by the following relation (Figs. 12 and 14):

$$a = \beta_1 c \quad (24)$$

or inversely:

$$c = \frac{a}{\beta_1} \quad (25)$$

in which the factor β_1 is defined above (Eqn. (15)) and a is from Eqn. (20).

In an analysis situation, the above equations of equilibrium (e.g., Eqns. (20) and (22) for reinforced concrete) have two unknowns, a and M_n, which can be solved. In a design situation, the value of A_r is unknown. By setting $M_u = M_n$ a third equation is introduced, thus allowing one to obtain a unique solution for a, M_n, and A_r. Hence, for design, A_r is obtained from Eqn. (22) where M_n is replaced by M_u/ϕ.

8. Design for Bending by USD or LRFD

8.1 General Criteria for USD of Bending Members

To satisfy strength design requirements in bending the following general conditions must be satisfied to insure strength and safety.

(i) Condition for strength:

$$M_u \geqslant \phi M_n \quad (26)$$

where M_u is the factored moment due to external loads, M_n is the nominal moment resistance, and ϕ is the strength reduction factor in bending (see above).

(ii) Condition for maximum reinforcement: this condition would guarantee some ductility for the member by forcing yielding of the steel prior to failure of the concrete.

(iii) Condition for minimum reinforcement: this condition insures that the amount of reinforcement is sufficient in order to warrant that failure/collapse does not occur just after cracking.

8.2 Strength Criterion

Whether an analysis, investigation, or design of a given section is carried out, once the nominal bending resistance, M_n, is calculated, the following design criterion must be checked (Eqn. (26)):

$$M_n \geqslant \frac{M_u}{\phi} \quad (27)$$

which implies for design that the nominal bending resistance $M_n \geqslant M_u/\phi$. When used at equality, this condition, combined with the two equations of equilibrium, allows for the computation of the required amount of reinforcement.

8.3 Maximum Reinforcement

Let us assume that a section satisfying Eqn. (27) has been determined. To satisfy criteria related to the maximum and minimum reinforcement, it is convenient to determine the depth, d_{re}, from the extreme compression fiber to the centroid of the tensile force in the reinforcement. Its value can be calculated from the following equation (Fig. 14) assuming all tensile reinforcement is at yield:

$$d_{re} = \sum A_{ri}\sigma_{ryi}d_{ri} / \sum A_{ri}\sigma_{ryi} \quad (28)$$

To guarantee ductile behavior or equivalently that excessive reinforcement is not used, the following general condition which is adopted in the AASHTO LRFD Bridge Design Specification (AASHTO 1994)

is recommended:

$$\frac{c}{d_{re}} \leqslant 0.42 \qquad (29)$$

8.4   Minimum Reinforcement

To guarantee that failure does not occur at onset of first structural cracking, the ACI Building Code (ACI 1995) and the AASHTO LRFD Bridge Design Specification (AASHTO 1994) provide different requirements for reinforced and prestressed concrete structures. The author developed the following simple and unified condition which, while not given in any code, simulates very well the requirements given by ACI and AASHTO. It applies to all types of reinforced, prestressed, and partially prestressed concrete sections:

$$\frac{c}{d_{re}} \geqslant \frac{0.033}{\beta_1} \qquad (30)$$

in which β_1 is from Eqn. (15) and d_{re} is from Eqn. (28).

9.   Reinforced Concrete Tensile Members

The analysis and design of reinforced concrete tensile members presents no mathematical difficulty. Since concrete is weak in tension and will crack under service loads, its tensile resistance is neglected in design; thus the entire tensile load is carried by the reinforcement. However, since concrete does have some tensile resistance, it is necessary to provide a minimum amount of reinforcement in tensile members in order to avoid their sudden brittle failure and collapse at onset of concrete cracking.

9.1   Analysis

Consider the tensile prism shown in Fig. 15. The following notation is adopted:

A_c = cross-sectional area of composite tensile member

Figure 15
Assumed model of composite with load applied to the reinforcement.

A_m = cross-sectional area of matrix (concrete, mortar, paste)
A_r = cross-sectional area of reinforcement; here reinforcing steel only
A_{tr} = area of transformed section assuming all concrete
E_m = elastic modulus of matrix
E_r = elastic modulus of (longitudinal) reinforcement
$n = E_r/E_m$ = modular ratio
N = externally applied tensile load
N_m = tensile load resisted by the matrix
N_r = tensile load resisted by the reinforcement
ρ = reinforcement ratio; the definition for tensile members is different from that of bending members
u = subscript for ultimate
y = subscript for yield
ε_c = tensile strain in composite
ε_m = tensile strain in matrix
ε_r = tensile strain in reinforcement
σ_c = tensile stress in the composite
σ_m = tensile stress in the matrix
σ_r = tensile stress in the reinforcement

It follows from the above and from Fig. 15 that:

$$A_c = A_m + A_r \qquad (31)$$

$$\rho = \frac{A_r}{A_c} \qquad (32)$$

$$n = \frac{E_r}{E_m} \qquad (33)$$

For any applied external tensile load, N, the stress in the composite at any section is given by:

$$\sigma_c = \frac{N}{A_c} \qquad (34)$$

The following assumptions are made.

(i) The load is applied to the reinforcement and then transferred to the concrete matrix; this is the same as if a through-matrix crack is assumed to exist at each end of the composite.

(ii) Under tensile load, cracking in the matrix occurs at an early stage when the stress in the matrix reaches its tensile strength, σ_{mu}.

The detailed analysis of stresses in the tensile composite in the precracking and postcracking stages and during the multiple cracking process can be found in other specialized texts (Naaman 1982, 2000). Here it will be sufficient to determine the necessary area of reinforcement needed to carry the tensile load with a sufficient level of safety reserve.

The stress in the composite at any section is given by Eqn. (34); stresses in either the matrix or the

reinforcement, at a cracked section, are given by:

$$\sigma_m = 0 \qquad (35)$$

and

$$\sigma_r = N/A_r \qquad (36)$$

Thus

$$\sigma_c = N/A_c = \sigma_r/\rho \qquad (37)$$

or

$$\sigma_r = \rho\sigma_c \qquad (38)$$

The minimum required value of reinforcement ratio for tensile members, ρ, is defined as that ratio of reinforcement for which collapse will not occur immediately after cracking. It can be shown that:

$$\rho_{min} \geqslant \frac{1}{1 - n + \dfrac{\sigma_{ry}}{\sigma_{mu}}} \qquad (39)$$

where σ_{mu} is the tensile strength of the matrix, σ_{ry} is the yield strength of the reinforcement, and n is the modulus ratio defined as $n = E_r/E_m$.

9.2 Design

For design the following equation can be used:

$$N_u \leqslant \phi N_n \qquad (40)$$

where N_u is the factored tensile load and N_n is the nominal resistance in tension. The factored tensile load is defined above in Eqn. (5). The nominal tensile resistance in tension is taken as:

$$N_n = A_r\sigma_{ry} \qquad (41)$$

where A_r is the total cross-sectional area of tensile reinforcement and σ_{ry} is its yield strength.

In designing for the reinforcement, Eqn. (40) is taken at equality, leading to:

$$N_n = \frac{N_u}{\phi} \qquad (42)$$

Thus the required area of reinforcement can be obtained:

$$A_r = \frac{N_n}{\sigma_{ry}} = \frac{N_u}{\phi\sigma_{ry}} \qquad (43)$$

It can be observed that for reinforced concrete tensile members the ultimate strength of the member is essentially the same as that of the reinforcement. This makes the computation of cross-sectional area of reinforcement very simple as shown above. However, one still needs to determine the area of the concrete tensile member or of the matrix. For this the following approach is suggested. Select a reasonable reinforcement ratio, ρ, such as from 2% to 4%. Thus:

$$A_m \approx A_c = \frac{A_r}{\rho} \qquad (44)$$

where A_r is from Eqn. (43). Make sure that $\rho > \rho_{min}$ (Eqn. (39)).

It should be observed that while dimensioning the area of reinforcement and matrix is very simple, there is a need to detail the reinforcement in order to keep crack widths and stresses within acceptable limits. Crack width is proportional to the stress in the reinforcement. Also, for a given load, the higher the reinforcement ratio and the smaller the bar diameter, the smaller is the crack width. The design should also be checked for maximum displacement or elongation of the tensile member, which can be controlled by changing the area of the cross-section of concrete.

Once a preliminary cross-section is obtained, some iteration may be needed to fine-tune the results to select a safe, serviceable, and cost-effective member.

In prestressed concrete tensile elements, several criteria are used to determine the amount of reinforcement and the area of the concrete section. These include the ultimate tensile strength criterion similar to Eqn. (39) as well as criteria setting limits on compressive stresses, load to decompression, load to cracking, minimum reinforcement, and maximum deformation. Their treatment is covered in specialized texts (Naaman 1982).

10. Concluding Remarks

This article presents an overview of methods of reinforcement for structural concrete, which includes reinforced and prestressed concrete members as well as ferrocement and fiber-reinforced concrete. It describes the current limit state design philosophy for such members, and presents the underlying principles for the analysis and design of reinforced concrete beams and tensile elements. For additional details or for the design of other typical members such as columns or slabs, the reader is referred to more specialized publications on the subject listed in the Bibliography.

Roofing Materials

The basic function of roofing materials is to provide a pathway to direct storm water around the enclosed space. Functions such as shielding the structure from the effects of sun and wind are also important, but are secondary to the primary function of excluding and directing precipitation.

The entire roofing industry is divided into material and systems for low-sloped and steep-sloped roofing in recognition of the vital slope-to-drain function. Low-sloped roofs are usually defined as roofs having a slope of less than 25% (3 inches rise per foot (25 centimeters per meter)). Steep-sloped roofs are defined as roofs with a slope equal to or greater than 25%. The mean durability of selected steep and low-sloped roofs are shown in Figs. 1 and 2, drawn to the same scale. These data show the clear benefit of slope and how slope can greatly increase durability of the roofing by a factor of two or more.

1. Steep-sloped Roofing

Steep-sloped roofing became popular shortly after mankind left caves; it continues to be popular for residential roofing and is increasingly used on commercial and institutional buildings. In 1998 steep-sloped roofing accounted for 36% (9.5 billion dollars) of the total roofing market. Table 1 lists the 1998 market share (Kane 1999), and the mean service life and the life cycle cost from a 1995 roofing industry wide survey, for many types of steep roofing. The "other" category in Table 1 includes low-sloped roofing materials used at a slope of greater than 25%.

Approximately three quarters of the steep roofing material sold each year is for reroofing existing structures; the balance is used in roofing new construction. Of the reroofing portion, the old roofing materials are removed before the new materials are installed approximately 75% of the time; the old roofing materials are covered over in about 25% of the instances. All steep-sloped roofing materials are rain shedding rather than waterproof. As such, they must rely, to varying degrees, on the underlayment for additional water penetration resistance.

1.1 Asphalt–Glass Fiber Shingles

Asphalt–glass fiber shingles continue to dominate the steep-sloped shingle market in the USA due to their low life cycle cost and durability. The data in Table 1 is for "20 year" commodity shingles—a longer service life can be expected for the heavier and more costly shingles that prudence recommends. The total market volume in any year is directly proportional to population, while the local markets are dominated
Figure 1
Mean durability of steep-sloped roofing systems.

Figure 2
Mean durability of low-sloped roofing systems. AGA, asphalt coated glass fiber felts and asphalt built-up roofing; AGP, asphalt coated glass fiber felts and coal tar pitch built-up roofing; AOA, asphalt saturated organic felts and asphalt built-up roofing; APP, atactic polypropylene polymer modified roofing; CPE, chlorinated polyethylene; CSPE, chlorosulfanated polyethylene (Hypalon); CtGP, coal tar coated glass fiber felts and coal tar pitch built-up roofing; CtOP, coal tar saturated organic felts and coal tar pitch built-up roofing; EPDM, ethylene–propylene–diene terpolymer rubber; MP, metal panels; OT, other thermoplastic (thermoplastic polyolefin); PE, polyethylene; PIB, polyisobutylene; PUF, polyurethane foam; PVC, poly (vinyl chloride); SBS, styrene–butadiene–styrene block copolymer modified asphalt roofing.

by demographic changes and the state of the local economy.

These shingles are made by coating a non-woven glass fiber felt with hot asphalt that contains a substantial quantity (> 50%) of fine mineral filler, embedding colored mineral granules in the top surface, dusting the back surface with a release agent such as talc or fine sand, often adding dots or strips of self-sealing adhesive, and die cutting the individual shingles. The shingles can weigh 3.5 to 6.2 kg m^{-2}, depending on the grade and design. The typical sales unit in the United States is a roofing square; that is, enough material to cover 100 ft^2 (9.3 m^2) of deck. The most popular current shingle design is the three-tab strip shingle in a single thickness, with overall dimensions of 12×36 in (305×914 mm). Laminated

Table 1
Steep-sloped roofing market share (1998), mean service life, and life cycle costs.

Roofing materials	Market share (%)		Mean service life (yrs)	Life cycle cost ($ft^{-2} yr^{-1})
	New roofing	Reroofing		
Asphalt–glass shingles	47.1	48.8	18	0.20
Metal, architectural	17.3	8.4	28	0.74
Asphalt–organic shingles	11.2	14.0	18	0.20

Slate	2.7	2.0	60	1.09
Wood shingles	2.0	2.5	no data	no data
Cement shingles	0.3	0.4	no data	no data
Other	8.5	16.8	—	—

shingles are increasing in popularity because of the appearance of the added thickness they provide. Asphalt–glass fiber shingles are covered by ASTM standard D 3462.

Shingles are installed over an asphalt-impregnated felt underlayment with galvanized roofing nails. Field applied adhesive is used for very steep applications, and in areas that experience high winds. Specific application instructions are usually printed on each shingle wrapper.

Some manufacturers have introduced APP (atactic polypropylene) or SBS (styrene butadiene styrene block copolymer) polymer modified asphalt shingles. They have impressive flexibility and some have high wind resistance, but they have not yet been on the market long enough to demonstrate their performance.

1.2 Architectural Metal

Architectural metal such as copper, lead-coated copper, lead, and related alloys are used for roofing monumental buildings such as railroad stations, post offices, and capitol buildings. Copper continues to be the most popular, and can be gilded with gold leaf to provide the gold dome look of many capitols. Lead-coated copper or stainless steel is used where the roof runoff might stain the masonry or concrete walls.

The metal panels are installed over wood decking with nailed metal cleats, and locked joints may be soldered. The standing seam or flat seam panels are installed over an underlayment and use hidden fasteners.

1.3 Asphalt–Organic Felt Shingles

The asphalt shingles made on organic felt were precursor to today's asphalt–glass fiber shingles. They are manufactured by saturating a wood fiber felt with

soft asphalt saturant before the sheet is coated, surfaced, and cut in a manner similar to that described for asphalt–glass fiber shingles. The higher asphalt content provided by the saturant reduces the fire resistance of the asphalt–organic felt shingles to an ASTM E108 Class C fire resistance (better than wood shakes but not as good as the Class A fire resistance of asphalt–glass fiber felt shingles). The asphalt–organic felt shingles are usually thicker, heavier, stronger, and more wind resistant (less brittle) than their asphalt–glass offsprings, and are preferred by many roofers in northern climates. It is not known if this preference is due to the conservatism of the roofers or the properties of the shingles, but the asphalt–organic shingles will be completely replaced as stronger and less brittle asphalt–glass shingles are introduced to the market.

1.4 Concrete Tile

Concrete tiles are a relatively recent (~1960) addition to the clay and concrete roof tile classification of roofing materials. They are primarily used in climates that experience few freeze–thaw cycles, where the high water absorption they demonstrate is of little consequence. Often overcoated with latex paints or whitewash to minimize dirt accumulation and fungus growth, concrete tiles are very popular in Florida. The tiles can be cleaned and recoated when they become dirty. Concrete tiles require a mechanically fastened, waterproof underlayment, and are attached to the underlayment with mortar, mechanical fasteners, or, more recently, plastic foam adhesive.

1.5 Structural Metal

Corrugated steel, aluminum, and similar metals are currently used for applications where they provide

dual roles of waterproofing and structural support. With the advent of the floating roof concept, where factory-formed metal panels are allowed to expand and contract freely within their restraints, structural metal roofing became practical. Structural metal roofing is lightweight, can include any desired quantity of insulation, and is economical to install. It presents problems with odd shaped buildings, roofs that require many penetrations, and many of the details at penetrations and perimeters can be very challenging. On steep slopes structural metal roofing is water-shedding. Low-sloped structural metal roofs rely on factory-applied sealants or edge gaskets to be watertight; these seals may fail at ice dams or other severe exposures to ponded water.

1.6 Natural Slate

Natural slate shingles have the longest service life. As with any natural product, the local quality can vary significantly. Laboratory tests such as in ASTM Standards C217 and C406 should be applied to each source of slate. Individual slates are usually checked by an experienced slater as they are installed. It is important to use stainless steel or other fasteners with a long service life because the service life of the assembly might otherwise be limited by the life of the fasteners.

1.7 Wood Shingles

The wood shingle appearance is admired by many because of its rustic, rough texture; this appearance has been copied with many other materials in varying degrees of success. Its durability is dependent on the wood species used and the exposure. Wood shingles have a relatively low fire resistance and cannot be recommended where severe fire exposure may be present.

1.8 Cement Shingles

Many of the original cementitious shingles were reinforced with asbestos fibers and have a history of excellent performance. Since asbestos-containing products have fallen out of environmental favor, wood-fiber-reinforced cement shakes and shingles have been introduced. Without the long history of the asbesto-reinforced products, some of these wood-reinforced products are performing well, while others have failed to live up to the claims made by their manufacturers.

2. Low-sloped Roofing

Low-sloped roofing represented approximately 65% (~$17 billion) of the 1999 roofing industry sales. About 25% of the sales represent roofing new construction; 75% was used for reroofing. In reroofing, the old roof was torn off ~65% of the time. The old roof was covered over with new material in ~35% of the reroofing.

Table 2 lists the market share, mean service life, and life cycle costs associated with many of the low-sloped roofing systems currently available. This is not a complete list because new types of systems are continuously being introduced. The "other" category in Table 2 includes many of these new materials and materials intended for steep-sloped applications.

2.1 EPDM (Ethylene–Propylene–Diene Rubber)

EPDM roofs are widely used in the northeastern part of the USA. They are used less frequently in the mid- and far-western states. EPDM is usually supplied in large sheets, making it ideal for large roof areas with few penetrations. EPDM is available in several thicknesses, in both reinforced and unreinforced, and in FR (fire-retardant) and regular grades. The rubber

Table 2
Low-sloped roofing market share (1998), mean service life, and life cycle costs.

Roofing materials	Market share (%)		Mean service life (yrs)	Life cycle cost ($ft^{-2} yr^{-1})

sheets can be glued to the substrate with contact cements, mechanically fastened, or ballasted with an overburden of stones or concrete pavers. Currently, uncured butyl rubber tapes are used to seal the joints between the sheets. Reinforced EPDM is usually used for mechanically attached systems. EPDM has a moderate service life. It is attacked by oils and greases.

2.2 Asphalt Built-up Roofing

Asphalt membranes using glass fiber felts are the most popular of the built-up roofs; they have largely replaced their cousins made with organic felts. Properly applied, asphalt–glass built-up roofs are in the class of low-sloped roofs, with the longest service life. Three to four felt plies alternate with layers of asphalt; hence the built-up roof name. Asphalt built-up roofs should not be used in exposure to organic acids, and the odor of hot asphalt can be objectionable to sensitive individuals.

2.3 SBS (Styrene–Butadiene–Styrene Block Copolymer) Polymer-modified Asphalt

SBS polymer-modified asphalt membranes usually have two plies of coated felt. The top ply must be granule surfaced. The sheets are very flexible and are as extensible as their reinforcing allows. The sheets are usually installed in hot asphalt or cold process adhesives. SBS cap sheets are sometimes used over an asphalt–glass built-up membrane (composite construction) for difficult exposures. Excellent long-term exposures are reported from northern European countries.

2.4 APP (AtacticPolypropylene) Polymer-modified Asphalt

APP polymer-modified membranes use blends of polypropylene to modify the coating asphalt on sheets that are usually applied with a torch to melt the cap sheet onto a base sheet. Protective coatings are recommended to maximize the membrane's service life. Excellent weathering performance is reported from southern Europe.

2.5 Architectural Metal

Copper, lead-coated copper, stainless steel, and similar metals are used on low-slope applications. These low-sloped applications differ from the steep-sloped applications in that all the seams must be soldered waterproof, not merely bent to be water shedding. Systems are offered with gaskets and sealant-filled joints, but these should only be used on steep slopes because it is unwise to rely on sealant joints for water tightness.

2.6 PVC (Poly(Vinyl Chloride))

Reinforced PVC sheets are resistant to most chemicals; the seams between sheets are heat sealable, to provide a membrane where the integrity of each seam can be checked. The narrower (one meter) wide sheets are ideal for roofs with many penetrations. The PVC sheets are installed with mechanical fasteners, fully adhered, or ballasted. Some manufacturers offer waterproofing sheet systems. The PVC sheets are very slippery when wet.

2.7 Sprayed Polyurethane

Polyurethane foam is sprayed over the surface of the prepared substrate. The polyurethane foam is coated with acrylic, urethane, or silicone rubber coatings. Roofing granules may be broadcast into the wet coating to improve weatherability. Uncoated foam "rusts" (forms a brown dusty layer). The quality of the installed system is very dependent on the skill of the applicator, and "bird baths" (ponded water) should be avoided. This system is useful for domes and other roofs with irregular shapes; it has the highest life cycle cost of any of the other systems listed in Table 2.

2.8 TPO (Thermoplastic Polyolefin)

TPOs are a recent addition to the US market; they are widely used in Europe—principally in an inverted roof or a waterproofing application where they are protected from sunlight. The correct balance between fire-retardant and ultraviolet resistance additives is said to be critical. The principal olefins used are blends of polypropylene and polyethylene. These membranes are of great interest because it may be possible to recycle them into new membranes after they have outlived their service life.

2.9 Coal-tar Pitch Built-up Roofing

Coal-tar pitch membranes using coal-tar saturated organic felts is one of the oldest systems listed in Table 2. These systems perform very well historically, but are limited to very low slope applications and must be gravel surfaced because of the low viscosity of coal-tar pitch at normal rooftop temperatures. Coal-tar systems are prime candidates exposed to organic acids, such as the roofs on milk processing plants, or soup-canning factories. These membranes frequently contain four felt plies. Some people find the mothball odor evident during the roofing process objectionable; it is a carcinogen.

Coal-tar pitch membranes using compatible bitumen glass fiber felts are relatively new to the field. Some of these membranes made with asphalt-coated glass felts and coal-tar pitch have performed poorly

because of incompatibility between the asphalt and the pitch. Additional problems have been reported when the glass fiber felts are too porous for the low viscosity pitch, permitting the felts to float upward before the gravel surface is applied, or allowing the felts to sink to the bottom of the membrane under the weight of the gravel surfacing. Standards have not been set for felt porosity.

2.10 CSPE (Chlorosulfanated Polyethylene)

CSPE membranes are often a blend of CSPE (Hypalon®) with PVC, or other thermoplastic polymers to permit the sheets to be heat sealable. The CSPE membranes have been decreasing in popularity because of performance difficulties.

3. Summary

The number of roofing materials on the market has been constantly increasing, and shows little sign of decreasing in the future, although many of the current systems may fall out of favor and disappear when competitive pressures or relatively poor life cycle performance become evident.

Rubber Tires

The pneumatic tire is the most complex composite product in mass production today. It consists of a variety of materials such as natural rubber (NR), synthetic elastomers such as polybutadiene (BR), textiles such as nylon and polyester, and a range of different brass-coated steel wires. Since the 1960s, tires have undergone a major evolution. In the 1960s they were typically of a bias construction and required use of an inner tube for air retention. Bias or diagonal ply tires describe a tire construction

Figure 1
Tire construction, (a) radial and (b) bias types.

where the ply cords extend to the beads, and where the ply cords are laid at an angle substantially less than 90° to the centerline of the tread or the direction of the beads cables (Fig. 1). Typically in this time period automobile tires reached up to 20 000 miles, after which they were replaced. In the 1970s, the radial tire emerged with significant improvements in mileage, fuel economy, and safety. Radial tires have a structure where the casing ply cords extend to the beads and are laid at a 90° angle to the centerline of the tread. The casing is stabilized by an essentially ridged belt system. This was followed by the introduction of the tubeless tire, which used an airtight membrane inside the tire, and formed an airtight seal between the tire and the rim through compressed fitting of the tire bead on an inclined steel wheel. "Ultralow-aspect ratio" tires are now emerging where the sidewalls of the tires are considerably shorter, allowing improvements in vehicle stability, rolling resistance, and, in the case of commercial trucks, cargo volume. They are also providing a basis for the development of "run flat" technology, where tires can operate at near zero inflation pressure.

Tires fall into essentially eight categories, based on the mission profile for the product. These are: racing and sports vehicles; passenger or consumer vehicles; light truck and sports utility vehicles (SUV), where gross vehicle weights do not exceed 7250 kg; commercial trucks; farm applications; earthmoving equipment, where gross vehicle weights can approach 300 tons; aircraft; and finally nonpneumatic specialty tires for applications such as fork lift trucks. All tires, whether they are designed for something as simple as a bicycle or as complex as a large commercial aircraft, must meet a fundamental set of performance functions:

(i) provide load carrying capacity;

(ii) provide cushioning, damping, and minimum noise and vibration;

(iii) transmit driving cornering, steering, and braking torque;

(iv) resist abrasion;

(v) have low rolling resistance; and

(vi) be durable and safe through the expected service life of the product.

1. Basic Tire Design

Figure 2 illustrates the components of a typical commercial truck tire used on vehicles which would have a gross vehicle weight (GVW) up to 40 tons. In summary, the components can be described as follows.

1.1 Tread

Tread is the component of the tire that is in contact with the road. It must show wear resistance, good traction characteristics, fuel economy, and resist service-related damage. A base underneath the tread is designed to dissipate heat and ensure good adhesion between the tread and the tire casing. Automobile tires tend to contain blends of styrene butadiene rubber (SBR) and polybutadiene (BR) rubber, oils, carbon black (up to 45% by weight), and silica. Heavy-duty truck tire treads tend to contain high levels of natural rubber (NR) and approximately 30% by weight of fine particle size carbon black. Other tires such as for aircraft, farm equipment, or earthmoving equipment can contain blends of NR, BR, and SBR.

1.2 Sidewall

The sidewall protects the tire from impact and curb scuffing. It also provides long-term weathering protection and casing durability. It is typically a blend of NR and BR and contains carbon black, high levels of antioxidants, and antiozonants.

1.3 Bead Region

The bead region consists of a number of components, such as the bead cable which locks the tire onto the

Figure 2
Radial truck tire components.

wheel or rim, apex or bead filler, chipper wire which protects the ply from rim damage, and the chafer, which is the abrasion-resistant rubber component in contact with the rim.

1.4 Plies

Consisting of steel or fabric, plies extend from bead to bead, and serve as the primary reinforcing member on the tire. They provide strength to the tire to enable high-pressure air retention. Fabric plies can be made from either poly(ethylene terephthalate) (PET), nylon-6, or nylon-66.

1.5 Belts

Belts consist of layers of steel wire and fabric forming a hoop under the tread. They restrict deformation of the casing and provide rigidity to the tread region, thereby allowing improved wear and handling performance, better damage resistance and protection of the ply cords. Belts are composed of either steel wire, PET, nylon-66, or nylon-6 coated with a NR based compound.

1.6 Shoulder

This is a wedge, which is a stiff component composed of compounded natural rubber, designed to provide stability of the belts and tread.

1.7 Liner

The liner is a membrane consisting of a compounded bromo-isobutene-isoprene rubber (BIIR), or other derivatives of this polymer or blends of butyl (IIR), halobutyl, and NR polymers, and whose function is to retain compressed air inside the tire.

2. Tire Engineering

Tire section width is the section width of the tire from sidewall to sidewall, illustrated in Fig. 2. The section height is the distance from the bottom of the bead of the tire to the top of the tread. These two parameters are important in describing the tire size seen on the sidewall. For example, the tire size designation LT235/75R15 denotes:

LT   light truck

235   approximate section width in millimeters

75   aspect ratio or the ratio of section width to section height

R   radial construction

15   nominal rim diameter in inches

Other sidewall markings include construction and manufacturing information, speed rating, and load carrying capability. Reference should be made to the
Tire and Rim Association Inc. Year Book, or the European Tyre and Rim Technical Organization (ETRTO) *Standards Manual*, for a full description of tire nomenclature and rim specifications for a given tire size.

The tread pattern influences the ability of the tire to transmit steering, braking and driving forces while operating in a broad range of highway and off-road surfaces. Reference should be made to Clark (1982) for a description of tread pattern design and influence on wear, traction, vehicle handling, tire damage resistance, and tire rolling resistance.

3. Tire Reinforcements

A tire is a textile/steel cord/rubber composite, where the steel and fabric cords reinforce the rubber compounds and are the primary load-bearing structure within the tire.

Polyester (PET) is used as the ply cord in automobile and light truck tires. It is also used for belts of fabric reinforced tires such as farm tires. The selection and strength of a polyester cord are defined by the tire performance requirements. These in turn are determined by the mission profile of the vehicle for which the tire has been designed.

Nylon-6 (polycaprolactam) and *nylon-66 (poly(hexamethylenediamine) adipamide)* are used in the plies of commercial tires (farm, aircraft, bias truck) and also as an overlay in high-performance passenger and light truck tires. The overlay sits over the steel belts and serves to hold the belts in place while the tire is operating at high speeds. Nylon-66 is preferred over nylon-6 due to its higher melting point (265 °C vs. 225 °C). Nylon has good fatigue resistance, durability, and tenacity. However, it tends to have poor dimension stability.

Steel cords used in tires are brass coated. Steel rod is first drawn down to a diameter of 1.2 mm and the brass plating applied. The filaments are then drawn down to their final diameter, which could range from 0.15 mm to 0.45 mm depending on the application for which the cord is needed. Steel cord construction terminology such as $3 + 6 \times .22$ describes a cord of three filaments, wrapped with six additional filaments with a diameter of 0.22 mm. Steel cords used for plies have been designed for fatigue resistance. Belt wires have greater rigidity for stiffness. Ford and Charles (1988) have a comprehensive discussion on steel cord design and application.

Cotton and rayon are no longer used in tires to any significant extent. Aramid is used in special applications such as in aircraft tires. New technology cords under development include hybrid cords of nylon, aramid, and polyester, very high tensile strength steel cords, and new polyesters such as PEN (poly (ethylene-2,6-naphthalene dicarboxylate)), POK (polyethylene ketone), and carbon fibers.

Cord construction such as 1400/1/3 defines the linear density of base yarn, in decitex (1400), the number of yarns in the ply (1), and number of plies in the cord (3). The direction of twist on the filaments or yarns in a cord can be described as in the "S" direction, which is clockwise around the central axes of the tire cord, or "Z" twist, which is counterclockwise around the central axes (Bhakuni *et al.* 1997).

4. Tire Compounds

Compounding ingredients fall into one of five general categories: (i) polymers, which are typically natural rubber (NR), styrene butadiene rubber (SBR) and polybutadiene (BR); (ii) fillers such as carbon black, silica, clays, and calcium carbonate, though the latter two are used more in rubber products for industrial applications; (iii) protectant systems consisting of antioxidants, antiozonants, and waxes; (iv) a vulcanization system; and (v) special purpose chemicals such as processing aids, oils, and resins. Product performance objectives define the initial selection of materials. These materials must be benign with respect to environmental concerns, must facilitate processing in production plants, and be cost-effective.

Natural rubber is classified into three categories: (i) technically specified rubbers (TSR), where contaminant levels such as ash, nitrogen-containing chemicals, and viscosity are defined; (ii) visually inspected rubbers such as smoked sheets and crepe, which are shipped in 115 kg bales; and (iii) specialty rubbers such as epoxidized natural rubber and powdered rubber. Natural rubber use in radial tires has increased over that used in bias tires because of improved green strength, i.e., strength before vulcanization, tear strength, tire component-to-component adhesion, lower heat generation (hysteresis) under dynamically loaded conditions, and lower tire rolling resistance (Roberts 1988).

Classification of synthetic rubbers is governed by the International Institute of Synthetic Rubber Producers (IISRP). For SBR, polyisoprene, and polybutadiene, a series of numbers have been assigned which define the basic properties of the polymer. For example, the IISRP 1500 series describes the range of commercially available, cold-polymerized emulsion SBR polymers. The series 1200 through to 1249 defines non-oil extended polybutadienes, and 2200 to 2249 is for polyisoprene and copolymers of isoprene.

A series of empirical guidelines can be used in designing a tread compound polymer for a set of tire performance criteria (Nordsiek 1985):

(i) there is a nearly linear drop in abrasion resistance, or tread wear, as polymer glass transition temperature (T_g) increases;

(ii) as T_g increases, wet grip or traction improves;

(iii) inclusion of styrene, and an increase in the styrene level, increases tire wet traction and decreases tire tread wear performance.

Carbon black grades fall into one of typically seven classes: SAF (super abrasion furnace), ISAF (intermediate super abrasion furnace), HAF (high abrasion furnace), FEF (fast extrusion furnace), GPF (general purpose furnace), SRF (semi-reinforcing furnace), and MT (medium thermal). Selection of the appropriate grade of carbon black, further described in ASTM D1765, can, however, lead to significant improvements in performance. For example, the larger surface area carbon blacks (SAF) are required for tread wear. However, as particle surface area increases with a corresponding improvement in tread wear, rolling resistance of the tire can increase with adverse effects on fuel economy. Reduction in carbon black loading will lower tire rolling resistance (see also *Elastomers, Reinforcement of**).

Addition of silica to a compound will improve tear strength, reduce heat build up, and improve compound adhesion in multicomponent products such as tires. Two fundamental properties of silica influence their use in rubber compounds: ultimate particle size and the extent of surface hydration.

Unsaturated elastomers are susceptible to oxidation. Atmospheric ozone will also readily degrade elastomers. For example, tire sidewalls which are subject to a high degree of flexing will show crazing and cracking; such damage is clearly visible in most tires after about four years of operation. To protect an elastomer from oxidation or ozonolysis, three categories of materials are added to the elastomeric formulation, i.e., waxes, antioxidants, and antiozonants (see *Elastomers in Oxygen and Ozone, Degradation of#*).

Antioxidants are mainly amine or phenolic derivatives such as 1,2-dihydro-2,2,4-trimethylquinoline (TMQ), and they function by reacting with oxides or broken polymer chain ends caused by reaction with oxygen. They therefore prevent the propagation of oxidative degradation, enabling the retention of the physical properties of the elastomer.

Ozone protection is obtained through the use of two materials, waxes and, typically, paraphenylene diamines. A number of empirical guidelines can be used to develop an antidegradant system for a compound in a tire. Short-term static protection is achieved by use of paraffinic waxes. Microcrystalline waxes provide long-term ozone protection while the finished product is in storage. A critical level of wax bloom is required to form a protective film for static ozone protection. Optimized blends of waxes, paraphenylene diamines such as N-(1,3-dimethylbutyl)-N-phenyl-paraphenylenediamine (6PPD) and antioxidants, such as TMQ, provide long term tire protection under both static and dynamic applications, and over an extended temperature range.

The vulcanization system in a tire compound consists of three components: the activation system, typically zinc oxide and stearic acid; the vulcanizing agent, which is typically sulfur; and accelerators, such as cyclohexylbenzothiazole sulfenamide (CBS). In an idealized tire compound, zinc oxide and stearic acid react to form zinc stearate at tire vulcanization temperatures. The zinc stearate then reacts with the accelerators in the compound to form a "sulfurating complex," which with sulfur creates the required cross-link network. Accelerators can be classified into different categories, depending on the reaction rate and nature of the cross-links they create. Thiurams such as tetramethylthiuram disulfide (TMTD) give predominantly monosulfidic sulfur cross-links. Sulfenamides, when used with high sulfur concentrations, build predominantly polysulfidic cross-links. The structure of the cross-link network can therefore be designed to meet a specific set of service requirements.

A broad range of other materials are used in a compound. For example, titanium dioxide is used for tire white sidewalls; processing oils are used to assist in mixing, extrusion and calendaring of compounds through the factory. Plasticizers such as dioctylphthalate are also used as processing aids. Chemical peptizers such as pentachlorothiophenol are added to the compound during the initial mixing to reduce energy consumption in mixing and provide a more uniformly mixed compound. Resins include extending or processing resins, tackifying resins, which help in handling of components during the tire assembly operation, and curing resins, which are used to improve properties such as tensile strength.

A comprehensive review of materials used in rubber compounding has been compiled by Mark *et al.* (1994), further reference to which is recommended.

5. *Examples of Tire Compounds*

Excluding the weight of the tire reinforcements, a tire's material composition might typically consist of 36% natural rubber, 20% synthetic polymers, 33% carbon black and silica, 6% chemicals, 2% protectants, 2% zinc oxide, and 1% sulfur. Tread compound composition is dependent on the mission of the vehicle for which the tire has been designed. Treads for tires on high-performance cars will use high T_g synthetic polymers, silica, and high levels of oil for traction and vehicle handling. For commercial truck tires, where parameters such as tread wear and fuel economy are more important, high levels of natural rubber and high surface area carbon blacks are used. Wire coat compounds are always composed of natural rubber with a HAF or ISAF grade of carbon black and in some instances silica. Sidewalls are composed of blends of natural rubber and polybutadiene, present in a 1:1 ratio. Carbon black levels

are typically 25% of weight of the compound. Other internal components such as shoulder wedges, apex or bead fillers, and base compounds are made primarily of natural rubber, for adhesion, hysteretic properties, and tear strength. Innerliners of radial tires contain chloro- or bromo-isobutene-isoprene rubber (CIIR, BIIR) compounded with HAF, FEF, GPF, or SRF carbon black. Carbon black levels can range from 25% to 50% of the compounded formulation weight, depending on the tire design.

6. Tire Testing

Tire testing occurs in three stages: initial laboratory testing; general proving ground testing, where tires are mounted on vehicles which are then tested on specially prepared roads; and commercial fleet tests. Materials tests include studies of vulcanization kinetics, measurements of compound physical properties such as tensile strength and tear strength, and dynamic properties in both shear and tension. Tire laboratory testing includes tire uniformity tests, speed rating determination, rolling resistance, durability assessment, and basic handling characteristics such as cornering coefficient.

Proving grounds consist of high-speed test tracks, gravel roads, wet and dry skid pads, and tethered tracks for testing of farm tractor tires. Testing is conducted under defined conditions such as loads, inflations, speeds, and specific vehicle types. The vehicles have been specified to meet a set of defined conditions such as wheel alignment, vehicle horsepower, wheel base, and axle configuration.

Finally, commercial testing enables the tire materials engineer to obtain an assessment of how compounds and reinforcements will perform under a broad range of service conditions that the end consumer will experience. The result of the testing protocol which tires undergo is a broad range of products to meet the vehicle manufacturers', as well as the end users', needs for optimum performance under a broad variety of service conditions.

Sporting Materials: Ski Equipment

The use of sophisticated materials in the design and manufacture of ski boots, bindings, and skis has been a major factor in the advancement of recreational and performance skiing, and "high tech" materials are frequently emphasized in the advertising campaigns promoting new equipment and clothing. Skiing, like tennis, cycling, and golf, has benefited from technological advances that have produced more "user friendly" equipment. In fact, materials development in skis, tennis racquets, golf clubs, and bicycle frames is remarkably similar. This is due in part to the similarities in desired performance characteristics; e.g., lightweight, high strength, durable, responsive, shock absorbing, etc., and the need to tailor these properties to the skill level of the user. From a historical standpoint, Howard Head, an entrepreneur and avid skier, had much to do with transforming both ski and tennis racquet design and the associated materials innovations. Head pioneered the use of metal in ski construction, and much later he introduced the first large-body tennis racquet. He realized the significance of using modern structural materials, and the related design innovations that could be introduced as a result of moving beyond traditional wood structure and manual fabrication techniques.

From the early days of simple wood skis, which Head and others recognized as excessively heavy and difficult to maneuver, the ski industry has graduated to equipment manufactured using more complex, performance-oriented structures. Wood laminates, metal, fiberglass, and plastics were incorporated into ski structures as the materials became available and commercial interest in skiing grew during the 1950s and 1960s. The most important material property contributing to performance was specific stiffness (modulus/density), and glass and carbon-fiber composites had some advantage in this respect over steel and aluminum. Vibration damping, fatigue life, and durability were also improved with composite materials.

The major problem in moving from wood structures to designs incorporating metals and other materials was the integrity of the joints between these dissimilar materials, e.g., wood and steel. Few adhesives were available, and the technology and equipment for assembling and curing complex material combinations was very limited. The development was strictly empirical, and ski testing took place on the slopes; many sets of Head's revolutionary metal skis were subject to premature failure before a successful manufacturing process was developed.

The choice of materials used in modern skis can be linked to specific performance criteria and the trends in ski design, which have paralleled the transition from traditional to contemporary ski technique. Performance is now the single most important issue determining the material of choice, whether the aim is to produce a competitive product for the racer or advanced recreational skier, or an "easy to use" ski for the beginner and intermediate recreational skier. An almost unlimited variety of materials are available and there are markets for even the most expensive products (graphite and specialty composites). Safety and durability are additional factors that influence design decisions, and which are directly linked to the materials selection criteria, specifically in relation to bindings and attachment components, as well as to the structural integrity of the ski. The differences in criteria determining modern ski construction vs. those of the 1950s are compared in Fig. 1. Availability and cost of material, although important, are no longer the limiting factors. Performance and safety are the key issues. Intense competition within the ski industry also promotes the use of "high tech" materials as marketing ploys, thus complicating the picture to some degree. Overall, the modern ski provides a much improved performance, is more user friendly, and is significantly more durable than its predecessor from the 1950s.

As indicated above, the same materials innovations have tended to occur in skis, tennis racquets, mountain bikes, and golf clubs. The common thread in performance is dynamic motion and impact, with a requirement for the athlete to remain in balance and control. Beginners need equipment designed to absorb and insulate them from external impact forces, whereas the experienced athlete can profit from equipment that is more responsive. "Sensitivity" and "feel" are juxtaposed to shock and vibration, and skis are therefore rated according to the skill and performance level of the individual athlete.

For many years skis were characterized as rigid and lively for the racer or advanced athletes, or soft

Figure 1
Materials selection criteria of the 1950s and 1990s.

---

and damp for the beginner and recreational skiers. The introduction of metal in the early 1950s was a major step leading to the introduction of composite structures engineered to flex and distribute the stresses according to the desired performance criteria. The biggest problem confronting designers like Head was the joining of the dissimilar materials, and the integrity and durability of those joints during use.

Layered structures became quite complex as designers aimed at providing the desired characteristics in the ski, based on the specific use. Specialty alloys, polymer composites, graphite, Kevlar, and ceramic fibers were used to distribute stress, dampen vibration, and determine the manner in which the ski would flex and respond to external forces during use. Materials played an increasingly important role as the construction evolved from a monolithic structure to a multicomponent system incorporating a top layer, side walls, core, edges, and base layer. Some of the more common structures are shown in Fig. 2.

These configurations reflect the requirement for the ski to exhibit significant variable flexibility along its length (to conform to terrain variations), but to have good torsional strength to retain a stable platform for balance and control.

The stress distribution across the surface and the core of the ski is a function of the individual material properties, particularly the yield strength and modulus. The peak stresses can be modulated by the material selection and design considerations. The higher modulus material will carry the bulk of the stress for any given level of strain. This can be shown on a simple stress/strain diagram (Fig. 3).

This can be further illustrated in a simple thin-section composite lay-up under a static load producing an elastic strain (Fig. 4). For the monolith, the stress field is symmetrical with the peak compressive and tension stresses located at the opposing surfaces. The location and distribution of the stress in the layered

composite is a function of the material modulus and the position of the layer within the lay-up. For any given amount of (elastic) strain, the higher modulus material will carry a greater portion of the total stress. The peak stress can therefore be concentrated in high-strength, high-modulus material layers within the structure.

Advanced materials including lightweight metal alloys, carbon fibers, Kevlar, and even piezoelectric ceramic devices have been identified as performance-enhancement factors in recreational skis. The case for using such sophisticated materials is based on the severity of the dynamic loading experienced by the ski in the course of normal operation. This is described in a simplified form as follows.

In operation the ski is subjected to variable dynamic loads at multiple impact points, and is required to flex elastically to conform to extreme terrain variations. The ski must also represent a stable platform on which the skier can balance at speeds which can exceed 50 km h^{-1} for recreational skiers, and significantly higher for racers and advanced athletes. In Fig. 5, the primary forces operating on this platform (the skis) are indicated for one plane only. As long as

Figure 3
Stress–strain behavior of a typical composite layer material.

Figure 2
Examples of composite layer structures.

Figure 4
Distribution of stresses in monolith vs. composite.

Figure 5
Primary forces operating on skis indicated for one plane only.

the resultant force vector is inside the ski(s)–snow contact points, the skier remains in balance. Any deviation in direction or lateral slippage of the skis requires readjustment by the skier to retain dynamic balance. The strength and rigidity of the ski are therefore key factors determining the performance limits as a function of speed, terrain, weight, and skill level of the skier.

The conflicting requirements (flexibility vs. stability) are addressed by combining dissimilar materials with different functions within the structure, and in some instances employing multifunctional materials to enhance both the efficiency and the performance. The resistance to flexure becomes progressively higher (with amplitude) as the load is transferred to the higher modulus materials in the composite structure. Vibration damping is accomplished with rubber-like absorbing materials in the sandwich layers or in the core. Innovations have favored external damping devices, including mechanical and electromechanical devices such as piezoceramic materials. The latter are based on the dissipation of high-frequency mechanical energy by conversion to electrical energy. Similar concepts are under development for aircraft and automotive structures.

There is a growing awareness of the underlying physics that applies to skiing and the resultant performance characteristics that govern the design and construction details of skis. The move in skis to wider body, "shaped skis" mirrors the similar design trends in tennis racquets, and the enabling technology in both instances has been the materials and related manufacturing development.

There is a vast range of ski equipment that caters for all levels of ability and all types of ski terrain and snow conditions. The choice of construction materials usually accounts for the differences in the performance level. There is no "universal ski" for all abilities and conditions, although most recreational models will provide adequate performance for the average skier under most conditions. Materials will continue to dominate the innovations in ski equipment and ski clothing for the foreseeable future.

Spun (Slurry and Sol–Gel) Ceramic Fibers

Commercial polycrystalline ceramic oxide fibers are produced by spinning and heat treating chemically derived precursors. This chemical process approach is commonly called sol–gel or metal-organic processing. The use of chemical processing allows the preparation of ceramic oxide fibers with high-temperature properties not accessible by traditional approaches, such as spinning of molten glasses. A key characteristic of chemically derived fibers is their ultrafine or even nanoscale microstructure; a grain size below 0.5 μm is optimal for high strength. All commercial ceramic oxide fibers are based on the alumina–silica system since those compositions are particularly useful for high-temperature applications.

Sol–gel fibers are spun in the form of tows or rovings, which typically consist of 400–1000 filaments each having a diameter of 10–15 μm. Fiber tows are flexible and easily handled, which allows them to be woven into fabrics and other complex shapes. The tensile strength of ceramic oxide fibers is typically 1.8–3.0 GPa and their elastic modulus is 150–380 GPa. Major uses for ceramic oxide fibers are as high-temperature thermal and electrical insulation for applications requiring flexibility and light weight, such as sleeves for pipes and electrical cables, high-temperature shielding, belts, blankets, and gaskets. Reinforcement of high-temperature metals and ceramics is an additional area of growing interest.

Advantages of ceramic oxide fibers include stability in air at high temperatures, stability in molten metals such as aluminum, high compressive strength, high elastic modulus, and high electrical resistivity. Disadvantages include low strength compared with SiC and carbon fibers, comparatively high density ($3.2–4.0\,\mathrm{g\,cm^{-3}}$), and poor high-temperature creep resistance. The cost of ceramic oxide fibers is higher than that of glass and carbon fibers but lower than that of SiC fibers.

1. Chemical Processing

Chemical or sol–gel processing was first used to produce ceramic oxide fibers in the 1960s (Wainer 1965). A number of chemically derived alumina–silica fibers, notably Saffil (noncontinuous 95% Al_2O_3–5% SiO_2 fibers) and Nextel[TM] 312 (continuous aluminum borosilicate fibers), were commercialized in the late

1970s (Stacy 1988, Birchall *et al.* 1985, Sowman 1988). Most applications for these fibers are for thermal insulation, where load-bearing capability is not a major concern. More recently, fibers designed specifically for the reinforcement of composites have been produced e.g., DuPont's Fiber FP and Nextel[TM] 610 and 720 ceramic oxide fibers.

2. Oxide Fiber Precursor Chemistry

There are a number of alumina precursors available that are suitable for forming fibers. The aqueous chemistry of aluminum allows for the formation of viscous basic aluminum salt solutions that can be made into fibers by dry spinning. Polymeric aluminoxane precursors have also been used to produce alumina-based fibers. More recently, aluminoxanes that can be melt spun into fibers have been produced. Details of both types of chemical precursor are given below.

The spinning solution or spin dope must be a high-viscosity (10–$100\,\mathrm{N\,s\,m^{-2}}$ ($10\,000$–$100\,000\,\mathrm{cP}$)) liquid, stable with respect to both crystallization and precipitation of insoluble salts and organic-containing complexes and to rapid increases in viscosity or gelation resulting from the progression of cross-linking of precursor species. Spin dopes prepared using exclusively colloidal sols (e.g., boehmite, AlOOH) are not suitable for forming continuous fibers because they are shear thinning. Colloidal SiO_2 is, however, commonly used as a component in oxide fiber spin dopes. Other SiO_2 precursors such as partially hydrolyzed alkoxides and polysiloxanes have also been used as a method of introducing SiO_2 into fiber compositions. Other inorganic modifiers to oxide fiber compositions can be readily added using soluble salts (e.g., nitrates). Long-chain organic polymers such as polyethylene oxide are commonly added to improve fiber-forming ability and green strength. Using organic polymers as spinning aids, spin dopes can also be prepared using slurries. Slurry-based fibers (e.g., Fiber FP) have high ceramic content relative to organics, so that shrinkage is reduced, leading to simple heat-treatment. Using slurries, a wide variety of compositions can be produced, limited only by the availability of submicrometer powders (French and Cass 1998). For instance, $BaTO_3$, PZT, YAG, and SiC fibers have been produced using a slurry technique. Sol–gel processes have also been used to prepare a variety of fiber compositions not based on alumina, including ZrO_2, ZrO_2–SiO_2, TiO_2, YAG, and Y_2O_3.

2.1 Basic Aluminum Salts

Basic aluminum salts are salts with less than the stoichiometric 3 moles of anion per Al, and have the nominal formula $AlX_n(OH)_{3-n}$, where X is a ligand such as Cl^-, NO_3^-, or CH_3COOH^-. Basic aluminum

salts can be formed using a number of methods, including dissolution of aluminum metal in salt solutions, dissolution of aluminum hydroxides in acid, hydrolysis of alkoxides, and neutralization of acidic salt solutions. The polycationic complexes formed are stabilized against further cross-linking and hydrolysis by complexing ligands (Bertsch 1989). Basic aluminum salts used for fibermaking contain 0.5–2.0 moles of anion ligand per mole of aluminum. If the amount of ligand is too low, gelation via cross-linking of polynuclear clusters will occur; high amounts of ligand cause difficulties during fiber heat treatment because excessively large amounts of fugitives must be removed during pyrolysis. Large ligands such as lactic acid or acetyl acetonate can be used to produce spinnable precursors but are not desirable, since ceramic yield on firing is lower than smaller ligands such as chlorine. Aluminum chlorohydrates ($AlCl_x(OH)_y$) are used to prepare a number of commercial fibers, including Fiber FP and PRD-166, Almax[TM], and Alcen[TM]. Rubilon[TM] and the Nextel[TM] series of fibers are produced using aluminum carboxylates.

2.2 Polymeric Aluminoxane

Aluminoxanes consist of an Al–O backbone polymer coordinated by chelating ligands such as carboxylates and aceto-acetonates (Glaubitt *et al.* 1994, Yogo and Iwahara 1992). Aluminoxanes are synthesized by the addition of the ligand to aluminum alkyls or alkoxides to partially chelate the aluminum, followed by the addition of 0.5–1 moles of water per mole of aluminum to polymerize the aluminoxane. Depending on the ligands used, these precursors can be either melt spun or dry spun. Melt-spun fibers are cured (to make them infusible) by completing hydrolysis by exposure to humid atmospheres. Sumitomo Altex[TM] fibers are produced using this technique.

Figure 1 shows a schematic of the sol–gel fiber process. Spin dope is extruded through a spinneret to form small-diameter fibers. The fiber becomes rigid as solvent is evaporated. If the viscosity is too low, the extruded liquid spherodizes into droplets; too high, and the fibers become brittle and are easily fractured. After spinning, the green fibers are conveyed into a furnace for heat treatment. Pyrolysis (the conversion of the chemical precursor into a ceramic) typically involves the loss of 50–80% of the initial weight of the green fiber. Volumetric shrinkage can be 80% or higher. Volatile components (including CO, CO_2, H_2O produced by oxidation, plus low molecular weight organics, depending on precursor chemistry) must diffuse out of the fiber during this stage. Thus, pyrolysis must be performed with care to gently decompose the green fiber to the oxide form without forming defects or flaws. Too-rapid evolution of gases can cause pinholes, bubble or void formation, or even bloating, trapping of carbon, phase separation, and

cracking. The addition of colloidal or particulate slurries to fiber precursors increases ceramic yield, thereby reducing shrinkage and facilitating pyrolysis.

The goal of heat treatment is to develop a ceramic microstructure with both good strength and good high-temperature properties (i.e., resistance to thermal degradation via grain growth). To achieve high fiber strength at room temperature, a small grain size ($\leqslant 1.0\,\mu m$) is required. The Griffith equation, $\sigma = K_{Ic}/\sqrt{\pi c}$, indicates that for Al_2O_3 ($K_{Ic} = 3$), a strength of 3 GPa can only be achieved if the flaw size c is $< 1.0\,\mu m$. Thus, not only must defect concentration be kept low by careful fiber processing, but grain size should not exceed this limit. During fiber manufacture, extreme care must be taken in all process stages to prevent the formation of defects and flaws that reduce fiber strength.

Figure 1
Schematic of sol–gel fiber process.

3. Heat Treatment and Fiber Microstructure

Microstructures in alumina-based fibers must be viewed through an understanding of crystalline transformation sequences in alumina, and the effect of silica on microstructure and transformation kinetics. As shown in Table 1, all commercial oxide ceramic fibers are based on alumina with varying amounts of silica. The stable phases for alumina–silica fibers with $\leqslant 28\%$ Al_2O_3 at all temperatures are α-Al_2O_3 and mullite. However, a series of cubic alumina spinels commonly called transition aluminas form in the temperature range 800–1200 °C during heat treatment of alumina and alumina–silica precursors. The first phase to crystallize is either η-Al_2O_3 (cubic) or γ-Al_2O_3 (tetragonal), which form in the range 800–900 °C. In many systems, δ-Al_2O_3 and Θ-Al_2O_3 are formed with additional heating in the range 1000–1150 °C. These polymorphs are similar to γ-Al_2O_3 but have a higher degree of ordering on the cation lattice. The transformation to α-Al_2O_3 (a hexagonal crystal structure) occurs above 1200 °C; mullite ($3Al_2O_3 \cdot 2SiO_2$) also may crystallize above 1280 °C.

For alumina and alumina–silica fibers, the crystallization of new phases such as mullite and α-Al_2O_3 often result in large grains, causing the fibers to become brittle and weak. A low volumetric nucleation density, which leads to large grain sizes, is typical of both alumina and mullite. For instance, crystallization of α-Al_2O_3 in high-alumina fibers causes the formation of large, porous, spherulitic grains several micrometers in size (McArdle and Messing 1993). These large grains cause the fibers to become brittle and weak. To avoid this problem, most commercial fibers are stabilized as transition alumina by the addition of SiO_2. The addition of SiO_2 to alumina fibers increases the

Table 1
Composition and properties of commercially available oxide fibers.[a]

Fiber	Manufacturer	Composition Al_2O_3–SiO_2	Density	Crystal phase	Tensile strength (GPa)	Elastic modulus (GPa)
Nextel™ 312	3M	62–24 (+14% B_2O_3)	2.7	$9Al_2O_3 \cdot 2B_2O_3$ + am. SiO_2	1.7	150

[a] Composition data taken from vendor specifications, precursor composition taken from the patent literature. [b] No longer commercially available.

temperature of the α-Al_2O_3 transformation by as much as several hundred degrees centigrade. This allows the preservation of the submicrometer transition alumina microstructure (and therefore strength and flexibility) for extended periods above 1100 °C. At high silica contents, mullite may crystallize. B_2O_3 is added to some fibers as a grain growth inhibitor; B_2O_3 promotes the formation of a fine-grained mullite structure via $9Al_2O_3 \cdot 2B_2O_3$ intermediate phase (Richards *et al.* 1991). High silica contents will lead to the formation of mullite above 1280 °C, which also can cause weakening of the fibers via grain growth.

Table 1 compares the density, strength, and elastic modulus of commercial ceramic oxide fibers. Commercial fibers can be divided into two classes: (i) those consisting of a mixture of transition alumina and amorphous silica; and (ii) fibers containing crystalline α-Al_2O_3. Alumina–silica fibers have density between 2.7 and 3.2 and elastic modulus between 150 and 200 GPa. α-Al_2O_3 fibers have much higher elastic modulus (380 GPa) as well as higher density (3.6–4.2 $g \, cm^{-3}$). Within each class, density and elastic modulus is inversely proportional to the alumina content: fibers with high alumina content have high elastic modulus and high density. The density and modulus of γ-Al_2O_3 is in the range 3.2–3.6 $g \, cm^{-3}$ and 220 GPa respectively; the addition of SiO_2 at 2.2 $g \, cm^{-3}$ and 70 GPa will reduce both. The addition of B_2O_3 will also reduce density and modulus. The effect of silica content on strength is less clear, since strength is related to flaw size and distribution as well as composition. Most fibers have tensile strength in the range of 1.7–2.1 GPa. An exception is Nextel 610, which has a strength of 3.0 GPa.

Fibers containing crystalline α-Al_2O_3 have much higher chemical stability and elastic modulus than fibers containing transition aluminas. They are also not prone to shrinkage at high temperatures caused by crystallization and sintering, and can have higher creep resistance under load at high temperatures. For these reasons, they are used for the reinforcement of metal and ceramic composites; however, achieving fine grain size in α-Al_2O_3 fibers is not straightforward. α-Al_2O_3 has an intrinsically low volumetric nucleation density, which leads to large grain size and low strength. The addition of seeds or nucleation agents to promote high nucleation density during crystallization is essential if the fine grain sizes required for high strength (0.5 μm) are to be achieved. Seeding with submicrometer α-Al_2O_3 particles (e.g., Fiber FP) or Fe_2O_3-based nucleation agents (e.g., Nextel 610) have been used to produce fine-grained, high-density α-Al_2O_3.

Ceramic oxide fibers have limited creep resistance at high temperatures compared with SiC fibers; however, progress in fiber processing during the 1990s has enabled the preparation of fibers with significantly improved high-temperature creep properties. Fibers with increased amounts of crystalline phases such as α-Al_2O_3 and mullite, and lesser amounts of amorphous phases such as SiO_2, have reduced deformation at high temperatures. For instance, Nextel 720 fiber, which consists of a mixture of α-Al_2O_3 and mullite, has demonstrated considerably greater creep resistance above 1000 °C than either alumina–silica or α-Al_2O_3 fibers. This has been attributed to the presence of mullite, which is a more creep resistant phase than alumina, plus larger grain size. YAG fibers that exhibit even better creep resistance have been developed at several laboratories. Such YAG fibers have the potential for long-term composite reinforcement at 1200 °C and above.

Superconducting Wires and Cables: Materials and Processing

1. Introduction

The phenomenon of superconductivity was first observed in 1912 in the laboratory of Heike Kamerlingh Onnes, at the University of Leiden (Holland). At low

temperatures certain materials (~ 800 superconducting compounds have been recently tabulated by Poole and Farach 2000) suddenly lose their resistance to the flow of electricity. The phenomenon remained a laboratory curiosity until 1954 when G. B. Yntema at the University of Illinois made the first successful superconducting magnet. At that point, magnet performance fell well below that predicted by the properties of the superconductor. The slow progress can be partially attributed to (i) the difficulty in obtaining the extremely low temperatures required and (ii) the lack of understanding of how to create electrically and thermally stable wires from superconductors. The primary limitation, however, was that the superconducting phenomenon was not only limited to low temperatures but also to a restricted range of electrical current density and magnetic field and that the range of these properties was particularly limited in early superconductors. The maximum values of temperature, electrical current, and magnetic field are interdependent and, when plotted in three axes, form a "critical surface" (Fig. 1). Those early superconductors, such as Pb, In, and Hg are classified as type I superconductors. These are superconductors in which magnetic flux is excluded from their bulk and the critical current density is limited to a surface layer of approximately one-tenth of a micrometer. The maximum fields in which these superconductors can operate are usually less that 0.1 T (similar to the flux-density between the poles of a horseshoe permanent magnet). These limitations make type-I superconductors impractical for wire and cable applications. All "technical superconductors," i.e., superconductors that can be readily fabricated into wires and cables for high-current applications, are type-II superconductors. In type-II superconductors,

magnetic flux penetrates the bulk of the superconductor to form individual flux quanta (see *Electrodynamics of Superconductors: Flux Properties*[#]). In the most widely used technical superconductors, Nb–Ti and Nb$_3$Sn, the upper critical fields are 13 T and 27 T, respectively, and current densities $> 10^9 \, A \, m^{-2}$ can be carried (compared to $\sim 10^7 \, A \, m^{-2}$ for domestic Cu wire). In Fig. 2, the critical current densities at 4.2 K are compared for strands or tapes that are fabricated in lengths of more than 100 m. The temperature range is still limited (the critical temperatures for Nb–Ti and Nb$_3$Sn are 10 K and 18 K, respectively), but for many applications the cost of insulation and refrigeration is more than offset by the reduced energy costs resulting from nonresistive current flow. Because the amount of energy lost in current flow through a superconducting magnet is extremely low, it can be operated without a power supply once the magnet has been charged. This mode of operation, termed "persistent" is very desirable for MRI and NMR applications because the current flow (and consequently the field) is very stable. Liquid He is now readily available and provides cooling to 4.2 K at atmospheric pressure and as low as 1.8 K at reduced pressure. Recent advances in insulation and

Figure 1
Schematic illustration of the critical surface for a type-II superconductor. The applied field (B), the temperature (T), and the current density (J) must be maintained below the critical surface in order to retain superconductivity.

Figure 2
Comparison of critical current densities (at 4.2 K unless otherwise stated) available in strands and tapes of more than 100 m.

refrigeration technology have also made the application of superconductors more widespread. The discovery of high-temperature superconductivity (HTS) superconductors (ceramic superconductors with critical temperatures above the boiling point of liquid nitrogen (77 K) in 1986 (see *High-temperature Superconductors: Thin Films and Multilayers*[#])) dramatically increased interest in the application of superconductivity. The discovery of superconductivity at 39 K in MgB_2 in 2001 further extended the temperature range for intermetallic superconductors.

Superconductors must be formed into composite wires in order for them to be used in high-current applications and these wires may also be cabled. The wide variety of mechanical properties of superconductors: the range from strong ductile alloys like Nb–Ti to brittle ceramics such as HTS superconductors means that the wire processing routes vary greatly. Of the HTS superconductors only one, Bi-2212, is manufactured in round-wire form and HTS superconductors are more commonly manufactured as multifilamentary tapes. The brittle superconductors cannot undergo wire drawing and are consequently mechanically processed in the form of ductile precursors or fine powders that are reacted to form the final superconductor. For Nb–Ti, the alloy can be cold-worked to a remarkable extent but heat treatments are also applied during processing in order to introduce a second phase into the microstructure that will ultimately pin the fluxoids in the final wire. Because of these variations, the types of processing will be introduced separately and by superconducting material. There are, however, key components that are common to all superconducting strands.

2. General Strand Requirements

2.1 Matrix and Filaments

Superconducting wires are almost always of a multifilamentary design in which individual continuous filaments ($< 30 \mu m$ in diameter) are embedded in a high-conductivity matrix. When conditions in a localized region of a superconductor exceed the critical surface conditions, that area will start to conduct resistively and produce local heating. The resulting heat and current transfer will start a cascade effect and result in a rapid transition of the whole superconductor to the normal state. The ability to transfer heat and current away from localized regions by subdividing the filaments into a high-conductivity matrix was a key step towards producing practical superconductors. The primary components of cryogenic stabilization were not formulated until the mid-1960s (Stekley and Zar 1965). The most desirable matrices are Cu or Al, but Ag is required for the processing of HTS superconductors where oxygen diffusion through the matrix is required during heat treatment. External stabilizer is often added after heat treat-

ment; this is particularly the case for Al, which has thermal and density advantages over Cu, but is difficult to fabricate as the matrix of a composite wire. In addition to stability requirements, fine filaments also serve the purpose of limiting hysteretic loss, not only for a.c. applications but also for d.c. applications. The filament diameter requirements for a.c. applications are quite severe with desired filament diameters of less than 1 μm. For a.c. applications, a Cu–Ni matrix is often used to reduce proximity coupling of the filaments.

2.2 Filament Uniformity

As the critical current per unit cross-sectional area is limited by the material properties, the amount of current that can be carried by an individual filament is reduced if the filament is locally necked to a smaller diameter. Current may be locally transferred to adjacent filaments, but there is a broadening of the critical current transition and a reduction in time that the strand may be operated in the persistent mode (crucial for MRI application). With final filament diameters of less than 20 μm often required, this imposes a very high level of quality control on the processing of the strands. The degree of filament uniformity is reflected in the sharpness of the superconducting transition with increasing current. In the early stages of the resistive transition, the curve of voltage, V, against current, I, can be described by the power law:

$$V \propto I^n \tag{1}$$

The value of n (the transition index) decreases with field; the more uniform the filament cross-sectional areas, the more linear the decrease in n-value and the higher the initial low field value (Warnes and Larbalestier 1986). An electric field, E, is generated along the superconductor carrying a current density, J, that is related to the critical current density of the superconductor J_c at field E_c by the transition index, n:

$$E = E_c (J/J_c)^n \tag{2}$$

For composites based on Nb–Ti strands, the value of n (5 T) can be 50–100, in Nb_3Sn for NMR application the values are in the range of 40–80. The high n-values in Nb–Ti strands correspond to variations in filament cross-sectional area of less than 2% (coefficient of variation) (Lee and Larbalestier 1993). In HTS superconductors the range of available n-values is presently only 10–20 and persistent mode operation is not feasible under these conditions.

2.3 Critical Current Density and Flux Pinning

Pure annealed superconductors do not carry very much current because once current passes through the

superconductor, a Lorentz force is induced on the flux lines. When they move, the flux line lattice (FLL) dissipates energy and the superconductor eventually goes ''normal'' (see *Electrodynamics of Superconductors: Flux Properties*[#]: *Superconducting Materials: Irradiation Effects*[#]). The flux lines, however, can be held in place by defects in the superconductor, a process termed ''flux-pinning.'' In A15 based superconductors (such as Nb_3Sn), increasing the grain boundary density has been shown to increase critical current density (Scanlan *et al.* 1975, Ochiai *et al.* 1986). In Nb–Ti a linear increase in critical current density is observed with vol.% of α-Ti precipitate (Lee *et al.* 1990). Consequently the introduction of pinning defects and the refinement of grain size are key elements to the success of technical superconductors.

2.4 Twisting

Twisting of the strand about its drawing axis is typically required to reduce flux-jump instability caused by varying external fields, and to reduce eddy-current losses. The twisting is ideally applied just before a multifilamentary strand has reached final size, so that the twist can be locked into place by a further die-pass. The higher the expected rate of change of field, the tighter the required twist pitch. For the relatively steady-state dipole magnets for the Superconducting Supercollider, ~ 80 rotations along the drawing axis per meter were required, for a.c. application with a similarly sized strand the number of twists per meter might be 300. Typically, twist pitches cannot be higher than 8 times the wire diameter, and normally a twist pitch of 10–20 times the diameter is used.

2.5 Final Shaping and Cladding

The final cross-section of the strand can be controlled by die shape and size or by using independently adjusted rollers operating along the strand surface. In this way, square or rectangular cross-section filaments can be produced. Alternatively, the strand can by inserted into a channel in a larger form, most commonly a rectangular aluminum external stabilizer.

2.6 Cabling

Individual strands can be cabled or braided together to form a conductor with a higher current carrying capacity. The most common design for Nb–Ti magnets is the Rutherford cable, which consists of a fully transposed, flat cable. Using this approach, high-aspect-ratio cables can be produced with as many as 46 strands (Scanlan *et al.* 1997). Strands may also be drawn into a larger conduit or combined with external stabilizers. A cross-section of a cable-in-conduit-conductor (CICC) is shown in Fig 3. As in the single strand-in-channel aluminum process, multiple strands

Figure 3
CICC: this 51 mm diameter Incoloy® jacketed cable contains 6 sub-cables; each containing 180 Nb_3Sn based superconducting strands.

have been applied to surface channels in circular cross-section aluminum rods.

2.7 Length-Dependent Parameters

Both commercial Nb–Ti and Nb_3Sn strands are made in lengths of over a kilometer and variations can occur over the length of the strand, due to differences in mechanical properties of the components and bonding of the monofilaments that occurred during mechanical reduction. In Nb–Ti variations in critical current, I_c, along the length of strands can be directly correlated with variations in Cu/Nb–Ti ratio along the length as shown by Kanithi *et al.* (1990). In their study of strands developed for the Superconducting Supercollider project, they showed that the variation in I_c (due to variations in the intrinsic superconducting properties, the strand diameter and Cu/Nb–Ti ratio as well as measurement error) was more than twice the variation seen in J_c (due to just the intrinsic superconducting properties and measurement error). As HTS-based strands are still in their production infancy, a different phenomenon is observed: as production length is increased, the overall I_c declines because it is very difficult to maintain the ideal conditions (grain alignment, heat treatment temperature, low porosity) necessary for good HTS strand over long lengths.

3. Superconducting Strand and Cable Manufacture by Material

3.1 Nb–Ti

(*a*) *Alloy Composition.* Nb–Ti has become the dominant commercial superconductor, because it can be

economically manufactured in a strong and ductile form with both high current density and high resistive transition index. The starting point for fabrication of Nb–Ti strand is an alloy of between 46.5 wt.% Ti and 50 wt.% Ti. Decreasing Ti over this range increases both the critical temperature, T_c, and the upper critical field, H_{c2} (which at 4.2 K has a maximum value of 11.5 T at 44 wt.% Ti). The increase in T_c and H_{c2}, however, is offset by a decrease in the amount of Ti available for precipitation of the α-Ti phase desired for flux-pinning and high critical density. The composition of the Nb–Ti also affects the precipitate morphology: if the α-Ti is formed at grain boundary intersections, it tends to be uniform in size and distribution and does not significantly affect strand ductility. Higher Ti compositions, however, also produce fine distributions of Widmanstätten-type precipitation in the grain interiors resulting in both a nonuniform microstructure and a significant hardening of the Nb–Ti. As all these factors are sensitive to composition, it is very important to start with a homogeneous alloy. With final filament diameters well below 0.05 mm, the alloy must also be free of unmelted Nb or nonductile inclusions that may result in filament and ultimately strand breakage. Although the large difference in the melting points of Ti and Nb makes this a difficult alloy to manufacture, homogeneity levels in commercial Nb–47 wt.% Ti alloys are now typically much better than ± 1.5 wt.% Ti. Impurity content has been traditionally kept low and consistent, but recent work has shown that increasing the allowable content of iron can considerably refine the precipitate size without adversely affecting the precipitate volume (Smathers *et al.* 1996).

(*b*) *Extrusion and Billet Assembly*. The (as-cast) Nb–Ti ingot is hot forged to the required diameter and then annealed in the single phase β region (~ 2 h at 870 °C). For fine filament Cu matrix composites, the Nb–Ti ingot is then sealed inside a high-purity Cu extrusion can, that subsequently (warm-extruded) forms a (well-bonded) monofilament. Monofilament production billets ready for extrusion are shown in Fig. 4. Billet assembly is performed in a clean environment, in order to avoid introducing particles that would not co-deform to the sub-0.05 mm filament size. Where high critical current densities and fine filaments are desired, an Nb diffusion barrier is wrapped around the Nb–Ti rods in order to inhibit the formation of brittle Cu–Ti intermetallics during heat treatment (Wilson 1972). The monofilament is then reduced in diameter by wire drawing, typically finishing with a hexagonal die to produce filaments that can be efficiently (restacked). The thickness of Cu around the Nb–Ti at this stage is important because it determines the spacing between Nb–Ti filaments when Cu/Nb–Ti monofilaments are stacked together. For optimum mechanical stability in Nb–Ti/Cu

Figure 4

multifilamentary composites, a filament spacing to filament diameter (s/d) ratio of 0.15–0.20 is ideal (Gregory *et al.* 1987). Usually additional stabilizer is required and that may be added by increasing the wall thickness of the extrusion can or adding a central core of stabilizer. For d.c. magnet application, it has been established by Ghosh *et al.* (1987) that a minimum Cu thickness of 0.4–0.5 μm is required to reduce the magnetization associated with proximity filament coupling. For s/d ratios of 0.15–0.20, the minimum Cu thickness requirement limits the minimum filament diameter to ~ 3 μm when using a pure Cu matrix. If smaller filaments are required, Ni or Mn can be added to the Cu between the filaments (Hlasnik *et al.* 1985, Cave *et al.* 1989, Kreilick *et al.* 1988).

The monofilament is then restacked inside another Cu extrusion can to form the final multifilamentary composite. The size of this extrusion can be up to 330 mm in diameter with a weight of 400 kg. As many as 4000 filaments may be assembled in one extrusion. Alternatively, large numbers of fine filaments can be produced by restacking a previously extruded multifilamentary billet. Using this approach, strands with up to 40 000 filaments have been manufactured. Where a small number of large filaments are desired (typically for low-field MRI application), Nb–Ti rods can be directly inserted into gun-drilled holes in a solid high-purity Cu extrusion billet. Warm extrusion helps bond the composite, as much of the subsequent processing involves cold work by wire drawing, and the resulting strain introduces into the Nb–Ti an essential element in developing the high critical current microstructure.

(*c*) *Precipitation Heat Treatment*. Such a treatment qis applied after sufficient cold work has been carried

out following the multifilamentary extrusion. If too little cold work is applied before heat treatment, Widmanstätten-type precipitation will occur, causing increased hardness (reducing drawability) and producing a non-optimum precipitate size and distribution. Lee *et al.* (1989) found that the amount of (prestrain) required increases linearly with wt.% Ti. Consequently, a higher prestrain is required to suppress Widmanstätten-type precipitation in a chemically inhomogeneous alloy than would be required in a homogeneous alloy. For Nb–47 wt.% Ti, the required prestrain is ~5 but this rises steeply to 9 for a 55 wt.% Ti alloy. Heat treatments are typically at 375–420 °C, ranging from 20 h to 80 h in duration. Multiple heat treatment and drawing cycles are required to produce high critical current densities (Cheng-ren *et al.* 1983). Whereas an initial heat treatment will only yield ~10 vol.% precipitate, by applying additional cold work strain, the effect of the slow diffusion rate at these temperatures is again overcome and more precipitate is produced. Second and third heat treatments typically yield 15 vol.% and 20 vol.% of α-Ti precipitate respectively. The strain between heat treatments is 0.8–1.5 and at least three heat treatments are usually applied. A linear relationship between the optimized critical current density and the volume of precipitate Nb–47 wt.% Ti alloys has been established by Lee *et al.* (1990) 20% volume of α-Ti precipitate is sufficient to produce a critical current density of >3000 A mm^{-2} at 5 T, 4.2 K. Increasing Ti content increases the precipitation rate and amount, but higher pre-strains are required if good ductility and long piece length is to be maintained. Alternatively, the pinning sites can be introduced mechanically by hand-assembling the desired microstructure at a large-size, in the same way as the multifilamentary billets are assembled, and then reducing the dimension to match the fluxoid spacing by multiple restacking and drawing cycles. This approach is called APC for artificial pinning center. With APC strand, no additional heat treatment is necessary and a greater flexibility is possible in the microstructural components. Despite superior low field (<5 T) performance, the APC approach has not reached commercialization because of the costs associated with the multiple restacking approach.

(*d*) *Final Wire Drawing*. After final heat treatment the α-Ti precipitates are roughly equiaxed in transverse cross-section, 100–200 nm in diameter with an extension along the wire axis giving an aspect ratio of 5–20. The extensive final wire drawing (an engineering true strain of 5), however, produces a plain strain condition in the b.c.c. *β*-Nb–Ti, which is supported by (inter-curling) of the Nb–Ti grains. This results in distortion of the α-Ti precipitates into densely folded sheets during final wire drawing (Fig. 5(a)). The folding process rapidly decreases the precipitate thickness

Figure 5
(a) Transmission electron microscope image of high critical current density Nb–Ti microstructure with folded sheets of α-Ti precipitate. (b) Etched cross-section of Nb–Ti-based superconducting strand fabricated by IGC-AS (now Outokumpu Advanced Superconductors) for the Interaction Region Quadrapole Magnets of the Large Hadron Collider at CERN.

and spacing with a dependence of $d^{1.6}$ (where d is the strand diameter) and increases the precipitate length per area with a dependence of $d^{-1.6}$, as measured by Meingast *et al.* (1989). The critical current density increases as the microstructure is refined until it reaches a peak, after which there is a steady decline. The peak in critical current density for a monofilament or a multifilamentary strand with uniform filaments occurs at a final strain of ~5. If the filaments are nonuniform in cross-section (sausaged), the peak occurs earlier and at a lower critical current density. A strand that has a premature (and lowered) peak in critical current density during final drawing is described as "extrinsically limited" because it has not attained the intrinsic critical current density of the microstructure. The most common source of extrinsic limitation is sausaging of the filaments, due to intermetallic formation or lack of bonding between the

components of the composite. A high-performance strand (Fig. 5(b)) has sausaging reduced to a very low level—a coefficient of variation for the filament cross-section of $\sim 2\%$. With tight quality control, uniform properties and piece lengths exceeding 10 km should be expected.

3.2 Nb₃Sn

Nb_3Sn is the second most widely used superconductor and has a higher upper critical temperature (18.2 K) than Nb–Ti. It is one of several A15 structure compounds that are superconducting. Other A15 superconductors of interest include Nb_3Al (T_c of 19.1 K) and Nb_3Ge (T_c of 23.2). Nb_3Al has been manufactured in long lengths and has a better strain tolerance than Nb_3Sn and better performance at a very high field (> 22 T) making it of importance to high-field NMR inserts. Nb_3Al is much more complex and expensive to fabricate than Nb_3Sn because of the mechanical differences between Nb and Al and because the optimum Nb_3Al composition for a A15 structure, can only be formed by high temperature processing ($> 1000\,^{\circ}$C). Nb_3Sn, on the other hand, is widely manufactured and has shown sufficient strain tolerance in practice to be used successfully in very large solenoids such as the ITER CS model coil which stored 640 MJ of energy (Kato *et al.* 2001) and high-field (> 21 T) inserts for NMR application (Kiyoshi *et al.* 2001). Because A15 materials are brittle, all production routes use ductile precursors that are heat treated to form the A15 at final size by solid-state diffusion. At an early stage it was found that the presence of Cu greatly aids the formation of Nb_3Sn at temperatures below $800\,^{\circ}$C. It has also been found that adding Ti (0.7–1 wt.%) or Ta (7.5 wt.%) improves the critical current density at high fields (> 12 T).

The three basic production routes currently used by commercial Nb_3Sn vendors—the bronze process, the internal Sn, and the powder-in-tube (PIT) fabrication techniques—are illustrated in Fig. 6. The internal Sn process may use a jelly roll of Cu and Nb sheets, as illustrated in Fig. 6, or may use Nb (or Nb alloy) rods in a Cu matrix as shown in Fig. 7.

(*a*) *Bronze Process.* For MRI application the most common route is the "bronze process" in which Nb alloy rods are first clad in high-purity ductile Cu–Sn bronze and then assembled inside another Cu–Sn tube in a way similar to the production of Nb–Ti filaments in Cu for Nb–Ti strand. As with Nb–Ti alloy, multiple restacks can be used to increase the filament number. Under heat treatment (typically 650–725 °C) the Sn from the bronze reacts with the Nb to form the superconducting A15 compound. As the Cu–Sn alloy does not act as a stabilizer, additional high-purity Cu must be added outside, and/or

Figure 6

inside the bronze–Nb filament composite, with a Ta and/or Nb diffusion barrier to eliminate Sn contamination of the stabilizer. An example of a bronze–process strand is shown in Fig. 8. Vanadium has also been used as a barrier but results in a reduced critical current density. This process can yield a strand with a very high uniformity in filament size and distribution, which makes it an ideal product for high-field NMR and other applications where a minimum of hysteresis loss is desired. The bronze, however, quickly work hardens during wire drawing and must be annealed frequently in order to maintain strand ductility, this extra processing step significantly increasing the cost of the strand. The Sn content in the composite is also limited by the amount of Sn (< 15 wt.% Sn) that can be added to bronze while maintaining ductility. The impact of insufficient Sn is most
Figure 7

Nb$_3$Sn strand prior to diffusion heat treatment. This
strand was designed for high critical current density by
IGC-AS (now Outokumpu Advanced
Superconductors).

noticeable on critical current density. Recent devel-
opments in the bronze process have centered on the
use of specially processed high Sn bronzes (up to
16 wt.% Sn) that have good ductility and high ho-
mogeneity (Sakamoto *et al.* 2000) (Fig. 9).

(*b*) *Internal Sn Process*. Higher Sn content and
higher critical current density can be achieved by
keeping the Sn separate from the Cu during strand
fabrication. This is the basis for the internal Sn proc-
ess which places an Sn core inside an Nb–filament/Cu
matrix. The Sn core can be alloyed as a carrier for the
Nb$_3$Sn allowing-element or to improve the mechan-
ical properties of the soft Sn. Strands produced by
this process have achieved the highest critical current
densities for Nb$_3$Sn (in excess of 2400 A mm^{-2} in the
non-stabilizer package). The high critical current
densities are achieved, in part, by reducing the
amount of Cu in the Cu/filament/Sn package and
the resulting reduction in filament coupling results in
an undesirable increase in filament coupling. There
are two distinct sub-categories of internal Sn process
strand based on the form of the Nb filaments. In the
"rod-in-tube" (RIT) process internal Sn–Nb fila-
ments are assembled by inserting rods of Nb into pre-
drilled holes in a Cu billet. The second internal Sn
method is termed modified jelly-roll (MJR) and used
an expanded metal sheet of Nb co-wrapped with a Cu
sheet to create the individual Nb filaments in a Cu

Figure 8

Vacuumschmelze for ITER shown in (a) full cross-
section and (b) in filament detail. The filaments have a
central unreacted core of Nb.

matrix. Both of these techniques achieve very high
current densities, but limitations to the sizes of the
billets (because of the restricted depth of the gun-
drilled holes for rod-process and size limitations to
deforming the MJR stacks) means that billet sizes are
typically only 20 kg and processing costs are subse-
quently much higher than for Sn. As in the bronze
process, the individual Cu–Nb–Sn sub-elements are
clad in a diffusion barrier (Ta or Nb or TaNb alloy)
to prevent poisioning of the Cu stabilizer by Sn dif-
fusion. Sn diffuses rapidly through Cu at the tem-
peratures used for the A15 forming heat treatment
(up to 700 °C) and barrier integrity is consequently of
great concern. The heat treatment of the strands to
form the A15 phase is preceded by multiple lower-
temperature steps designed to combine the Sn with

Figure 9

the Cu without Sn melting. Both the RIT and MJR technique can also be used to fabricate precursor strand for Nb$_3$Al production.

(*c*) *PIT Process*. Nb$_3$Sn may also be formed from higher Sn content Nb–Sn phases (Nb$_6$Sn$_5$ and NbSn$_2$) by inserting the intermetallics in powder form into tubes of Nb and reacting at 650–700 °C. The presence of Cu is also required to allow the formation of the A15 phases in the 650–700 °C temperature range in which fine grain size is maintained (Lefranc and Muller 1976). Elemental Sn is also added to improve the Sn-to-Nb ratio. No low-temperature heat treatment is required for these strands and the A15 formation heat treatment takes a relatively short time, 50–75 h (180–270 ks). This process uses the best combination of high critical current densities ($>2200 \, \mathrm{A \, mm^{-2}}$ at 12 T and 4.2 K in the nonstabilizer volume) and low effective filament diameter (as low as 30 μm in high critical current density strand). The process is used to manufacture small quantities for demanding applications (Lindenhovius *et al.* 2000) and has not received the cost benefits of

commercial scale-up. The PIT technique can also be used for MgB$_2$, Bi-2223, and YBCO, but porosity is an issue for these conductors when fabricated by this technique.

3.3 Nb$_3$Al

Nb$_3$Al has not achieved commercial strand status, but it can be described as a technical superconductor as it has been fabricated into high performance and uniform kilometer lengths that have in turn been fabricated into full-scale devices. At magnetic fields above 20 T, critical current densities can be obtained that are comparable to the best Nb$_3$Sn strands and useful critical current densities ($>100 \, \mathrm{A \, mm^{-2}}$ nonstabilizer) can be achieved above 24 T. Perhaps the most important feature of Nb$_3$Al is the high strain tolerance of the Nb$_3$Al strands compared to Nb$_3$Sn. One ton (total length of 210 km) of mass-produced "jelly-roll" process strand (Yamada *et al.* 1994) was manufactured for the 13 T–46 kA Nb$_3$Al insert for the ITER Central Solenoid model coil. The jelly-roll of Nb and Al is created by co-winding sheets of Nb and Al together on an oxygen-free pure copper core. This will eventually become an individual filament in the final multifilamentary strand. The assembled jelly-roll and core are inserted into an oxygen-free pure copper tube to create an extrusion billet. After hydrostatic extrusion, the billet is drawn down to a small enough size that it can be restacked to create a multifilamentary billet. The billet is hydrostatically extruded and drawn for a second time, to the desired strand diameter size. The extrusion and restack process reduces the thickness of the Nb–Al layers in the filaments to less than 1 μm. The production yield rate for the ITER insert strand was 70% for strands longer than 1.5 km. The final strand is heat treated (800 °C for 10 h is typical) to produce Nb$_3$Al. The critical current densities obtained by this technique are $\sim 600 \, \mathrm{A \, mm^{-2}}$ at 12 T and 4.2 K (Hosono *et al.* 2002).

The highest critical fields and critical temperatures for Nb$_3$Al are based around high-temperature heat treatments and rapid cooling. In the rapid-heating, quenching, and transformation (RHQT) (Iijima *et al.* 1997) process Nb/Al composites (MJR or RIT) are resistance heated to 1900–2000 °C and then rapidly quenched into a molten Ga bath at 40–50 °C producing a metastable b.c.c. supersaturated solid solution, Nb(Al)$_{ss}$, inside an Nb matrix. The heating time is ~ 0.1 s. The Nb(Al)$_{ss}$ has excellent ductility and the strand can consequently be mechanically clad or cabled with Cu at this stage and the stabilized strand may also be wound into device form. The Nb(Al)$_{ss}$ is then transformed to Nb$_3$Al at 800 °C. Both the critical temperature, T_c, of ~ 17.8 K and the critical magnetic field, B_{c2}, of ~ 26 T are 0.7 K and 4 T lower for RHQT composites than the highest values obtained by laser or electron beam irradiation processed

Nb₃Al (Takeuchi *et al.* 2000) and this difference has been attributed (Kikuchi *et al.* 2001a) to stacking faults formed in the A15 phase. Two successful modifications to the basic RHQT technique specifically address the stacking fault issue. In the double rapidly heating/quenching technique (DRHQ), the standard RHQT process is followed, but instead of a conventional low temperature ($<1000\,^{\circ}$C) transformation heat treatment, a second RHQ process produces the A15 phase and this is followed by a long-range ordering heat treatment at $800\,^{\circ}$C for $\sim 12\,$h (Kikuchi *et al.* 2001b). The T_c for these stacking fault free strands has been measured at 18.4 K, which suggests very good stoichiometry. Furthermore, a critical current density of 135 A mm^{-2} was obtained at 25 T (Kikuchi *et al.* 2002). A disadvantage of this technique is that the brittle A15 phase is formed during high-temperature processing. Alternatively, the transformation-heat-based up-quenching technique (TRUQ), follows the initial RHQ of the RHQT process with a short heating step to $1000\,^{\circ}$C. At this temperature, the heat released by local transformation from the Nb(Al)$_{ss}$ to the A15 phase produces a rapid local heating and propagation of the reaction along the length of the strand. As the self-heating is localized to the A15 volume, the heat is quickly dissipated after reaction across the Nb and stabilizer volumes, so that external Cu stabilizer applied after the initial RHQ process is not melted (Takeuchi *et al.* 2000).

3.4 HTS Superconductors

HTS superconductors have demanded great interest because of their ability to superconduct with relatively inexpensive liquid nitrogen cooling and their impressive high-field performance. HTS wires and tapes have not achieved the same commercial impact as LTS strands, however, because of the relative difficulty of producing long, low-cost lengths of conductor. The primary sources of this difficulty are the anisotropy in their superconducting behavior and the barrier to current flow presented by high-angle grain boundaries in these materials. Consequently, the strands must be fabricated with a remarkable degree of grain alignment. Further complicating the process is a high sensitivity to heat treatment temperature ($<1\,^{\circ}$C control must be exerted across the entire strand length for Bi-2212) and a need for oxygen diffusion into the HTS composite during fabrication. This second requirement effectively means that silver must be used as the superconducting strand stabilizer. Of the HTS superconductors, only Bi-2212 can be readily made into round-wire form strand. All the other HTS superconductors require a tape format. (Bi,Pb)₂Sr₂Ca₂Cu₃O$_x$ based conductors have been shown to be capable of application to superconducting power cables, magnetic energy-storage devices, transformers, fault current limiters and motors, but

widespread application will require significant cost reduction in processing. YBCO-based superconductors have the highest recorded critical current densities, but at present there is no viable wire production technique available for YBCO and critical current densities fall rapidly with superconductor thickness above 0.5 µm and with length beyond 1 µm.

(*a*) *Bi-2223*. (Bi,Pb)₂Sr₂Ca₂Cu₃O$_x$ ("Bi-2223") is most readily fabricated using PIT techniques very similar to those used for Nb₃Sn, with Ag replacing the Cu tubes used for Nb₃Sn. In addition to standard wire drawing techniques, groove rolling is also incorporated to bring powder-filled monofilaments to restack size. Hot extrusion can then be used to bond the multifilamentary composite while increasing the powder density and reducing the billet diameter. Extrusion is followed by further drawing and groove rolling, and finally rolling into tape. As a conventionally mechanically processed material, this is readily scalable to large production quantities. The key issue is to increase the connectivity between the grains of the conductor. The prospect of two- to fivefold improvements in the performance of the present process, coupled to cost reductions triggered by significant scale-up and alternative routes such as overpressure processing (Rikel *et al.* 2001) or melt processing (Flükiger *et al.* 2001) could accelerate the early penetration of superconducting technology into the utility network.

Demonstration HTS transmission cable projects have utilized Bi-2223 strand including test installations at Detroit Edison and Southwire in the USA. For the Detroit–Edison project, a conductor was fabricated by American Superconductor that used four layers of Ag-sheathed Bi-2223 tapes (29 km in total), each tape having an average critical current of ~ 118 A d.c. at 77 K. The tapes utilized oxide-dispersion-strengthened silver matrices as well as stainless steel reinforcement added to both sides of the HTS tape (Masur *et al.* 2001). For the Southwire project, 30 m cables were produced from PIT Bi-2223 tapes manufactured by IGC. The measured critical current for the cables was 2980 A at 77 K (Sinha *et al.* 2001).

(*b*) *MgB₂*. Since its discovery in early 2001, MgB₂ has generated much interest as it has the highest T_c (39 K) of any intermetallic superconductor and has the lowest cost components. Like Bi-2223, MgB₂ wires or tapes can use essentially the same technology as that used for Nb₃Sn PIT composites. PIT offers a scaleable technology for future production of kilometer-length MgB₂ and has already been exploited for strand fabrication (Jin *et al.* 2001, Grasso *et al.* 2001). The perpendicular irreversibility field is less than that for Nb₃Sn, the most widely used intermetallic

superconductor, and this may restrict MgB_2 to applications of lower field.

4. Summary

Nb–Ti and Nb_3Sn superconductors are well established as commercial superconductors with stable markets for NMR and MRI devices as well as high magnetic field testing equipment. Future markets in fusion reactors, accelerator magnets, and energy storage drive further developments. The strain tolerance of Nb_3Al should maintain interest in this material for high-field applications where conductor cost is not an issue. The ability to use liquid nitrogen as a coolant for HTS conductors, such as Bi-2223, is important for applications such as power transmission lines that are not well suited for low temperature refrigeration. Further performance improvement and cost reduction will be required before HTS strands are economically viable. MgB_2 offers the potential of a low-cost superconductor for the future that, while not being able to use liquid nitrogen cooling, is still able to benefit from reduced refrigeration costs due to its high T_c.

Supported Catalysts

Heterogeneous catalysts are widely exploited in many industries, particularly the chemical, petrochemical, agrochemical, and pharmaceutical sectors. However, for their successful use, heterogeneous catalysts have to withstand the conditions within the chemical reactor without attrition or degradation. Although some heterogeneous catalysts can be used in bulk or nonsupported form, many involve materials that cannot be used directly without the aid of an additional material, termed a catalyst support. There are many reasons why a support is required and these include stability of the catalyst phase, e.g., stabilization of small metal particles, as well as cost, i.e., dilution of an expensive catalyst component. In this article the choice of the support material, the types of supported catalysts available, and the characterization of the support–catalyst interaction will be described.

1. Choice of Support

The function of the support is to provide a sound base on which to disperse the active catalyst component. Key features of supports that govern their selection are the required porosity/surface area and the chemical properties, acidity, and basicity. The first factor that has to be taken into account in the selection of a support is the nature of the chemical reaction being catalyzed since this can be used to determine the porosity of the support material. For example, if the thermodynamically preferred product is required (as in the water gas shift reaction (Twigg 1989)) then high-surface-area supports can be considered. If the products of kinetic control are required then low-surface-area supports are generally used, e.g., the partial oxidation of ethene to the epoxide using silver supported on α-Al$_2$O$_3$(Bowker 1998). The selection of a specific support material will then depend on the chemical properties required for the support surface which will be specific to any particular reaction. The particular feature that is of crucial importance is the relative concentrations of acidic and basic sites. Support surfaces, particularly oxides, can contain Brønsted and Lewis acidic or basic sites; e.g., surface hydroxyl groups on the surface of γ-Al$_2$O$_3$ can act as a Brønsted acid. Typically oxides are used as support materials, with the most common being alumina (α and γ forms), silica, magnesia, titania, zirconia, and zeolites.

2. Types of Supported Catalysts

This section sets out the different types of supported catalysts in current use.

2.1 Zeolites as Supports

Zeolites make excellent candidates for catalyst supports due to their stability, high surface area, and probably most importantly, the regularity of their pore structure (van Bekkum *et al*. 1991, Thomas and Thomas 1997) (see *Zeolites**). The well-defined pore sizes of zeolites means that when used as catalysts or supports they can impose selectivity on the reaction products by restricting access of reactants to the active site, the formation of certain transition states, or the egress of certain products. Thus it is vital when

preparing catalysts supported on zeolites that as little active material as possible ends up on the external surface of the zeolite where this selectivity will not be available.

Zeolitic frameworks are negatively charged, and this negative charge is balanced by the presence of extra-framework cations such as Na^+ or H^+. The cationic sites in zeolites can be substituted with metal cations, thus introducing potentially new catalytic species into the structure. However, although metals supported in this form are used as catalysts it is more common for further treatment to be carried out to form the active catalyst. In the majority of cases calcination and reduction are carried out on the metal cations to form neutral metal atoms or groups of atoms which act as the catalytically active site. Zeolites can therefore be used as supports for metal cations that are active catalysts (Thomas and Thomas 1997) (see *Acid Catalysts*[#]).

The most important ways for introducing metal cations into zeolites are ion exchange and the incipient wetness technique. In ion exchange the cations present in the zeolite are substituted by the required metal cation by treating the zeolite with a solution of a metal salt. This can be reduced to form small metal particles if required. The exact nature of all of treatment steps is crucial to the structure of the final product (van Bekkum *et al.* 1991) due to the difference they can make to the final location of the metal, as zeolites generally have several different sizes of pores within their structure. It is important that the introduced metal ends up in the larger pores of the zeolite structure, otherwise access of reactants to the metal, vital for catalytic reactivity, is reduced or even made impossible. There is often a tendency for the metal ions to migrate to the smaller pores due to the highly coordinating nature of the oxygen atoms which can envelop them in such confined areas. This can be avoided by blocking the smaller cages with inactive cations before introduction of the catalytically active metal.

One advantage that zeolites have over other supports is the ability to isolate metal atoms in the pores and so prevent sintering of the metal atoms, which would greatly reduce the effective surface area of the catalyst. However, to prevent agglomeration of the metal it is important to control all the stages in the preparation to avoid atom migration. Other strategies exist for introducing the metal to the zeolite, some of which introduce the metal as part of a neutral complex using either condensation from the vapor phase (CVD) or adsorption from an organic solvent. In this, complexes can be inserted into the zeolite pores and used as catalysts either as they are or with the ligands removed and the metal reduced under milder conditions than would be possible using more conventional methods. It is also possible to introduce more than one metal to the zeolite using any of these methods.

Structured mesoporous amorphous silicas and silica aluminas (denoted MCMs) have been fabricated that contain ordered pore structures with channel apertures of 2.5–10 nm. These can also be used as supports for cations, complexes and metals (Thomas and Thomas 1997).

2.2 Well-defined Oxides for Supporting Active Catalysts Molten at Reaction Temperature

Support of catalysts which are molten at the reaction temperature can be considered as a special case of supported liquid-phase catalysis. The molten catalyst fills all the pores on the support and so, if properly prepared with a support-to-catalyst ratio calculated to give a thin layer of catalyst, will give a high catalyst surface area. The catalytic process itself is in effect homogeneous, with the reactant molecules dissolving in the melt from the gas or vapor phase, reacting in the liquid phase, and then the products diffusing out. Thus the advantages of heterogeneous catalysis (large reaction area, easier reactor design, and ease of separation of products) and those of homogeneous catalysis (high catalyst dispersion and increased specificity) are combined. Advantages over supported liquid-phase catalysis are that catalyst loss due to evaporation at operating temperatures is minimal and also that operating temperatures can be higher.

To obtain a catalyst that will melt at reasonable temperatures (not high enough to destroy thermally the reactants or be too expensive to maintain) there are a number of approaches. If possible a single catalyst component with a suitably low melting point can be used. However, the stable metals and metal salts and oxides used for catalysis rarely have this property. An alternative strategy is to use a eutectic mix, where the combination of two or more materials lowers the melting point of the resulting mix. An example of this is the mixture of Cs_2O, MoO_3, and V_2O_5 (pure oxide melting points 490 °C, 795 °C, and 690 °C, respectively) which melts at 350 °C, described by van Setten *et al.* (1999).

Another more general approach uses a low-melting-point salt as a solvent for the active catalyst components. Chloride salts are often used both to form eutectics and as low-melting ionic solvents (Lago *et al.* 1995). Tetrabutylammonium chloride is an example of a commonly used organic solvent (melting point 44 °C). Obviously the use of such organic salts limits the upper temperature at which the system may be used, as decomposition will occur at elevated temperatures. Thus while inorganic salts such as CuCl/KCl are used at temperatures exceeding 400–500 °C, mixtures containing organic salts are generally not suitable for use above 200 °C.

The choice of support is important as not all supports are suitable for all catalyst mixes. It is important that the molten material "wets" the support

thoroughly. For example, while silica has been found to be a good support for many molten catalysts it is unsuitable for the mixture of Cs_2O, MoO_3, and V_2O_5 cited previously.

Characterization of supported molten catalysts can be problematical. Most of the characterization reported in the literature has been done on cooled or quenched samples rather than *in situ* on molten samples. X-ray diffraction data suggest that in the quenched state these systems remain amorphous.

2.3 Supported Oxide Monolayer Catalysts

The use of supported metal oxide catalysts, where the active oxide material is present in monolayer form as illustrated in Fig. 1, can produce significantly different catalyst performance from that obtained for the corresponding bulk metal oxide material (Roozeboom *et al*. 1979). This is also observed when

Figure 1
TEM characterization of a WO_3/TiO_2 monolayer catalyst, WO_3 visible on TiO_2 by virtue of mass-contrast (reproduced by permission of Baltzer Science from *Catal. Lett*., 1996, **39**, 219–31).

monolayer catalysts are compared to supported oxide catalysts where the active oxide loadings and general preparation methods result in the formation of bulk-like oxide species at the catalyst surface. For example, CuO supported on γ-alumina at monolayer CuO coverage exhibits higher activities for nitrous oxide decomposition, a reaction of considerable environmental importance, in comparison to catalysts prepared by impregnation or mechanical mixing of equivalent CuO loadings (Yao *et al*. 1998). Also, molybdenum oxide at monolayer coverage on alumina displays the highest activity for dehydrogenation of *n*-butane (Harlin *et al*. 1999). Other reactions in which supported metal oxide monolayer catalysts demonstrate superior catalyst performance are selective oxidations, *i*-propanol decomposition, and ammoxidation of aromatics (Bond and Tahir 1991). Most research on monolayer oxide catalysts has involved vanadium oxide species supported on materials such as titania, alumina, zirconia, and ceria. Supported vanadium oxide monolayers have therefore been adapted as the model systems for fundamental research in this area of catalysis.

The introduction of a support increases the thermal and mechanical stability of the metal oxide or oxo species along with increasing the surface area of the active material. Using a support may also prove to be more economically favorable as less active material is required. The nature of the oxide support can itself be an important factor in determining the catalyst performance and this is demonstrated in the oxidation of *n*-butane to maleic anhydride over vanadium oxide monolayer catalysts (Bond and Tahir 1991). This is related to the extent or strength of interaction between the support and the monolayer species, the bonding within the monolayer itself, and the acid–base properties of the system.

A number of suggestions are given by Yao *et al*. (1998) as to the origin of the differences in catalytic behavior of supported monolayer oxides. It is proposed that changes in the environment around the metal cations due to variations in lattice energy, chemical bonding between the support and active material, or the formation of an epitactic layer can exert significant influence on the catalytic activity.

Several methods have been employed in the preparation of monolayer catalyst systems. The catalyst precursor materials can be formed via impregnation, grafting (adsorption from solution), co-precipitation, or chemical vapor deposition methods. The precursor materials are then calcined at the appropriate temperature to form the active catalyst. Factors such as the preparation conditions (temperature, solvent, and precursor compound), pretreatment of the support material, and calcination conditions can play a major role in determining the uptake of the precursor species and characteristics of the final oxide monolayer.

A number of techniques can be used to characterize monolayer formation and the surface chemistry of

these materials relating to structure and monolayer–support interactions. Laser Raman spectroscopy can be used to establish the point at which monolayer coverage is reached, as well as providing important structural information by discriminating between species present at submonolayer coverages and those present at above monolayer coverage, i.e., crystalline oxide material. In the case of supported vanadium monolayers the point of monolayer formation is thought to occur immediately prior to the appearance of a crystalline V_2O_5 phase. Species which indicate lower than monolayer coverage, such as isolated VO_4^{3-} tetrahedra and distorted vanadate octahedra, can be identified by the presence of bands at 830 and $970 \, cm^{-1}$ respectively (Bond and Tahir 1991).

2.4 Supported Metal Catalysts

Supported metal catalysts are used extensively in the chemical industry, from bulk and fine chemicals production to petrochemicals. A wide range of reactions can be performed effectively over supported metal catalysts such as hydrogenation, hydrogenolysis, dehydrogenation, reforming reactions, and cracking of petroleum hydrocarbons. The main active components in these systems are typically Group 10 or 11 metals.

Although a number of industrial processes employs unsupported metal catalysts, e.g., Raney nickel in the hydrogenation of glucose to sorbitol and platinum–rhodium gauze in the oxidation of ammonia in the manufacture of nitric acid, the use of a support has many advantages. Firstly, smaller amounts of the often expensive active metal component are required as the metal is highly dispersed on the support material as small metal particles. The use of a support also increases the available metal surface area which can be directly related to the catalytic activity. The support therefore provides a structural framework and stabilizes the active species (small metal particles) as well as making the catalyst more mechanically robust. In some cases the support itself can introduce new active sites to the system, which are usually acidic or basic or both, and a polyfunctional catalyst is obtained.

Typical support materials include high-surface-area, porous, metal oxides (e.g., Al_2O_3, SiO_2, and TiO_2), zeolites, and carbons. In some cases the support only plays a physical role and is considered inert towards the catalytic process. However, depending on the material used, the support can influence the electronic environment of the active sites, change the number of active sites, and exert influence on the morphology of the metal crystallites. When this occurs, metal–support interactions are in operation and the strength of these interactions can have significant effects on the catalytic performance (Bond 1982, Augustine 1995).

In general, when reducible metal oxides are employed as the support the metal–support interactions are strong, particularly after high-temperature reduction pretreatment (Bond 1982). For example, with TiO_2, this reduction treatment causes reduced TiO_x species to migrate across the metal surface and this results in the creation of new active sites associated with Ti cations or oxygen vacancies. This phenomenon is known as a strong metal–support interaction, termed SMSI. This is not observed with nonreducible metal oxide carriers such as SiO_2 and zeolites although relatively weak metal–support interactions can be prevalent which can still have considerable or at least observable effects on the catalyst behavior.

In most industrial applications small amounts of additives or "promoters" are present in the supported metal catalyst system and these can have a number of functions which improve the catalyst efficiency (Twigg 1989). For example, the introduction of promoters can increase both the number and intrinsic activity of active sites.

Most supported metal catalysts are susceptible to poisoning by molecules containing sulfur, nitrogen, chlorine, and oxygen, even at low concentrations, and this can have serious effects on large-scale industrial applications. However, in certain cases (Hutchings *et al.* 1994) controlled doping of supported metal catalysts with small amounts of such molecules can improve the catalyst selectivity and therefore act as promoters. The action of promoters and poisons can usually be described in terms of electronic or geometric effects.

The main techniques utilized in the preparation of supported metal catalysts are impregnation and co-precipitation methods. A number of other techniques may also be used including ion exchange (particularly for zeolite-supported metals), deposition (precipitation–deposition and reduction–deposition), and metal vapor deposition (Bond 1982, Che and Bennet 1989).

Impregnation involves contacting the support material with a solution of suitable metal salt, e.g., nitrate, under controlled conditions over a period of time to allow adsorption of the catalyst precursor salt from the solution. The volume of solution can either be equal to the total pore volume of the support (incipient wetness) or in excess of the pore volume. Incipient wetness is generally used when reproducible metal loadings are required and when there are only weak interactions between the support and the precursor material. A number of variables is important in impregnation procedures such as the concentration of the precursor salt solution, the time of contact, the solvent, and the temperature.

In the case of co-precipitation, the metal precursor and support materials are formed simultaneously by addition of a basic precipitating agent (usually carbonate or hydroxide) to a solution containing

appropriate metal and support precursor salts. This results in the distribution of the metal component throughout the bulk structure of the material, whereas with impregnation the active metal species are deposited on the surface only. The latter may be more economically favorable since a larger quantity of metal salt will be required to give an equivalent surface metal loading, and therefore active surface area, than with the co-precipitated method.

After the catalyst precursors have been formed and dried the samples are then usually calcined in air to decompose the precursor species to the oxide as these can often be more easily reduced to the metallic state. Calcination is followed by reduction in a gas such as hydrogen or carbon monoxide under controlled conditions. In some cases, it is more favorable to omit the calcination step and reduce the catalyst precursor directly. Sometimes during calcination highly stable compounds are formed which are difficult to reduce under typical reduction conditions, e.g., metal aluminates and silicates.

The choices of preparation method and pretreatment conditions are important in determining the performance of the catalyst. These factors can have direct effects on metal surface area, dispersion (ratio of number of metal atoms exposed at the surface to total number of metal atoms present), and in particular the metal particle size and morphology. These are important parameters which are directly related to catalyst activity, selectivity, and stability and therefore need to be characterized in order to obtain accurate and quantitative measurement of catalyst performance.

3. Characterization of Support–Catalyst Interaction

A vast array of techniques can be used to characterize supported catalysts with the aim of gaining information concerning the metal surface area, dispersion and particle size, oxidation states of surface species, metal–support interactions, and the factors which influence these characteristics. In general, measurement of active surface area and dispersion is achieved using selective chemisorption. Adsorption of a gas (e.g., hydrogen, oxygen, or carbon monoxide) on the metal particles alone can be used to calculate the number of metal atoms exposed at the surface of the catalyst, providing the adsorption stoichiometry (number of gas molecules or atoms adsorbed per metal atom) is known. Metal particle size can also be obtained by means of electron microscopy, e.g., transmission electron microscopy (TEM), x-ray line broadening using the Scherrer equation, as well as magnetic methods. Electron microscopy is particularly useful as the shapes of the metal particles can be observed visually and values for dispersion and

particle size distributions obtained. *In situ* Fourier transform infrared (FTIR) spectroscopy can be used to determine the oxidation states of the metal species present at the surface by means of CO adsorption studies. X-ray photoelectron spectroscopy (XPS) can also be used to establish oxidation states, and as with FTIR spectroscopy vital information on metal–support interactions can be obtained, such as the nature and strength of the bonding between the metal component and the support. Other techniques which can be used to study the nature of metal–support interactions include NMR (nuclear magnetic resonance) spectroscopy, UPS (ultraviolet photoelectron spectroscopy), Mössbauer spectroscopy, and EXAFS (extended x-ray absorption fine structure) as well as monitoring the effects of the support on chemisorptive and catalytic properties. To date, the best methods for studying the nature of the support–catalyst interactions are TEM, HREM (high-resolution electron microscopy) (Thomas and Thomas 1997), and STM (Bowker 1998).

Textile Fibers: A Comparative Overview

Fibers from natural sources, twisted by hand into yarns, and then woven into textile fabrics, constitute a materials technology which dates back over 10 000 years. Apart from hand-tools, the technology changed little until the industrial revolution, with the invention of power machines concentrated in 1775–1825. The available fibers, namely cotton, some fibers extracted from the stems or leaves of plants, wool, other hairs, and silk, remained unchanged for another 100 years. All except silk were short fibers, with staple lengths of about 1–10 cm. These fibers had to be twisted into yarns. Even silk filaments were of finite length and had to be "thrown" together into longer yarns, which were smooth and lustrous in contrast to the hairy staple-fiber yarns. Advances in chemistry led to solutions of cellulose derivatives, which could be extruded through multiple holes, coagulated, and regenerated as continuous filament yarns of effectively infinite length. For a time, these were known as *artificial silk*. The most successful, *viscose rayon*, was first commercially produced in 1905. The recognition of the idea of macromolecules in the 1920s led to manufactured, synthetic yarns of several vinyl polymers, but the major invention was nylon, which became commercial in 1938. Polyester followed 10 years later. The two other major synthetic fibers of this first generation were acrylics and polypropylene. A second generation of high-performance fibers started with the aramid fiber, *Kevlar*, followed by high-modulus polyethylene. Elastomeric fibers, such as *Lycra*, were another development.

The uses of textile fibers fall into three categories. Both *clothing* and *furnishing fabrics* are somewhat unusual in materials technology, since color and the other esthetic features of pattern and feel, which are determined by the fiber and textile structures, are as important as the functional requirements for cover, protection, warmth, and durability. The third category of *technical textiles* includes some old and simple uses, ranging from ropes to wiping cloths, but is becoming of increasing importance in demanding engineering and medical applications.

All the fibers mentioned above are polymeric materials, and they, with some other polymer fibers of more limited or specialist interest, comprise the main scope of this article. Inorganic fibers, namely glass, ceramic, carbon, and metallic, although they can be formed into textile structures, will only be mentioned briefly.

[The sizes of fibers are most conveniently expressed in terms of linear density, namely mass per unit length, rather than area of cross-section or diameter. The SI unit is the tex, which is grams per kilometer ($g \, km^{-1}$). The submultiple decitex (dtex) is widely used; an older unit, denier, is grams per 9000 m. This leads to the mechanical quantities specific stress, modulus, and strength (tenacity) being expressed as (force/linear density). The preferred unit is newtons per tex ($N \, tex^{-1}$), which is dimensionally equivalent and equal to gigapascals per gram per cubic centimeter ($GPa \, g^{-1} cm^3$), kilojoules per gram ($kJ \, g^{-1}$), or, in a link to wave propagation velocity, the square of kilometers per second ($km \, s^{-1}$)^2.]

1. Fibers and Fiber Types

1.1 Fibers as a Material Form

Fibers, which are materials in a one-dimensional form characterized by flexibility, fineness, and high ratio of length to thickness (McIntyre and Daniels 1995), perform many functions in living organisms and are used in a wide variety of manufactured structures. A list of values of the fiber form, some of which are more relevant to other fiber uses than to textiles, includes:

(i) Combination of flexibility with strength, in contrast to the usual association of stiffness and strength.

(ii) Crack-stopping at the discontinuities, which gives strength to composites.

(iii) High surface area, which is important in absorption.

(iv) Large included volume between fibers in textile structures.

(v) Continuity over long lengths, which is vital in optical fibers.

(vi) Ability to form networks.

(vii) Structural control: in natural fibers, by genetics; in manufactured fibers, due to the rapid heating, cooling, evaporation, and stress changes.

(viii) Small defect size (less than fiber diameters), typified by the high strength of glass fibers.

(ix) Ability to modify chemistry or introduce additives to give specific properties.

(x) Control of end-use performance at several levels: chemical constitution, fiber fine structure, macroscopic fiber form, yarn structure, fabric structure, etc.

1.2 Characteristic Features of Textile Fibers

For clothing and household textiles, the common fiber requirements are:

Appropriate dimensions: commonly, textile fibers are in the range 1–20 dtex, which gives diameters of 5–50 μm. Coarser forms, typically 0.1–1mm, are known as monofilaments. *Microfibers*, down to 0.1dtex (~ 3 μm diameter) or less, have been introduced in

---

recent years. *Nanofibers*, with linear densities from 10^{-3}–10^{-7}dtex (ca. 3–300 nm), have been produced by electro-spinning, which involves the extrusion of polymer solutions or melts in a high electric field (Reneker and Chun 1996).

Mechanical, thermal, and chemical stability in everyday use.

Accessibility to dyestuffs for coloration.

An intermediate range of elastic extensibility; break extensions from 5 to 50%.

The only materials that have been found to satisfy these requirements for natural or manufactured fibers are *partially oriented*, *partially crystalline*, *linear polymers*. For special purposes, fibers outside this range of requirements may be polymeric or inorganic. High-stretch, elastomeric fibers have break extensions up to 500%, and high-modulus, high-tenacity (HM-HT) fibers down to 2%. Coloration is not needed for engineering fibers. Higher temperature or chemical resistance or other special properties are needed for some applications.

1.3 Chemical and Manufacturing Classification and Importance

The general textile fiber market is satisfied by six chemical types:

(i) cellulose, in cotton, other plant fibers, and rayon and its derivative cellulose acetate;

(ii) proteins in wool, hairs, and silk;

(iii) polyamides, mainly nylon 6 and 66;

(iv) polyesters, mainly polyethylene terephthalate (PET or 2GT);

(v) polyacrylonitrile (PAN) acrylic fibers, and other vinyl polymers;

(vi) polyolefins, mainly polypropylene.

In addition, the elastomeric fibers are polyurethanes. Aramids (aromatic polyamides) and other polymers are used as HM-HT fibers, for high-temperature resistance, and for other special purposes. Table 1 gives statistics, which show the relative importance of the different materials, with some indication of the division between different forms and applications of the same material.

Cotton, other natural cellulose fibers, wool, and hairs are laid down over weeks in living cells. Silk is extruded as an aqueous solution stream, which dries into the filaments. In spider silk, the rate of extrusion may be as high as $10 \, \text{cm} \, \text{min}^{-1}$. Manufactured polymer fibers are produced at rates of 100–$10\,000 \, \text{m} \, \text{min}^{-1}$. There are several methods of production. From polymer solutions, either *wet-spinning* into a coagulating bath, sometimes involving a chemical reaction, or *dry-spinning* with evaporation may be used. Thermoplastic polymers enable the faster *melt-spinning* process to be used. High-modulus polyethylene (HMPE) fibers are made by *gel-spinning*.

Inorganic fibers are dealt with in detail in other articles, particularly in relation to composites. Glass fibers have been known since ancient times, and became of major importance, manufactured in various ways, in the twentieth century. They are occasionally used in clothing or furnishing fabrics, but their major uses are in technical textiles and composite preforms (see *Glass Fibers**). Optical fibers may be of glass or organic polymers (see *Glass Optical Fibers*[#]). Low-grade ceramic fibers, used for insulation, are made by melt processes. High-performance ceramic fibers, such as those based on silicon carbide or alumina, may be formed as polymer fibers, with the inorganic elements either incorporated in the polymer or mixed as compounds in the polymer solution, and then heat treated for conversion to ceramic; their main use is in composites (see *Ceramic Fibers from Polymer Precursors**; *Spun (Slurry and Sol–Gel) Ceramic Fibers**). Other ceramic fibers, such as boron or silicon carbide, may be made by chemical vapor deposition (see *CVD Monofilaments**). The highest strengths are achieved with single-crystal whiskers (see *Whiskers**). Most carbon fibers (see *Carbon Fibers**) are made by heat treatments of acrylic fibers, but rayon can also be used, and pitch-based fibers have somewhat different structure and properties. Moderate heat treatment gives thermally resistant fibers used in protective clothing, and higher temperature treatments give high-strength, high-modulus fibers, which are mainly used in composites (see *Fibrous Reinforcements for Composites: Overview**) but can also be used, for example, in medical textiles. Fine metal wires can be regarded as fibers, and may be used for decorative or physical reasons (see *Metallic Filaments**).

1.4 Comparative Properties

Table 2 lists typical properties of the more important textile fibers. Where two sets of mechanical properties are given, these are typical of different types, but the available range may be greater. Figure 1 shows stress–strain curves. These values are for "dry" fibers, namely fibers in equilibrium at a standard atmosphere of 65% relative humidity and 20 °C. Roughly, the fibers can be divided into five groups: *low strength*, *low extension*, e.g. rock wools; *high strength*, *low extension*, e.g. aramid and HMPE; *tough*, due to combined strength and extension, e.g. nylon, polyester, and polypropylene; *less tough*, lower combined strength and extension, e.g. cotton, wool, and rayon; and *very high extension*, e.g. *Lycra*. However, for the natural fibers, properties vary with variety and growth conditions, and, for manufactured fibers of any given type, the degree of orientation imposed allows for a range from lower strength/higher extension to higher strength/lower extension.

The densities of textile fibers are typically in the range $1–1.5 \, g \, cm^{-3}$, which gives them a considerable weight advantage compared to many structural materials. Cellulose, protein, and, to a lesser extent, nylon absorb appreciable quantities of water, which causes swelling and changes properties. When dry, the polymeric textile fibers are insulators. As water is absorbed the dielectric constant increases, reaching high values at high humidities; this allows ions to dissociate, and lowers the specific resistance to about $10^3 \, \Omega \, cm$ in moisture-absorbing fibers at high humidity. The addition of additives to fibers gives special

Table 2
Typical properties of textile fibers.

Fiber	Density (g cm^{-3})	Melting point (°C)	Moisture at 65% relative humidity, 20 °C (%)	Tenacity (N tex^{-1})	Break extension (%)	Work of rupture (J g^{-1})	Initial modulus (N tex^{-1})
Cotton	1.52	∼200(chars)	7–8	0.19	5.6	5.1	3.9

properties, for example, flame resistance, antimicrobial action, and ultraviolet protection.

Most textile fibers will stand temperatures up to 200 °C, but at some higher temperature they melt, char, or chemically decompose in other ways. The thermoplastic fibers can be "permanently" heat set at temperatures appreciably below their melting points, and temporarily set at lower-temperature transitions. Similar temporary setting in cellulose and protein fibers is strongly influenced by wetting and drying.
1.5 Textile Processes and Products

Figure 2 outlines the major ways in which textile fibers are assembled into fabrics, which then have to be fabricated into the wide range of final products. In order to give yarns any strength, the natural staple fibers have to be twisted, entangled or bonded together. This is not necessary for continuous filaments, though limited interlacing or twisting is used to give some cohesion to the yarns. In order to get a rougher "natural" fabric character, coarse tows are made and cut into staple fibers for spinning, often in blends with natural fibers. Texturing processes can be used to set or trap filaments in helical or looped paths, in order to give more stretch and bulk to continuous filament yarns.

Most textiles are planar sheet materials. In woven fabrics, warp (lengthwise) yarns pass under and over weft (fill, crosswise) yarns. In braids, interlacing occurs between diagonal sets of yarns. In knits, yarns

Figure 2
Principal routes for assembly of fibers into fabrics.

are looped together in neighboring rows, either across the length in weft-knitting or along the length in warp-knitting. Nonwoven fabrics are more-or-less random sheets of fibers, which are held together by adhesive bonding, entanglement, or stitching. One-dimensional assemblies are used in cords and ropes. Three-dimensional fabrics are used as composite preforms, either in the form of shaped sheets or thick structures, but also have other applications, such as, respectively, knitted garments and conveyor belts.

Dyeing of fibers, yarns, or fabrics in the wide range of needed colors involves selection of dyestuffs to match the chemical composition and structural accessibility of fibers. Acid, basic, and other reactive dyes are readily taken up by cellulose, protein, and nylon fibers, which are swollen in water. *Mordanting* fibers with metal salts allow dyes that form organometallic complexes to be used. Vat dyes are insoluble

in water, but become soluble on reduction; fabric is reoxidized after dyeing. Disperse dyes, which are sparingly soluble in water, are used for thermoplastic fibers. Chemical and mechanical finishing of fabrics is used to stabilize dimensions, modify surfaces, and impart special functions.

2. Cellulose and Related Fibers

2.1 Basic Chemistry, Formation, and Properties

Cellulose, which is the main structural material in plants, is a condensation polymer formed by biosynthesis from carbon dioxide and water with glucose as the intermediate monomer. The chemical formula is
In terms of physical fiber structure and properties, the important molecular features are shown in Fig. 3. The long chain, which has a natural degree of polymerization (DP) of over 10 000, has direction. In the crystal form, cellulose I, in natural fibers, the chains are parallel, but mercerization (see Sect. 2.2) or solution and regeneration converts this form to cellulose II with antiparallel chains. The molecule is ribbon-like, which allows for easy twisting and relatively easy bending in one plane. The hydroxyl groups, which stick out of the chain, form hydrogen bonds within or between chains and with absorbed water.

Biosynthesis occurs at enzyme complexes within plant cells. At each complex, glucose units add on to about 30 growing molecules, which automatically crystallize as fibrils with a width of 3.5 nm. In this sense, natural cellulose fibers can be regarded as 100% crystalline. The lower fiber density, absorption of water, x-ray diffraction, and chemical evidence, which suggest the presence of around one-third disordered material, can be attributed to imperfect packing of fine fibrils with high surface area. Under genetic control, the fibrils are laid down in helical arrays, specific to particular plants, to form cell walls.

$$5 \times 10^{-4} \, \mu m$$

Figure 3
Essential features of the cellulose molecule.

The processing of cellulose to make regenerated fibers reduces the DP to between 250 in cheaper forms and 600 in improved forms. The amount of disordered material increases to about two-thirds, which doubles the water absorption.

Studies of the dynamic mechanical properties of viscose rayon, which are also generally applicable to other cellulose fibers, show glass-to-rubber transitions above 200 °C when dry and below 0 °C when wet. Consequently, wetting and drying leads to formation of creases. These can be reduced by crosslinking treatments with formaldehyde resins, which have the negative effect of making the fibers more brittle and less resistant to wear. Swelling in water makes for easy dyeing and chemical finishing of cellulose fibers (see also *Cellulose: Chemistry and Technology#*).

2.2 Cotton

Cotton accounts for almost half the world's fiber usage. Until challenged in price by polyester, its combination of low cost and useful properties made it the commodity fiber, which could be used in every application, including demanding technical textiles. Now, it is used more selectively, particularly for its comfort and its aesthetic and environmental appeal in clothing and household textiles.

The cotton fiber is a single plant cell, which is the seed hair of the genus *Gossypium*. Plant breeding has led to many varieties from different natural species. Genetic engineering is now introducing new traits. Many fibers grow from each of many seeds within the cotton boll, which forms after flowering. When the fibers are mature, the boll opens, and the fibers dry, ready for picking. Early opening, due to frost or disease, leads to thin-walled immature fibers. Cell formation starts with a primary wall, which grows to the full fiber dimensions in a few days. In the next 24–30 days, the secondary wall, which constitutes the main part of the fiber, is laid down in layers inside the primary wall with a helical angle of about 21°. At intervals, the helix reverses sense from left-handed to right-handed. At maturity, an open lumen remains at the center of the circular fiber. Drying causes the fiber to collapse into a flatter, bean-shaped cross-section. The helix reversals lead to the fiber taking the form of a convoluted ribbon. Natural waxes are present on the surface of the fiber. Raw fiber is slightly yellowish, but becomes white after bleaching. Some special varieties contain green or brown pigments. Cotton fiber dimensions range from short, coarse fibers (1.5 cm, 3 dtex) to long, fine fibers (5 cm, 1 dtex), with the bulk of the crop around 2.5 cm, 2 dtex.

The stress–strain curve of cotton, as shown in Fig. 1, is slightly concave upward, and can be explained by the elastic modulus of the crystal lattice, modified by the effects of the helix angle, twisting at helix reversals, and removal of convolutions (Hearle

and Sparrow 1979). The elastic recovery progressively decreases as extension increases, reaching a value of about 0.4 near break in dry cotton.

In the dry state, hydrogen bonding between fibrils resists shear, which occurs when a helical assembly is extended. The absorption of water introduces mobility between fibrils, and leads to a reduction in modulus and increase in break extension as humidity increases. Cotton, and other plant fibers, are unusual in having a higher strength wet than dry, due to the relief of internal stresses. The form of break also changes (Hearle *et al.* 1998). The tenacity and break extension of the weaker Indian cottons, which have been largely replaced by American varieties, have values of 0.19 Ntex^{-1} and 5.6%, compared to 0.45 Ntex^{-1} and 6.8% for strong Sea Island cottons. Typical values for the bulk of the crop are 0.35 N tex^{-1} and 7%.

Mercerization is a treatment of cotton with a sodium hydroxide solution. This disrupts the crystals, swelling and plasticizing the fibers but leaving sufficient cohesion to retain fiber identity and allow processing. The effects are reversed, though with changes in structure, when the caustic soda is washed out. If shrinkage is allowed, mercerized cotton will be weaker and more extensible, but stretching under tension in the process increases fiber strength and reduces extensibility. A main reason for mercerization is that it converts the fibers to unconvoluted round cross-sections with a smaller central lumen, thus increasing the fiber luster.

2.3 Other Natural Plant Fibers

Wood provides the commonest plant fibers, and is the raw material for regenerated cellulose fibers, but wood fibers are too short for textile processing (unless paper is regarded as a wet-laid nonwoven textile (see *Paper: History of Development*[#]; *Pulp and Paper: Wood Sources*[#]). *Kapok*, which is a hollow fiber used for buoyancy, is a seed fiber, and the coarse fiber *coir*, from the outer coat of the coconut, is a fruit fiber, but both have limited textile usage. Apart from cotton, the main textile plant fibers are extracted from stems (*bast fibers*) (e.g. flax, sunn hemp, true hemp, jute, kenaf, ramie) or stiff leaves (*leaf fibers*) (e.g. abaca (Manila hemp), sisal, henequen, phormium tenax (New Zealand flax)). At different times and locations, fibers from many other plants have been used. Currently, there is interest in promoting the use of waste products, such as pineapple fiber. The bast fibers were once of major importance, particularly before the supply of cotton from America, for clothing and other textiles; and the leaf fibers were dominant in ropes and cordage. However, with the additional competition from manufactured fibers, their use is now limited. The lower-cost fibers have inferior properties, and the superior fibers are expensive to produce.

Bast and leaf fibers are multicellular. The fiber ultimates are small and short, but in bundles they provide the reinforcement to stems and leaves. Extraction of the fibers starts with *retting*, which is a biological or chemical attack on the non-fibrous tissues, and is followed by mechanical beating and further textile processing. The size of the fibers, as they are used in yarns and fabrics, depends on the severity of the treatments. The helix angle in these fibers is lower than in cotton, typically around 10°, so that when, as in flax and ramie, they are almost pure cellulose, they have greater strength and lower break extensions than cotton. Other fibers, such as jute, contain substantial fractions of noncellulosic material, lignins and hemicelluloses, which lower strength and break extension.

Flax, which is used to make linen, and *ramie* are high-quality fibers with good color and an attractive appearance and handle in fabrics. *True hemp* (*Cannabis sativa*) was a major European and American fiber, which was largely displaced, though attempts are being made to revive its production. *Jute* was widely used for low-grade uses, such as sacking and carpet backing, but, in developed markets, has lost out to polypropylene. Trials for other uses are being made in jute-producing countries. In cordage, *abaca* and *sisal* were dominant, but have been replaced by synthetic fibers.

2.4 Regenerated Celluloses

The first factory to manufacture textile fibers, by extruding and regenerating cellulose nitrate (nitrocellulose) dissolved in ether and alcohol, opened in 1890 but this method is no longer used. The second process continues in limited production in Japan. Cellulose forms a soluble complex with cuprammonium hydroxide. The solution is extruded into a dilute acid bath, which precipitates the cellulose fibers. The third process, which in a variety of forms is now dominant, began commercial production in 1905 as *viscose rayon*. However, there are environmental problems with the viscose process, and it is doubtful if building a new, clean factory would be economically viable. This has led to research into organic solvents for cellulose, and semicommercial production of *lyocell* fibers began in 1988. These are likely to become more important. Other methods, such as making acetate yarns, stretching and then regenerating cellulose fibers, have been used at various times.

Marketing of cuprammonium and viscose rayon started with continuous filament yarns as a cheap "artificial silk." Waste yarn was chopped into short lengths for processing into spun yarns on cotton and wool machinery. In the 1930s, high-tenacity yarns began to replace cotton in tire reinforcement, and the production of thick tows for conversion into staple fibers began. By 1950, staple had exceeded filament yarn production, and new variants with improved

properties were introduced. Other developments and changing economics mean that rayon is no longer a low-cost commodity fiber, but is used to give added value either alone or in blends with polyester and cotton.

Viscose is an alkaline solution of sodium cellulose xanthate, which is made by reacting cellulose with sodium hydroxide and carbon disulfide. After filtering and aging, it is extruded into an acid bath. The filaments coagulate as regenerated cellulose fibers, which are stretched to increase strength and reduce extensibility. An early discovery was that the addition of zinc salts to the coagulating bath improved properties, by causing the regeneration to pass through an intermediate stage as zinc cellulose xanthate. Because hydrogen ions move faster than zinc ions, the zinc route occurred near the surface but the direct route operated in the center, giving a skin–core structure. Removal of excess solvent led to a collapse into a serrated cross-section.

The fine structure of "standard" viscose rayon is probably a classical fringed micelle structure, with little if any crystallographic chain folding. Chain molecules link crystalline micelles through tie-segments in amorphous regions. The crystals hold the structure together, deformation and rupture occurring in the disordered material. Chain ends between micelles reduce strength, but their effect can be minimized by increasing molecular weight, which is done for superior fibers, and by reducing the size of micelles and the intervening lengths. The last explains the influence of zinc: the skin structure has a finer texture than the core. For general textile purposes, moderate or low strength and a break extension around 20% was suitable, but for tire cords the stretch in manufacture was increased to give higher strength and reduced extension. The early tire cord yarns were skin-plus-core fibers, but the process was then modified to increase the skin thickness and eventually make stronger, "all-skin" fibers with a round cross-section. Similar techniques were later applied to more extensible staple fibers. By forcing the formation of an asymmetric skin, which contracts differentially, it is possible to make fibers that crimp spontaneously on drying.

In the 1950s, modifications, such as extrusion into a bath of a weak acid, made it possible to coagulate fibers of the cellulose derivative, stretch these, and then regenerate the fibers. This gives a fibrillar, instead of a micellar, fine structure. The resulting high-wet-modulus (HWM) fibers, which are also known as *polynosic* fibers, are closer to cotton in properties. Other developments included the production of hollow filaments, which give added bulk or can be collapsed in to ribbon forms, bulky multilobal fibers from shaped spinneret holes, deep-dyeing fibers, flame-retardant fibers, and superfine fibers (~ 0.5 dtex).

In the dry state, the tensile stress–strain curve of standard viscose rayon, as included in Fig. 1, shows an initial stiff region, with a yield at 1% or 2% extension to a lower-modulus section, which stiffens somewhat toward break. This is a micellar composite, so deformation occurs in the amorphous regions with only limited stiffening by the crystallites. Extension is initially restricted by the hydrogen bonds between cellulose molecules. Yield occurs when these bonds break. In the wet state, mobile water molecules replace the direct hydrogen bonds, and the low modulus yield region effectively starts at the origin. The fibrillar structure of the HWM fibers gives a parallel composite, in which the crystals stiffen the structure. This has some effect when dry, giving more cotton-like properties, and a major increase in wet modulus.

Lyocell fibers are made by dissolving cellulose in a concentrated amine oxide, *N*-methylmorpholine-*N*-oxide [7529–22–8] (NMMO), solution, and then extruding into a dilute NMMO solution, which precipitates the cellulose. With effective recycling, the process is environmentally and economically attractive. Due to their high DP and fibrillar structure, lyocell fibers, such as *Tencel*, have good properties. Fibrillation, namely the splitting off of fine fibrils from the fiber surface, occurs easily. This is advantageous in enabling fabrics to be finished to "peach skin" textures and in bonding hydro-entangled nonwovens, but, if not wanted, its extent can be controlled by process adjustments.

2.5 Cellulose Acetate

Treatment of cellulose with acetic acid and acetic anhydride converts it into cellulose acetate. Partial acetylation, with one in six hydroxyl groups remaining, gives *secondary acetate*, which is soluble in acetone and can be dry-spun into fibers. Due to their poor crystallinity, secondary acetate fibers are comparatively weak and extensible. Their low modulus means that fabrics have low bending stiffness, which is useful when soft, drapable materials are in fashion. Acetate fibers have low moisture absorption and are thermoplastic. The largest usage of acetate fibers is now in cigarette filters.

Complete acetylation gives cellulose triacetate, for which more expensive solvents are needed. Triacetate fibers, although weaker than nylon or polyester, have the same heat-setting advantages, and found a market when the synthetic fibers were expensive.

2.6 Alginate Fibers and Other Polysaccharides

Salts of alginic acid, derived from seaweed and with-COOH replacing the -CH_2OH of cellulose, can be made into fibers. Their main use is as calcium alginate fibers, which are soluble in hot, soapy water, and can be used to give temporary strength to a fabric. Calcium and sodium alginate fibers, and the other polysaccharides, chitin and chitosan, are used in wound dressings and other medical textiles.

3. Protein Fibers

3.1 Basic Protein Chemistry

The basic repeat unit in proteins is
The diversity of proteins is due to the choice and order of side groups -R, which derive from 20 amino acids. The side-groups are inert (-H and hydrocarbons), acidic, basic, hydroxyl-containing, and more complex. Of particular importance are two anomalous forms. Proline is a ring structure, which joins on to the main-chain carbon in place of -H and distorts chain geometry. Cysteine is formed as $-CH_2SH$, but can be oxidized to cystine, $-CH_2SSCH_2-$, which forms cross-links within or between chains. In addition to the cystine cross-links, covalent isopeptide bonds between lysine and glutamine, acid–base links, and hydrogen bonds influence fiber properties.

The residue sequence, which is controlled genetically, causes protein molecules to take up specific geometric forms. Some protein molecules, or parts of molecules, crystallize in one or other of two lattice forms. In variants of the α helix of simple polypeptides, the chains follow helical arrays, with internal hydrogen bonds and different chemical and geometrical repeats. Intermediate filaments (IFs) contain 32 chains, consisting of coiled-coil dimers, packed in tetramers and then octamers to form the microfibrils of wool. Alternatively, proteins crystallize as β sheets of extended molecules linked by hydrogen bonds between neighboring chains. Under tension, intermediate filaments undergo a reversible $\alpha \rightarrow \beta$ crystal structure transition, with an extension of 120% for an ideal α helix, but down to 80% in wool. Another class of proteins are globular, formed by individual chains folding into specific but irregular forms with internal cross-links.

3.2 Wool

Wool was formerly a more expensive commodity fiber, used for a wide variety of purposes. It is more resilient and durable than cotton, and can be made into warm, attractive clothing, upholstery, and carpets. Some of the attributes of wool have been replicated in synthetic fibers, and it must now compete on quality and tradition. Production costs are high, and farmers can change to other products. It has been demonstrated that genetic engineering can change the structure and properties of wool, though not yet in beneficial ways. This may be a route to a future for different wools with characters aimed at particular high-quality markets. Wool fibers are slightly elliptical, with mean diameters between 15 μm and 50 μm. Finer fibers command a higher price. A typical length of Australian Merino wools (~ 22 μm) is 100 mm and of coarse New Zealand wool (~ 35 μm), used in carpets from sheep grown mainly for meat, is 150 mm.

Wool, which is multicellular, grows under genetic control in a sequence of stages out of skin follicles at a rate of around 100 mm per year, and has the most complex structure of any textile fiber. Characteristic features are present at many levels. Chemically, there are families of keratin proteins of types I and II and of a variety of keratin-associated proteins (KAPs). The major part of the keratin I and II molecules pack into crystalline IFs, but there are also terminal groups (tails), which are rich in cysteine and project from the IFs. The KAPs are globular proteins, some of which are rich in cysteine while others are rich in glycine and tyrosine. The fine structure consists of a parallel assembly of IFs (microfibrils) with a diameter of about 7 nm, spaced about 10 nm apart in a matrix of KAPs. The IF structure, which is laid down first, is now well documented, but there is considerable uncertainty about the matrix, which is laid down later. The final actions are keratinization, which converts cysteine into cystine, and coating the fiber surface with a lipid layer. Some of the cystine cross-links will be within globular KAPs, but it is likely that some will be between globules and also to the tails of the IF proteins, which act as spacers between IFs. In this scenario, the matrix would act as a fairly strongly cross-linked rubber with a maximum extension of about 50%.

Most of the fiber consists of spindle-shaped cells held together by the cell membrane complex (CMC), which is rich in lipids. Cells in this central cortex are of two types, separated by a boundary, which rotates along the fiber. In the *para*-cortex the IFs are oriented parallel to the fiber axis; in the *ortho*-cortex the IFs are associated in helical arrays as macrofibrils. On the surface there are several layers of a cuticle, which contains scale cells, overlapping like tiles on a roof.

The structural features determine the specific properties of wool. The surface scales cause a directional frictional effect, which leads to *felting* (fiber entanglement by wet agitation) as movement is easier with scales than against scales. Felting is a defect, which causes shrinkage and can be avoided by chemical removal of scales, but can also be used to make fabric. Differential shrinkage of *ortho*- and *para*-cortex on drying causes fibers to bend, and the rotation of the boundary converts this into helical crimp, which gives bulk to wool yarns. The CMC generally holds the cellular composite together, but if it is weak it may allow slip and reduce fiber strength. The many amino acid side-groups present allow for a range of chemical treatments, including the introduction of covalent cross-links to give crease-resistance.

The tensile stress–strain curve of wet wool is stiff up to 2% extension, but then yields with an almost constant stress up to 30% extension, followed by a sharp change to a stiffer postyield region up to break at about 50% extension. A feature, which is unusual for yielding materials, is that recovery is complete from 30% extension or less, though on a curve at a lower stress level. Above 30% there is a small loss of recovery. In the dry state the yield stress increases, and recovery is incomplete. However, subsequent wetting will restore the fiber to its initial state. This is an important factor in the durability and appearance retention of wool fabrics.

The tensile properties have been explained (Chapman 1969) as the mechanics of a composite system. Up to 2% there is deformation of the IF crystal lattice with only a small contribution from the elastomeric matrix. At 2%, the $\alpha \to \beta$ transition is initiated in IFs and, locally, the IF stress drops from the critical value for nucleation of the β form to the equilibrium value for the $\alpha \to \beta$ transition, with stress transfer to the neighboring matrix, which extends to 30%. Only a limited zone can open, but the sequence proceeds with more zones opening until all the zones have joined up. Beyond 30% extension the matrix is stretched more, and the elastomer stress–strain curve is followed. Some cross-links break, which accounts for the loss of recovery and leads to fiber rupture in a granular form typical of a composite structure. Nucleation is not needed in recovery, which, below 30%, follows the elastomer curve with a shrinkage of opened zones until they disappear and the extension curve is rejoined below 1% extension. In the dry state, hydrogen bonding causes the matrix to have an initial stiff region, before yielding. The evidence is strong for the above explanation, but alternative views are still current (Feughelman 1997).

3.3 Other Hair Fibers

The hairs of other animals (and humans) have structures that are generally similar to wool but have specific differences. Coarse hairs, such as cow or horse, were used for undemanding uses, such as furniture stuffing, but also for special purposes, such as violin bows, where long fibers are needed. Other hairs, which find textile uses, are finer than wool or have other characteristics, which give particular qualities to fabrics. The main sources are varieties of goat, such as mohair and cashmere, camel, alpaca, vicuna, and angora rabbit.

3.4 Silk and Spider Silks

Silks differ from other natural fibers in not being formed as living cells, being extrusions of protein solutions which coagulate on drying. Silk used in the textile industry comes from the covering of the cocoon of the silk moth *Bombyx mori*. Pairs of triangular filaments (2–3 dtex) are stuck together by gum, and can be unreeled after soaking the cocoon in hot water. Each cocoon yields about 700 m of useful length of silk. As the only continuous filament yarn available to the textile industry until the twentieth century, silk gave expensive, lustrous fabrics. Even today, the shape of the fibers and their bulk and surface properties give special qualities, which command a high price in luxury fabrics. Production involves feeding mulberry leaves to silk worms, which then change to larvae within cocoons. Most cocoons are harvested for filament production. The silk from larvae that hatch out to continue the cycle is chopped into staple fiber for spun silk fabrics. There is also some use of wild tussah silk.

Silk is a natural block copolymer. Segments of a simple repeating structure of glycine, alanine, serine, and tyrosine form β-crystalline regions linked by segments with more diverse chemistry. Cysteine is absent. Silk is the toughest (highest work of rupture and good recovery) of natural textile fibers, due to moderately high tenacity and break extension. This led to uses such as parachutes until it was superseded by nylon.

Spider silks have not found textile uses, but have remarkable and variable properties. Different proteins are formed from the same glands for different purposes. Drag-line silk is extremely strong, and derives from an oriented liquid crystal solution, similar to production of HM-HT fibers such as *Kevlar*. Other spider silks in the web are more extensible and elastic. Currently, there is interest in the genetic engineering of spider silk proteins by bacteria as a route to polymers for high-performance fibers from aqueous solutions, but other factors such as the form of the "spinneret" in the spider and the relatively slow extrusion rate may be critical (see *Silk Produced by Engineered Bacteria*[#]).

3.5 Regenerated Protein Fibers

Fibers can be regenerated from solutions of proteins, but the price/property ratio was not sufficiently favorable for continued commercial production. The fibers are weaker than wool and have poor elastic recovery. The most successful was made of casein from milk, but proteins from corn and ground-nuts were also used.

4. Melt-spun Synthetic Fibers

4.1 General Features: Polyamides and Polyesters

The invention by Carothers of the polyamide *nylon 66*, which was commercialized by DuPont in 1938, marks the real start of a major synthetic fiber manufacturing industry. It was followed by *nylon 6*,

invented in Germany, and by the polyester *polyethylene terephthalate* (PET), which has now overtaken nylon in world production. These are all polymers with melting points between 215 °C and 260 °C. Molten polymer is extruded, cooled, and solidified, and stretched (drawn) to give orientation. Continuous filament yarns contain 1 to about 1000 filaments. Staple fibers are cut from massive tows.

In the first production method, polymer chips were melted, extruded and wound up at under 1000 m min^{-1} as unoriented yarns, which were partially crystalline for nylon but amorphous for polyester. In a second stage, the undrawn yarn was stretched by draw ratios of around $\times 4$. Later, combined spin–draw processes were introduced, with first-stage rollers at around 1000 m min^{-1} and wind-up at 3000 m min^{-1}. A major change, particularly important in polyester, was the production of *partially oriented yarn* (POY) by direct wind-up at high speed. The orientation results from the rapid elongation and attenuation of the molten threadline before solidification. The necessary residual draw ratio of around $\times 1.5$ is imparted simultaneously with the following textile operations: yarn texturing or warp-drawing. Even higher-speed winding machinery, 5000–10000 m min^{-1}, allows production of comparatively low-strength, high-extension yarns suitable for direct use in fabrics for some purposes. Continuous polymerization, which feeds molten polymer directly to extrusion, is now common.

Other heat treatments, with tension or relaxation, can be applied to change the tensile, thermal shrinkage, and other properties. For general textile purposes, fibers of moderate strength and break extensions around 20% are produced, but for tire cords and other technical uses higher strengths and lower break extensions ($\sim 10\%$) are used. Fiber cross-sections are usually circular, but other shapes, such as bulky trilobal fibers, can be formed from shaped spinneret holes. Finishes are applied to reduce electrostatic charging and to give frictional properties needed for different markets. Internal additives, such as delustrants, pigments, or conducting carbon or polymer, can be incorporated. For some uses, bicomponent fibers, with skin–core or side-by-side forms, or multicomponent fibers are produced. An important example of the latter is the islands-in-a-sea process which gives very fine microfibers embedded in a matrix, which can be removed.

Nylon 6 and 66 and PET are characterized by polymers with long repeat units that contain flexible inert sequences alternating with more interactive sequences, which in PET are also stiffer. This gives rise to thermal transitions which have led these polymers to dominate the market for synthetic fibers. At some temperature around -100 °C, the amorphous regions of the polymer change from a fully glassy state to give some extensibility as freedom of rotation around C–C or similar bonds becomes possible. At

around 100 °C, another second-order transition occurs, as hydrogen bond mobility develops in nylon and benzene ring interactions become free in PET. In addition to lowering the modulus, this opens up the structure for dyeing. At about 80 °C below the melting point the structure loosens up still more, probably by some form of crystal mobility, but possibly in PET by transesterification in amorphous tie molecules.

Heat setting, namely the fixing of fibers within yarns and fabrics in new shapes, is an important attribute of nylon and polyester fibers. The intermediate transition at around 100 °C causes a temporary set, which can be released by reheating. The higher transition allows "permanent" heat-setting treatments to be applied to nylon 66 and PET yarns and fabrics between 180 °C and 240 °C, when fibers start to stick together. The temperatures are lower for nylon 6. Setting processes are used in the production of textured yarns and to fix creases or otherwise stabilize fabrics. In nylon, it is necessary to go to more severe conditions to overcome a prior treatment, but PET can be reset at any temperature in the range.

Superficially, the extrusion, attenuation, and solidification of a molten threadline looks like a steady process, and the macroscopic relations between forces, elongation, and rheology and between heat transfer and temperature have been extensively studied. However, at the molecular level the motions may be more complicated. The semicrystalline structure is established at high speeds (1ms corresponds to 5cm at 3000 m min^{-1}). In addition to polymer dynamics in situations far from equilibrium, the phenomena will involve aspects of the emerging science of complexity, chaos, fractals, kinetics of nonhomogeneous processes, nonlinear irreversible thermodynamics, and, possibly, quantum superposition, but it is not easy to see how to apply these ideas.

Despite studies by many analytical techniques, there is still considerable uncertainty about the fine structure of these fibers. Degrees of orientation, which vary with stretch in processing, can be measured. Crystallinity can be estimated on the basis of a scale from crystal to amorphous of a parameter such as density, and is always close to 50% in fibers as used. Some indications of the size, spacing, and linkage of crystals can be obtained, but the details remain obscure. Partly this is due to the many ways in which molecules can be arranged in a partially oriented, semicrystalline structure, and partly to the fact that the structures formed and modified by annealing at temperatures close to the melting point will vary with processing history. There have not been comprehensive investigations and interpretation of well-characterized samples by the several available techniques. Almost all pictures drawn to illustrate views of structure have been simplistic and not quantitative.

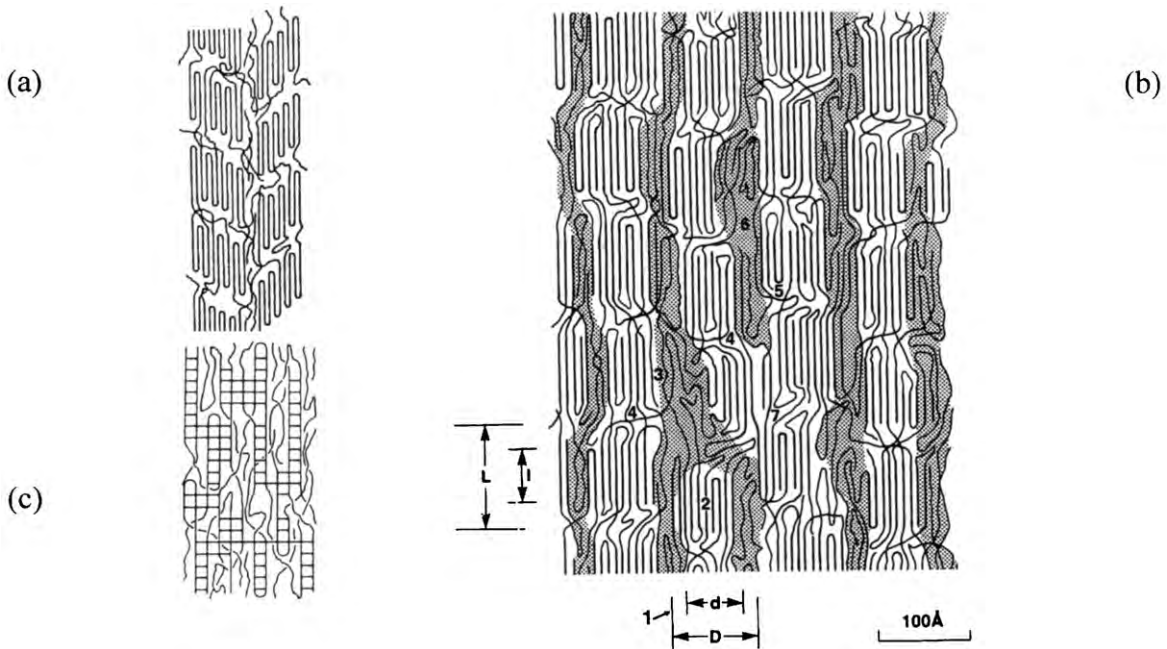
The common view is that the fine structure is a modified fringed micelle form. Crystallites, with a mix of fringing and folding at their ends, are stacked


Figure 4
(a) Schematic view of nylon fine structure, intended to explain the small-angle X-ray diffraction pattern by the angled lattice repeat. (b) Fine structure of nylon 6, as interpreted from SAXS and WAXD data (Murthy *et al*. 1990). (c) Alternative continuous partially ordered structure.
in a pseudofibrillar array and linked by tie molecules, as suggested in Fig. 4(a). Figure 4(b) is an attempt to be more specific on the structure of a nylon 6 fiber and, while retaining the main features of more idealized representations of the common view, introduces some variability and three-dimensionality. Other views have been suggested. The long repeat length means that defects, such as those that occur in polyethylene due to additional units, are not possible without disruption of crystals, but, in contrast to Figs. 4(a) and (b) and similar pictures, there could be defect forms in which molecules follow paths across crystallites and emerge from the sides. More rapid quenching may give continuous structures of partial order, such as illustrated in Fig. 4(c), in which the boundaries between crystalline and amorphous regions are less well defined.

The partial order and molecular characteristics give strong, extensible nylon and polyester fibers. Tensile rupture is a ductile break in which a crack opens to a V notch, before final transverse rupture. Apart from the range of possibilities for each fiber type, there will be generic differences between nylon 6, nylon 66, and PET. Cracks induced by shear stresses move across nylon fibers at an angle of about 10° but are parallel to the axis in polyester fibers, which suggests that crystallites may have higher aspect ratios. The structural

differences, together with the stiffening effect and different intermolecular forces of the benzene ring in amorphous regions, lead to the significant differences between nylon and polyester in properties and uses.

4.2 Polyamides: Nylon 6 and 66

The chemical formulae of nylon 66 and two repeats of nylon 6 are

$$-\overset{\overset{\displaystyle O}{\|}}{C}CH_2CH_2CH_2CH_2\overset{\overset{\displaystyle O}{\|}}{C}NHCH_2CH_2CH_2CH_2CH_2CH_2NH-$$
Nylon 66

$$-\overset{\overset{\displaystyle O}{\|}}{C}CH_2CH_2CH_2CH_2CH_2NH\overset{\overset{\displaystyle O}{\|}}{C}CH_2CH_2CH_2CH_2CH_2NH-$$
Two repeats of nylon 6

The same units are present with a slight rearrangement in two repeats of nylon 6 as in one repeat of nylon 66. The main difference is that the nylon 6 molecule has direction, which is absent due to the symmetry of nylon 66. This affects the possibilities

for crystal packing, and is probably the reason for the lower melting point of nylon 6.

Although some sigmoidal curvature can be put into the tensile stress–strain curve of nylon fibers by temporary setting, the curves are usually almost linear up to a yield region close to the break stress. The modulus is comparatively low. Depending on the last treatment by the manufacturer, nylon fibers will often shrink by 10% in boiling water, which lowers the modulus. Alternatively, setting under tension may increase length by 10% and raise the modulus. Moderately high strength and break extension combine to make nylon a tough, durable fiber. Elastic recovery is good, being around 70% from near break stress, but time-dependent. Nylon shows an appreciable amount of primary (recoverable) creep and stress relaxation. Due to the presence of -CONH- groups, nylon absorbs water, which leads to changes in properties. The glass transition drops from near 100 °C when dry to near 0 °C when wet, and strength is reduced. Near the transition temperature the dissipation factor (tan δ) due to internal friction, increases to over 0.1, and above the transition the modulus is lower.

The first uses of nylon in parachute fabrics and ladies' stockings resulted from its toughness and durability. After 1945, markets developed for nylon as the first "ease-of-care," "wash-and-wear" fabric, due to the ability to give a permanent set. Setting also led to high-stretch yarns, which were made by twisting, heat setting, and untwisting, at first in separate steps and then by continuous false twisting. Nylon production was overtaken by polyester in the 1970s, and nylon is now used selectively for applications for which its properties are well suited. These features are low modulus, high work of rupture, good durability when dry, and resilient recovery from large deformations. In addition to underwear and some other items of clothing, there is a large market for carpet yarns, which can be made either from staple nylon spun in the same way as wool or from bulked continuous filament yarns (BCF) made by a jet-screen buckling and setting process. Industrial uses, such as ropes, come when a limited number of applications of high forces, for example in the shock loading of climbing ropes, are expected. When wet, nylon has poor wear resistance in applications such as marine ropes, due to shear cracks from surface abrasion under repeated cycling at moderate loads.

4.3 Other Nylons

Polyamides with more -CH$_2$- groups, such as nylon 11 or nylon 610, will have lower melting points, density and moisture absorption, and will tend to be more extensible. They have mainly found application in thick monofilaments as bristles. Reducing the number of -CH$_2$- groups, for example in nylon 4, will give a stiffer fiber, which is advantageous for some

applications. Attempts have been made to follow this route, but there is a large barrier of lower price in the larger volume of nylon 6 and 66 to overcome. In the 1970s, DuPont made a more expensive, luxury fiber, *QIANA*, from the polymer of an amine with two cyclic rings, *trans,trans*-di(4-aminocyclohexyl)methane, with dibasic acids having 6–10 -CH$_2$- groups; but sales did not justify continuing production.

4.4 Polyethylene Terephthalate

PET (or 2GT) is the ester of ethylene glycol and terephthalic acid, which are polymerized either directly or through other intermediates, and has the chemical formula
The -COCCOC- sequence acts in a similar way to the -CH$_2$- sequence in nylon. The benzene rings make the molecule stiffer, and form intermolecular cross-links analogous to hydrogen bonds.

PET has a good combination of properties for a wide range of textile products. Depending on the molecular orientation, combinations of moderate strength and high break extension or high strength and moderate break extension give a high work of rupture. The initial modulus is about three times that of nylon, which is beneficial in many applications. Elastic recovery from high loads is less than for nylon, but from strains under tensions up to about half the break load is better. The extent of creep is small. The glass transition is above 100 °C and, since PET absorbs little water, is almost the same wet and dry. This means that creasing is not imposed by normal washing and drying. "Permanent" heat setting can be achieved repetitively above 180 °C. Twist-textured PET yarns are processed continuously over two heaters. The first stage of twist–set–untwist gives a yarn with a potential for high contraction, like the nylon stretch yarns, but second-stage setting after contraction by around 15% gives a yarn with high bulk but limited stretch.

The majority of polyester filament yarns are produced as POY yarns at around 3000 m min^{-1}. This speed induces an incipient crystallinity, which prevents the rapid structural aging of yarns spun at lower speeds. Lower-strength yarns, for undemanding end uses in flat-filament fabrics, can be produced directly at speeds from 5000 m min^{-1} to 10 000 m min^{-1}. Staple fiber is cut from large tows, which have been hot-stretched in wet conditions and crimped by passing through stuffer boxes. Continuous filament webs are extruded and thermally bonded as nonwoven fabrics.

However, there is considerable diversity beyond the simplest round cross-section fibers of PET homopolymer, which are used in the commodity apparel textile market. Microfibers and shaped fibers give special effects in handle, drape and other aesthetic characteristics, particularly in the *Shingosen* fabrics from Japan. Examples are the peach-skin feel from microfibers and the characteristic luster and rustle of silk from three-petal shaped fibers. Copolymers are used to enhance dyeability, or to give differential dyeability by incorporating groups attractive to acidic or basic dyes. Pilling, which can be a nuisance, is reduced by using weaker fibers, which allow pills to break off.

Industrial grades are processed to give strengths that are the highest of any except the newer high-performance fibers, and special finishes are applied to meet needs such as promotion of adhesion to rubber in tire cords or low-friction to reduce internal abrasion in marine rope grades.

Owing to the ease of manufacture, large volume, and good properties, PET polyester has become the low-cost fiber for a universal range of purposes. This can be shown by the list below of chapters in the applications section of a book celebrating 50 years of polyester (Brunnschweiler and Hearle 1993). Each chapter covers many products. The last item in the list is typical in going from cheap disposable nonwoven surgeons' gowns and sanitary products to expensive knitted tubes for arterial grafts and braided replacements for ligaments.

Woven and knitted apparel fabrics. Man-made suedes and leathers. Household products. Fashion and function in Italy. Textiles for the home. The revolution in sewing threads. Competing with feathers and hair: the *Fiberfill* story. Tyres and industrial textiles. Polyester inside cars. Forming paper: a success for monofilaments. Ropes and nets. Building with polyester fabrics. Geotextiles. Composites: a lost opportunity or an exciting future. Medical textiles: perfect fit for a critical use.

Once five times the price of cotton, the PET commodity fibers and yarns are now similar or lower in price and account for about 25% of world fiber production. The use of the cheapest PET fibers in lower-quality fabrics has given polyester a poor image. This is not justified when premium fibers are used in quality fabrics. It is possible to combine excellent aesthetics with durability and ease-of-care.

4.5 Other Polyesters

Analogues of PET (2GT), derived from other glycols with more -CH$_2$- groups in the chain, give fibers with broadly similar properties. Their viability depends largely on economic factors. There has been commercial production of 4GT. Genetic engineering of bacteria to convert sugar from corn into trimethylene glycol opens a route to 3GT.

Polyethylene naphthalate (PEN) fibers, produced in experimental quantities in the 1990s, are made from the double-ringed naphthalene analogue of terephthalic acid. This development results from the commercialization of an economic route to intermediate chemical production. The fibers have a higher modulus and a higher melting point than PET, which is useful for some industrial applications.

4.6 Polyolefins

The hydrocarbon polyolefins, *polyethylene* (PE) and *polypropylene* (PP), have the chemical formulae

$$-CH_2- \qquad\qquad -CH_2CH(CH_3)-$$
$$PE \qquad\qquad\qquad PP$$

These are short repeat units without interactive groups. The polymers can be melt spun into fibers, but, except for toughness, strength, and break extension, do not share the similarities of nylon and polyester. Their density and melting points are lower; recovery is poorer; fiber feel is waxy; moisture absorption is zero; chemically they are inert and resistant to solvents; dyeing is impossible without modification; and coloration has to be achieved by adding pigments to the melt. The single large glass transition in PE makes it undesirably soft for most textile purposes, and the approach to melting cause its properties to fall off below 100 °C. The single transition in PP spans room temperature, which makes the fiber stiffer, but gives large energy losses in deformation.

PE has not penetrated the general textile fiber market. Thick monofilaments are used as an alternative to natural fibers in canvas fabrics and in ropes. *Tyvek*, which can be regarded as a stiff nonwoven textile or a tough paper, is flash spun from solution to give a fibrillated web, which is bonded by heat. Gel spun HMPE fibers are described in the high-performance fiber section below.

PP is more widely used, but 40% of its textile use is in the form of slit film, which is used for coarse fabrics such as carpet backing; there are similar uses for *Typar*, which is a directly produced, thermally bonded, continuous-filament web. The hydrophobic character of PP has been promoted as advantageous in thermal underwear. For nonwovens, its ability to be thermally bonded without undue compression of fiber webs is superior to polyester. However, PP continuous-filament yarns and staple fibers have mostly found textile markets where lower cost offsets poorer properties. Major uses are disposable nonwovens, and cheaper carpets, upholstery, and ropes. PP yarns are easy to produce, so that ropemakers, for example, have their own production facilities.

5. Solution-spun Synthetic Fibers

5.1 Polyacrylonitrile (Acrylic)

Polyacrylonitrile (PAN) was the third major synthetic fiber of the 1950s, but has not achieved the wide usage of nylon and polyester. Apart from providing precursor yarns for carbon fibers, PAN is almost entirely produced as staple fiber. The major uses are in warm, bulky fabrics, such as knitwear, blankets, and pile fabrics, as an alternative to wool. Its synthetic-fiber carpet market has been lost to nylon.

The basic chemical formula of PAN is

$$-CH_2CH(CN)-$$
In order to make dyeing possible, acrylic fibers (specified as $>85\%$ PAN) are copolymers with added reactive groups. Acrylic fibers can be melt spun, but are usually produced from solution by wet or dry spinning. The diversity of materials and processes leads to differences in properties in fibers from different manufacturers and in different options.

Acrylic fibers are weaker than nylon or polyester, yield at 2% extension, and have poor recovery from higher extensions. Breaks are granular. They are regarded as quasicrystalline, and have a major second-order transition near 100 °C. Fibers which have been highly stretched, or broken, show a high shrinkage when heated. Blending of no-shrink or preshrunk and high-shrink fibers is a way of making bulky yarns.

5.2 Other Solution-spun Fibers

Modacrylic fibers contain less PAN and more copolymer groups. Properties are generally similar to those of acrylic fibers, but the copolymer is used to give special properties such as flame resistance.

Vinyl and vinylidene polymers and copolymers were the first polymers to be used as fibers, but have not achieved widespread use, as can be seen from the small figure in Table 2 for "others," which also includes some high-performance fibers. *Polyvinyl chloride* (PVC) fibers are produced in the same way as acrylic fibers, and have somewhat similar properties. Polyvinyl alcohol (PVA) fibers have good properties, and have been produced in substantial quantities in Japan and China, but the cost/performance ratio has not worked out as favorably as some have expected.

## 6. High-performance and Specialty Synthetic Fibers

6.1 General Features

Following the success of nylon, polyester, and acrylic fibers, research moved to a second generation of high-performance, synthetic-polymer fibers. The major drive was for HM-HT fibers for industrial uses such as tire cords and for advanced composites and other defense-related applications. The structural requirement is to have long polymer chains (high molecular weight), fully extended and oriented parallel to the fiber axis. They will usually, but not necessarily, be highly crystalline. Two routes were found. The first uses stiff, interactive polymers, which form liquid crystals in solution or melt. These become oriented during extrusion. From solution, the technique is dry-jet, wet-bath spinning, with a gap between the end of the spinneret and the coagulating bath. The second route uses flexible, inert polymers, which form an orientable gel in concentrated solution. Unfortunately, no method has been found to produce the right structure in nylon or PET fibers, which would have technical and economic advantage.

Another need was to produce fibers with high temperature resistance. Glass, carbon, and ceramic fibers are high-modulus and high-temperature fibers, but, as mentioned in the introduction, are not the concern of this article. Another group of advanced polymer fibers has special physical or chemical properties.

6.2 Para-aramid Fibers

The aramid fiber *Kevlar*, *polyphenylene terephthalamide* (PPTA), was the first successful HM-HT polymer fiber. It is a *para*-aramid, with benzene rings from dibasic acid and diamine joined along the chain in 1,4 positions. The chemical formula is
The polymer cannot be melted, but degrades chemically at around 500 °C. To be spun, it is dissolved in concentrated sulfuric acid and extruded into an alkali bath. The fiber, as first produced, is highly crystalline and highly, but not perfectly, oriented. The structure consists of pleated sheets, which are slightly off-axis. This structure causes the stress–strain curve to be concave upward, and results in some creep under low loads. Further heat treatments under tension increase orientation and give higher modulus forms. Other techniques can reduce modulus, as needed in some applications.

Covalent bonds give the high axial properties, including a tensile strength around 3 GPa, but intermolecular forces are weak. Hydrogen bonding between -CONH- groups occurs only in one plane. Tensile rupture results from axial splits, which run across the fiber, giving long fibrillar forms. The shear modulus is low. Axial yield occurs at about 0.4 GPa. Although the low compressive strength is a disadvantage in many ways, it has the advantage that the fibers are not brittle in bending. Yielding on the inside of a bend allows fibers to bend back on

themselves through 180° without breaking. Kink bands can be seen internally with polarized light microscopy and externally with electron microscopy. Although a few repetitions of sharp bending do not cause major damage, a few thousand cycles will cause breakage by flexural fatigue. This is seen as axial compression fatigue when component yarns in ropes are allowed to go into compression. The nature of the tensile break and the compressive yielding lead to high-energy absorption in structural impacts.

Technora is a copolymer aramid fiber in which half the *p*-phenylene diamine is substituted by 4,4′-diaminodiphenyl ether. Its properties are similar to PPTA fibers, but with differences which may be advantageous in some applications.

It was hoped that *para*-aramid fibers would find a large market in tire cords. However, apart from the high price, they are stronger than is needed for the general market. Going from cotton to rayon to nylon and polyester, it was possible to reduce the amount of cord needed as strength was increased. However, there is a limit to the sparseness of cords within the tire, so that advantage could not be taken of the added strength of aramids. Their use depends on applications where high strength and high stiffness justify a high price. This includes: heavy-duty tires; light, strong ropes and industrial fabrics; ballistic impact resistance; and advanced composites.

6.3   Other Liquid Crystal Fibers

The *para*-aramid polybenzamide (PBA), which is the analog of nylon 6, and other polymers with benzene rings in the chain are alternatives to PPTA, which is the nylon 66 analog, but have not been commercialized as of 2000. Superior properties come from polymers with more complicated rings, which were the subject of US Air Force research.

One of these, *polybenzoxazole* (PBO), has been commercialized by Toyobo as *Zylon*. The chemical formula is
Production methods, structure, and properties are similar to those of aramids, but the modulus and strength are higher.

Experimentally, *M 5* fibers with higher shear modulus and strength and higher compressive yield stress have been produced from a polymer with a similar ring structure to PBO, but with -OH side-groups giving hydrogen bonding in both planes. HM-HT cellulose fibers have been made from solutions in phosphoric acid.

Vectran is a melt-spun fiber, based on the fully aromatic polyester *polyphenylene terephthalamide*, which has the following chemical formula:
Limited copolymerization gives a thermotropic liquid-crystal material, which orients in flow through the spinneret. Melt spinning is much cheaper than solution spinning with strong acids, but this is offset by the need for an expensive subsequent heat treatment to build high molecular weight. The properties of *Vectran* are generally similar to aramids, but with specific differences, such as an absence of creep, which are beneficial in some applications.

6.4   High-modulus Polyethylene

HMPE fibers are made by gel spinning of ultra-high molecular weight polyethylene. The extruded gels, which form in concentrated solutions, can be stretched to give highly oriented, chain-extended, highly crystalline fibers. The strength and modulus are higher than for aramids, but the fibers have the disadvantage of a low melting point. Properties start to fall off appreciably as temperatures rise above 40 °C. Substantial creep is due to molecules sliding over one another. The rate of creep increases with tension, and ultimately leads to creep rupture. Post-treatments can increase modulus and reduce creep. There are major differences in the incidence of creep among the different grades from different manufacturers. In one set of tests, one HMPE yarn broke after 4 days at 30% of break load, whereas another lasted 123 days. Improved grades have been introduced since these tests were carried out. The converse of creep failure is the excellent resistance to high-speed loading. HMPE fibers have low compressive strength, but are somewhat more resistant to axial compression fatigue than aramids. Gel spun HMPE fibers find applications in ballistic protection, in high-performance ropes and industrial fabrics, and in some composites.

An alternative route to HMPE fibers is super drawing of melt-extruded polymer. However, the strength is about half that of gel-spun fibers, and commercial production has not been successful.

6.5   Thermally Resistant Fibers

The meta-aramid fiber *Nomex*, which is *poly*-m-*phenylene isophthalamide*, has the chemical formula

857
The 1,3 links between benzene rings gives a less compact molecule than the 1,4 *para*-aramids. The polymer can be spun into fibers with mechanical properties comparable to general textile fibers. The advantages of *Nomex* are excellent thermal stability, flame resistance, and good dielectric properties. It is used in industrial apparel, aircraft upholstery, composites, and electrical insulation subject to high temperature.

Other linear polymers, such as poly-*m*-phenylene benzimidazole and aromatic polyimides, can be used to make thermally resistant fibers. Flame-retardant fibers, with the FTC designation *novaloid*, are made from cross-linked phenol–formaldehyde polymers.

6.6 Elastomeric Fibers

Elastic threads can be made from natural or synthetic rubbers, but it is not possible to make good fine fibers. Spandex fibers, such as *Lycra*, are made from segmented polyurethanes from the reaction of a diisocyanate with polyethers or polyesters. Amorphous soft segments give the elastic extension, and crystalline hard segments cross-link the structure and hold it together. The fibers are relatively weak, though the true stress at break is high, and have elastic extensions over 400%. They are resistant to physical and chemical damage in use, and are incorporated in fabrics when high stretch is required.

6.7 Fibers with Special Functions

There are a variety of fibers used in specialized applications, because of particular chemical and physical properties. *Teflon*, *polytetrafluorethylene* (PTFE), which cannot be melted or dissolved, is spun into fibers by heat sintering a dispersion of particles. The fibers are used where low friction or high chemical resistance are needed. In addition to the use of Teflon and polyesters in arterial grafts, several new fibers are being used for medical purposes. For example, fibers of polyglycolic acid are used for sutures, because they are assimilated by the body after the limited period for which they are needed to function.

A great variety of smart fibers are now being explored, and some are in commercial use. They are mostly made by incorporating additives. By way of example, the range seen on a visit to one Japanese company in 1993 comprised: exothermic, electrically conducting yarns, which can be incorporated as resistance elements to control temperature in fabrics; antistatic fibers for clean rooms; polypeptides that absorb and disperse water; fibers that melt and bind; filaments that vary in thickness to match natural non-uniformity; fibers with zirconium carbide that warm by absorbing near infrared and emitting far-infrared radiation; chitin fibers for wound dressing; activated carbon fibers to absorb and desorb chemicals;

amorphous metal fibers with high strength and special magnetic properties; and glass fibers with special coatings for printed circuits.

7. Conclusion

Textile fibers exist in great variety and are used for many applications in a diversity of structures. Much more could be written on their place in materials science and technology than can be included in this article. However, in another sense, the materials are limited. Table 2 shows that about 80% of the world's textile fibers are now based on cellulose or polyester, 18% on nylon, polyacrylonitrile and polypropylene, and 2% on proteins. Some vinyl polymers, which have not achieved wide market acceptance, and the newer high-performance and specialty fibers, which are expensive, account for about 0.5%. The diversity is mainly achieved by form, shape, size, process parameters, copolymerization, additives, and finishes.

Textile Fibers: Mechanical Properties

Aside from their traditional use in clothing or home furnishing and decorating, textile fibers are widely employed in technical applications such as ropes, containers, covers, belts, filters, tires, and the expanding range of fiber-reinforced composites. While the strength of fibers is just one of several design criteria in the fabrication of, for example, clothing, it is generally the major and crucial factor in engineering applications. The resistance of fibers to failure under imposed mechanical stresses, given certain thermal and chemical influences as well as exposure to UV light, depends on chemical composition, but more importantly on supramolecular structure (morphology).

1. Fiber Structure and Technology

A discussion of the strength of fibers and its structural basis is not possible without a knowledge of fiber structure itself. The essential concepts will be summarized here.

Organic fibers, which account for more than 95% of fiber production, are based on macromolecules or polymers. They may be subdivided into natural fibers such as cotton, wool, etc., with cellulose or proteins as the molecular basis, and fabricated fibers based on either natural or synthetic polymers. In the latter category, polyesters (mainly polyethylene terephthalate), polyamides, polyacrylics, and polyolefins form the few types of polymers used to make the majority of commodity fibers. The production of high-performance specialty fibers (fibers with enhanced thermal or chemical stability, high-strength/high-modulus fibers)

makes use of a variety of mainly aromatic or heterocyclic polymers. However, polyethylene can also form a high-strength fiber if processed in a special way (gel spinning).

What sets fibers apart from other polymeric materials is that they are generally highly anisotropic. On the molecular and supramolecular level, this means that there is a high degree of orientation of structural units with respect to the fiber axis. It is worthwhile to consider this in view of the forces acting between the atomic groups making up the material. In macromolecules, covalent bonds having rather high strength are effective along the chain direction, whereas the intermolecular forces perpendicular to the chain direction are relatively weak (van der Waals-type bonds, hydrogen bonding). In order to achieve high strength in the fiber direction, one would like to have the macromolecules arranged extended and parallel to the fiber axis.

Most polymers used for fiber manufacture are partially crystalline, the degree of order in the crystalline regions being much higher than that in the remaining amorphous phase (two-phase model). The alternative microfibrillar concept, where crystalline domains and intrafibrillar disordered domains are coupled in series to form the microfibrils, is used in particular with the natural cellulosic fibers (see *Natural Cellulose Fibers: Properties**). Which model is most appropriate is subject to the nature of the fiber and the property considered.

The spinning process has a decisive influence on the development of a certain morphology. Thermoplastic polymers are usually melt spun, the physical structure of the filaments being controlled by the solidification conditions such as rate of cooling and spinline stress. High spinline stress, achieved by high winding speed, results in increased orientation, and this in turn favors crystallization. Usually the as-spun filaments do not have adequate mechanical properties and a subsequent drawing process slightly above the glass transition temperature is necessary to achieve the required modulus, strength, etc., via further controlled orientation and crystallization. By varying the drawing conditions, fibers with different property profiles can be obtained.

Dry and wet spinning, usually employed with nonthermoplastic polymers (polyacrylonitrile, cellulose, polyaramides), involve dissolution of the starting material in a suitable solvent. After extrusion through an orifice, the solvent is either evaporated (dry spinning) or the extrudate is led through a coagulation bath containing a nonsolvent, where phase separation takes place (wet spinning). In the latter case, a gel fiber is formed, a highly dispersed system of a polymer-rich continuous phase with inclusions of excess liquid. When the solvent is evaporated after drawing, the porous structure collapses, but most likely the original void surfaces remain as weak boundaries separating the material into fibrillar elements. Such

morphology is also exhibited by the natural cellulosic fibers (cotton, flax).

A special variant of wet spinning is used for rigid-chain polymers such as p-aramids. In suitable solvents above a certain concentration, nematic solutions are formed. The nematic domains are macroscopically aligned by shear and elongational flow during spinning, and after coagulation fibers having a considerable molecular orientation are obtained. This results in fibers with mechanical properties substantially superior to those of fibers made by melt spinning of flexible polymers.

A completely different way of achieving extraordinarily high chain orientation and extension is by gel spinning—a process successfully realized only with high molar mass polyethylene. The polymer is dissolved in a nonvolatile solvent to form a low-concentration solution. The filaments formed after extrusion (at high temperature) into a cooling bath can be drawn to very high draw ratio, yielding fibers with exceptionally high modulus and strength.

Carbon fibers have a structure similar to the graphite layer lattice. However, their density is appreciably below that of graphite, an indication of the high level of imperfections. Their strength and stiffness depends on the degree of orientation of the layer planes parallel to the fiber axis. The orientation in the perpendicular direction shows a strong local variation. To obtain high-strength/high-modulus carbon fibers, it is imperative to start from precursors that are very well oriented, because this orientation is essentially retained when carbonization and graphitization take place. Glass and ceramic fibers are amorphous and polycrystalline, respectively, with little or no molecular orientation.

2. Mechanical Failure

The usual way to study tensile failure of fibers is by conducting a stress–strain test up to breaking of the fiber (with force and deformation applied along the fiber axis). In most cases this is done at a constant (specified) rate of elongation. A different shape of the stress–strain curve is obtained when experiments are performed at a constant rate of loading, and this should be kept in mind when results of laboratory tests are transferred to technical applications.

Generally load is normalized by the initial cross-sectional area to give stress, the SI units being pascals ($1\,Pa = 1\,Nm^{-2}$). However, in fiber technology it is more common to normalize by the linear density of the material to obtain specific stress (stress per density). Linear density is expressed in tex ($1\,tex = 1\,gkm^{-1}$), and specific stress is given in N tex^{-1} ($GPa\,cm^3g^{-1}$). Elongation is divided by the length of the undeformed fiber to obtain tensile strain or percentage extension.

Some typical shapes of stress–strain curves of fibers are shown in Fig. 1. The initial slope of the

Figure 1
Schematic stress–strain curves of fibers (see text for details).

Table 1
Tensile properties of fibers.

Fiber	Strength (GPa)	Modulus (GPa)
Polyester	0.4–1.3	10–16
Polyamide	0.4–1.0	0.6–6
Polypropylene	0.2–0.6	1–7
Polyacrylonitrile	0.4–0.6	6–9
Rayon	0.3–0.4	8–13
Polyethylene (gel-spun)	2–3	120–170
p-Aramid	2–3	80–140
Carbon	3–4	200–400
Glass	3–5	70–90
Ceramic (Nicalon)	3	200

stress–strain curve is the modulus, a material property of the fiber. In contrast, the ultimate properties of elongation at break and strength (stress at break) or tenacity (specific stress at break) are sample properties, showing quite a variation when several samples of the same material are inspected. Whereas material properties are averages over the whole sample volume, ultimate properties reflect the property of the weakest link. As a consequence, the strength of fibers shows a decrease with rising sample length owing to the effect of variability. Some typical data for different fibers are compiled in Table 1.

The different types of stress–strain curves correspond to materials with different types of fracture. Brittle fracture is the typical appearance of failure of glass, carbon, and ceramic fibers. Such fibers have a simple Hookean stress–strain curve (curve 1 of Fig. 1). The break proceeds from a flaw or crack at the fiber surface or (less commonly) in the interior, where peak stresses are generated on loading. When the

strength of the material is locally exceeded and the crack starts to grow, the stress at the tip increases even higher giving rise to catastrophic rupture of the fiber. This usually results in a rather flat cleavage plane perpendicular to the fiber axis. There is no indication in the stress–strain curve that the material is approaching the breaking elongation, and the strain is predominantly elastic with no plastic yield.

While brittle fracture is typical for the high-modulus or high-strength reinforcing carbon, glass, or ceramic fibers whose breaking elongation seldom exceeds 1–2%, it is also observed with the highly extensible elastomeric (rubbery) fibers (curve 4 of Fig. 1) having breaking elongations of several hundred percent.

Melt-spun polymeric fibers like polyamide, polyester, and polypropylene show rupture by yield (curves 2 and 3 of Fig. 1). The actual shape of the stress–strain curve reflects how much the fiber is drawn during manufacture. Starting from a flaw, a crack propagates in a controlled manner and opens into a broad notch while the remainder of the fiber is drawn (plastic deformation) under the increasing stress. Eventually, overall failure occurs when the stress on the remaining cross-section exceeds a critical value. Since the plastic deformation is markedly time dependent, the rate of deformation has a significant influence on the appearance of the break.

When the rate of elongation is drastically increased, a different type of failure is observed. This is thought to be owing to a change from isothermal to adiabatic conditions. The heat dissipated on drawing causes a local temperature jump with a softening of the material and rupture by viscous flow. The thermally stimulated molecular relaxation of the polymer gives rise to a mushroom-like broadening of the fracture surface.

Wet-spun fibers such as polyacrylonitrile, rayon, etc., whose stress–strain curves resemble curve 3 of Fig. 1, show breaks with a granular fracture surface. This is a consequence of the coagulation process during fiber formation: The fibrillar elements formed in the gel state on drawing build up fairly independent load-bearing strands. These do not break at exactly the same axial position, but rather at nearby locations in a certain range, thus giving rise to the roughness of the break.

With high-strength wet- or gel-spun fibers like p-aramid and polyethylene, the strength of the fibrillar entities becomes so large that the fracture mechanism turns over to long axial splitting. The weakness of these fibers is in the lateral cohesion of the fibrils, being overcome even by small shear stresses originating at some structural inhomogeneities when the axial tension exceeds a critical level. Up to this level, the stress–strain behavior is practically Hookean (curve 1 of Fig. 1).

Whereas the study of failure through the application of a single excessive load is fairly straightforward

and gives reasonable numbers for comparison of different materials, the real situation is often more complicated. Fiber failure can occur after repeated moderate loading over a long period of time. This is termed fatigue. The breaks formed often differ appreciably from that described above, with the detailed conduct of the experiment having a major influence. Owing to the anisotropy of fibers, the direction of the cyclic stresses is important and at least tensile fatigue and flex fatigue need to be distinguished.

Thermally Contracting Materials

Thermal contraction in metal (M) oxides is usually the result of the thermal motion of oxygen transverse to M–O–M linkages. However, thermal motion of M transverse to O–M–O linkages can also give rise to thermal contraction. There are only a few examples of this because twofold coordination of metal cations is unusual. However, both Cu_2O and Ag_2O contain linear M–O–M linkages, and both compounds possess negative thermal expansion behavior, as shown by both EXAFS and diffraction studies. Thermal contraction in Cu_2O occurs only below room temperature and is not strong, $\Delta l/l$ $(\alpha) = -2.4 \times 10^{-6} K^{-1}$. However, in Ag_2O, thermal contraction is observed from $40\,K$ to $470\,K$, close to where it decomposes. The thermal contraction is substantial, $\alpha = -6.7 \times 10^{-6}\,K^{-1}$. EXAFS studies show that the Ag–O distances increase and Ag–Ag distances decrease with increasing temperature, consistent with thermal contraction caused by vibration of Ag transverse to the O–Ag–O linkage. Linear O–M–O linkages where M is Cu or Ag also exist in compounds with the delafossite ($CuFeO_2$) structure. The degree of thermal contraction of the O–Cu–O linkage can be substantial, $\alpha = -4.2 \times 10^{-6}\,K^{-1}$ as in $CuScO_2$ below room temperature. In the case of $CuLaO_2$ significant thermal contraction of this linkage continues to the highest measured temperature of $600\,K$. However, in

the case of $AgInO_2$ the thermal contraction of the O–Ag–O linkage is much less than in the case of Ag_2O.

Another, purely electronic, mechanism for thermal contraction is found in some compounds containing Sm or Yb. This mechanism is based on excitation of 4*f* electrons to a conduction band. As more 4*f* electrons are excited with increasing temperature, the rare-earth atoms become smaller, and this can overcome the forces that usually give thermal expansion to yield an overall thermal contraction. The band accepting the 4*f* electrons may be based primarily on 5*d* states of the rare-earth atoms or it can be a band based primarily on states from other atoms in the compound (Fig. 1). For cubic $Sm_{0.75}Y_{0.25}S$ thermal contraction is observed over the entire measured temperature range of 4.2–350 K. In this case the band accepting the 4*f* electrons is the Sm 5*d* band. For hexagonal YbGaGe, the band accepting the 4*f* electrons is the Ga 4*p* band. For the measured temperature range of 100–300 K, thermal contraction occurs along the *a*-axis and thermal expansion occurs along

the *c*-axis, giving an overall very small change of volume with temperature. For hexagonal YbCuAl thermal contraction is observed along both the *a*- and *c*-axes below 60 K.

The potential for thermal contraction exists in all oxide framework structures where the oxygen coordination does not exceed two, provided that the framework is not stuffed with cations or molecules. Examples of this are found for tetrahedral MO_2 compounds, $A_2M_3O_{12}$ compounds, cubic AM_2O_7 compounds, compounds with the cubic ZrW_2O_8 structure, and in $AOMO_4$ compounds, which can be monoclinic or orthorhombic. In the case of orthorhombic $TaOVO_4$, thermal contraction occurs along all three crystallographic axes giving an overall thermal expansion coefficient of $\alpha = -5.1 \times 10^{-6} K^{-1}$ from 290 K to 900 K. Thermal contraction might be expected in the AO_3 family based on metal oxygen octahedra sharing corners. In fact, most compounds with this structure, such as WO_3 and ReO_3, show only thermal expansion. However, for TaO_2F,

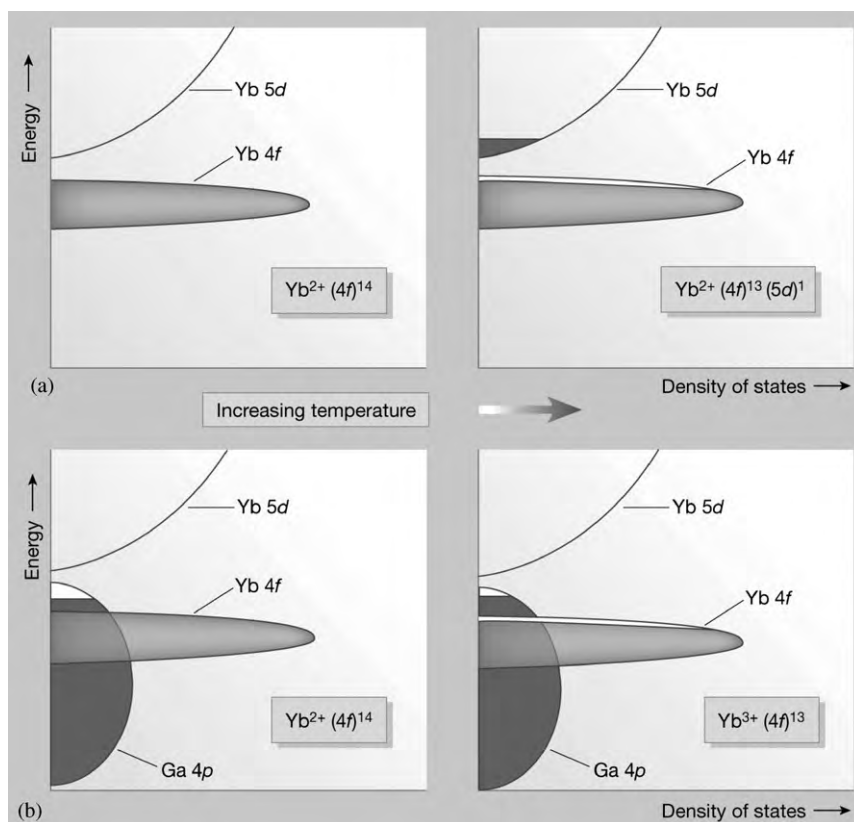

Figure 1
With increasing temperature, electrons are excited from the very narrow Yb (4*f*) band to a broad conduction band. The conduction band may be either the Yb 5*d* band (a) or a band based on another element present in the compound, such as Ga 4*p* in the compound YbGaGe (b). Thermal contraction of Yb occurs in both cases. Reproduced from Sleight (2003) Materials science: Zero-expansion plan, *Nature* **425**, 674–5, with permission.

no detectable expansion or contraction could be detected over the 20–400 K temperature range. This very low thermal expansion is presumed to be the result of nearly exact compensation of the tendencies for thermal contraction and thermal expansion.

Whiskers

Filamentary crystals, or whiskers as they are more often known, are usually defined as single crystals having an aspect ratio (ratio of length to diameter) of at least 100. In practice, aspect ratios as high as several thousands are quite common in whiskers.

In the 1930s it was observed that crystals including whiskers often grew from the vapor phase at a supersaturation much too low to allow for growth to proceed by the nucleation of new atomic layers on the growth surface. Frank postulated a crystal growth mechanism that involved a screw dislocation coaxial to the crystal growth axis. This mechanism allowed for very high aspect ratios coupled with growth at low supersaturations, and soon became universally accepted as the mechanism for whisker growth until the advent of the transmission electron microscope (TEM). Since dislocations can be observed with a TEM, workers soon examined the whiskers of several materials looking for the "postulated screw dislocation" at the core or the whisker. Frank's screw dislocation was observed in the whiskers of several materials; however, in the vast majority of instances no dislocation was observed. In those instances in which no dislocation was observed it was simply postulated that two dislocations of unlike sign annihilated each other or that the dislocation responsible for growth glided out of the crystal. In the late 1950s and early 1960s workers reported observing metallic globules attached to the tip of growing whiskers. These "flagpole" whiskers were soon observed to be quite common and in 1964 Wagner and Ellis proposed the vapor–liquid–solid (VSL) mechanism of single-crystal growth. The VLS process soon became the preferred method for the laboratory and commercial growth of whiskers.

A variety of both metal and ceramic whiskers have been growth in the laboratory. Metal whiskers include palladium, silicon, germanium, zinc, cadmium, iron, copper, and silver. Ceramic whiskers grown include aluminum oxide, aluminum nitride, beryllium oxide, molybdenum trioxide, and silicon carbide. Most of the metal whiskers are grown for the purpose of studying the mechanical properties of these fine-diameter single crystals, which are extremely strong with ultimate strengths approaching the theoretical "ideal" limit dictated by atomic cohesion forces. Strengths near the theoretical limit are possible because whiskers have very few structural imperfections and are the closest thing to perfect single crystals achieved. Silicon, germanium, and, at first, silicon carbide whiskers were grown for their semiconducting properties. With the advent of composites, silicon carbide whiskers were also investigated as the reinforcing element in composite structures.

1. Morphology of Whiskers

The considerations that dictate the morphology of whiskers are much the same as those for crystals in general. The high-index crystal planes that are less close packed and tend to grow quickly, "grow out" leaving the slower-growing, low-index planes. Both vapor–solid (VS) and VLS whiskers are commonly observed to have either triangular or hexagonal cross-sections. The cross-section is bounded by low-index planes, and the growth direction is most commonly $\langle 111 \rangle$ in cubic systems and $\langle 11\underline{2}0 \rangle$ in hexagonal systems. Growth in the $\langle 111 \rangle$ direction can produce a triangular cross-section or if twinning occurs the cross-section will be hexagonal. Growth in the $\langle 11\underline{2}0 \rangle$ direction produces a hexagonal cross-section.

2. VS Whiskers

VS whiskers are so named because growth of the solid whisker occurs by direct condensation from the vapor phase. This growth method is particularly simple for metals with low melting points such as zinc and cadmium. In practice, a temperature gradient is maintained in a gas-tight chamber so as to result in the transfer of material through the vapor phase from the hot end to the cold end. To start the growth process, the chamber, usually quartz, is evacuated and then the hot end containing a crucible of the whisker material is heated so as to maintain a significant vapor pressure. The cold end of the chamber usually contains a seed crystal to encourage nucleation of the whisker and is maintained at a temperature below the melting or sublimation point. For ceramics and metals with higher melting points the process is modified slightly since the necessary vapor pressure must now be achieved through a suitable chemical reaction rather than evaporation. For these systems the crucible at the hot end of the chamber might contain a compound of the whisker material and a reactive gas or a mix of gases is passed through the chamber to produce a volatile species.

The growth of whiskers from the vapor phase was first modeled using the nucleation and growth theories developed in the 1930s. These theories required growth to occur via the nucleation of a "pillbox" that then spreads perpendicular to the growth direction until it covers the entire growth surface (see Fig. 1). Growth therefore required the continuous nucleation of new pillboxes that requires a high thermodynamic driving force or supersaturation. Laboratory experiments soon showed that crystal growth from the vapor occurred at supersaturations much too low to support the continuous nucleation of pillboxes. Frank proposed a mechanism of crystal growth
Figure 1
Schematic of whisker growth via nucleation of a pillbox on the tip of a growing whisker. In accord with nucleation and growth theory, whisker growth was thought to occur via the nucleation of pillboxes and growth of the pillbox laterally to cover the tip of the whisker.

Figure 2
Emergent screw dislocation. A screw dislocation coaxial to the crystal growth axis provides a continuous surface for the attachment of atoms from the vapor. The presence of the screw dislocation allows growth at small driving forces without the need for nucleation (after Burton *et al.* 1951).

based to the (then) new theory of dislocations, which at the time was quite novel given that dislocations had not yet been observed and dislocations were still only "theoretical." In Frank's mechanism a screw dislocation is coaxial with the crystal growth direction. The screw dislocation forms a spiral growth terrace where it exits the growth surface as shown in Fig. 2.

The structural imperfection of the screw dislocation provides a continuous surface for vapor atoms to attach without the need to nucleate "pillboxes" and allows for continuous growth at low supersaturations. If a screw dislocation is present, atom attachment to the growing whisker is easy and the rate-controlling step for whisker growth is generally the rate at which atoms can be supplied from the gas phase.

The screw dislocation central to the Frank mechanism proved difficult to find. One TEM study of whiskers from nine different metals was only able to find a dislocation in whiskers from one of the metals. When dislocations were not observed, which was the vast majority of instances, it was simply postulated
that two dislocations of unlike sign annihilated each other or that the dislocation responsible for growth glided out of the crystal. In spite of the paucity of experimental evidence to support the dislocation theory of whisker growth, researchers continued to expound it while ignoring the strange metallic spheres they often observed attached to whisker tips. These metallic spheres would soon be recognized as the hallmark of a new class of whiskers.

3. VLS Whiskers

The discovery of the VLS technique occurred by accident. Liquid metallic spheres were observed to form on the tips of growing whiskers because of the presence of impurities. Impurities tended to concentrate at the whisker tip where they formed low-melting eutectic phases. Wagner and Ellis were the first to identify the VLS process as a separate whisker growth process; however, several previous groups of workers grew whiskers by this method without realizing it. It was soon observed that whiskers with

metallic spheres grew faster than those without spheres. The metallic sphere soon became know as a "catalyst" because of its role in accelerating the growth process. The VLS technique is now the preferred technique for growing whiskers and the catalyst is intentionally added to system.

The VLS whisker growth process is shown schematically in Fig. 3. A metallic catalyst is applied to a growth substrate that is heated in a controlled atmosphere furnace. The catalyst melts and beads, and depending on the chemistry, may dissolve material from the substrate until saturation, thus creating a pit. Process gases are then passed and/or generated in the furnace and the catalyst becomes supersaturated and begins to precipitate a whisker. The whisker grows in a preferred orientation and continues growing as long as the supply of process gases continues. Silicon carbide whiskers have been grown up to 10 cm long using this technique. Figure 4 shows a photomicrograph of silicon carbide whisker nucleation.

The metallic catalyst ball at the tip of the VLS whisker (Fig. 5) has a complex function. In addition to being a catalyst for gas-phase reactions, it also serves as a solvent and medium for whisker precipitation. The size of the catalyst ball determines the diameter of the whisker grown, which can vary from less than $1 \mu m$ to over $35 \mu m$. For a given catalyst–whisker combination the ratio of the diameter is a function only of the respective surface energies. Whisker growth is quite sensitive to variations in the surface energy of the catalyst ball. Anomalies such as bamboo structures observed in silicon and silicon carbide whiskers are caused by variations in surface energy resulting from perturbations in catalyst chemistry, which in turn is caused by changing gas composition.

The actual size of the catalyst ball varies from the metallic particles applied to the substrate since, in practice, the metallic particles react with the substrate and divide into numerous individual particles of

Figure 4
Nucleation of silicon carbide whiskers on a graphite substrate. In this photomicrograph the whiskers have only just nucleated and have not grown to any appreciable extent. The whiskers correspond to stages (c) and (d) in Fig. 3.

Figure 3
Schematic of VLS whisker growth process. (a) A catalyst (in this case iron) is applied to the substrate. (b) The catalyst particles melt and spread out on the substrate as the temperature of the furnace is raised. (c) The catalyst droplet dissolves substrate material up to the saturation limit and creates a crater. (d) The catalyst absorbs reactants from the gas phase and nucleates a whisker. (e) The whisker achieves the preferred growth direction and grows rapidly.

Figure 5
Silicon carbide whisker with catalyst ball. Note triangular profile of whisker (courtesy of J. J. Petrovic).

various sizes giving rise to a range of whisker diameters. The nucleation rate has been shown by Katz to be inversely proportional to the square of the diameter of the catalyst particle; hence, nucleation of submicrometer whiskers occurs rapidly. As the whisker growth process proceeds, however, larger diameter whiskers nucleate and grow, eventually coming to dominate the growth process as the supersaturation in the gas phase decreases and the submicrometer-sized whiskers stop growing. In practice, how fast a whisker grows is determined by the supply of reactants to the catalyst droplet.

Aside from the role impurities played in the discovery of the VLS whisker growth process, they are still essential to the growth of some types of whiskers. For example, nitrogen is added to the gas stream when growing silicon carbide whiskers to promote the formation of the high-temperature β-phase. Nitrogen also gives silicon carbide whiskers their characteristic green color that is evident in Fig. 6. Impurities or the lack of them can cause the color of silicon carbide whiskers to vary from albino (colorless) to blue to black. If surface-active impurities such as sulfur are present they will interfere with the reactions on the catalyst droplet, and if present in large enough quantities shut down the growth process.

Whisker harvesting is usually performed by scraping the growth substrate with a razor blade. In another technique a jet of compressed air is used to fracture the whisker at the base separating it from the substrate. If the whiskers are ceramic and the intended use is in a ceramic composite it is important to remove the metallic catalyst particles. This is accomplished by placing the whiskers in an acid solution to dissolve the catalyst particles.

A commercially important variant of the VLS process involves the production of silicon carbide whiskers from rice hulls. Rice hulls are the waste product left over after the rice is extracted from the kernel. In addition to containing organic matter, rice hulls contain between 15 wt.% and 20 wt.% of silicon. By heating them under carbon monoxide at a temperature of 1350 °C it is possible to produce silicon carbide. Soaking the rice hulls in an iron-containing solution before heating causes VLS whiskers to form. This process was the basis for the first commercially available silicon carbide whiskers.

4. Mechanical Properties of Whiskers

Because of the intense scientific and commercial interest in whiskers their mechanical properties have been the subject of several studies. Table 1 contains
Figure 6
Silicon carbide whiskers on graphite growth substrates awaiting harvesting and further processing.

Table 1
Physical properties of whiskers.

Material	Density (10^3 kg m^{-3})	Melting point (°C)	Tensile strength (GPa)	Young's modulus (GPa)
Aluminum oxide	3.9	2082	14–28	550
Aluminum nitride	3.3	2198	14–21	335
Beryllium oxide	1.8	2549	14–21	700
Boron oxide	2.5	2449	7	450
Graphite	2.25	3593	21	980
Magnesium oxide	3.6	2799	7–14	310
Silicon carbide (α)	3.15	2316	7–35	485
Silicon carbide (β)	3.15	2316	7–35	620
Silicon nitride	3.2	1899	3–11	380

estimated and measured properties for several whiskers. In one study a custom-built microtensile testing apparatus was constructed and used to measure the strength of β-silicon carbide whiskers grown by the VLS process. These whiskers were determined to have tensile strength as high as 23.74 GPa. A theoretical estimate of the tensile strength using the Orowan expression yields a value of 46.3 GPa. The close agreement between the actual measured strength and the theoretical estimate indicates that β-silicon carbide whiskers grown by the VLS process are near-perfect single crystals.

Silicon carbide whiskers have been used as a discontinuous random strengthening element in the fabrication of metal, ceramic, and polymer composites. Silicon carbide whiskers are typically grown to about 2–4 cm in length, and in a few instances to as long as 10 cm. Unfortunately, the typical 2–4 cm length is not long enough to allow their use as a continuous fiber reinforcement element in composites. Whisker felts and tows have been fabricated from 2–4 cm whiskers to allow for their use as a continuous reinforcement element. Coatings have also been applied to whiskers to prevent their reaction with the matrix material and to promote slip on fracture that absorbs additional energy.

5. Outlook

The commercial applications and hence the future outlook for whiskers are quite limited. Metallic whiskers were grown only for scientific studies. Semiconducting whiskers such as silicon, germanium, and silicon carbide have not been successfully exploited in electronic devices. A few of the ceramic whiskers such as silicon carbide have found applications as a reinforcing element in ceramic composite materials. For the foreseeable future it seems as though the commercial applications of whiskers will be limited to a few ceramic composite systems.

Wood Composites: Mineral-bonded

Mineral-bonded composites are composed of materials which combine wood particles or fibers with such minerals as Portland cement, magnesite cements, and gypsum. Examples of products include siding, roof shakes and shingles, tiles, slates, fencing, cladding, tile backer boards, subflooring, and building blocks (Moslemi 1988).

These composites use not only virgin wood fibers and particles, they can also utilize such waste resources as newspapers, magazines, and other solid wastes. In these composites, fibers or particles are held together by the mineral "matrix" generating products that are often water resistant and durable in outdoor applications. Almost all are either fireproof or highly fire-resistant. They combine the characteristics of their component parts, namely wood particles or fibers and the mineral matrix.

1. Cement-bonded Composites

Cement-bonded composites utilize Portland cement or other types of cements as the matrix. The proportion of cement in the composite varies from about 20% to over 90% by mass, depending on the type of composite manufactured. Products ranging from flat sheets to building blocks or slabs are made for construction applications.

1.1 Manufacturing Methods

The basic steps of manufacturing process are: preparation of wood or fiber raw materials, mixing these materials with the mineral binder, water and additives, pressing, hardening, or curing (Berkenkamp 1997). Depending on the type of process used, there are substantial differences in the basic layout of the manufacturing plant (Buchmayer 1999). Manufacture of cement-bonded composites is basically divided into three categories: (i) the wet process, (ii) the semidry process, and (iii) the dry process (Kuroki *et al.* 1993).

(*a*) *Wet processes.* These processes rely on a slurry with a great deal of water content to carry and

distribute the board-making material. Water is used to develop an aqueous suspension of cement, fibers, and additives. Four different manufacturing techniques are noted here.

The Hatschek Process: This is a continuous operation using a slurry of cement, water, fiber, and additives to form a flat sheet. The forming machine relies on winding very thin sheets (often one millimeter or less in thickness) around an accumulator roll until the target thickness is achieved. At this stage, a knife cuts the ''green'' sheet, which drops onto a conveyor belt that carries it on for further processing (i.e., pressing, embossing, etc.) (Buchmayer 1999). This is a modification of the process that can also use asbestos fibers and cement in manufacturing a variety of building products.

The Fourdrinier Process: This is similar to the forming concept used in a pulp mill. Both rely on a slurry of cement, water, fibers, and additives, which are poured onto a moving screen conveyor where some of the water is drained. There are two different versions: multilayer or single-layer (Kuroki *et al.* 1993). In the multilayer version the wet sheet is composed of a very thin layer that winds around an accumulator roll in a similar manner to that described for the Hatschek process. In the single-layer design, the mat consists of a single layer, which eliminates the need for an accumulator roll. The single-layer system permits deep embossing but can result in a nonuniform board with more cement precipitating to the bottom of each board formed.

The Batch Process: The fiber–cement slurry is poured into a forming box in a batch system wherein the excess water is drained by pressing the batch. The water exits from the bottom of the batch leaving a malleable cement–fiber mix in the batch. This process can produce deep molds and intricately embossed products.

The Extrusion Process: In this process, the fiber–cement material is extruded through an extrusion machine in a continuous operation. It permits the production of items with complicated cross-sections, hollow-shaped and L-shaped, or corrugated types of product. The process is also in use in connection with asbestos fibers and cement for those regions of the world that permit the use of asbestos.

(*b*) *Semidry processes*. In this type of process, the material used to form the board is relatively dry to the touch. The mixture of cement, wood particles, water, and additives are formed into a mat by machines that use a relatively dry furnish. In fact, these forming machines are very similar to those used for manufacturing resin-bonded particle boards.

Cement-bonded particle board: Wood particles (instead of fibers) are used in combination with Portland cement, water, and additives. Water, cement, and additives are mixed to produce the ''furnish'' for board manufacture. The furnish is then directed to a forming machine, which deposits the material onto a moving conveyor to produce a mat. The mat is later consolidated by pressing in combination with clamps that hold the pressure for a number of hours to permit the curing of the cement binder. To accelerate the cure, the consolidated mats are placed in elevated room temperatures for some eight or more hours. Upon completion of this step, the clamps are released and boards removed for further processing. This includes curing, drying and sanding. Boards can also be preprimed or finished depending on the intended market. This process permits the use of embossing to produce deep-molded products.

Fast-set cement-bonded board: This process is similar to that of cement-bonded particle board with important exceptions. It does not need long clamp times to permit cement to set in the process described above (Kuroki *et al.* 1993). It accomplishes this by using a mixture of alumina cement and cure accelerators in combination with hot pressing.

Light-weight cement-bonded board: This process reduces board density from about 1250 to approximately $1000 \, \text{kg m}^{-3}$. It is accomplished by incorporating low-density aggregates into the furnish. For example, the addition of expanded perlite lowers board density. It is important to note that such additions not only lower density but they also affect other board properties (Kuroki *et al.* 1993). In some cases, autoclaving of the boards is incorporated in the manufacturing steps to enhance board properties (strength, dimensional stability, etc.).

(*c*) *The dry process*. Fibers (often asbestos), cement, and additives are dry-mixed. The dry mixture is formed into a mat on a screen conveyer. The loose mat is compressed using a roll press before water is sprinkled onto the mat and, once again, roll-pressed. Cutting of the mat follows this second roll pressing. To produce decorative surfaces, coloring agents or colored silicates are then spread on to the compressed mat followed by a third roll-pressing (which may have a special pattern) followed by curing. Autoclaves are used to enhance product properties by promoting interaction between calcium silicates and calcium hydroxide. Attempts are being made to replace the asbestos fibers with wood fibers. Further research and development, however, is needed before wood fibers can successfully be used in this process.

2. Magnesia-bonded Composites

The bonding agent is the basic salt of magnesium chloride, sulfate, nitrate, or phosphate. For composites, magnesia cement, or Sorel cement composed of magnesium salts of hydrochloric, sulfuric, or carbonic acids, are used. Included among magnesia-based binders, for example, are magnesium oxyphosphates,

which readily bond lignocellulosic materials in producing composite products (Paszner and Klemarevsky 1989). These cements produce strong bonds when aluminum polyphosphate is reacted with oxides, hydroxides, or carbonates of alkaline metals. The reaction is self-initiating, exothermic, and unaffected by sugars and extractives present in wood which can inhibit Portland cement from hardening (Moslemi 1989). The reaction is rapid. High strength, fire-retardant, and water-resistant composite materials can be manufactured. Products are made by cold-pressing, molding, extrusion, or spraying.

3. Gypsum-bonded Composites

In these composites, gypsum forms the matrix (Lempfer 1995). It is the gypsum hemihydrate ($CaSO_4 \cdot \frac{1}{2}H_2O$) which is obtained by the calcination of natural gypsum, phospho-gypsum (waste gypsum from chemical processes), or FGD (flue-gas desulfurization) gypsum (Lukevich 1997). Basically two different forms of gypsum exist, called alpha- and beta-gypsum. Due to high cost, alpha-gypsum is not used for the manufacture of gypsum-bonded composites. However, beta-gypsum is a low-cost gypsum due to its simple manufacturing process and low energy requirements. Similar to cement-bonded composites, gypsum-bonded composites generally contain a high percentage of gypsum in the product. The gypsum matrix, therefore, participates substantially in the performance of the composite being manufactured. Organic fibers or particles added to gypsum reduce brittleness and improve product toughness.

3.1 Manufacturing Methods

Although there are several methods of manufacturing gypsum fiber and particle boards (Sattler and Lempfer 1989), these processes can be categorized as using either fibers or particles. The former is called gypsum fiber board and the latter particle board. Gypsum fiber boards are made by mixing gypsum

with the reinforcing fiber in a relatively dry or slightly moist condition. Not much moisture can be added to the gypsum early in the process due to rapid setting of gypsum. In addition to gypsum and fibers, other materials are often incorporated into the mix (such as gypsum retarders or low-density aggregates) prior to board formation. Once the mixture has been formed into a mat, water is sprayed on this mat just prior to entering a press for mat consolidation. Press time is short due to rapid setting of the gypsum matrix. Once the board exits the press, additional curing and conditioning are performed (Takahashi and Shigekura 1991). During the pressing, embossing can be done through the use of special dies.

The manufacture of gypsum-bonded particle board, with some exceptions,is similar to that described for cement-bonded particle boards. Wood particles are used as the reinforcing element (Sattler and Lempfer 1989).

4. Product Properties

Table 1 summarizes some of the product properties for mineral-bonded composites. Fiber–cement products have emerged as the direct result of attempting to find a replacement for asbestos–cement products. With its adverse impact on human health, the use of asbestos has been discontinued in some industrial nations. In the search for a suitable replacement, a variety of fibers such as steel, glass, synthetic polymers, and cellulosic fibers have been examined. In this search, both technical merits and economic considerations have been evaluated. Cellulosic fibers have emerged as the most technically and economically suitable fiber for fiber–cement products (Ni 1995). In addition to flat sheets, corrugated products are also produced. Gypsum fiberboard is suited not only in applications where traditional wall board is used, but it can be used as a substrate for laminating a variety of surface laminates such as wood veneer, vinyl, foil, etc. It expands market opportunities as compared to traditional wall board. In Europe,

Table 1
Properties of mineral-bonded composites.

Property	Units	Fiber–cement board	Cement-bonded particle board	Magnesia-bonded particle board	Fiber–gypsum board	Gypsum-bonded particle board
Density	$kg\,m^{-3}$	1000–1350	1000–1350	1000–1200	900–1000	1000–1200
Bending strength	MPa	6–15	6–15	7–14	4–7	6–9
Modulus of elasticity	GPa	8–16	3–5	3	4–5	3–5
Thickness swelling	% 24h soak	1·0–2·0	1·2–1·8	4–8		
Linear expansion	% 35–90% RH	0·04–0·16	0·12–0·25	0·25	0·04	0·05–0·07

gypsum fiber board in smaller sizes is also used by do-it-yourselfers because of its ease of application (no need for taping, etc.). As Table 1 indicates, gypsum-bonded composites have similar strength properties to those made with cement; however, gypsum is decidedly sensitive to water exposure. An important attribute of most of these composites (made with either cement or gypsum) is their high resistance to fire, an important consideration for construction applications.

5. Blocks and Slabs

These composites combine wood particles with a cementitious binder in the production of building blocks and slabs of relatively low weight (Walter 1999). Some of these products have been produced in Europe since the end of the nineteenth century. Since 1928, wood fiber (shavings and wood wool) products mixed with cement have been on the market under various trade names. Further developments in these technologies have occurred since World War II.

Blocks and slabs are molded and compressed to suit the desired aesthetic and technical requirements. They are made from wood particles which are neutralized and mineralized before being bonded together with cement. Products are relatively lightweight ($750 \, \mathrm{kg \, m^{-3}}$), porous, and durable, have high strength-to-weight ratio, good thermal insulation properties, and good sound absorption. They are dimensionally stable and exhibit good freeze/thaw resistance. In addition to blocks and slabs, waffle floor forms, roof panels, acoustic facing panels, and wall components are made.

6. Market Acceptance

Markets for cement-bonded siding and roofing products are expanding in North America and elsewhere. Some of the attributes that contribute to market acceptance are:
* Durability resulting in reduced callback and maintenance
* Resistance to hail and other impacts
* Resistance to high winds
* Lightweight (no need to reinforce roof framing or deck)
* Reduction of waste and scraps
* Resistance to rot, termites, woodpeckers
* Long-lasting, uniform colors
* Dimensional stability especially for fiber–cement and fiber–gypsum products
* Freeze–thaw durability (100-cycle minimum)
* Aesthetic similarity to substitute products
* Code approvals
* Resistance to ultraviolet light
* Comparable installation to all-wood products (saw, nail, etc.)

Given the suitability of mineral-bonded composites for many applications, it is likely that these composites will play a greater role in meeting a variety of construction needs.

Wood Products: Decay During Use

Decay of wood during use is a serious problem causing significant losses in strength in stages of decay so early as to be difficult to diagnose even microscopically. The key to preventing decay in wooden buildings is the exclusion of water. Although emphasis in this article is placed on experience with wood in structures, the principles of wood decay are equally applicable to any wood in use.

1. Causal Fungi and their Requirements for Growth

Decay of wood is caused by members of the group of higher fungi called Basidiomycetes related to the common edible mushrooms. These fungi are primitive plants that lack chlorophyll and therefore cannot manufacture their own food, relying instead on the organic matter produced by plants possessing chlorophyll such as the wood produced by trees.

Decay fungi have four basic requirements for growth and production of decay in wood: air, water, a favorable temperature, and a food source. The food is of course the wood itself. This food may be made unavailable to the fungus by poisoning it with a preservative, but normal use of wood in above-ground portions of structures does not usually involve such treatment. Decay fungi have a wider tolerance to temperature than people who occupy wooden structures. Freezing temperatures will stop the progress of decay but will not kill the decay fungi. Temperatures must usually exceed about 60 °C before thermal death occurs. Decay fungi require so little oxygen that it is usually not possible to control decay by limiting this factor in structures; water submersion or deep burial, however, excludes oxygen sufficiently that wood in such conditions is not attacked by decay fungi. Thus, the remaining factor—water—is the key to controlling decay in buildings. Throughout history a major goal of the design and construction of structures has been to shed water effectively. If this is done, and no water leaks are allowed, there is no reason why above-ground portions of wooden buildings should decay. Wood kept dry will never decay.

2. Sources of Inoculum

Any living cells of a fungus, when transferred to a new location favorable for growth, have the potential for reproducing the fungus in this new site. Decay fungi produce spores, which act like seeds of higher plants in that they are capable of starting a new growth of fungus in an area where conditions are favorable. The fungi produce great numbers of such spores light enough to be carried by the winds, thereby assuring that fungi are present wherever conditions conducive to decay exist. Moreover, the careless manner in which wood products often are handled tends to ensure that wood in structures is infected before being placed in service.

Wood may be shipped and stored in the green condition thereby allowing time for it to become infected. One study found that the principal fungi isolated from green lumber were the same ones responsible for most above-ground decay (Dietz and Wilcox 1997, Wilcox and Dietz 1997). Wood products may be delivered to the job site and set on the soil; since decay fungi live in the soil this provides an opportunity for them to move into the wood before it is placed in the structure. If the wood is allowed to dry and remains dry throughout the life of the structure, such preinfection may be of no consequence. However, if conditions later become conducive to decay, the necessary fungi may already be present in a dormant state.

3. Types of Decay

There are two major categories of decay produced by Basidiomycetes: brown rot and white rot. The brown-rot fungi decompose only the carbohydrate fraction of wood, leaving the lignin modified but not metabolized. The residual lignin is darker than cellulose, leading to the brown coloration of the rot, and has very little strength, leading to the excessive shrinkage and cubic checking typical of brown-rotted wood.

White-rot fungi decompose all the major components of wood and can lead to 100% loss in cell wall material. Some of the white-rot fungi attack lignin preferentially in the early stages of decay, while others, sometimes called simultaneous rots, decompose both lignin and carbohydrates at a rate proportional to their original relative concentration in the wood.

4. Microscopic Diagnosis of Decay

Not all decay fungi attack wood in the same way, and a given fungus may produce different effects in different woods. Therefore, not all the features discussed below will necessarily be found in any given piece of decayed wood. However, the following microscopic features may frequently be required for diagnosing

early stages of decay; the more they are present, the more confident the diagnosis.

A fungus can be thought of as being like a ball of cotton with filaments running in all directions. The filaments that make up the body of a fungus are called hyphae. Individual hyphae are too small to be seen easily without a microscope, but massed together they can form what is known as a mycelium, which can be seen readily on the wood surface. The hyphae of decay fungi may contain very distinctive loop-like structures called clamp connections. Only Basidiomycetes have them, and the only Basidiomycetes that would be present in wood would be decay fungi. Therefore, if microscopic examination reveals hyphae with clamp connections, then the fungus is a decay fungus. Unfortunately, many decay fungi do not produce clamp connections and some that produce them in culture do not produce them in wood. Clamp connections, then, are a valuable diagnostic tool if present, but their absence supplies no useful diagnostic information.

The hyphae of decay fungi may invade wood in early stages by growth through ray cells and large longitudinal elements, such as resin ducts or vessels. The decay fungi normally leave these elements and ramify throughout the wood. In some cases decay-fungal hyphae may be most numerous in the strength-providing longitudinal elements (fibers or tracheids). Penetration may be through pits or by means of boreholes dissolved through the wood cell walls by the enzymes from the hyphae. The boreholes of decay fungi are usually numerous. They enlarge to several times the hyphal diameter, tend to run in series (serial boreholes) through a number of wood cells walls in a relatively straight line (as seen in radial section) and bear little relation to pits.

Early stages of attack on the cell walls may be characterized by separations within or between cells, and shallow depressions or gouges at the wall–lumen interface. In later stages of decay, white-rotted wood cell walls may appear thinned in a uniform fashion from cell to cell, whereas brown-rotted wood cells appear shrunken and distorted on a very irregular basis from cell to cell. The earliest microscopically detectable stages of brown rot, as low as 1–2% mass loss, are characterized by hyphae in cell lumina, loss of birefringence of secondary walls in cross-sections, serial boreholes, and boreholes smaller in diameter than the hyphae (Wilcox 1993a 1993b).

White-rot fungi decompose all the major cell-wall components and some remove them at rates approximately proportional to the amounts present in sound wood, thereby leading to the observed progressive thinning of the cell walls.

Brown-rot fungi decompose primarily the carbohydrate fraction of the wood. Lignin is altered by their attack, but little of it is removed. In early stages of brown rot the wood constituents may be depolymerized more rapidly than the decomposition products

Table 1
Expected strength loss at an early stage of decay (5–10% mass loss) in brown-rotted softwoods. Because of the drastic reduction in most strength properties caused by decay at such an early stage as to be difficult to diagnose, it is easy to see that it is considerably safer to prevent decay in the first place than to rely upon ability to detect and diagnose it accurately in sufficient time to effect a remedy before failure occurs.

Strength property	Expected strength loss (% of strength of sound wood)
Toughness	$\geqslant 80$
Impact bending	80
Static bending (MOR and MOE)	70
Compression perpendicular to grain	60
Tension parallel to grain	60
Compression parallel to grain	45
Shear	20
Hardness	20

Source: Wilcox (1978).

are metabolized by the fungus, leading to a buildup of low-molecular-weight molecules which constitute mass but provide no strength.

5. Effects of Decay on Strength Properties

Resistance to impact loading is the mechanical property of wood most sensitive to the presence of decay. Toughness, for example, may be largely destroyed at a stage of decay so early that it may be hard to detect even microscopically (Table 1). Those strength properties relied upon in the use of wood as a beam, a common mode of service, are also severely diminished in very early stages of decay. In such early decay stages there is little difference noted between brown rot and white rot with regard to the magnitude of strength losses. However, as decay advances, further effects on strength are much more severe in brown rot than in white rot.

Wood Products: Weathering

The surface degradation that occurs when wood is used outdoors and above ground is termed weathering. Weathering should not be confused with decay caused by basidiomycete fungi (see *Wood Products: Decay During Use**), which can significantly reduce the strength of structural timber (Feist 1990). Because weathering is a superficial phenomenon its effects on the mechanical properties of wood are small and, accordingly, there are examples of wooden buildings such as the stave (pole) churches in Norway that are still structurally sound despite having been exposed to weathering for over 900 years (Borgin 1970). The most obvious features of weathered wood are its gray coloration and rough surface texture (Fig. 1). Microorganisms colonize weathered wood, but conditions at exposed wood surfaces generally do not favor decay. Hence, the defining features of weathering are its superficial nature and the minor role of microorganisms compared to environmental factors in degradative processes. This article reviews the weathering of

wood, with emphasis on the causal agents of weathering, the effects of weathering on wood properties and performance, and, finally, the protection of wood from weathering. The first scientific article on the weathering of wood appeared in the nineteenth century (Berzelius 1827 cited in Feist and Hon 1984), and extensive reviews have been published by Kalnins (1966), Feist and Hon (1984), and Feist (1990).

1. Mechanisms and Environment

The main environmental factors that cause weathering are: solar radiation (ultraviolet and visible light), oxygen, water, heat, particulate matter, and environmental pollutants. The maximum amount of solar radiation available at the earth's surface on a clear day is normally $1000 \, \text{Wm}^{-2}$. The composition of such radiation is approximately 5% ultraviolet (286–380 nm), 45% visible (380–780 nm), and 50% infrared (780–3000 nm). In order to act upon wood, solar radiation must be absorbed by one of wood's chemical constituents. Experimentation has shown that the aromatic lignin component of wood (see *Wood, Constituents of**) strongly absorbs ultraviolet (UV) light with a distinct maximum at 280 nm and a tail extending beyond 400 nm into the visible portion of the spectrum (Kalnins 1966). The heartwood of many wood species also absorbs light beyond 500 nm because of the presence of low molecular weight extractives such as flavonoids, tannins, stilbenes, and quinones. In the case of synthetic homopolymers, photodegradation can be represented in a simplified manner as follows. Energy from absorbed radiation (*) can be dissipated in the polymer through the cleavage of molecular bonds (photolysis) resulting in the formation of a free radical ($R^* \rightarrow R\bullet$); that is a molecule which is highly reactive because it has an unpaired valence electron. Once a free radical has formed it can readily react with atmospheric oxygen to form a peroxy radical ($R\bullet + O_2 \rightarrow ROO\bullet$). The peroxy radical is capable of attacking the polymer backbone (RH) via hydrogen abstraction, forming a hydroperoxide and another free radical ($ROO\bullet + RH \rightarrow ROOH + R\bullet$). The hydroperoxide is very unstable to UV radiation and undergoes photolysis forming additional free radicals ($ROOH \rightarrow RO\bullet + \bullet OH$). The increasing accumulation of free radicals results in extensive cleavage of molecular bonds and consequent loss of the physical properties of the polymer. The photodegradation of wood proceeds in an analogous manner except that its degradation is more complicated because it consists of a blend of polymers (lignin, cellulose, and hemicellulose) and low molecular weight extractives that differ in their susceptibility to solar radiation. Furthermore, the precise mechanisms and reaction pathways involved in the photodegradation of each of these components have yet to be elucidated. However, it is clear that the key step involved in the photodegradation of wood is
Figure 1

photolysis and fragmentation of lignin resulting in the formation of free radicals (Feist and Hon 1984). These free radicals may then cause further degradation of lignin and photooxidation of cellulose and hemicellulose. Free radical reactions may be terminated by reaction of radicals with photodegraded lignin fragments forming colored unsaturated carbonyl compounds, which explains why wood yellows when exposed to light. In accord with energetic considerations, the UV portion of the solar spectrum is most effective in causing degradation of wood, but visible light is also involved in weathering. Thus Derbyshire and Miller (1981) noted that "wood exposed only to wavelengths greater than 400 nm will degrade at about half the rate of material exposed to the full solar spectrum."

Water has an important role in the weathering of wood. The leaching of photodegraded lignin and hemicellulose fragments from weathered wood surfaces by rain is in part responsible for the characteristic gray color of weathered wood. Dimensional change caused by the wetting and drying of wood generates surface stresses that cause checking and warping of timber (Feist 1990). The photodegradation of wood also proceeds more rapidly in the presence of moisture, possibly because water molecules swell wood thereby opening up inaccessible regions of the cell wall to degradation (Feist and Hon 1984).

Heat accelerates the chemical reactions involved in the weathering of wood. Exposure of wood to low temperatures and repeated freezing and thawing can also contribute to the physical deterioration of wood.

An additional factor involved in the weathering of wood in cold climates is abrasion by windblown particles of ice. For example, the Australian Antarctic explorer Mawson (1915 pp. 123–4) wrote: "the abrasion-effects produced by the impact of the snow particles were astonishing ... A deal (*Pinus* sp.) box, facing the wind, lost all its painted bands and in a fortnight was handsomely marked; the hard knotty fibres being only slightly attacked, whilst the softer, pithy laminae were corroded to a depth of one-eighth of an inch [approximately 3 mm]." Windblown sand and salt can also cause similar, if less spectacular, abrasion of wood (Feist 1990).

The main pollutants in the atmosphere are dust and smoke particles and volatile pollutants including sulfur compounds, ammonia, nitrogen oxides, carbon monoxide, and saturated and unsaturated aliphatic and aromatic hydrocarbons and their derivatives. There have been relatively few studies of the effects of these pollutants on the weathering of wood, but observations in the field and *in vitro* experiments have all tended to suggest that the weathering of wood is more rapid in polluted than in unpolluted atmospheres (Williams 1987).

The frequent wetting and drying and high temperatures and levels of solar radiation at exposed wood surfaces are unfavorable to microbial activity. Nevertheless bacteria and certain microfungi are frequently observed colonizing weathered wood, where they contribute to its gray coloration. The dimorphic black yeast *Aureobasidium pullulans* (de Bary) Arnaud in

particular is frequently isolated from weathered wood. *A. pullulans* is capable of withstanding temperatures of 80 °C, growing over a pH range of 1.9 to 10.1 and surviving for long periods without moisture. Hence it is particularly well suited to the microenvironment of weathered wood (Schmidt and French 1976). *A. pullulans* metabolizes photodegraded lignocellulose, but organisms capable of enzymatically degrading wood also colonize weathered wood. However, their ability to cause significant degradation is, as mentioned in the introduction, limited by conditions at weathered wood surfaces.

2. Effects of Weathering

Wood exposed to the weather changes color very rapidly. Light colored woods, including most coniferous species, darken in color and become yellow or brown due to the accumulation of photodegraded lignin compounds in the wood. Dark colored woods that are rich in phenolic extractives may fade initially before becoming yellow or brown. Irrespective of these initial color changes, wood exposed outdoors for 6–12 months (depending on climatic conditions) becomes gray as photodegraded lignin fragments are leached from the wood resulting in surface layers that are rich in cellulose. Wood exposed outdoors in coastal or very dry environments is often silvery-gray in color, but in other environments weathered wood has a dark gray, blotchy appearance due to the presence of fungal spores, hyphae, and pigments within surface wood layers.

The rapid erosion of low-density earlywood often gives weathered wood a corrugated appearance (Fig. 1). The rate of erosion of wood during exterior exposure largely depends on its density, and accelerated weathering studies have shown a linear relationship, within the density range 0.3–1.0 g cm^{-3}, between wood density and erosion (Sell and Feist 1986). Accordingly, low density species such as western red cedar (*Thuja plicata* D. Don) erode at a rate of 12 mm per century when exposed vertically facing south in the northern hemisphere, whereas comparable figures for higher density softwoods such as Douglas fir (*Pseudotsuga menziesii* (Mirb.) Franco.) and high density hardwoods are 6 mm and 3 mm, respectively (Feist 1990). In addition to erosion, the surface texture of weathered wood is further degraded by the formation of checks. Photodegradation of wood and stresses generated by wetting and drying result in the formation of macroscopic checks where adjacent cells or tissues differ in cell wall thickness or strength. For example, checks often develop at growth ring boundaries and at the interfaces between rays and tracheids. Microscopic changes to the structure of wood precede any evidence of macroscopic damage during weathering. The lignin-rich middle lamella that bonds adjacent tracheids and fibers together is

rapidly eroded during weathering, and adjacent primary and secondary cell wall layers show progressive thinning with increasing exposure (Fig. 2(a)–(d)). The most obvious changes to the microscopic structure of longitudinal surfaces are the formation of microchecks originating in bordered and half-bordered pits (Fig. 2(e)–(f)) and the degradation of ray tissues.

All of the major chemical constituents of wood are degraded during weathering. Lignin is depolymerized and, as mentioned above, low molecular weight lignin fragments are leached from wood by rain. The use of spectroscopic techniques, such as Fourier transform infrared spectroscopy (FTIR) and x-ray photoelectron spectroscopy, that can probe the chemical composition of surfaces, has shown that the degradation of lignin at exposed wood surfaces is extremely rapid. For example, FTIR spectroscopy of weathered radiata pine (*Pinus radiata* D. Don) veneers showed a remarkably rapid decrease in the peak at 1505 cm^{-1}, which corresponds to aromatic C=C bond stretching in lignin. Spectra suggested perceptible surface (1–2 μm) delignification after 4 hours exposure, substantial delignification after 3 days, and almost complete surface delignification after 6 days (Fig. 3) (Evans *et al.* 1996). Hemicelluloses, particularly those containing xylose and arabinose, are also degraded and leached from weathered wood, and hence, as mentioned above, weathered wood surfaces are rich in cellulose. Because of this it was assumed for many years that cellulose was less affected by weathering than the other chemical constituents of wood, but viscometry studies of cellulose isolated from weathered wood have shown that cellulose in wood is rapidly depolymerized when exposed to the weather (Evans *et al.* 1996).

The effects of weathering on the structure and chemical composition of wood are superficial in nature. Hence, processing technologies and applications of wood that depend on its surface properties are severely affected by weathering. Notable in this regard is the painting and finishing of wood. Weathering of wood for 2–4 weeks prior to painting has been shown to significantly reduce the adhesion and performance of finishes applied to wood (Williams *et al.* 1987). Weathering also reduces the natural durability of western red cedar roofing shakes by leaching fungitoxic thujaplicins from wood. Because weathering is confined to wood surface layers the mechanical properties of wood, assuming decay to be absent, are largely unaffected by prolonged exposure to the weather. In contrast the mechanical properties of wood composites, which depend in part on the strength of wood–adhesive bonds, can be significantly reduced by moisture-induced dimensional changes when they are used outdoors. Despite these deleterious effects of weathering on the utility of wood, in certain specialized applications weathered wood is preferred to fresh wood. A good example of this is the use of weatherboards for the construction
Figure 2
Effects of weathering on the microscopic structure of Scots pine (*Pinus sylvestris* L.) wood. (a) Unexposed earlywood tracheids with thin undamaged cell walls and large cell lumens. (b) Unexposed latewood tracheids with thick cell walls and small lumens (note the middle lamella that cements tracheids together, arrowed). (c) Earlywood tracheids exposed to the weather for 30 days (note erosion of middle lamellae, particularly at cell corners and thinning of cell walls). (d) Latewood tracheids exposed to the weather for 30 days (note erosion of middle lamellae and delamination of cell walls, arrowed). (f) Earlywood tracheids exposed to the weather for 30 days (note microchecking originating in bordered pit apertures).
surface wetting and erosion. A correctly applied and maintained paint system including a primer and at least two topcoats can greatly reduce the deleterious effects of weathering on wood. However, paints are less effective in controlling decay and dimensional movement and therefore they often perform better on wood that has been pretreated with a water-repellent preservative. The high maintenance requirements of paints and their tendency when used on nondurable timber to trap water and encourage decay has led to increased use of penetrating water repellent stains as a means of protecting wood used outdoors. Stains contain a variety of additives to reduce the weathering of wood, including pigments and UV stabilizers to screen wood from solar radiation, hydrophobic additives to repel water and reduce checking, and a biocide to control the growth of microorganisms. Stains provide protection against weathering for 3–6 years depending on wood species and surface texture, type and quantity of stain applied to the wood, and degree of exposure to the weather. Paints and to a lesser extent stains modify the appearance of wood. For end uses where it is important to retain the wood's natural color or texture the wood can be finished with a clear coating. Clear coatings, however, although they often contain UV stabilizers and a biocide, are limited in their ability to protect wood from weathering because they transmit light, which can degrade the underlying wood surface. Hence they perform badly on wood used outdoors and invariably fail by peeling and cracking within 2–3 years of application. One means of increasing the performance of clear finishes on wood is to photostabilize the underlying wood surface prior to application of the clear finish. Pretreatment of wood with dilute aqueous solutions of transition metal compounds (chromium, manganese, titanium, copper), and particularly chromium trioxide, can photostabilize wood and increase the longevity of clear coatings applied subsequently to the wood. Health concerns about the use of hexavalent chromium, however, have discouraged commercial development of this concept except in Japan where pretreatment of wooden doors with chromium trioxide was used in the 1980s to enhance the weathering resistance of acrylic-urethane finishes. When wood is treated with chromium trioxide, lignin phenolic subunits at wood surfaces are modified producing oxidized lignin complexes with considerable light, thermal, and solvolytic stability (Schmalzl *et al.* 1995). It has been suggested that such complexes could function as an "ultraviolet screen" protecting wood from the effects of the weather. Chemical treatments or additives such as UV absorbers and hindered amine light stabilizers that achieve similar photoprotective effects may also be useful in improving the performance of clear finishes. Chemical bonding or grafting of UV absorbers to wood is particularly effective in photostabilizing wood and improving the performance of clear finishes (Kiguchi

of "New England type" barns, where the wood may be artificially weathered prior to building construction in order to give the building an aged appearance in keeping with its rural surroundings (Anon 1976).

3. Protection

The most common method of protecting wood from weathering is through the use of coatings (see *Wood: Finishes and Coatings*[#]). Paints contain pigments that screen wood from solar radiation and because they form a film over the wood surface they prevent

and Evans 1998), but commercialization of such treatments awaits the development of less costly UV absorbers that can be more easily bonded to wood. Until more effective methods of photostabilizing wood have been developed it is unlikely that clear finishes on wood will be able to match the exterior performance of paints and other pigmented finishes.

4. Future Directions

Architects and engineers are increasingly insisting on materials that offer longer service life and lower repair and maintenance costs. In addition there is pressure to use materials that can be recycled and produced on a sustainable basis. Wood is a renewable material that can be easily repaired and in most cases recycled. However, weathering reduces the service life of wood and increases its maintenance costs. For example, premature failure and replacement of chromated copper arsenate-treated pine poles and decking are often caused by checking, and the higher maintenance costs of exterior wooden joinery compared to substitutes made from unplasticized polyvinyl chloride or aluminum are caused in part by weathering-induced failure of surface coatings. Hence there is likely to be continuing interest in the development of additives and treatments to reduce the weathering of wood. A deeper understanding of the mechanisms involved in photodegradation of wood could lead to more economical and effective methods of photostabilizing wood, which could significantly improve the durability of clear finishes for timber. Wood is increasingly being converted into a wide range of composites and being combined with a diverse range of other materials including thermoplastic and thermosetting polymers, ceramics, and other lignocellulosics. The evaluation of the weathering resistance of such materials and the development of appropriate treatments to enhance their durability will become increasingly important in future.

Wood, Constituents of

Wood is a cellular lignocellulosic material consisting of cellulose embedded in a hemicellulose/lignin matrix. The composition of wood varies at all levels from species to species, among cell types, and within the cell wall itself. The chemical composition of softwoods (conifers) differs from that of hardwoods (arboreal angiosperms) in the structure and content of lignin and hemicelluloses (Table 1). Wood may also contain significant quantities of extractives (resins and gums) in the form of low molecular weight extracellular compounds. The inorganic component of wood is typically less than 0.5%.

1. Cellulose

Cellulose is one of the most abundant organic compounds on earth. It is a linear homopolysaccharide made up of β-1,4-linked D-glucopyranoside residues in the $^4C_1$ chair conformation (Fig. 1, (**1**)). In both softwoods and hardwoods the cellulose content is approximately 42%. In the native state, adjacent parallel cellulose chains are aggregated together, by inter- and intramolecular hydrogen bonds, to form microfibrils approximately 4nm wide. These microfibrils contain both highly ordered (crystalline) and less

Table 1
Chemical composition of normal and reaction woods in typical softwood and hardwood species.

ordered (amorphous) regions. The native crystalline structure of cellulose is classified as the cellulose *I* allomorph. The measured degree of polymerization of native cellulose is of the order of 10 000. The microfibrils are further aggregated with lignin and hemicelluloses to form macrofibrils. The high level of bonding in cellulose micro- and macrofibrils results in both high tensile strength and general insolubility in most solvents.

2. Hemicelluloses

Classification of plant polysaccharides has been based on their extraction methods. Hemicellulose is a term used for plant cell wall polysaccharides, other than cellulose and pectin, which are soluble in alkali solutions. Hemicellulose consists of various heteropolysaccharides, which are deposited in the cell wall at a level of $30 \pm 5\%$, and are closely associated with cellulose and lignin. They can be readily isolated, after delignification, by sequential alkali extraction of increasing concentration. In softwoods the predominant hemicellulose $(20 \pm 5\%)$ is *O*-acetyl galactoglucomannan (Fig. 1, (**2**)). The polysaccharide is composed of a linear backbone of β-1,4-linked D-mannopyranosyl and β-1,4-linked D-glucopyranosyl residues in a ratio of approximately 4:1, respectively. Some of the mannosyl residues are substituted with (i) α-D-galactopyranosyl units at position C-6 and (ii) *O*-acetyl groups, predominantly at position C-3 and to a lesser extent at position C-2. The level of galactose sub-stitution can vary, relative to glucose, from 0.1 to 1.0. The ratio of *O*-acetyl to mannose residues is about 1:6.

An acidic arabino-4-*O*-methylgluconoxylan hemicellulose fraction is also present in softwoods at about 10%. This heteropolysaccharide is made up of a β-1,4-linked D-xylopyranosyl backbone substituted with α-L-arabinofuranosyl and 4-*O*-methyl-α-D-glucuronopyranosyl side groups at positions C-3 and

C-2, respectively (Fig. 1, (**3**)). Generally, the xylose to arabinose to uronic acid ratio is 6:1:1. In certain softwoods, such as larch, arabinogalactan II is readily extracted by hot water to give yields of between 5% and 30%, and is a highly branched polysaccharide built up of a β-1,3-linked D-galactopyransoyl backbone to which at position C-6 oligosaccharide side-chains are attached.

In hardwoods, *O*-acetyl-glucuronoxylan is the predominant hemicellulose $(25 \pm 5\%)$ which has the same main chain of a β-1,4-linked D-xylopyranosyl units, as in softwoods, and substituted with 4-*O*-methyl-α-D-glucuronopyranosyl and *O*-acetyl groups at positions C-2 and C-3/2, respectively (Fig. 1, (**4**)). Typically the xylose to acetyl to uronic acid ratio is about 10:7:1.

Furthermore, hardwoods contain a small amount of glucomannan $(< 5\%)$, which is composed of a linear chain containing β-1,4-linked D-mannopyranosyl and β-1,4-linked D-glucopyranosyl residues generally in a ratio 2:1.

3. Lignin

Lignin is a three-dimensional polymer built up of phenylpropane units that is laid down within the cell wall after tracheid elongation has ceased. The incorporation of lignin into the cellulose microfibril structures within the cell wall greatly enhances the mechanical strength properties of wood, over pure cellulose. Typically softwoods contain $30 \pm 5\%$ lignin while hardwoods generally have a lower lignin content $(25 \pm 5\%)$. Lignin can be isolated by solvent extraction in reasonable yield from finely ground wood, after a cellulase pretreatment. Monomeric lignin precursors are *trans p*-coumaryl, coniferyl, and sinapyl alcohols (Fig. 1, (**5a**), (**5b**), and (**5c**), respectively) that undergo dehydrogenative polymerization by peroxidase and/or laccase activity to form macromolecular lignin by random coupling. The reactivity and levels of the lignin precursors govern
Figure 1
Common chemical structures found in wood.

the final constitution of lignin. The most predominant linkage between phenylpropane units in both softwood and hardwood lignin is the β-O-4 linkage (Fig. 1, (**6**); guaiacylglycerol-β-coniferyl ether; 50%), the β–β linkage (Fig. 1, (**7**); pinoresinol; 5%), the β-5 linkage (Fig. 1, (**8**); phenylcoumaran; 10%), and the α-O-4 linkage (10%). Softwood lignin also contains the 5–5 linkage (Fig. 1, (**9**); biphenyl; 10%). Soft-

woods contain lignin made up of guiacyl units, while hardwood lignin is built up from both guiacyl and syringyl units.

Production of wood pulp for the paper industry often involves the chemical removal of lignin, which is burned to drive the chemical recovery systems. A few lignin-derived chemicals are produced, such as vanillin and lignosulfonates.

4. Extractives

The term "extractives" means a mixture of compounds that are extracted from wood by a solvent or solvents. Lipophilic extractives are referred to as wood resin. Typically, extractives are of low molecular weight and are located outside the cell wall. Extractives, in part, contribute to the natural durability of wood by containing substances that are toxic to bacteria, fungi, and insects. In pulping, extractives can be collected as by-products such as tall oil and turpentine. However, extractives can have a negative effect on paper quality such as pitch deposits. Heartwood generally contains higher levels of extractives than sapwood. Extractives can be broken down by classes of compounds, such as monoterpenes (e.g. β-pinene; Fig. 1, (**10**)), resin acids (e.g. abietic acid; Fig. 1, (**11**)), fatty acids (e.g. oleic acid; Fig. 1, (**12**)), fats, sterol esters, phenolics, tannins, flavonoids, lignans, cyclitols, carbohydrates, and amino acids.

5. Reaction Wood

Reaction wood is produced as a response to stem lean, and has the function in the tree to generate growth stress to correct the stem lean, thus maintaining the most efficient position of the stem for photosynthesis. Reaction wood occurs in two different forms, compression wood in softwoods, and tension wood in hardwoods. Compression wood typically has more lignin, and less cellulose and galactoglucomannan, compared to normal wood, while tension wood has a higher cellulose content. Compression wood lignin has a higher content of *p*-coumaryl units. Both compression wood and tension wood contains a β-1,4-linked D-galactan not found in normal wood. The increased lignification of compression wood tracheids is thought to produce significant longitudinal swelling during wood formation, thus generating an expansion on the lower side of the stem, which attempts to correct the lean. In tension wood, the additional cellulose is thought to generate tension on the upper side of the stem due to shrinkage during wood formation. Unfortunately the growth stress which is beneficial to the tree has undesirable effects on timber properties resulting in abnormal shrinkage and dimensional instability.

6. Topochemistry

The wood cell wall has a complex structure with variations in chemical composition among different cell wall layers. Wood also contains different cell types, which in turn may have a different chemical composition. In softwoods, the tracheid accounts for 95% of the wood substance and thus has a dominant effect on the chemical composition. The tracheid cell wall consists of a highly lignified middle lamella incorporating the primary wall. The secondary wall is lignified to a much lesser extent than the middle lamella with higher lignin concentrations often present in the S3 layer lining the lumen. Both the inner S3 and outer S1 layers have a denser hemicellulose matrix than the S2 layer which is usually the thickest layer. An important effect of this complex variation in chemical composition across the cell wall is that chemical composition of a bulk wood sample can be altered significantly by changes in the proportion of the different cell wall layers. Chemical composition can also vary in proportion to wood density for the same reason. This often makes it difficult to distinguish true changes in chemical composition from changes resulting from anatomical or ultrastructural variations.

The middle lamella typically contains 20–25% of the total lignin content while the lignin concentration in this region varies from 50% to 80%. Interestingly, some of this variation has been shown to be genetically inherited among clones within a species. The secondary wall typically has a lignin concentration of 20–25%. In compression wood the distribution of lignin alters dramatically, with reduced lignification of the middle lamella and increased lignification of the secondary wall, especially in the outer S2 region at the corners of the tracheids known as the S2L region, where the lignin concentration may exceed that in the middle lamella. In tension wood the increased cellulose content is due to the presence of an additional cell wall layer consisting largely or entirely of cellulose known as the gelatinous layer because of its characteristic detached appearance under the light microscope.

In hardwoods, lignin varies in its chemical composition among cell types and cell wall regions. Guiacyl lignin predominates in cells involved with water conduction (vessels) while syringyl lignin predominates in fibers and parenchyma cells. The middle lamella region of vessels also contains guiacyl lignin while the middle lamella of fibers contains a mixed guiacyl/syringyl lignin.

7. Conclusions

The chemical composition of wood is highly variable and this variability has a significant effect on wood properties. Research is increasingly being aimed at the manipulation of chemical composition by genetic engineering and the use of molecular biology to study the process of wood formation. The driving force behind this research is the need to develop environmentally friendly processing options and to develop novel wood based products.

Wood: Creep and Creep Rupture

Because of the time-dependent properties of its constituents, wood experiences creep, that is, deformation resulting from constant load over time. An everyday example is the gradual sagging of a heavily loaded bookshelf. If stresses are low, the rate of creep can become negligible after 2–3 yr. At relatively high stresses, however, a deformation will be reached where the rate of creep starts to increase. Once this occurs, failure (creep-rupture) is inevitable under that load. While the underlying biological mechanisms controlling the extent of creep are complex, the engineers have to accommodate creep and creep-rupture in the design of timber structures. In some wood design codes, to avoid excessive deflections, creep effects are accounted for in calculation of deflections for the expected service life of the structure. To avoid creep-rupture of a structural member, design codes require that short-term strength values be adjusted to account for the duration of load (DOL) effect.

1. Stages of Creep

At low stress levels (<35% of the ultimate short-term strength), and under indoor environments, wood can be considered as a linear, viscoelastic material. In these cases, the creep deformation under sustained loading can be divided into two stages: a primary stage where the creep rate decreases; and a secondary stage where the creep rate is nearly constant. At higher stress levels, in addition to the primary and secondary stages, a tertiary stage, where the creep rate increases, will occur and lead to eventual creep-rupture.

Creep in wood at a given time may be described as the sum of three components: the instantaneous elastic and recoverable deformation at time zero; a delayed and recoverable elastic deformation; and a viscous deformation, which is permanent and irrecoverable. This simple description, however, may not be applicable to some wood composites. On unloading, a progressive recovery, total or partial, to the

initial state occurs. Total recovery corresponds to pure viscoelasticity. Partial recovery means that plastic damage, even microscopic, has occurred.

In a stable environment, and for stresses less than about 35% of the short-term strength of the wood, the deformations under two different stresses have a constant ratio independent of time (STEP 1 1995). As a first approximation, creep compliance (strain/stress) is independent of the stress, and linear theory will be applicable. This assumption of linearity is generally appropriate at design load levels where Boltzmann's principle of superposition will be valid. However, at higher stress levels wood shows nonlinear viscoelastic behavior and Boltzmann's principle of superposition will not be applicable.

2. Factors Affecting Creep and Creep-rupture

The magnitude of creep depends on many factors such as level and type of stress, rate and duration of stress, moisture content, variations in moisture content, temperature, and grain orientation. Although there are complex interactions among these variables, and despite the fact that these interactions change from one wood material to another, they are accounted for independently in most design codes, with the exception that the combined effects of load duration and moisture content are taken into account in the European timber design code (ENV 1994).

The polymeric nature of wood constituents makes wood sensitive to moisture content and temperature. Further details about the rheological characteristics of wood and wood-based materials including a discussion on deformations at the molecular level may be found in Bodig and Jayne (1982) and in Morlier (1992). For practical purposes, the higher the moisture content and temperature, the greater the creep. However, the influence of temperature on creep is considered negligible when the temperature does not exceed 50 °C (STEP 1 1995). Higher temperatures are reported to reduce the stiffness of timber in bending, tension or compression as lignin alters its structure and hemicelluloses begin to soften (Morlier 1992). Moisture in wood acts as a plasticizer, therefore, creep increases with moisture content. The effect resulting from the interaction of moisture movement (drying and wetting) with the mechanical properties of wood is called the "mechano-sorptive effect." Fluctuations in humidity may result in increases in creep amplitude. Armstrong and Kingston (1962) report that during all desorptions, the creep increases faster than it would at constant moisture content, regardless of the rate of desorption. This phenomenon also occurs in the first sorption, but during subsequent sorptions at the same moisture level, the creep deflection usually decreases.

Creep increases with load duration. It strongly depends on load level, which must be lower when the

duration is extended, in order to ensure an acceptable deformation limit with time. If the duration of applied stress is sufficient, wood may commence tertiary creep preceding rupture, which can be described as progressive damage in the wood. The higher the stress, the shorter the time to rupture. In other words, the time to creep-rupture depends on the sustained load level. In design codes, the specified strength is selected such that creep remains within the secondary stage where the rate of deformation is low and stable during the lifetime of the structure. Experimental results show that this stability exists at stress levels below 35% of the short-term strength.

Creep deflections also occur in other types of loading, e.g., a ramp load may be considered as a series of step loads for which Boltzmann's principle of superposition may be used to predict creep. When the loads are increasing with time, wood exhibits the influence of rate of loading by showing relatively larger strain under slowly increasing stress. Thus, specimens tested at a slower rate of loading will fail at a lower stress level (Karacabeyli and Barrett 1993).

3. Modeling Techniques

Modeling of the creep deformation behavior of wood has followed the outlines suggested by Alfrey (1948). The mathematical models here used to describe linear viscoelastic behavior resemble models built from discrete elastic and viscous elements. To adequately describe wood, multi-parameter Voight or Maxwell models have been used. These models allow calculation of the time-dependent uniaxial stress-strain behavior for many types of load excitations such as: creep (sustained loading), stress-relaxation (constant kept deformation), constant rate of ramp loading, and vibration-damping behavior at various frequencies.

To account for creep in design, engineers rely on good judgment supported by available models. Wood researchers applied a variety of techniques in modeling creep behavior (Schniewind 1968, Bach and Pentoney 1968, Morlier 1992, Bodig and Jayne 1982, Fridley *et al.* 1992). Models based on damage accumulation (Foschi *et al.* 1989) and fracture mechanics (Valentin *et al.* 1991) also have been used in predicting creep-rupture of wood.

4. Evaluation of Creep and Load Duration Performance

Creep deformation and DOL strength effects on lumber and some panel products have been studied widely, and research findings have been implemented in various design codes. For example, in the European timber design code (ENV 1994), material-specific creep and load duration factors are specified for several load duration and service classes. This format allows the factors to reflect the interaction between load duration and moisture effects.

Given that there may be substantial differences between the long-term structural performance of different composite wood products, it is important to determine the creep and DOL performance for each structural composite wood product. This may be achieved by showing an equivalency to lumber through a verification program, or by quantifying the factors through a comprehensive testing and reliability study.

4.1 Verification Method

A verification approach is a pass/fail method, which requires the producers to demonstrate the equivalency of the long-term structural performance of their products to that of lumber. The following method has been successfully used for a number of engineered wood products in North America for indoor environments. In this method, a representative sample is subjected to a constant load for a time longer than the expected duration of extreme occupational and snow loads. In other words, the level of the constant load tests is selected to represent overload levels. Usually a minimum sample size of 28 specimens is sampled and tested for 3–4 months. The constant load level is selected as a percentage of the short-term strength of a matched control group, determined in ramp tests of duration from 1–10 min. A constant load level of 55% of the lower fifth-percentile point estimate came into use in the 1990s in North America. Finally, an equivalency of the creep and creep-rupture behavior of a composite wood product to lumber can be shown by comparing some of its performance parameters to those established for lumber.

The following sections describe the creep and DOL performance parameters used as criteria in the verification method for the evaluation of the long-term structural performance of a wood product. If the product satisfies all the criteria, then it passes the verification test and designers may use the creep and load duration factors assigned for lumber for that product.

(*a*) *Stress levels for avoiding creep-rupture.* Under certain constant stress levels, lumber does not fail within a given time, e.g., the large database developed under the US/Canada Duration of Load Test Program (Karacabeyli and Soltis 1991) shows that lumber does not fail under a stress level of 55% of its short-term strength within 3 months under bending, tension or compression parallel-to-grain loading. The equivalent load level for 2 years is about 45%. Laufenberg *et al.* (1999) show that plywood and oriented strandboard (OSB) also will not fail over a 3-month period when subjected to a constant bending stress level of 55%. For loads perpendicular to grain,

this ratio may be different. Madsen (1972) reports that for various rates of tension loading perpendicular to the grain, the reduction in strength is considerable with decreasing rate of loading. Bach (1975) shows that the effect of sustained loading on relative strength is more severe in bending perpendicular to grain than in bending parallel to the grain. Three-month constant bending load tests at 55% stress level have come into use in North America for the creep and creep-rupture evaluation of engineered wood products.

(*b*) *Decreasing creep rate*. A criterion based on the decreasing creep rate is used to ensure that no individual specimen shows evidence of tertiary creep that signals an eventual failure. For example, creep in the first month is usually significantly greater than that in the second month, and second month creep is slightly greater than or equal to third month creep. This suggests that the specimen is exhibiting primary creep in the first month, and secondary creep in the second and third months. If the creep rate increases due to fluctuations in the environmental conditions, the test period is normally extended for a month to show that the increase is not due to the onset of tertiary creep.

(*c*) *Fractional deflection limit*. If a wood product satisfies the above two criteria but exhibits relatively high absolute creep deflections, a criterion based on fractional deflection is being used, that is, the ratio of total deflection and initial deflection, where total deflection is the sum of initial deflection and creep deflection. A fractional deflection requirement of 2.0 (i.e., a relative creep of 1.0) established from lumber data is used as the fractional deflection criterion.

(*d*) *Permanent deformation limit*. Although generally a one-month creep-recovery period is used to determine the permanent deformations, the recovery in fact continues for almost three times the constant load period. Naturally, most of the recovery happens in the first month. After the creep recovery period, the ratio of the permanent deflection and creep deflection can be determined. This ratio is a good indicator of damage, e.g., a ratio of zero indicates that the entire creep was due to delayed elastic deformations, and is fully recovered (purely viscoelastic) when the specimen is unloaded. Alternatively, a ratio of unity indicates that the entire creep deflection is nonrecoverable, viscous deflection. The creep-recovery test allows us to check if all the individual specimens show delayed elastic deflections, and if nonrecoverable viscous deformations are within acceptable levels after the removal of the load. The author has evaluated several laminated veneer lumber (LVL) products under a 3-month constant bending load at 55% of the fifth percentile point estimate of the control group.

Within a month of creep recovery, all individual specimens showed delayed elastic recovery. On average, these products recovered about 30% of the creep deflection during 1 month of creep recovery.

(*e*) *Residual stiffness and strength*. Predicting long-term properties of a new product from a three-month constant load test has limitations. An assessment of residual stiffness and strength may provide the engineers with increased confidence. The author, therefore, recommends that after the completion of creep and creep-recovery tests, the survivors be tested under short-term ramp loading with the same loading rate used for the control group. By collecting strength and stiffness data before and after the constant load tests, the strength and stiffness degradation due to long-term loading can be assessed. Several LVL products that the author evaluated did not exhibit any appreciable degradation when subjected to a constant bending load of 55% of the fifth-percentile point estimate of the short-term strength of the control group. Based on the results obtained to date using that stress level, a criterion based on an average 5% maximum degradation for the group may be used both for strength and stiffness.

The above five criteria may be used to evaluate product's equivalency in indoor environments. However, if the product was going to be used in other applications, appropriate additional testing would be necessary. For example, constant-load and slow ramp loading tests under high and cyclic humidity conditions would be very useful for assessing the performance for outdoor environments. For end-use applications requiring good performance in other conditions, e.g., elevated temperatures, it is advisable to design a program of testing, which includes those conditions.

4.2 Probabilistic Approach for Quantification of Load Duration and Creep Factors

Load duration and creep factors for a particular wood product may be determined by following procedures similar to those employed for lumber (Foschi *et al.* 1989, Ellingwood and Rosowsky 1991). These procedures include substantial testing and analysis. In summary, the following are recommended for this approach:

(i) Establish a minimum of five matched groups, one for short-term (control) testing, two for creep testing, and two for creep-rupture testing. Ramp test the control group to failure within 10min. (under constant rate of loading or displacement), and obtain short-term strength distribution. Test the creep groups under two relatively low constant stress levels (e.g., 15% and 30% of the mean strength of the control group) for 6 months. Unload the creep groups for 1

month for creep-recovery data. Test the two creep-rupture test groups under relatively high constant load levels (e.g., 60 and 75% of the mean strength of the control group) for 1 year. Fit a damage accumulation model to the time-to-failure data.

(ii) By using selected load distributions and the short-term strength distribution, develop reliability indices without DOL effects for different performance factors. Repeat the same analysis with the inclusion of a damage accumulation model to account for the load duration effects. The DOL can then be determined as the ratio of two performance factors obtained from those two cases, at a given reliability index. Creep factors may be developed by using the relative creep values, or by carrying out a reliability analysis similar to that described above, but using a creep model.

5. Test Considerations

The following parameters should be considered for creep and creep-rupture behavior: (i) intended application of the product which should be reflected in test conditions, service history, and experience; (ii) material size, span, grade, species, quality, and class; (iii) load type (ramp, constant, cyclic), mode (bending, shear, tension, compression, parallel or perpendicular-to-the-grain) and level; and (iv) process variables. Matching between constant-load test groups and control groups requires special care, e.g., with composite products, pair matching (cutting lengthwise into two pieces—test and control) has proven to be a reasonable method. Conditioning must be done in the same environment.

5.1 Short-term (Control) Testing

Usually, short-term tests and long-term tests are performed in different test machines, which may cause different results, e.g., if bending tests are used, the lateral supports in both bending test machines should be similar.

5.2 Long-term Testing

There are many designs of testing frames for constant load tests. Detailed descriptions of some of these may be found in SP-27 (Forintek Canada 1986).

6. Concluding Remarks

Creep and creep-rupture in wood are important parameters that should be considered in the design of timber structures. As described here, creep is a combination of elastic and viscous deformations that occurs in three stages. It is most strongly affected, in normal environments, by load level, load type, load duration, and moisture movement (drying and wetting); whereas temperature has a significant effect above 50 °C. Two methods are presented that can be employed to evaluate the creep and creep-rupture performance of wood-based products: a pass/fail verification method which requires producers to demonstrate equivalency of the creep and creep-rupture performance of their products to that of lumber, and a probabilistic method, useful for quantification of design factors for creep and creep-rupture. Finally, short- and long-term test considerations are discussed.

Wood: Macroscopic Anatomy

Wood is a cellular material produced by a living tree to support the leafy crown, conduct water and dissolved nutrients from the roots upward to the crown, store reserve food (primarily carbohydrates) that is later used for tree growth, and to synthesize extractives during heartwood formation or in response to injury. The anatomy of wood reflects these biological functions. Support and conducting cells are usually "pipe-like"; they have rigid walls, generally are longer than they are wide, and normally are oriented with their long axes parallel to the long axis of the tree. Water-conducting cells are dead hollow cells, as are the support cells in most commercially important US woods. Storage cells (parenchyma) generally are very small, and are aggregated into horizontally oriented structures called rays. In addition, in many hardwoods and a few softwoods there may be longitudinally oriented storage cells. Reserve food materials are moved "in and out" of the wood via the rays. The anatomy of wood affects its material characteristics. For example, the interfaces between rays and the longitudinal elements seem to be "weak points" in wood. It is at these interfaces and within the rays that separations between cells (checks) originate during wood drying, and wood is easiest to split.

As one would expect for a substance of biological origin, wood is a variable material. The types of woody cells, their relative abundance, and arrangements differ among species. There also is within species a variation in cell structure related to growing conditions, and within trees variation related to tree age. Major challenges for the forest products industry have been, and continue to be, the ability to grow wood that is predictable in its behavior and to match wood characteristics to product requirements.

1. Wood Types: Hardwoods and Softwoods

In the forest products industry, the terms softwood and hardwood are applied to two major groups of trees that correspond to two major botanical groupings. Softwood trees have seeds that are not covered, but are produced in cones (conifers such as pine, redwood, cedar, cypress). Hardwood trees produce covered seeds within flowers (dicotyledonous angiosperms such as oak, ash, maple, teak, mahogany). The use of the terms softwood and hardwood is somewhat unfortunate as it implies absolute differences between the two groups in the hardness of their woods. However, the wood of some hardwoods is softer than that of some softwoods (and vice versa). One of the world's lightest woods, *Aeschynomene hispida* ($30\,\mathrm{kg\,m^{-3}}$), comes from a dicotyledonous tree, and, in that sense, is a hardwood. For commercially important woods native to the USA the density of softwoods is 290–$600\,\mathrm{kg\,m^{-3}}$, average $410\,\mathrm{kg\,m^{-3}}$; of hardwoods is 320–$810\,\mathrm{kg\,m^{-3}}$, average $500\,\mathrm{kg\,m^{-3}}$. Density is more variable within tropical woods than it is within temperate-zone woods.

The wood structure of hardwoods and softwoods is distinct, with softwoods having the simpler wood anatomy. In softwoods, a single cell type, the longitudinal tracheid, functions for both support and conduction, and constitutes 90% of the wood volume (Fig. 1). Longitudinal tracheids are usually 100 times as long as they are wide, with lengths usually of 2–4mm, and up to 8mm in large softwood trees, such as redwood (*Sequoia*). Rays in softwoods account for no more than 10% of the wood volume, and are very narrow.

Hardwoods have vessels for water conduction, and fibers for support (Fig. 2). Vessels are composite structures composed of open-ended vessel elements that have relatively large diameters, thin walls, and large central openings (lumens). Individual vessel

Figure 1
Scanning electron micrograph of softwood block: X, cross-section; e, earlywood with longitudinal tracheids with relatively wide openings; l, latewood with longitudinal tracheids with narrow openings; R, radial section; r, ray extending across growth ring boundaries; T, tangential section (courtesy of N. C. Brown Center for Ultrastructure Studies, SUNY College of Environmental Science and Forestry).
Figure 2
Scanning electron micrograph of ring porous hardwood block: X, cross-section; T, tangential section; R, radial section; V, vessel. Note the wide vessels (V) that are filled with tyloses. In the conducting sapwood the vessels would be hollow. In this wood, the tyloses fill the vessels and reduce permeability (courtesy of N. C. Brown Center for Ultrastructure Studies, SUNY College of Environmental Science and Forestry).

elements are usually 25–300 μm wide and 0.2–1mm long. The composite vessels range from a few centimeters to more than 10m long. Fibers are narrow tubes (usually 10–30 μm wide and 1–2 mm long) with varying cell wall thickness. Support and conducting cells usually are dead at functional maturity, although in some species fibers are living in the sapwood and are involved in food storage. Ray size varies between hardwood species. In commercially important hardwoods, rays usually account for 10–30% of the wood volume, and vary from 1 cell wide and not visible to the eye (e.g., willow (*Salix* spp.) and cottonwood (*Populus* spp.)), to more than 20 cells wide and visible on all surfaces of the wood (as in oak (*Quercus* spp.)).

Proportions and arrangements of the different cell types, as well as cell wall thickness, differ from species to species. Woods that have a high proportion of thick-walled fibers are hard and heavy. Hickory (*Carya* spp.) is such a wood, and is the preferred material for tool handles in the USA. Woods with a high proportion of vessels and/or thin-walled fibers are soft and light. Balsawood (*Ochroma* spp.) is such a wood, and is used for model airplanes, and as an insulator because of the high proportion of open lumens.

2. Cell Orientation

The orientation of the woody cells within the trunk is of major importance in explaining many of the properties of wood. Cells that function in support and conduction, and, at times, some parenchyma cells, have a longitudinal orientation, i.e., the long axes of the cells are parallel to the long axis of the tree. Grain refers to the orientation of the support and conduction cells. In straight-grained wood, the support and conducting cells are oriented parallel to the outside of the tree; in spiral-grained wood, the support and conducting cells literally spiral (right-handed, left-handed, or alternating between the two) around the tree trunk. Some species (e.g., sweetgum (*Liquidambar styraciflua*)) are more apt to produce spiral grain than others. Straight-grained wood is preferred for most applications, as it is easier to dry without warping and twisting. However, in some mahogany trees, alternating spiral grain imparts a pleasing appearance to the wood, and such ribbon-striped mahogany is valued as a decorative veneer and for inlays.

Because wood is composed of cells oriented longitudinally and horizontally, it will have a different appearance depending on how it is cut, as different aspects of the cells are exposed (Fig. 3). A cross-section is produced when the cut is at right angles to the long axis of the tree. When a tree is cut down, the end of the stump reveals a cross-section. In this section, growth rings are evident as a series of concentric circles, and rays appear as fine lines crossing the growth rings at right angles. Longitudinal sections are produced by cutting parallel to the long axis of the tree. There are two types of longitudinal sections: radial and tangential. When the longitudinal cut is made by cutting parallel to the rays and perpendicular to the growth rings, a radial section is produced. In radial sections rays are viewed from the side, look like stripes, and have a "brick-wall" appearance with the individual cells in a ray being equivalent to individual bricks in the wall. Hard maples and oaks have a distinctive ray fleck on their radial surfaces. A tangential section is produced by cutting parallel to growth ring boundaries, or the surface of the tree, and cutting across the rays at right angles. The ends of rays are visible in tangential sections; ray height and width can be determined from tangential sections. Lumber cut along the radial section is termed quarter-sawn and that cut in the tangential plane is flat-sawn.

Wood behaves differently along the different axes. Water is lost most readily from the cross-section, and penetration of fluids (e.g., preservatives, pulping liquor) is easiest into the cross section. It is easiest to split wood longitudinally, particularly along rays, as it is easier to split cells apart, rather than cut across their cell walls. Most of the mechanical properties of wood are greatest along the grain, while shrinkage and swelling with changes in moisture content are less along the grain.

3. Growth Rings

New wood and new inner bark are inserted between existing wood and inner bark by cell divisions within
Figure 3
Block of red oak (*Quercus* sp.) showing bark (OB, outer bark composed of alternating layers of cork and dead food-conducting cells; IB, inner bark with functional food-conducting cells) and wood (SW, sapwood, in oak usually 10–12 outer rings; HW, heartwood, the region where the storage cells are dead). Cross, radial, and tangential surfaces are labeled as such, and the broad rays of oak are visible in all three surfaces.

the vascular cambium, a layer that is considered to be but one cell wide. Stripping the bark from around a tree can seriously injure (or kill) it, as usually the vascular cambium will also be stripped off, and the ability of the tree to form new conducting tissues is seriously compromised.

When trees grow in seasonal climates, they almost always produce trunk wood with growth rings. Cell production varies with the season, and there often are differences in the texture of the wood formed during different seasons. The wood formed at the beginning of the growing season is the earlywood (in north temperate regions often referred to as springwood); the wood formed later in the season is the latewood (in north temperate regions often referred to as summerwood). The latewood generally is denser and darker than the earlywood. Growth rings are visible because of the difference in texture between the latewood (usually comprised of relatively small and

thicker-walled cells) and the earlywood of the subsequent year (with relatively large and thin-walled cells). In the north temperate region, a growth ring usually represents the amount of wood accumulated during one year and so is often called an annual ring. In the tropics, growth rings can be distinct, indistinct, or absent. If growth rings are present, they do not necessarily represent the growth of a single year, since growth often reflects wet and dry seasons. Determining the age and growth rate of tropical trees is more difficult than for temperate woods because growth rings do not always correspond to annual rings.

The appearance and properties of wood are affected by the ratio of earlywood to latewood, and how well defined the differences are in the transition between these zones. Diffuse porous hardwoods do not have a pronounced difference between earlywood and latewood, and the size and spacing of the vessels is nearly the same throughout a growth ring (Fig. 4).
Figure 4
(A) Birch (*Betula* sp.), an example of a diffuse porous hardwood; vessel size and distribution is similar throughout the growth ring. (B) Ash (*Fraxinus* sp.), an example of a ring porous hardwood. The earlywood zone (EW) has large diameter vessels and the latewood (LW) has narrow vessels. Earlywood width does not vary much from year to year, but latewood width varies depending on growing conditions.

Almost all tropical hardwoods are diffuse porous. Ring porous hardwoods have earlywood with large diameter vessels, and a distinct latewood zone with small diameter vessels (Fig. 4). Approximately 25% of the hardwoods from the north temperate zone are ring porous. Some woods are intermediate between diffuse porous and ring porous and have a gradual change in vessel diameter throughout the growth ring (e.g., walnut (*Juglans* sp.)), and are called semi-ring porous.

Growth rate affects the density and openness of ring porous woods (e.g., oak (*Quercus* spp.), ash (*Fraxinus* spp.), hickory) more than it affects diffuse porous woods (e.g., birch (*Betula* spp.), maple (*Acer* spp.)). In ring porous woods, within a growth ring there is an earlywood zone that is of near-constant width each year, while the width of the latewood zone varies. Slow-grown ring porous woods with narrow growth rings will have proportionally more earlywood with a high vessel volume than latewood per unit area, and so will have a lower density than rapid-grown ring porous woods that will have proportionally more latewood with a high fiber volume and, consequently, a higher density.

Softwoods also vary in the proportions of earlywood and latewood, and the degree of difference between the two regions. Some species have an abrupt transition from the earlywood to the latewood, and a distinct band of latewood is formed (e.g., hard pines such as loblolly pine (*Pinus taeda*)). Others (e.g., soft pines such as eastern white pine (*P. strobus*)) have a gradual transition from earlywood to latewood, and not much latewood at all. The relationship between ring width and density in softwoods varies; in some species growth rate does not affect density, while in others an increase in growth rate can result in either a decrease or an increase in density.

Cell size and variation therein affect wood texture. Hardwoods with narrow vessels and fibers, and softwoods with narrow tracheids are fine-textured; hardwoods with large diameter vessels, and softwoods with wide tracheids are coarse-textured. The

hardwoods boxwood (*Buxus* sp.) and dogwood (*Cornus florida* L.) and the softwood yew (*Taxus* spp.) are noted for their even, fine texture and even wear during use. Ring porous hardwoods and softwoods with a distinct latewood band have an uneven texture, because of the pronounced difference in earlywood and latewood cell sizes. Some textures are correlated with particular regions of the world; hardwood trees with diffuse porous wood and large diameter vessels (more than 200 μm across) only occur in the tropics.

4. Sapwood and Heartwood

The outer wood with living parenchyma cells is sapwood. The number of years that the parenchyma cells live and therefore the width of the sapwood zone varies from species to species, but parenchyma cells eventually die, and the wood with only dead cells is termed heartwood. Often, but by no means always, the heartwood is darker colored than the sapwood. Before dying, parenchyma cells often manufacture extractives. These extra chemicals may color the wood, coat cell walls and passages between cells and thus lower permeability, change the affinity of the wood for water, alter its dimensional stability, and affect its durability (resistance to decay). For instance, heartwoods of redwood, cedar, and teak are noted for their durability and are used for outdoor furniture and shingles, but the sapwoods of redwood and cedars with very low extractive content are not resistant to decay.

4.1 Tyloses

During normal heartwood formation or after an injury, parenchyma cells adjacent to a vessel may ''grow into'' that vessel. This occurs usually in hardwood species where the interconnections between the vessels and the storage cells (ray parenchyma) are large. These infillings of the vessels by parenchyma cells are called tyloses, and they lower the permeability of the wood. Woods with tyloses are slower drying and more difficult to treat with preservatives than woods without tyloses. White oak is noted for having many tyloses and a very low permeability.

5. Reaction Wood

It is termed abnormal wood, but the ability to form reaction wood to maintain the vertical alignment of a tree is important for the long-term survival of tree species. Reaction wood is of widespread occurrence. In hardwoods, reaction wood is formed on the upper side of a bend or lean and so is termed tension wood. If the growth rings are eccentric it is likely that

tension wood is present. Tension wood often is difficult to recognize without microscopic examination, and can be found in straight stems. Tension wood fibers have a different wall structure than normal wood fibers. This variation is correlated with tension wood twisting and warping during drying, and being difficult to plane to a smooth surface. In extreme cases, logs with large amounts of tension wood will split immediately upon being sawn.

In softwoods, reaction wood is compression wood, and formed on the underside of a bend or lean. Compression wood also warps during drying, and is brash, breaking suddenly under load. It is also less permeable than normal wood, and has shorter cells. Unfortunately, pines are prone to form compression wood. Minimizing and eliminating compression wood improves the quality of softwoods for solid wood products as well as for pulpwood.

Wood: Moisture Content, Hygroscopicity, and Sorption

Wood is a hygroscopic material that has the ability to adsorb or desorb water in response to temperature and relative humidity of the atmosphere surrounding it. This affinity of wood for water is caused by hydroxyl groups accessible in the cell walls of wood. As a consequence, the moisture content of wood is one of the most important variables affecting its physical and mechanical properties.

1. Definitions and Types of Water in Wood

The moisture content (M) of wood is expressed as a ratio of the mass of water (kg) per unit mass of oven-dry wood (kg):

$$M = \frac{w_i - w_o}{w_o} \times 100\% \qquad (1)$$

where w_i is the initial mass and w_o is the oven-dry mass. In terms of wet basis, M is given by:

$$M = \frac{w_i - w_o}{w_i} \times 100\% \qquad (2)$$

The fractional moisture content (m) is given by $m = M/100$.

The elemental composition of wood is carbon, hydrogen, and oxygen. These are combined into organic polymers, cellulose, hemicelluloses, and lignin, which are the primary components of wood (Haygreen and Bowyer 1996). The approximate percentages of these polymers making up the cell walls are 40–50%, 20–35%, and 15–35% respectively. Secondary components are tannins, volatile oils, resins, and ash (Panshin and de Zeeuw 1980). The primary components each adsorb moisture; hemicellulose absorb more compared with cellulose and lignin (Stamm 1964). They are mixed in the cell walls in a complex and highly ordered manner, which is reflected directly in the physical and mechanical properties of wood (Panshin and de Zeeuw 1980). Some species of wood contain nonwater- or water-soluble extractives and have a significantly lower hygroscopicity than other woods.

There are two types of water in wood. The "water of constitution" is the water included in the chemical structure of wood and it is inherent to the organic nature of the cell walls. It cannot be removed without modifying the chemical composition of wood. The second type of water comes in three forms: "bound" or "hygroscopic" water which is adsorbed by sorption sites in amorphous areas of cellulose and hemicellulose present in the cell walls; "free" water which is liquid-like water in the cell lumen and voids; and "vapor" water which is present in voids and cell lumen unless the wood is completely saturated.

As wood begins to lose moisture when exposed to ambient conditions in the atmosphere, water leaves from voids and cell lumen first while the bound water content remains constant. The moisture content level which corresponds to lumen containing no free water (but will contain water vapor), while no bound water has been desorbed from the cell wall material, is known as the fiber saturation point (M_F). For most temperate woods, M_F is in the range 25–30%, and is lower for tropical woods that have higher extractive contents. As the moisture content of wood decreases below M_F, bound water will begin to leave the cell wall material; most of the physical and mechanical properties vary with moisture content below M_F. At a certain point, equilibrium is attained between moisture in the wood and that in the surrounding atmospheric environment. This is where the wood will not gain or lose any moisture with time and it is known as the equilibrium moisture content (M_E) of the wood.

2. Measurement of Moisture Content

Several methods are used to determine the moisture content of wood. ASTM Standard D4442 outlines the accepted methods to determine the oven-dry mass of wood. The oven-dry method is the sole primary method where it has the highest accuracy or degree of precision for research purposes. A forced-convection oven is required to be maintained at a temperature of 103 ± 2 °C throughout the drying time. Specimens are weighed using a balance of the desired precision and then are placed in the oven. The endpoint is reached when the mass loss in a 3 h interval is equal to or less than twice the selected balance sensitivity. Other methods outlined in ASTM D4442 are less precise: distillation, Karl Fischer titration, infrared (heating and absorption), microwave (heating and absorption), NMR, and vacuum-oven drying.

Two types of electric moisture meters are used to measure the moisture content of wood: resistance and dielectric or power-loss meters. These meters are suitable for industrial uses as they are nondestructive to the wood and give immediate results. The resistance meter uses the d.c. resistance of wood to indicate the moisture content and is limited to the moisture content range $M = 6\%$ to M_F. The dielectric meter is based on the capacitance property of the wood and is limited to $M = 0\%$ to M_F range or higher. Other industrial moisture meters that exist, but have their limitations, are: laser, mass (density), microwave, and gamma ray.

3. Sorption Isotherms

A graphical representation of the equilibrium moisture content as a function of relative vapor pressure, h, or percentage relative humidity, $H = 100h$, at a constant temperature is referred to as a sorption isotherm. There are six different sorption isotherms and the wood moisture isotherm is described as Type 2. Figure 1 shows the wood moisture sorption isotherm for desorption and adsorption.

Never-dried wood, referred to as green, has a desorption isotherm higher than oven-dried wood adsorption and desorption isotherms. Also, the oven-dried desorption isotherm is always higher than the adsorption isotherm. The two desorption isotherms are the same for below 50% relative humidity. The difference between adsorption and desorption curves is known as sorption hysteresis and is present for many hygroscopic materials (Skaar 1988). It is
Figure 1
Typical initial desorption, adsorption, and secondary desorption moisture isotherm for wood at 25 °C.

Figure 2
Effect of temperature on typical moisture isotherms for wood.

Figure 3
Sorption isotherms for the cell wall of Sitka spruce in relation to hydrostatic stress, P (reproduced by permission of Springer-Verlag from "Wood–Water Relations," C. Skaar, 1988, p. 78, Figure 2.26).

expressed as a ratio of adsorption (A) to desorption (D) moisture content for the same relative humidity. The A/D ratio ranges from 0.785 to 0.844 (mean $A/D = 0.812 \pm 0.023$) for softwoods and 0.79 to 0.849 (mean $A/D = 0.828 \pm 0.018$) for hardwoods. Sorption hysteresis decreases with increasing temperature and disappears at temperatures about 75 °C (Skaar 1988).

The immediate effect of higher temperatures on the sorption isotherm is to decrease M_E for the same relative humidity (Fig. 2). M_F is also reduced as the temperature increases (Siau 1984). This effect is reversible. The long-term effect of subjecting wood to higher temperatures is to reduce permanently the hygroscopicity, especially at temperatures above 100 °C. This effect is not reversible when wood is brought back to room temperature. The mechanical
properties are also reduced by long-term exposure to high temperatures (Stamm 1964).

The presence of extractives in wood depresses the isotherm at higher relative humidity, typically above 60%, resulting in lower M_F. Isotherms of extracted and unextracted wood coincide very closely at relative humidity below about 60% (Wangaard and Granados 1967).

Mechanical stress affects the sorption isotherm. At constant relative humidity, a compressive stress reduces the sorption M_E and tensile stress increases it. This is known as the Barkas effect (Skaar 1988) and is shown in Fig. 3.

Not all wood is dried to a zero moisture content before use. If a green piece of wood is dried to a moisture content of 12% (humidity approximately 50%) and then subjected to a higher humidity of 85%, the new M_E would follow the general trend of its adsorption curve. Cycling the wood through two humidities at the same temperature will result in a closed ("hysteresis") loop between the desorption and adsorption isotherms (Skaar 1988).

4. Thermodynamics of Moisture Sorption

The energy levels of the three forms of water in wood are shown in Fig. 4. Water vapor has the highest level, followed by free water in the cell lumen and voids, which has the same energy as ordinary liquid water. Bound water in the cell walls is in the lowest energy state, increasing with increasing moisture content to M_F. Above M_F, bound water has the same energy level as free water. At low moisture contents, the bound water energy is lower than that of ice. The heat of vaporization of liquid water, E_o (kJ mol^{-1}), is the energy required to evaporate liquid water and E_v is the energy required to evaporate bound water,
Figure 4
Relative energy levels of the different forms of water in wood as functions of moisture content.

Figure 5
Typical curves of ΔG and E_s as functions of moisture content.

called heat of vaporization of bound water. The difference between these heats of vaporization is called the differential heat of sorption, i.e., $E_v - E_o = E_s$. It is a measure of the excess binding energy of the water molecules to the wood substrate above that between water molecules in the liquid state (Skaar 1988). The differential heat of sorption is strongly dependent on the moisture content of wood, ranging from $0\,\mathrm{kJ\,mol^{-1}}$ at M_F to $22.8\,\mathrm{kJ\,mol^{-1}}$ near 0% moisture content, and has an exponential behavior (Fig. 5). An approximate empirical equation in the hygroscopic range is (Skaar 1988):

$$E_s = \exp(a - bm) \qquad (3)$$

where a and b are constants.

Addition of water to oven-dry wood results in an exothermic reaction and the heat generated is defined as the heat of wetting, W, having units of energy per oven-dry mass of wood. At 0% moisture content, the heat of wetting is the "total heat of wetting", W_o, and at higher moisture contents, the difference between W_o and W is defined as the "integral heat of sorption." Both of these terms are related to the differential heat of sorption; to keep units the same, Q_s is
used on a mass basis for differential heat of sorption, equal to E_s divided by the molecular weight of water ($0.018\,\mathrm{kg\,mol^{-1}}$). The relationship of E_s (and Q_s) and W is given by:

$$\frac{E_s}{0.018} = Q_s = \frac{-\mathrm{d}W}{\mathrm{d}m} \qquad (4)$$

If Q_s is known then W can be evaluated using Eqn. (3):

$$W = \frac{Q_s}{b} = \left(\frac{1}{b}\right)\exp(a - bm) \qquad (5)$$

The total heat of wetting, W_o, is the value when $m = 0$.

The free-energy change, ΔG ($\mathrm{kJ\,mol^{-1}}$), associated with moisture sorption can be calculated from:

$$\Delta G = RT \ln h \qquad (6)$$

where R is the molar gas constant ($\mathrm{kJ\,mol^{-1}\,K^{-1}}$) and T is the temperature (K). Since h is less than unity, ΔG is negative, the absolute magnitude decreasing with increasing h (Fig. 5). The corresponding decrease in entropy, ΔS, associated with sorption is given by:

$$\Delta S = \frac{(E_s - \Delta G)}{T} \qquad (7)$$

5. Theories of Moisture Sorption

5.1 Unimolecular Sorption

Langmuir (1918) was the first to develop a sorption theory for localized unimolecular layer adsorption on an energetically homogeneous surface which was then

generalized to describe adsorption on real energetically heterogeneous surfaces. Langmuir's equation is:

$$m = \frac{m_{\mathrm{m}}ch}{1 + ch} \qquad (8)$$

where m_{m} is the moisture content fraction corresponding to the unimolecular layer and c is a constant related to the energy of sorption Theoretical development and extension of the Langmuir equation considered three concepts: attractive interactions between adsorbed molecules; nonelectrolyte solutions; and analogies to bulk systems, where the absorbed gas was considered as a two-dimensional gas exerting a spreading pressure (Rudzinski and Everett 1992). The primary concepts applied to wood sorption are formation of unimolecular and multimolecular layers, mixture of wood water and polymer solution, and formation of water clusters. Venkateswaran (1970) presents a review of mathematical models developed for moisture sorption on cellulosic materials and Skaar (1988) details sorption theories for wood. Most of the models were all derived for adsorption characteristics; however, they are used for describing the desorption curve.

5.2 Multilayer Theories

The multilayer theories are both based on a "multilayering" concept. Figure 6 shows a schematic view of the formation of layers during sorption. The theories propose a unimolecular layer tightly bound to the hydroxyl groups of the wood constituents, and secondary layers which are thermodynamically the same, but different from the unimolecular layer. Brunauer *et al.* (1938) developed the BET theory which assumes a unimolecular layer tightly bonded to the wood substrate, and secondary and higher layers having similar characteristics as liquid water. Dent (1977) modified the BET theory to consider the secondary and higher layers to be thermodynamically the same, but different from that of liquid water. The Dent model has been shown to be a more general model with the BET and Langmuir models being limiting cases. The BET equation is given by:

$$\frac{m}{m_{\mathrm{m}}} = \frac{ch}{1-h}\left(\frac{1-(n+1)h^n + nh^{(n+1)}}{1+(c-1)h - ch^{(n+1)}}\right) \qquad (9)$$

If $n = 1$, it reduces to the Langmuir model. The Dent theory introduces a term to account for a different sorption energy associated with secondary sorbed water molecules. According to this theory

$$\frac{m}{m_{\mathrm{m}}} = \frac{b_1 h}{(1 - b_2 h)(1 - b_2 h + b_1 h)} \qquad (10)$$

where $b_1 = S_1/(S_0 h)$ and $b_2 = S_i/(S_{(i-1)}h)$, $i \neq 1$. S_i is the area covered by water in layer i and S_0 is the total

Figure 6

available sorption area. The term b_2 is a constant that relates the statistical thermodynamic partition function of the secondary sorbed molecules to that of an external condensed liquid in equilibrium with the saturated vapor. In the BET theory, it was assumed that this constant was equal to unity, since the energies of the secondary molecules were the same as liquid water. Term b_1 is defined as the ratio of the partition function of the primary molecules to the external condensed liquid in the saturated vapor. Dent considered the secondary sorbed water to be different from liquid water as well as different from the primary sorbed water. A key assumption is that the partition functions of the secondary sorbed water molecules are the same for all layers.

Le and Ly (1992) developed a multilayer theory (denoted as the L–L model) similar to the BET theory. The L–L model closely follows the development of the BET model; however, the former has different underlying assumptions. The BET model assumes that the adsorption site area, S_i, is covered by i molecular layers, whereas the L–L model assumes that S_i is the area occupied by the ith layer of the adsorbed molecule. Their model presents a possible way to determine the fractions of primary and secondary sites available during the adsorption process. Based on these assumptions, the following model was developed:

$$m = \frac{m_{\mathrm{m}}ch}{1 + ch}\left(\frac{1 - \alpha h^n - (1-\alpha)h^p}{1-h}\right) \qquad (11)$$

The fraction of the adsorption sites that contain up to n layers is α and the rest of the sites have up to $p > n$ layers.

5.3 Solution Theory

Hailwood and Horrobin (1946) developed a model for water sorption by assuming that the process is governed by the formation of a solid solution of water in the polymer and the formation of hydrates between water and definite units of the polymer molecule. The mixture of polymer, polymer hydrates, and dissolved water forms a single solid phase. The two-component system, water and polymer, exists in two phases, and the dissolved water molecules in the solid phase are assumed to be mobile. A one-hydrate model represents the experimental sorption data quite well, given by:

$$M_p \frac{m}{18} = \frac{\alpha h}{1 - \alpha h} + \frac{\alpha \beta h}{1 + \alpha \beta h} \qquad (12)$$

where $\alpha = Ka/h$, $\beta = K_1$, M_p is the molecular weight of polymer, K is an appropriate equilibrium constant between the different phases of water, and a is the activity of the water (essentially the relative vapor pressure). The first term on the right-hand side of Eqn. (12) represents the fraction of free dissolved water and the second term the various fractions of water present as monohydrate. The coefficients K and K_1 have been determined as functions of temperature for purposes of obtaining a generalized sorption isotherm at different temperatures (Skaar 1988).

5.4 Cluster Theory

Hartley and Avramidis (1993) used statistical thermodynamics to describe the formation of water clusters during adsorption. Although there is no model developed to form the basis of adsorption, it provided insight into the mechanism of adsorbing water in wood. During the adsorption process, as the moisture content increases, water molecules are randomly adsorbed, then "bridges" and small clusters of two or three water molecules are formed at $h > 0.35$. Finally, larger clusters of four to six molecules form at higher relative vapor pressures, $h > 0.9$. The process is not temperature dependent; however, changes of sizes at relative vapor pressures occur at lower h as temperature increases.

Wood: Nonstructural Panel Processes

Nonstructural panels include particleboard and fiberboard, with the difference being mainly in the geometry of the wood elements that comprise them. Fiberboard can be further categorized as hardboard, medium density fiberboard (MDF), and insulation board. Density is the differentiating factor between the fiberboard types, as well as some important processing steps. Hardboard has a density of 900 kg m^{-3} or more, MDF between 500 and 900 kg m^{-3}, and insulation board between 150 and 500 kg m^{-3}. The categorizing of panel types is not always clear. Composite panel manufacturing allows for many combinations of particles and fibers, a broad range of density, with a variety of adhesive types. Nonstructural panels can be engineered to meet very specific performance criteria (see *Wood: Nonstructural Panels**).

The term panel usually refers to a flat panel. However, any of the nonstructural panels can be molded into a three-dimensional configuration. The following discussion is limited to flat-pressed, wood-based panels, although other plant-based materials may be used. Wheat straw is used in North America to produce

particleboard, as well as bagasse, bamboo, flax, and others in many parts of the world. The basic manufacturing steps are the same.

1. Raw Materials

1.1 Wood

Sources for wood used in the manufacture of nonstructural panels vary depending on availability and desired panel properties. Some roundwood is used in order to improve control over the particle or fiber geometry; however, roundwood is comparatively expensive. The most common sources of wood are residues from lumber and plywood manufacturing processes, including planer shavings, sawdust, trim, and other mill residues. Pulp chips are used frequently in the manufacture of fiberboard products. Both hardwood and softwood species can be used. The adhesive and manufacturing parameters can be adjusted to accommodate many wood species.

1.2 Adhesive

Urea–formaldehyde (UF) is the most common adhesive used in the manufacture of particleboard and MDF. This adhesive is nearly colorless, provides a strong bond, has a fast cure time, and is relatively inexpensive. However, UF adhesive is not stable in wet or high-humidity environments, which limits its use to interior and nonstructural applications. In some cases melamine–formaldehyde (MF) is used for better moisture resistance, either by itself or mixed with UF adhesive. Some phenol–formaldehyde (PF) and methyl diisocyanate (MDI) adhesives are used in the manufacture of particleboard and MDF. These adhesives are more expensive than UF but are resistant to moisture. Panels using these adhesives are intended for applications where moisture intrusion is a possibility, and comprise a very small part of the nonstructural panel market (see Wood: Adhesives[#]).

Hardboard is generally produced using a small amount of PF adhesive (1–2% of the panel weight), although it may be produced using no adhesive. High temperature and pressure during hot pressing promotes ligneous bonding. Hydrogen bonds, and perhaps covalent bonds, are initiated in the hot-pressing step as the thermoplastic lignin component of the wood substance flows, allowing intimate contact between the fibers. It has been proposed that some of the hemicellulose polymers degrade to yield reactive sites where covalent bonds could form. The addition of PF adhesive to hardboard improves its strength, stiffness, and moisture resistance.

Bonding between the fibers in insulation board is due partially to hydrogen bonds. Usually starch or asphalt is added to the fibers to provide some adhesive bonding. Since no hot-pressing step is used in the manufacture of insulation board, and the panel density is low, the bond strength is very weak.

1.3 Wax

A petroleum-based wax is typically added to the particles or fibers during the manufacture of nonstructural panels. The purpose of the wax is to impart some resistance to the penetration of liquid water into the panel. The wax provides no resistance to the penetration of water vapor. The wax may be added in a molten state, or more commonly emulsified and added as a liquid at room temperature. The wax content is quite small, perhaps 0.5–1.0% based on the weight of the panel. Other sizing agents are often used in hardboard and insulation board, including rosin and asphalt.

1.4 Other Additives

Other materials are sometimes added to the particles or fibers depending on the end use. Fire-retardant chemicals and preservatives may be added prior to mat formation. Some hardboard is tempered, which involves the addition of oil before or after (usually) hot pressing. Linseed, tung, soybean, and tall oils are used typically for tempering. In the case of UF adhesive, additional urea may be added as a scavenger of excess formaldehyde during the manufacturing process.

2. Particleboard Processing

2.1 Particle Preparation

Depending on the starting raw material, the preparation of particles suitable for particleboard may involve a variety of machines and processing steps (Fig. 1). In general, these machines employ knives, hammers, or grinding disks to break down the wood into small pieces of the desired size and shape. Small particles are desired for the surfaces of particleboard to impart a smooth and uniform texture. Particle sizes are usually defined in terms of a screen classification, since the particles have an irregular shape. Surface particle sizes may range from 0.5 mm down to individual fibers of approximately 50 μm. Particles to be used in the core of particleboard are thicker and longer, and usually much more variable in size and shape than surface particles. Core particles are long and slender, with length of perhaps 1–10 mm and thickness of 0.5–1 mm.

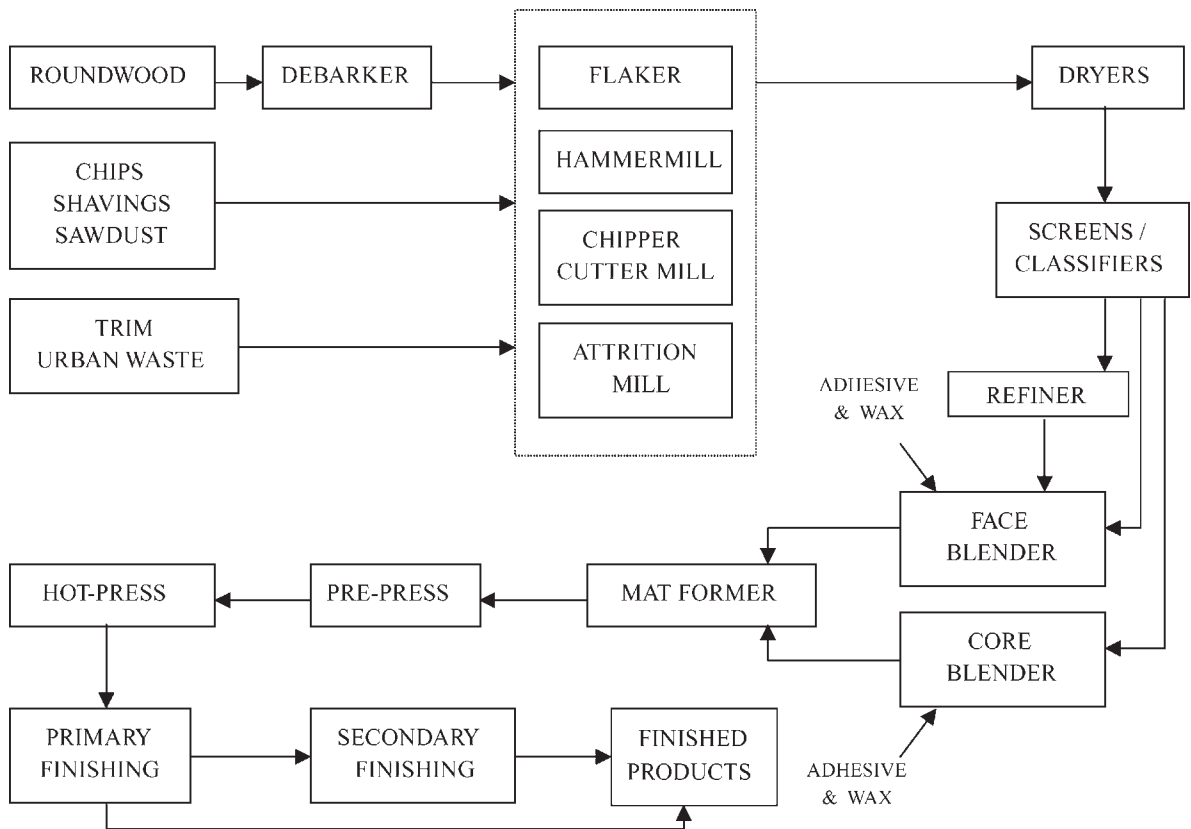
Roundwood (logs) must have the bark removed in a debarker prior to particle preparation. The presence of bark in particleboard generally reduces the product quality. The logs are then fed directly to a long-log flaker to produce relatively slender particles, or cut into short bolts to be fed to a chipper. Larger


Figure 1
Schematic diagram of particleboard manufacture.

sawmill residues, such as end- and edge-trim, may also be fed to a chipper to produce a wood chip. Such a chip must be further reduced to particles or fibers.

Smaller wood residues, such as plywood trim, chips, planer shavings, and sawdust, may be fed directly to a hammer mill, flaker, or attrition mill. Hammermills and impact mills are crude breakdown devices that literally beat the wood into smaller pieces. Flakers, of which there are several designs, use knives with precise set points to produce a uniform particle geometry. Attrition mills, also called refiners or "fiberizers," employ a shearing action to tear wood into bundles of fibers. In an attrition mill the wood to be processed is forced between two opposing disks, with one or both disks revolving at a high velocity. The disks are machined with ribs and channels to impart a shearing action when the wood passes between them. Attrition mills usually are operated in conjunction with a pressure vessel, which preheats the wood in steam for the purpose of softening the fibers prior to refining. Not all particleboard processing uses attrition mills. However, the fine wood-fiber bundles are used for the surface layers of particleboard.

Particles are segregated typically by size using a variety of mechanical screen systems. Usually face (smaller) particles and core (larger) particles are separated. Also the very small particles, called fines, are removed and used for fuel, and particles that are too large for the core are further refined and placed back into the process. Screening may occur prior to drying, or more likely after drying.

2.2 Particle Drying

Moisture content of the wood particles is a critical factor in the manufacture of particleboard. Moisture content influences adhesive bonding, heat transfer in the hot-pressing step, and the development of density variations in the panel. The most common method of wood particle drying is the rotary dryer. Rotary dryers consist of a large rotating drum, with its rotating axis in the horizontal position. In the drum the wet wood particles are in direct contact with the hot drying gases. The drying gases are a mixture of combustion gases, usually from a wood-fired burner, and ambient air. The drying gases serve two purposes in

this continuous drying process: heat transfer to the particles and pneumatic conveyance of the particles through the drum. The slow rotation of the drum promotes mixing of the particles with the drying gases.

2.3 Particle Blending

Blending of particles with liquid adhesive is typically performed in a short-retention-time blender. These devices consist of a fixed, horizontal cylinder of less than 1m in diameter and 3–4 m in length. As the particles enter the cylinder they are agitated with a high-speed rotor and a series of paddles, which move the particles through the blender. Liquid adhesive is applied using spray nozzles near the particle inlet. Much of the adhesive distribution is accomplished by the tumbling action and rubbing together of the particles. Wax and other additions may also be applied in the same blender as the adhesive, either with separate spray nozzles, or mixed with the adhesive prior to the blender.

2.4 Particle-mat Forming

After the blending process, the particles, now referred to as furnish, must be formed into a mat. Forming is accomplished with a system called a forming machine, which consists of a series of bins, spreaders, and a continuous conveyor that immediately precedes the hot press. Core and face furnish are fed to separate bins, which in turn supply spreader heads that are positioned above the conveyor. The spreader heads distribute the furnish onto the conveyor in layers.

A three-layer particleboard manufacturing process would have two surface-layer bins, each with a spreader head, and one core-layer bin, with a spreader head. Five-layer, or more, particleboard would have more bins and spreader heads. The forming machine controls the amount of furnish deposited for each layer. Particleboard properties can be manipulated by changing the composition and amount of each layer. Adjusting the adhesive content and particle geometry of the furnish in each layer, along with the adjustments at the forming machine, permit the particleboard properties to be engineered for very specific applications.

2.5 Particleboard Pressing

The purpose of the hot press is to consolidate the loose mat of furnish into a panel. The hot press provides the mechanical force necessary to bring the particles together and the thermal energy needed to cure the adhesive. The amount of press time needed depends on the thickness of the panel, temperature of the press platens, and the type of adhesive. Three to five minutes is typical, for a thickness of 12–18 mm,

when using a platen temperature of 130–160 °C. Both continuous, belt-type hot presses and multiopening, platen-type hot presses are used.

2.6 Postpressing Operations

After hot pressing UF-bonded particleboard is quickly cooled to prevent thermal breakdown of the adhesive and allow off-gassing of formaldehyde. PF-, MF-, and MDI-bonded particleboard does not require cooling. The panels are then edge-trimmed and cut to size. The panels are visually graded using industry standards, and a testing procedure is followed rigidly to ensure product quality. Testing includes strength, stiffness, moisture resistance, and dimensional stability.

A variety of secondary processing operations, such as sanding, milling, surface lamination, direct printing, and embossing, also may be performed.

3. MDF Processing

There are many similarities between the manufacture of MDF and particleboard. Indeed, these products are used for many of the same products. The major process differences occur in the fiber preparation, drying, and blending operations (Fig. 2). See Sect. 2 for a description of the pressing and postpressing operations.

3.1 Fiber Preparation

MDF fiber is produced from chips and shavings using a pressurized refining system. This is essentially a thermomechanical pulping process. The fiber is actually a collection of fiber bundles and individual wood cells. Hardwood and softwood species will produce substantially different MDF fiber due to the anatomical differences in regard to cell type and density.

3.2 Fiber Blending

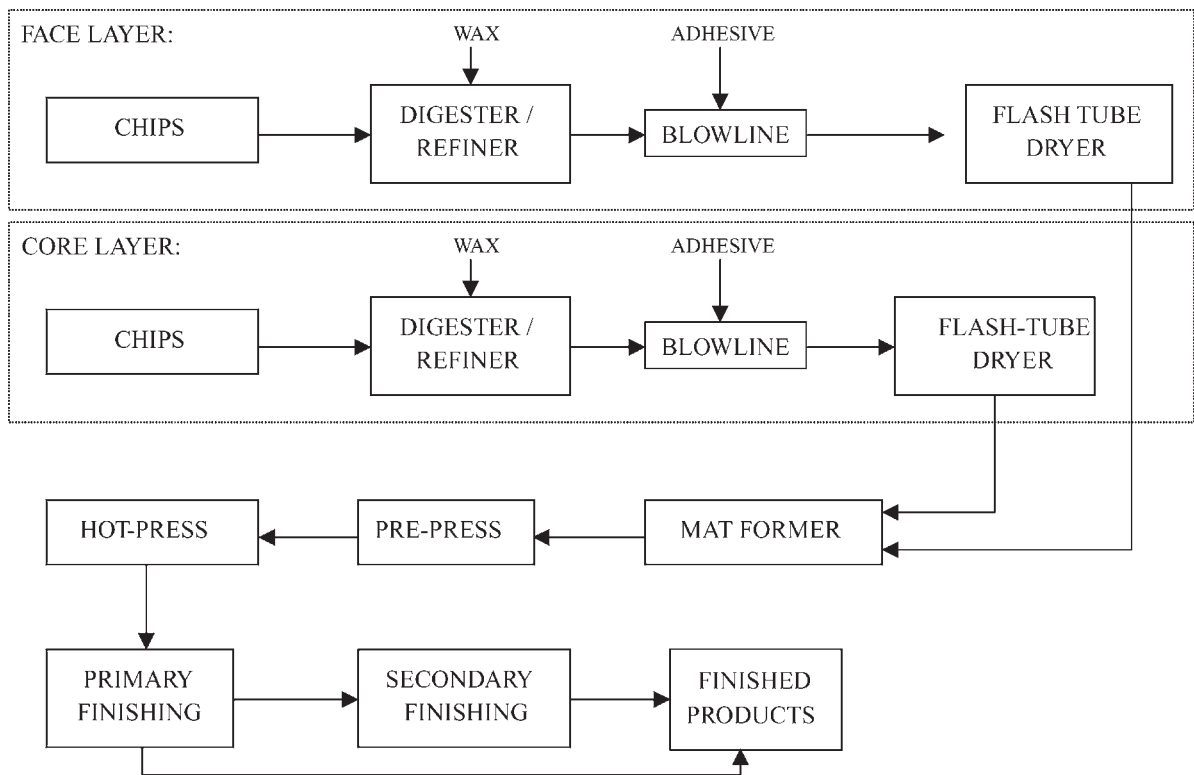
Adhesive and wax are added to the fiber either in the refiner or in the blowline. Blowline blending is the most common, and consists of an injection nozzle that is positioned inside the pneumatic duct between the refiner and the dryer. The distribution of the adhesive and the wax is accomplished to some degree by the atomization of the adhesive, but also due to the turbulent flow and mixing that occurs in the blowline after adhesive application. Some MDF plants may use a short-retention-time blender, such as employed for particle blending, instead of the blowline blending method.


Figure 2
Schematic diagram of medium density fiberboard manufacture.

3.3 Fiber Drying

Fiber dryers, sometimes called flash-tube or tube dryers, are pneumatic drying systems. Other than the blowers, there are no moving parts. The wet fibers are entrained by the hot drying gases at the inlet of the dryer and pushed through a long tube, approximately 50–100 m in length and 1m in diameter. At the end of the dryer the dry fibers are separated from the high velocity air using a cyclone separator. Retention time in the dryer is short enough to prevent cure of the adhesive.

3.4 MDF Forming

MDF mats are formed in a manner similar to particleboard. However, the spreader heads are replaced with felting heads, which break up clumps of fibers before they are deposited onto the conveyor. The mat formation is assisted with the application of a slight vacuum beneath the conveyor. In this case the conveyor is a porous screen, onto which the mat is formed. The vacuum allows the fibers to be filtered out of the air-stream and uniformly deposited on the conveyor. MDF mats are typically formed in three layers.

The remainder of the MDF manufacturing process is similar to particleboard manufacture.

4. Hardboard and Insulation Board Processing

The wood fiber used in the manufacture of hardboard and insulation board is produced in a manner similar to MDF fiber. Once the fiber is produced in the pressurized refining process there are three primary techniques for producing hardboard (Fig. 3). The difference is in the method of mat formation and the moisture content at the time of pressing. These methods are termed wet–wet, wet–dry, and dry–dry. Another difference between the hardboard processes is whether adhesive is added, which is not required for wet–wet process hardboard.

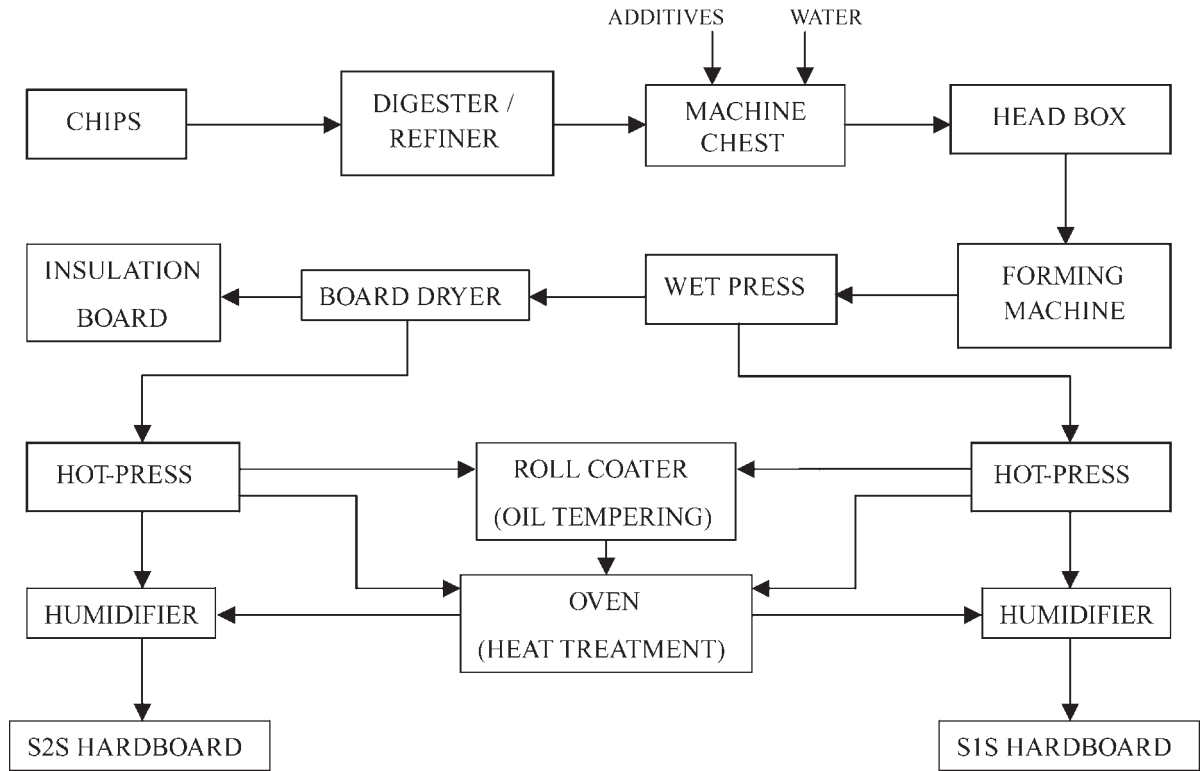
In the wet–wet method the mat is formed wet and consolidated in the hot press when wet. Starting with the wet fiber from the refiner, more water is added to produce a slurry of water and wood fiber. Although some adhesive may be added at this point, none is needed. A mat is then formed on a Fourdrinier machine. This procedure is similar to the manufacture of paper (see *Papermaking**). Some of the water is mechanically squeezed out of the mat prior to hot


Figure 3
Schematic diagram of hardboard and insulation board manufacture.

pressing, but the moisture content remains above 100% (dry basis). High temperature and high compaction pressure in the hot press results in a high-density panel. The bonding between the fibers is primarily the result of lignin flow and hydrogen bonds. Since the mat is wet at the start of hot pressing, it must be pressed on a wire mesh to allow the escape of steam. This causes an impression of the wire mesh on one side of the resulting panel, or what is called a smooth-one-side (S1S) panel.

The wet–dry process consists of the wet-forming step, but undergoes a mat-drying step prior to hot pressing. With the removal of the water before hot pressing the mat may be pressed on smooth, metal platens. This will produce a panel that is smooth-two-sides (S2S). As with the wet–wet process, adhesive is not needed due to the high temperature and high compaction pressure in the hot press, which promote natural bonding.

The dry–dry hardboard manufacturing process is similar to the MDF manufacturing process. The primary difference is that dry–dry hardboard is pressed to a greater density than MDF. In addition, a PF adhesive is used in dry–dry hardboard, whereas a UF adhesive is usually used in MDF.

Numerous secondary manufacturing processes may be employed with hardboard. Oil tempering and/or heat treatments are often used to improve moisture resistance. Overlay materials are commonly bonded to hardboard for such applications as paneling and furniture parts. Embossing and polymer coatings may be added for exterior siding.

The manufacture of insulation board follows the same procedure as is used for wet–dry hardboard, with the omission of hot pressing. Starch or asphalt is added to the furnish to enhance fiber bonding in this low-density product.

5. Summary

This article summarizes the basic processing steps in the manufacture of the most common types of nonstructural, wood-based panels. There are numerous panel configurations that are manufactured, as well as countless panel products that may be devised in the future. There is much attention paid to the blending of wood with nonwood materials, both natural plant fibers and synthetics, to produce new panel products. The nonstructural panel products are

produced in most parts of the world, and there are very few regional differences in the manufacturing technology. The classification of these panels is becoming less distinct, with greater emphasis on product performance than the method of manufacture or the raw materials.

Wood: Nonstructural Panels

Wood-based composite panels are constructed from wood and synthetic binder for a variety of applications. Most of these applications require mechanical performance but only those in building construction (i.e., sheathing, sub-floor, web-stock, etc.) are classified as structural. Often, nonstructural applications require a significant level of mechanical performance to function correctly. However, that performance is not regulated beyond product performance standards and poses low risk in the event of failure. Typical applications for nonstructural panels include furniture, case goods, interior doors, decorative paneling, and moldings.

These materials are developed to mimic the performance of wood with flat plate geometry. Typically, the panels are composed of wood in various forms that are bonded with thermosetting polymeric resins. Various manufacturing processes that center on flat pressing are employed and are discussed elsewhere. This article focuses on the definition, description, and use of lignocellulosic panels for various nonstructural uses.

1. Types of Panels

Both the production process and wood component form define a nonstructural wood composite. The majority of the composites are manufactured via a

Figure 1
Various nonstructural wood–composite panels (left to right decorative plywood, flakeboard, particleboard, medium density fiberboard, and hardboard).

dry flat press process. Alternative systems such as wet processing or extrusion, although technically applicable, are not the preferred methods of manufacture. Of the dry process nonstructural wood composites, four dominate: particleboard, hardboard, fiberboard (medium density), and decorative plywood (Fig. 1). Each of these composites can be found named and defined differently throughout the world. Below are definitions as offered by the American Society for Testing and Materials (ASTM) Standard D 1554 "Standard Definitions of Terms Relating to Wood-Base Fiber and Particle Panel Materials," the National Particleboard Association Standard NPA 4-73 "Standard for Medium Density Fiberboard," and the Canadian Standards Association Standard O115-M1982 "Hardwood and Decorative Plywood."

1.1 Particleboard

A generic term for a panel manufactured from lignocellulosic materials (usually wood) primarily in the form of discrete pieces or particles, as distinguished from fibers, combined with a synthetic resin or other suitable binder, and bonded together under heat and pressure in a hot-press by a process in which the entire interparticle bond is created by the added binder, and to which other materials may have been added during manufacture to improve certain properties (ASTM D 1554).

1.2 Hardboard

A generic term for a panel manufactured primarily from interfelted lignocellulosic fibers (usually wood), consolidated under heat and pressure in a hot-press to a density of $31\,lb\,ft^{-3}$ ($500\,kg\,m^{-3}$) or greater, and to which other materials may have been added during

manufacture to improve certain properties (ASTM D 1554).

1.3 Medium-density Fiberboard (MDF)

A dry formed panel product manufactured from lignocellulosic fibers combined with a synthetic resin or other suitable binder. The panels are compressed to a density of 31–50 lb ft^{-3} (500–800 kg m^{-3}) in a hot press by a process in which substantially the entire interfiber bond is created by the added binder. Other materials may have been added during manufacture to improve certain properties (NPA 4-73).

1.4 Decorative Plywood

A hardwood or softwood assembly made of three or more layers of wood veneers jointed together with an adhesive, of which one or both of the outer plies comprise veneers that have appearance as the primary consideration (CSA O115).

2. Raw Materials

2.1 Wood—Agricultural Residues

The manufacture of nonstructural wood composite panels is a global industry. As such the species of wood/agricultural fiber used for their production is dependent on available resources and is diverse. For composites such as particleboard, hardboard, and medium-density fiberboard, softwood (gymnosperm) species, namely pine, spruce, and Douglas fir dominate (Composite Panel Association 1999–2000). However, various other softwood/hardwood species, e.g., beech and birch, as well as agricultural crop residues are also regularly used (Composite Panel Association 1999–2000). Generally, panels will not be manufactured from one species alone. Rather a carefully controlled mixture of species will be metered into the production process. An example of the species mix that could be common to a European particleboard manufacturing facility is listed in Table 1.

Traditionally, the nonveneer wood composites industry has operated on residues from the forest products industry (Maloney 1997). Material of various forms: roundwood, sawmill residues and even recycled wood fiber can be used for panel manufacture. In countries other than the USA, the use of roundwood is common. However, because of their low cost and abundant supply, sawmill residues are the dominant raw material in the USA (Maloney 1997). As technology has advanced, and fears have grown over deforestation, crop stubble burning, and other environmental issues, the use of agricultural residues as an alternative feedstock for nonveneer composite panels has also increased. Currently, crop residues such as wheat straw, bagasse (sugar extracted sugar

Mixed broadleaf	10

cane), or ryegrass straw are all being used in the production of nonstructural wood composites. Irrespective of the form or species of the raw material to be used, various stages of furnish preparation are required before panel production is possible.

The decorative plywood industry is not able to make use of material gathered from sawmills, recycling schemes, or agricultural residue. Veneer peeled from solid timber is the mainstay of the industry. However, the species of this timber is still very much dependent on the resources available to the manufacturer, and will, therefore, vary throughout the world.

2.2 Adhesives

Due to the variety of applications in which nonstructural wood composites are used, the adhesive systems used to bind these products vary. Generally, four types of binder are used: urea formaldehyde (UF), melamine formaldehyde (MF), phenol formaldehyde (PF), and polymeric methyl diisocyanate (MDI). Of these, UF is the least expensive and most widely used. Maloney (1997) states that of the world's dry process composition board products, approximately 90% incorporate UF as their binder. The durability of composites made with such an adhesive is generally poor. Therefore, products incorporating UF-bonded composites can not be used in an environment where the risk of water contact is high (Dinwoodie 1981).

MF resin, although more expensive than UF, is also more resistant to moisture. This enables products bonded with MF to be used in situations where occasional product dampness may be a possibility (Maloney 1997). It is increasingly common for UF resins to be fortified with MF, so called MUF resins. Such blends, although more expensive than the UF, exhibit enhanced performance, allowing the finished product to be sold at a higher price.

PF resin offers far greater durability than UF, MF, or MUF systems. Products incorporating PF are deemed appropriate for exterior applications. There are two distinct types of PF resins available: resol or

one-stage and novolac or two-stage. Generally, resol PF resins are used for the manufacture of nonstructural wood composites; however, the commercial use of novolac PF resins is not unknown.

MDI resins, although relatively new and expensive, are gaining market share. The durability of such a resin system is particularly good. With the emergence of agricultural residue based products, MDI has proven to be the most appropriate binding option (Heslop 1997). Interest in MDI has also been enhanced by worries over the possible dangers associated with formaldehyde emissions from resins such as UF.

The resins outlined above could all be used for the manufacture of decorative plywood. However, the commonly used resins are PF, UF, MUF, and polyvinyl acetate (Sellers and Haupt 2000). As with nonveneer wood composites, the intended end use of decorative plywood will go a long way in determining the most appropriate resin system.

2.3 Additives

Various additives may be introduced to the composition during manufacture. The most common being moisture retardants, fire retardants, or decay inhibitors. The most frequently used additive is a moisture retardant or sizing agent, usually a wax emulsion. The sizing agent retards the rate of water penetration, safeguarding the composite against accidental wetting, while also aiding secondary gluing operations (Maloney 1997). The addition of a sizing agent also greatly improves composite performance during the standard 24 hour water soak test.

Fire retardants, although less common than moisture retardants, are occasionally added to composite panels. However, their use can also introduce other detrimental effects such as increased composite hygroscopicity (Maloney 1997). Compounds such as zinc borate, as well as inhibiting fire, also have the added benefit of inhibiting fungal decay. Decay inhibitors, although not commonly used in the USA, are popular and even required in other countries, e.g., Germany. Fire retardants, decay inhibitors, and moisture retardants can be added at various stages of panel manufacture. However, it is most likely that each will be added at the same time as the resin.

3. Panel Structure

Nonstructural wood composites generally have a layered construction. Layering is achieved by the variation of the wood components (Fig. 2) and/or the production of what is termed a vertical density profile. Composites such as fiberboard and hardboard are generally homogenous in particle size, i.e., fiber or fiber bundles. For this reason, fiberboard and hardboard panels are generally referred to as being of

Figure 2
Various wood–composite particle types (left to right fiber, surface layer particles, core layer particles, and flakes).

Figure 3
Typical vertical density profile of a hot pressed nonveneer wood composite.

single layer construction. However, layering of a fiberboard panel with high-density surfaces and a low-density core is common because of the production of a vertical density profile during hot-pressing (Fig. 3).

Composites such as particleboard are more commonly heterogeneous in their particle size, finer particles being laid on the top and bottom surfaces of the panel, and coarser particles being laid within the core region. This type of panel construction is referred to as being three layer (Fig. 4). By itself, this type of construction will lead to a panel with high-density surfaces and a low-density core. However, the layering effect is further compounded by the production of a vertical density profile during hot-pressing.
Figure 4
Layered construction of modern day particleboard (panel edge).

The production of a vertical density profile is due to a number of inter-related phenomena. As the hot-press makes contact with the mat, the top and bottom surfaces are consolidated and the resin cured, before the core region has been consolidated to final thickness. It is also common that the surfaces of a mat are of higher moisture content than the core, meaning that these areas are more easily consolidated than the core. Finally, smaller particles (if used for the surface layers) will merge more easily than larger particles, reducing interparticle voids, once again increasing surface density.

By altering the layered construction of a composite panel, its mechanical performance can be significantly altered. In general, those panels of higher surface density and lower core density will tend to exhibit better flexural properties and worse internal bond strength when compared to panels of similar overall density/resin content but more uniform vertical density profile. Variations in resin type and/or loading levels within a panel will also influence panel performance. It is common practice to use different adhesive systems, or application levels for different layers of a panel. A good example of this is the use of resins with faster cure rates in the core of a panel, enabling the various resins throughout a panel to cure as one, minimizing the time the panel spends in the hot-press. It is also common for more resin to be used in areas where fine particles (large specific surface area) are located.

Layering of particle size is also important for secondary processing. A fine, well packed surface layer will lend itself to good surface lamination or painting as telegraphing of large particles will be avoided.

Decorative plywood is also layered, the odd number of wood veneers being stacked with the grain of each being aligned at 90 ° to the next. It is important to note that any panel, regardless of its construction, should be symmetrical through its thickness. If it is not, warping of the panel is inevitable.

Irrespective of panel type, the layering a panel may or may not have prior to hot-pressing, or the vertical density profile desired after pressing, the hot-pressing procedure is uniquely important to panel performance. It is through this process that a composite's wood components are brought into contact, an intermediary layer of resin is allowed to harden or cure, and a

structure is formed that will be able to withstand the stresses subsequently applied to it.

4. Properties and Standards

Measurement of nonstructural wood–composite performance can take many forms. Composite strength is an obvious example: static bending strength, tensile strength perpendicular to the surface of the panel (generally referred to as internal bond strength), tensile strength parallel to the surface of the panel, compression strength parallel to the surface of the panel, shear strength in the plane of the panel, or edgewise shear strength. Other properties such as: static bending stiffness, fastener holding capacity, water sorption, thickness swell, linear expansion, hardness, abrasion resistance, surface smoothness, and general appearance are also important, and can limit composite use.

Numerous organizations around the world have established and constantly revise standards by which composite quality is determined. Each require various panel properties to be measured in order to characterize performance and several of these properties are common to most standards. Depending upon the overall performance of the composite, a grade or classification is then assigned. Generally, separate standards, or subsections of, address classification of the various nonstructural wood composites. Tables 2–4 list some of the characteristics by which the American National Standards Institute (ANSI), Joint Standards Australia/New Zealand Committee (AS/NZS) and the Comité Européen de Normalisation (EN), assess particleboard, MDF, and hardboard performance. The values listed represent the required performance of the highest-grade panel (standard application) endorsed by each particular organization. The assessment of decorative plywood is generally by both qualitative and quantitative methods, the diversity of which is beyond the scope of this review.

As both composite production and consumption becomes ever more international, the importance of unifying classifying standards has become paramount. At the time of writing, international unification of nonstructural wood-composite standards is proposed under the auspices of the International Organization for Standardization, while unification on a lesser level, namely the European Community, has already been established.

Wood: Strength and Stiffness

Wood is one of the oldest and best-known structural materials, and one of the few renewable natural resources. Wood is a desirable material for construction because it requires less energy to produce a usable end product than do other materials. Wood is also extremely versatile. Because wood has a wide range of physical and mechanical properties, species can be selected on the basis of how well they fit the requirements for a particular product. The ability of wood to resist loads depends on a number of factors, including the type, direction, and duration of loading; ambient conditions of moisture content and temperature; and the presence or absence of defects such as knots and splits. This article is concerned with the properties of clear wood and the factors that influence these properties.

1. Orthotropic Nature of Wood Properties

The cellular structure of wood and the physical organization of the cellulose chain within the cell wall make the physical and mechanical properties of wood dependent upon the direction of loading (see *Wood: Ultrastructure**). Wood may be described as an orthotropic material; that is, it has unique and independent mechanical properties in the directions of three mutually perpendicular axes (Fig. 1). The longitudinal axis L is parallel to the cylindrical trunk of the tree and therefore also to the long axis of the wood fibers (parallel to the grain). The tangential axis T is perpendicular to the grain but tangent to the annual growth rings, and the radial axis R is normal to the growth rings. Collectively, the tangential and radial directions are referred to as being perpendicular to the grain. The properties of wood parallel to the grain are higher than those perpendicular to the

grain, since the grain direction is also the direction of the primary bonds of the major chemical constituents of the wood cell wall.

1.1 Elastic Properties

The elastic properties of wood are those produced at low stress levels and are completely recoverable after

Figure 1
Three principal axes of wood with respect to grain direction and growth rings.

the loads are removed. Twelve constants, nine of which are independent, are needed to describe the elastic behavior of wood: three moduli of elasticity (E), three moduli of rigidy (G), and six Poisson ratios (μ). The three moduli of elasticity are denoted by E_L, E_T, and E_R for the three orthotropic axes. These moduli are used to characterize the unit deformation (or strain) in the orthotropic directions, and are usually determined from compression tests. However, data for E_T and E_R are not extensive. Average values for a few species are presented in Table 1 as ratios with E_L. The modulus of elasticity determined by bending (E_B) rather than by axial load may be the only value available for a given species. Average values of E_B determined by bending tests are given in Table 2 for selected species. As tabulated, these E_B values include an effect of shear deflection. The E_B values determined from bending tests are usually increased by 10% when estimating E_L for axial tests.

Values for the moduli of rigidity, also called shear moduli, are also given in Table 1 as ratios with E_L. The three shear moduli are denoted G_{LR}, G_{LT}, and G_{RT}, where the subscripts refer to the plane over which the shear strain is measured. When a member is loaded axially, the deformation perpendicular to

[a] Force at 5.6mm indention.

the direction of loading is proportional to the deformation in the direction of loading. The constants that characterize this proportionality are called Poisson ratios, and are denoted μ_{LR}, μ_{LT}, and μ_{RT}. Here, the first subscript refers to the direction of applied load and the second subscript to the direction of lateral deformation. The elastic constants, as well as the ratios of elastic constants, vary by species and the moisture content and temperature at which they are measured.

1.2 Strength Properties

When wood is loaded to higher stress levels beyond the elastic range, plastic deformation or failure occurs. Five strength properties that are commonly measured for design purposes include bending, compression parallel and perpendicular to the grain, tension parallel to the grain, and shear parallel to the grain. In addition, measurements are sometimes required for tensile strength perpendicular to the grain and side hardness. Strength data for clear, defect-free specimens for a few species are given in Table 2. Procedures for making these measurements using clear, straight-grained material are given in ASTM standard D143.

For clear defect-free wood, the bending test probably provides the most widely available strength property. The *modulus of rupture* (MOR) reflects the maximum load-carrying capacity in bending and is proportional to the maximum moment borne by the specimen. Modulus of rupture is an accepted criterion of strength, although it is not a true stress because the formula by which it is calculated is valid only within the elastic range. Compression strength parallel to the grain is much lower than tensile strength. During a bending test, initial yielding occurs on the compression side, followed by visible compression failures and enlargement of the compression zone. The neutral surface shifts toward the tensile side of the specimen as the tensile stress continues to increase. The maximum moment in the member is reached when failure in tension occurs. The MOR of clear wood is intermediate between tensile and compression strength parallel to the grain.

Ultimate compression stress parallel to the grain, UCS, when tested as a short column, is initially characterized by folding of the cellulose microfibrils. This folding can begin to occur at stress levels as low as one-half that of the ultimate failure stress. At higher stress levels, a similar folding takes place at the cell wall level, and eventually leads to gross failure of the specimen. In *compression perpendicular to the grain*, C-perp, failure occurs by collapse and flattening of the wood cells. During testing, clearly defined maximum load cannot usually be obtained, and only fiber stress at the proportional limit or stress at a defined deformation limit is reported. Although C-perp val-

ues do not show a particular maximum for either the radial or tangential orientation, values are often found to be a minimum at 45° to the annual growth increment for softwood species.

Ultimate tensile stress parallel to the grain, UTS, is difficult to obtain experimentally with clear defect-free wood. The value parallel to the grain is of the order of 45–120 MPa at 12% moisture content, whereas the *tensile stress perpendicular to the grain*, T-perp, may only be 2–6% of the parallel-to-grain value. Thus, it is difficult to get wood to fail in tension parallel to the grain without having excessive failure in tension perpendicular to the grain. For this reason, only a limited amount of data is available on the tensile strength of clear wood parallel to the grain. Values for T-perp are determined as an average of the values in the radial and tangential directions.

Shear strength parallel to the grain ranges from 3 to 15 MPa at 12% moisture content. Because wood is highly orthotropic, it is very difficult to get it to fail in shear perpendicular to the grain. Attempts to obtain shear failure perpendicular to the grain usually result in failure in another failure mode, such as compression perpendicular to the grain. A very limited amount of data suggests that shear strength perpendicular to the grain may be 2.5–3 times that of shear parallel to the grain.

2. Factors Affecting Wood Properties

2.1 Natural Characteristics Related to Wood Structure

Much of the variation in wood properties within and between trees can be attributed to density. The cell wall substance is actually heavier than water; with a specific gravity of about $1.5 \, \text{kg m}^{-3}$ regardless of species. The dry wood of most species nevertheless floats in water, and thus it is evident that part of the volume of a piece of wood is occupied by cell cavities and pores. Variations in the size of these openings and in the thickness of the cell walls cause some species to have more wood substance per unit volume than do other species. In the absence of knots and other defects, specific gravity is therefore an excellent indicator of the amount of wood substance present and is a good predictor of mechanical properties. Approximate relationships between various mechanical properties and specific gravity for clear straight-grained wood are given in Table 3.

A *knot* is that portion of a branch that has become incorporated in the bole of a tree. The influence of a knot on mechanical properties is primarily due to the interruption of continuity and change in direction of wood fibers around the knot. The influence of a knot on the performance of lumber depends upon the size, location, and shape of the knot as well as attendant grain deviation around the knot and the type of stress to which the wooden member is subjected. Knots

have a much greater effect on strength in axial tension than in axial compression. The effect on bending is somewhat less than that in axial tension.

In some wood products the direction of critical stresses may not coincide with the orthotropic axes of the material. This may occur by choice in design, or it may be a result of the way the wood was removed from the log. This *cross-grain* can have a major effect on mechanical properties. Elastic properties in directions other than those along the orthotropic axes can be obtained from elastic theory. Strength properties in directions other than parallel (P) or perpendicular (Q) to the grain can be approximated using a Hankinson-type formula:

$$N = \frac{PQ}{P \sin^n \theta + Q \cos^n \theta}$$

where θ is the angle to the grain. For bending and tensile strength, N ranges from 1.5 to 2, and for compressive strength from 1.5 to 2.0. For the modulus of elasticity an N value of 2 is often recommended.

2.2 Effects of Manufacturing and Use Environments

Many mechanical properties are affected by changes in *moisture content* below the fiber saturation point. Generally, most mechanical properties increase as wood is dried. The strength P at moisture content M in the range from 8 to 25% can be estimated by the following equation:

$$P = P_{12} \left(\frac{P_{12}}{P_g} \right)^{(12-M)/(M_p-12)}.$$

For the purposes of the formula, moisture content of green wood (M_p) is often assumed to be 25% for most species. ASTM D2555 gives "dry/green" ratios

of mechanical properties at 12% moisture content compared with green wood. Care must be taken if this formula is used at moisture contents very far below 12%. At low moisture content levels, the rate of change of properties becomes less than that predicted by the equation, and for some properties there may even be a maximum value with loss in property during further drying. Above the fiber saturation point, most mechanical properties are not affected by change in moisture content.

Temperature can have both immediate (reversible) and permanent (irreversible) effects on wood properties (see *Wood Products: Thermal Degradation and Fire[#]*). In general, one immediate effect is that mechanical properties tend to decrease as the temperature is increased (Fig. 2). There is an interaction with moisture content because dry wood is less sensitive to temperature change than is green wood. However, increases in temperature are usually accompanied by a reduction in moisture content. Permanent loss in mechanical properties can occur if wood is subjected to high temperatures over long periods. The magnitude of this effect depends upon temperature, duration of exposure, wood moisture content, and wood property. Permanent effects resulting from temperature are discussed in a report by the US Department of Agriculture Forest Service (1999).

In warm, moist conditions wood may be subject to *decay*. Decay fungi remove wood substance, thus lowering the gross specific gravity of the material. Strength losses can occur rapidly, even during the early stages of decay before noticeable loss in mass has occurred (see *Wood Products: Decay During Use**).

Mechanical properties, as given in Table 2, are usually referred to as static strength values. The tests of such properties are commonly conducted at a rate of loading such that failure occurs in 5–20 min. Higher values are obtained when wood is loaded
Figure 2
Immediate effect of temperature on bending strength, tensile strength perpendicular to grain, and compression strength parallel to grain. Variability is indicated by the width of bands.

faster, and lower values when it is loaded slower. Load capacity decreases from the static values by about 7–8% for each decade increase on a logarithmic time-scale. Thus, a wooden member subjected to a continuous bending load for 10 years may carry only 60% or less of the load required to produce failure in a static test. *Creep* is additional time-dependent deflection over that resulting from elastic deformation which occurs when wood is subjected to a constant load over a period of time. Changes in climatic conditions during a duration of load or creep test may produce a lower load capacity and more creep than that observed under constant conditions of temperature and moisture content. These effects can be quite substantial for small wood specimens. Fortunately, such changes are moderate for most wood structural members in typical service environments.

2.3 Allowable Engineering Properties of Lumber

When sawn, lumber yields wood of varying quality. Grading rules quantify the quality of lumber required for specific uses. Testing procedures for lumber and procedures for assigning allowable properties to the structural grades of lumber are given in ASTM standards such as D4761, D245, and D1990. In the USA, the National Design Specifications summarize allowable properties for structural grades of lumber and provide adjustment procedures for environmental and end-use conditions. The latest versions of national design specifications should be consulted when designing wood structures.

Wood: Structural Panel Processes

This article discusses the processes used to produce oriented strandboard (OSB) and structural plywood (for information on particleboard, fiberboard, and hardboard see *Wood: Nonstructural Panel Processes**).

The manufacturing process is designed to create structural panels by converting logs into veneer or flakes, combining these wood particles with adhesive, wax, and other additives, arranging them in a loose mat, and finally consolidating this mat under heat and pressure to form a large panel. Panel sizes can range from 1220 mm to 3660 mm wide and from 2440 mm to 8534 mm long. Regardless of whether the product is OSB or plywood the unit operations are basically the same although the equipment is quite different. These operations can be grouped as follows:

(i) the "green end" consisting of wood receiving, handling, sorting, preparing, and flaking or peeling;

(ii) particle drying (removing moisture);

(iii) applying adhesive to veneers or flakes;

(iv) forming a loose mat of flakes or veneers; and

(v) pressing the mat using heat and pressure to create a structural panel.

1. Raw Material: Wood

Wood makes up more than 90% of the panel. Therefore, the species available and the quality of the resource are very important to the successful operation of the manufacturing facility. Structural plywood and OSB can be made from many species although not all species will produce panels of equal properties.

The success of the manufacturing process is influenced strongly by raw material quality. Each mill sets requirements regarding the size of logs, the allowable species, the form such as crook, sweep, knots, and the amount of degrade such as decay that will be allowed. These requirements will have an impact on the efficiency of an operation. For instance, small diameter crooked logs or logs with considerable decay will increase waste and reduce the yield of on-grade veneer or flakes. Under these circumstances, manufacturing a given quantity of finished product will require handling more logs and disposing of more waste, thus increasing costs compared to using only high-quality, sound logs. In areas where there is little competition for wood, a mill will be able to set and maintain strict limitations on the quality of wood that will be accepted. However, in many areas where there is strong competition for wood, a mill may have little or no choice in the quality of wood that it receives unless considerably more is paid for it.

1.1 Woodyard

The purpose of the woodyard is to receive, inspect, and place into storage logs that meet the quality requirements of the mill. Wood is obtained either from company-owned lands or purchased from independent contractors who log public and private forests. Depending on the area traditions or the design of the mill, logs are purchased as pulpwood (about 2540 mm long) or tree length. Wood is received at the truck scale, and is purchased either by weight or volume. If it is weighed many mills will use seasonal moisture content factors which account for the fluctuations in moisture content of the wood throughout the year. The truck scale is usually the first point of inspection and the first opportunity to reject wood that does not meet quality standards. Once accepted the logs are stored. Some mills (especially plywood mills) will store logs in ponds or spray water onto the logs during storage to reduce degrade such as blue stain and to prevent the logs from drying. This is rarely done in the OSB industry. Most woodyards are not paved, although paving reduces the amount of sand, rocks, grit, and other debris carried into the process. Paving reduces the frequency of cleaning the conditioning ponds, reduces the maintenance on conveyors, chains, etc., and increases the knife life during the peeling and flaking operations. The rotation out of the woodyard is very important since wood recovery is highest when processing freshly harvested wood. The "first in, first out" scheme in inventory management is desirable.

(*a*) *Species mix.* Logs are either segregated by species or species groups, or well mixed as they are removed from the woodyard. Plywood plants usually process species separately or by groupings based on the strength and stiffness of the wood. The resulting veneer is kept separated throughout the process and the veneer from stronger and stiffer species is used in the surface layers of the panel. OSB plants may segregate and process species for use in the surface or core layers, but this is not common. OSB plants using more than one species must achieve good mixing to ensure consistent properties. This is accomplished as operators remove logs from inventory and put them into the conditioning ponds. If species are not well mixed then the only alternative is to manufacture a product at sufficiently high density and resin content to ensure that the species with the worst properties will perform adequately in the final panel.

1.2 Wood Preparation

The logs must be prepared in such a way that the resulting wood particles—veneers or flakes—will have the required dimensions, the smoothest possible surface, the least amount of cell wall damage, and the least amount of fines (waste particles). Minimizing wood damage is of primary concern in all of the unit operations at the green end of the mill and especially during the conversion of the log into the basic wood element used for panel manufacturing. Turner (1954) clearly demonstrated the effect of particle type and cell wall damage on the final properties of panels. He concluded that the particle shape and cell wall damage are of primary importance and have a greater influence on strength than resin content. Geimer *et al.* (1985) investigated the effect of wood damage in flakes on final properties of flakeboard (OSB) and concluded that flakes damaged during the flaking operation or during hot pressing could reduce significantly tensile strength and internal bond. Therefore, producing high-quality, undamaged veneer or flakes is the most important consideration in the structural panel process. Many people claim that the wood preparation area is where the structural panel is made, and, indeed, errors made in this area can have an enormous impact on profitability. Mistakes in manufacturing that occur in the preparation phase can only be corrected by using additional resin or increasing the density of the panel, which can increase costs significantly.

The most important considerations in converting logs to veneer or flakes include:

(i) Log conditioning or heating the wood to a proper temperature for the species. Wood temperature has a large effect on the quality of the veneer and flake. Surface smoothness, geometry, cell wall damage, and fines generation are all affected by the temperature of the log. If the wood is frozen it is impossible to produce an acceptable veneer or flake due to shattering, wood damage, and fines generation.

(ii) Proper orientation of the log to the knife during peeling or flaking. Whether peeling veneer or

cutting flakes or strands it is critical that the log be parallel to the knife and that the grain angle in the resulting wood element is aligned in the long direction of the resulting wood element. Grain deviation through the thickness or in the plane of the veneer or flake should be minimized.

(iii) Proper knife cutting angle. The angle between the log and the knife is critical. Low- to medium-density hardwoods such as aspen will produce excellent flakes at 32–35° cutting angles while softwood species such as southern pine produce better quality flakes using 28–30° cutting angles. Veneers are produced at cutting angles of 18–23°.

(iv) Proper pressure of log against knife. There must be enough pressure to minimize movement between the log and the knife, but not so much that excessive compression of the wood occurs. This will result in excessive thickness variation and cell wall damage (wood failure).

(v) Proper speed. The speed between the log and the knife can influence greatly the flake quality.

Wood preparation begins with log conditioning, especially in cold climates where freezing is common. OSB mills typically have log conditioning ponds or vats to thaw wood. Plywood mills often use steaming chambers or hot water vats to elevate the temperature of the logs. The OSB industry tends to remove bark after the logs have been conditioned whereas the plywood industry usually removes the bark before conditioning the logs. Logs are loaded into one end of the pond or chamber and are discharged from the other after reaching the desired temperature. Each species has an optimum temperature necessary to produce veneer or flakes with acceptable surface quality and strand dimensions. An excellent discussion of proper wood conditioning is given by Lutz (1974). Acceptable veneer or flakes cannot be made from frozen wood. Frozen wood shatters during peeling or flaking. If any acceptable wood elements are produced, the surface quality is extremely poor—rough and uneven. The percentage of on-grade flakes in OSB is greatly reduced when processing frozen wood and the fines content is very high. Simply thawing wood will not ensure that veneer or flakes will be acceptable and Lutz presents a figure showing the optimum temperature for peeling veneer from various species. For instance, quaking aspen (*Populus tremuloides*) should be conditioned to about 21 °C, yellow poplar (*Liriodendron tulipifera*) to 38 °C, and Douglas fir (*Pseudotsuga menziesii*) to about 55 °C.

Logs should be heated uniformly from the outer surface to the core. However, often this is not practical due to the long time required. Therefore, many mills will peel or flake logs when the core temperature is just above freezing (4–5 °C) in the winter to ambient summer temperatures (about 21 °C). Many plywood and OSB mills located in areas where winter temperatures are moderate, and freezing is not common, do not have steaming chambers or log

conditioning vats. The reasoning used is that acceptable quality structural panels can be produced even if the wood is cold but not frozen. However, these mills will tend to use more resin or manufacture a higher-density panel to offset the poorer quality of the resulting particle.

Bark is structurally weak compared to wood and is removed from the logs before peeling or flaking. Sand and grit is often embedded in bark, which reduces knife life during peeling or flaking. Debarking is accomplished by using ring debarkers (most common) or large, rotating drum debarkers, and may be done before or after log conditioning. Bark is used as fuel at the mill or sold for other uses. After the logs are properly conditioned and debarked they are peeled or flaked. Although the plywood industry usually maintains the length of veneer (grain direction) at about 2440 mm, the OSB industry generally produces flakes which are 75–150 mm long. Several studies (e.g., Brumbaugh 1960, Geimer and Price 1978) have shown that this is a sufficient length to achieve desired properties when aligned properly.

The structural plywood industry usually produces veneer using rotary lathes. The peeler logs are fixed on each end by chucks and the log is turned against a knife. Lutz (1974) states that knife cutting angle and pressure bar positioning are extremely important in creating high-quality veneer. The only movement should be the log turning against the knife and all other movement between the peeler log and the knife must be minimized. All veneer has tight and loose sides. The loose side refers to the small fractures—lathe checks—which occur on the knife side of the veneer as it is separated from the log. Proper knife grinding, proper knife cutting angle, and proper pressure applied by the pressure bar will ensure high-quality veneer with the least fractures on the loose side and with smooth surfaces. Veneer is fed onto long conveyors, which act as storage to handle the surge of veneer as it exits the lathe. A clipper is located at the end of the conveyor. This is a knife with rapid vertical movement. As the veneer moves beneath the clipper it is activated to cut the long ribbon of veneer into proper widths and to remove defects such as knots and splits.

The ring flaker is the most common machine used by the OSB industry to produce flakes. These machines have a series of knives (30 or more) set into a ring, and the ring and motor are mounted onto a moving carriage. Logs are fed into the center of the ring, held firmly in place and the rotating ring is moved into and through the logs. The knives extend slightly beyond the ring to allow this movement. Flakes pass through the ring and are collected on a conveyor beneath the machine and transported to a green flake storage bin. Proper knife cutting angle and accurate placement of knives into the flaker ring are important in achieving a high yield of good-quality flakes. The carriage hydraulic system must be

capable of moving the knife ring into the logs smoothly and at a consistent speed. Any inconsistencies and any movement of the logs will lower the flake quality, increase thickness variation, and increase the percentage of fines. Some manufacturers will remove the fines before the flakes are conveyed to the green bins.

The removal of defects from green veneer by the plywood manufacturer at the clipper and the removal of fines from the green flakes in OSB by screening is an important step in the process. By removing unusable material before drying, dryer capacity and energy is used to remove moisture only from on-grade material, which improves the efficiency of the process. The rejected material can be used as fuel.

2. Drying Wood Veneer and Flakes

The purpose of drying is to reduce the moisture content of veneer and flakes. The moisture content of the wood particles entering the dryer can be more than 100% (dry weight basis) and must be reduced to between 2% and 12% moisture content. Drying must be done in a manner that reduces defects such as surface deactivation (resulting in poor adhesive bonds) and buckling. Drying veneer is done using mechanical dryers, which not only transport the veneer through a hot, dry environment, but also apply restraining forces to reduce the degree to which the veneer will buckle. These conveyor dryers have several levels. Each level has closely spaced opposing rollers, which apply the restraining force as the veneer moves between them. Controlling veneer thickness at the lathe (absolute and variability) is critical to successful drying. The areas of greater thickness within a sheet of veneer or between sheets will dry more slowly resulting in higher moisture content. The temperature of the air, velocity of the air impinging on the surface of the veneer, and how much veneer is in the dryer will affect the final moisture content and the variability of moisture content between sheets of veneer. Also, mixing sapwood and heartwood veneer can result in moisture content variability.

The OSB industry usually uses single or triple pass rotary drum dryers to reduce the moisture content of flakes. These dryers are large rotating drums with internal structures enabling flakes to pass through the dryer just once or three times. It appears that selection of single or triple pass dryers is based on personal preference. There is little consensus as to whether one has an advantage over the other either in level of emissions, flake breakage, inlet air temperatures, or final flake moisture content. Conveyor dryers, while not common, are used in some OSB plants. These dryers place flakes on a screen conveyor and transport them through a long multiple-decked dryer. Hot air is forced through the screen and the mat of flakes removing moisture. The manufacturers

of these dryers claim less flake breakage, and lower temperature drying resulting in less dryer emissions. Pollution from any dryer can be significant. Manufacturers approach this problem either by lowering the inlet air temperature or by installing end-of-pipe control systems. There is a significant benefit to the former approach in that emissions are reduced by lowering air temperatures, thereby reducing the costs of purchasing, installing, and maintaining pollution abatement devices. In addition, the surface characteristics of the veneer or flake may be improved leading to better adhesive bonding and lower resin costs.

2.1 Dry Veneer and Flake Storage

In plywood manufacturing, veneer exits the dryer and is checked for moisture content. Wet pieces or pieces with significant wet spots may need to be dried further. Veneer is sorted by grade and width. Defects such as knots may be removed and a patch inserted if the grade of the finished panel requires smooth, defect-free surfaces on one or both sides of the panel. In addition, for certain grades or for larger panels (the majority of structural plywood is manufactured in standard 4 ft by 8 ft panels in the USA and in 1200 mm by 2400 mm panels elsewhere) veneer can be edge glued to create a continuous sheet. In the OSB process, dry strands are usually screened to remove fines and then conveyed to a dry flake storage bin. These bins are designed to spread the incoming material so that flakes with small variations in moisture content will not remain together and form a high-moisture pocket. The outlet end of the bin is designed similarly so that strands that passed through the dryer together are not fed out of the bin together.

3. Applying Adhesive

The purpose of this operation is to apply the proper amount of adhesive to veneers or flakes. The distribution of adhesive on the surface of the veneer or flakes is a critical factor in the performance of the structural panel. Those surfaces that are to receive adhesive should be uniformly covered with the proper amount of adhesive.

Structural panels are required to be glued with adhesives that are water resistant. The primary adhesive in both the plywood and OSB industries is phenol formaldehyde (phenolic), which is synthesized from phenol and formaldehyde. In addition, the OSB industry uses methylene biphenyl isocyanate (also known as isocyanate or MDI). These adhesives cure rapidly when subjected to elevated temperatures during the pressing operation. There are a variety of means available to alter the rate of cure, so that adhesives used in the core of OSB, for instance, will cure more rapidly and at lower temperatures than those used in the surface layers.

Plywood manufacturers use extenders to improve the flow of adhesive on the surface of the veneer and to increase the open assembly time (the time between the veneer assembly and when it is pressed). Adhesives can be modified to allow for differences related to species and seasonal changes.

Roll spreaders, spray lines, curtain coaters, and foam glue extruders apply phenolic adhesives to sheets of veneer in plywood manufacturing. The choice of equipment is dependent on the design and capacity of the process. The OSB industry primarily uses large rotating drums within which are either spinning disks or spray nozzles. These drums are angled and flakes are conveyed into one end. Adhesive is pumped through spray nozzles or onto the surface of a spinning disk. Both devices create droplets, which are discharged towards the mass of flakes. In both plywood and OSB manufacturing the accurate control of wood and adhesive is necessary to meet the required product specifications and to minimize variability within and between panels.

4. Mat Formation

In plywood manufacturing, the veneers with adhesive are quickly assembled into a loose mat. The proper grade of veneer must be placed in the appropriate position within this assembly. Veneers of lower strength or with more or larger defects can be placed in the core while the highest strength veneers with the fewest defects are placed on the surface. Plywood alternates the grain direction of adjacent plies. Surface veneers have grain running in the long direction of the panel. The plies just below the surface veneers have the grain running at right angles to the long direction. This alternating grain direction continues throughout the thickness. Linear expansion, strength, and stiffness are improved in the cross-panel direction while cupping, twisting, and warping are reduced by alternating the grain direction of the veneers throughout the thickness of plywood.

In OSB manufacturing, flakes are discharged from the blender and fed into four or more forming bins, which are positioned in a linear sequence above a long, wide conveyor (forming line). Flakes are discharged carefully from each former and must pass through orienters before falling onto the moving forming line belt. The first and last formers create the two surfaces of the mat and align the flakes in the long direction of the panel. These machine direction orienters are usually rotating shafts onto which are mounted closely spaced disks. Flakes are cast onto the rotating disks and must orient themselves lengthwise in order to fall through and onto the forming line. The formers between the surface formers create the cross-oriented core layers. The flakes are cast onto a finned aligning device, which causes the strands to turn in the cross-panel direction before falling onto the forming line.

5. Pressing

The purpose of this operation is to consolidate the loose mat of veneer or flakes as quickly as possible, elevate the temperature of the mat, and to cure the adhesive as quickly as possible, so transforming the mat into a structural panel. The plywood and OSB processes usually use multiple-opening presses with fixed platen dimensions. These may have up to 50 openings although most have between 12 and 24 openings. The size of the platens can be as small as about 1220 mm by 2440 mm to as large as 3660 mm by 7320 mm, and at least one is longer. One continuous press is used to manufacture OSB. This concept reduces waste (eliminates end trimming) and provides much more flexibility in finished panel size, which is limited only by handling equipment and shipping restrictions.

Both plywood and OSB technologies may use a prepress to consolidate the mat prior to loading into the hot press. This technique presses the surfaces of veneers or flakes into intimate contact with each other using low pressure. The purpose is to prevent drying of the adhesives and improve handling of the mat. This process also reduces the thickness of the mat making the hot-pressing operation more efficient. Plywood manufacturing would typically use a platen-type prepress (cold platens) and the OSB process would use continuous belt prepresses. Mats are then transported to a loading cage (in the case of multiple-opening presses) and then an entire press load is put into the hot press with all openings being filled at the same time. Since the platen temperature of these presses is maintained between 150 °C to as high as 210 °C, it is critical that the press closes rapidly and consolidates the mat to the final panel thickness before the adhesive begins to cure. If the press delays in closing then precuring of the adhesive will result in poorly bonded panels with poor durability.

6. Panel Processing

As the finished panels exit the press they are trimmed to rough dimensions. Panels are then usually sent directly to a hot stack where the adhesive finishes curing and properties improve. After a suitable duration the panels are cut to exact finished sizes and prepared for shipping.

Wood: Structural Panels

Structural-use panels is a term used to identify a class of utilitarian wood-based panel products used for construction and industrial applications. The primary market for structural wood panel products is the light-frame construction industry. Panel products are shipped to suppliers and contractors for on-site assembly of residential and commercial structures. These wood panels are manufactured and distributed in standard sizes and grades.

Structural panel products include plywood, oriented strandboard (OSB), and waferboard. Plywood is one of the oldest "engineered wood" products, and has a long history of application over a broad range of uses. OSB and waferboard began emerging in the late 1970s, and now represent over 50% of the structural-use panels in production in North America.

1. Plywood

Plywood comprises a number of thin layers of wood called veneers, which are bonded together by an adhesive. Each layer is placed so that its grain direction is at right angles to that of the adjacent layer. This cross-lamination gives plywood its characteristics and makes it a versatile building material. Plywood has been used for centuries; it has been found in Egyptian tombs and was in use during the height of the ancient Greek and Roman civilizations.

The modern plywood industry is divided into the so-called hardwood and softwood industries. While the names are truly misnomers, they are in common use, the former referring to industry manufacturing decorative paneling and the latter referring to plywood for building construction and industrial uses. This article is concerned primarily with the plywood manufactured for construction and for industrial uses in North America.

1.1 Standards

Construction plywood in the USA is manufactured under US Product Standard PS 1 for Construction and Industrial Plywood (US Department of Commerce 1995) or a Performance Standard such as those promulgated by the APA–The Engineered Wood Association, formerly the American Plywood Association. The Product Standard for plywood includes provisions for performance rating as well. The standard for construction and industrial plywood includes over 70 species of wood, which are separated into five groups based on their mechanical properties. This grouping results in fewer grades and a simpler procedure.

Certain panel grades are usually classified as sheathing and include C-D, C-C, and Structural I C-D and C-C. These panels are sold and used in the unsanded or "rough" state, and are typically used in framed construction, rough carpentry, and many industrial applications. The two-letter system refers to the face and back veneer grade. A classification system provides for application as roof sheathing or subflooring. A fraction denotes the maximum allowable support spacing for rafters (in inches) and the maximum joist spacing for subfloors (in inches) under standard conditions. Thus, a 32/16 panel would be suitable over roof rafter supports at a minimum spacing of 32 in (800 mm) or as a subfloor panel over joists spaced 16 in (400 mm) on center. Common "span ratings" include 24/0, 24/16, 32/16, 40/20, and 48/24.

Many grades of panels must be sanded on the face and/or back to fulfill the requirements of their end use. Sanding most often takes place on plywood panels with A- or B-grade faces and some C "plugged" faces are sanded as well. Sanded panels are graded according to face veneer grade, such as A-B, A-C, or B-C. Panels intended for concrete forming are most often sanded as well and are usually B-B panels. Panel durability for plywood is most often designated as Exterior or Exposure 1. Exterior plywood consists of a higher solids-content glueline and a minimum veneer grade of C for any ply of the panel. Such panels can be permanently exposed externally without fear of deterioration of the glueline. Exposure 1 panels differ in the fact that D-grade veneers are allowed. Exposure 1 panels are most often

made with an extended phenolic glueline and are suitable for protected exposure and short exterior exposure during construction delays.

1.2 Physical Properties

The plywood described here is assumed to be manufactured in accordance with US Product Standard PS 1, Construction and Industrial Plywood (US Department of Commerce 1983). The physical property data were collected over a period of years (O'Halloran 1975).

(a) *Effects of moisture content.* Many of the physical properties of plywood are affected by the amount of moisture present in the wood. Wood is a hygroscopic material, which nearly always contains a certain amount of water. When plywood is exposed to a constant relative humidity (RH) it will eventually reach an equilibrium moisture content (EMC). The EMC of plywood is highly dependent on RH, but is essentially independent of temperature between $0\,°C$ and $85\,°C$. Examples of values for plywood at $25\,°C$ include 6% EMC at 40% RH, 10% EMC at 70% RH, and 28% EMC at 100% RH.

Plywood exhibits greater dimensional stability than most other wood-based building products. Shrinkage of solid wood along the grain with changes in moisture content is about 2.5–5% of that across the grain. The tendency of individual veneers to shrink or swell crosswise is restricted by the relative longitudinal stability of the adjacent plies, aided also by the much greater stiffness of wood parallel as compared to perpendicular to the grain. The average coefficient of hygroscopic expansion or contraction in length and width for plywood panels with about the same amount of wood in parallel and perpendicular plies is about $0.002\,mm\,mm^{-1}$ for each 10% change in RH. The total change from the dry state to the fiber saturation point averages about 0.2%. Thickness swelling is independent of panel size and thickness of veneers. The average coefficient of hygroscopic expansion in thickness is about $0.003\,mm\,mm^{-1}$ for each 1% change in moisture content below the fiber saturation point.

The dimensional stability of panels exposed to liquid water also varies. Tests were conducted with panels exposed to wetting on one side as would be typical on a rain-delayed construction site (Bengelsdorf 1981). Such exposure to continuous wetting on one side of the panel for 14 days resulted in about 0.13% expansion across the face grain direction and 0.07% along the panel. The worst-case situation is reflected by testing from oven-dry to soaking in water under vacuum and pressure conditions. Results for a set of plywoods similar to those tested on one side showed approximately 0.3% expansion across the panel face grain and 0.15% expansion along the panel. These can be considered the theoretical maximum that any panel could experience.

(b) *Thermal properties.* Heat has a number of important effects on plywood. Temperature affects the EMC and the rate of absorption and desorption of water. Temperatures below $90\,°C$ have a limited long-term effect on the mechanical properties of wood. Very high temperature, however, will weaken the wood.

The thermal expansion of wood is smaller than swelling due to absorption of water. Because of this, thermal expansion can be neglected in cases where wood is subject to considerable swelling and shrinking. It may be of importance only in assemblies with other materials where moisture content is maintained at a relatively constant level. The effect of temperature on plywood dimensions is related to the percentage of panel thickness in plies having grain perpendicular to the direction of expansion or contradiction. The average coefficient of linear thermal expansion is about $6.1 \times 10^{-6}\,mm^{-1}\,°C^{-1}$ for a plywood panel with 60% of the plies or less running perpendicular to the direction of expansion. The coefficient of thermal expansion in panel thickness is approximately $28.8 \times 10^{-6}\,mm^{-1}\,°C^{-1}$.

The thermal conductivity, k, of plywood is about 0.11–$0.15\,W\,m^{-1}\,K^{-1}$ depending on species. This compares to values (in $W\,m^{-1}\,K^{-1}$) of 391 for copper (heat conductor), 60 for window glass, and 0.04 for glass wool (heat insulator).

From an appearance and structural standpoint, unprotected plywood should not be used at temperatures exceeding $100\,°C$. Exposure to sustained temperatures higher than this will result in charring, weight loss, and permanent strength loss.

(c) *Permeability.* The permeability of plywood is different from solid wood in several ways. The veneers from which plywood is made generally contain lathe checks from the manufacturing process. These small cracks provide pathways for fluids to pass by entering through the panel edge. Typical values for untreated or uncoated plywood of $\dot{m}$ in (9.5 mm) thickness lie in the range 0.014–$0.038\,g\,m^{-2}\,h^{-1}\,mm\,Hg^{-1}$.

Exterior-type plywood is a relatively efficient gas barrier. Gas transmission ($\times 10^{-5}\,cm^{3}\,s^{-1}\,cm^{-2}\,cm^{-1}$) for $\dot{m}$ in (9.5 mm) exterior-type plywood is as follows: oxygen, 2.9; carbon dioxide, 2.6; nitrogen, 2.1.

1.3 Mechanical Properties

The first design document for plywood was published by the APA–The Engineered Wood Association (APA 1986). The woods used to manufacture plywood under US Product Standard PS 1 are classified into five groups based on elastic modulus, and bending and other important strength properties. The 70

species are grouped according to procedures in ASTM D2555 (American Society for Testing and Materials 1987). Design stresses are published only for groups 1–4 since group 5 is a provisional group with little or no actual production. APA (1986) provides for development of plywood sectional properties based on the geometry of the lay-up and the species, and combining these with the design stresses for the appropriate species group. These data have been updated (APA 1999b).

(*a*) *Section properties.* Plywood section properties are computed according to the concept of transformed sections to account for the difference in stiffness parallel and perpendicular to the grain of any given ply. Published data take into account all possible manufacturing options under the appropriate standard, and consequently the resulting published value tends to reflect the minimum configuration. These "effective" section properties computed by the transformed section technique take into account the orthotropic nature of wood, the species group used in the outer and inner plies, and the manufacturing variables provided for each grade. The section properties presented are generally the minimums that can be expected.

Because of the philosophy of using minimums, section properties perpendicular to the face grain direction are usually based on a different configuration from those along the face grain direction. This compounding of minimum sections typically results in conservative designs. Information is available for optimum designs where required.

(*b*) *Design stresses.* Design stresses include values for each of four species groups and one of three grade stress levels. Grade stress levels are based on the fact that bending, tension, and compression design stresses depend on the grade of the veneers. Since veneer grades A and natural C are the strongest, panels composed entirely of these grades are allowed higher design stresses than those of veneer grades B, C-plugged, or D. Although grades B and C-plugged are superior in appearance to C, they rate a lower stress level because the "plugs" and "patches" which improve their appearance reduce their strength somewhat. Panel type (interior or exterior) can be important for bending, tension, and compression stresses, since panel type determines the grade of the inner plies.

Stiffness and bearing strengths do not depend on either glue or veneer grade but on species group alone. Shear stresses, however, do not depend on grade, but vary with the type of glue. In addition to grade stress level, service moisture conditions are also typically presented—for dry conditions, typically moisture contents less than 16%; and for wet conditions at higher moisture contents.

Allowable stresses for plywood typically fall in the same range as for common softwood lumber, and when combined with the appropriate section property, result in an effective section capacity. Some comments on the major mechanical properties with special consideration for the nature of plywood are given below.

Bending modulus of elasticity values include an allowance for an average shear deflection of about 10%. Values for plywood bending stress assume flat panel bending as opposed to bending on edge, which may be considered in a different manner. For tension or compression parallel or perpendicular to the face grain, section properties are usually adjusted so that allowable stress for the species group may be applied to the given cross-sectional area. Adjustments must be made in tension or compression when the stress is applied at an angle to the face grain.

Shear through-thickness stresses are based on common structural applications such as plywood mechanically fastened to framing. Additional options include plywood panels used as the webs of I-beams. Another unique shear property is that termed rolling shear. Since all of the plies in plywood are at right angles to their neighbors, certain types of loads subject them to stresses which tend to make them roll, as a rolling shear stress is induced. For instance, a three-layer panel with framing glued on both faces could cause a cross-ply to roll across the lathe checks. This property must be taken into account with such applications as stressed-skin panels.

2. Structural-use Panels

With the advent of waferboard and OSB, the term structural-use panels became commonly applied to panel products used in construction. Such common uses include wall, roof, and floor sheathing. Standards, code recognition, and end-use recommendations drive the acceptance of these products in the marketplace.

2.1 Performance Standards

Historical standards against which wood-based panel products have been manufactured have been product standards such as PS 1 for construction and industrial plywood and ANSI A208.1 for mat-formed wood particleboard. National consensus or product standards are most frequently promulgated through organizations such as the American National Standards Institute (ANSI) or, in the case of US Product Standards, the US Department of Commerce. Product or commodity standards are essentially manufacturing prescriptions for minimum-quality products. Requirements are not centered on the specific manufacturing process, and typically do not address the question of product application or how well the product is suited for any particular application.

A performance standard reverses the standard process by defining the end-use of the product and does not prescribe how the product will be manufactured. The objective of a performance standard is to ensure that the product will satisfy the requirements of the application for which it is intended. To do this the performance standard must define performance criteria and test methods. Performance standards were pioneered by the APA–The Engineered Wood Association in 1980, and have since been adopted by other trademarking organizations in the USA, and by the Canadian Standards Association in a standard adopted in 1988. The standards developed by the APA include one for single-layer floors and for sheathing. The intended end-use of these products is for light-frame wood construction as practiced in the USA. As the name implies, panels are intended for combination subfloor underlay and sheathing intended for roofs, walls, and subfloors. The products are rated for their particular end-use. The standards cover panels for supports spaced 400–1220 mm apart for floors and roofs. Provisions are also made for wall bracing when the studs (vertical framing elements) are spaced 400 mm or 600 mm apart. A recent development includes a similar standard for siding where the panels (or panels cut into strips for lap) are to be the exterior building surface.

Panel performance is evaluated through testing under a qualification procedure for three basic areas of investigation: structural adequacy, dimensional stability, and bond performance.

Testing for structural adequacy includes:

(i) verification of the ability to sustain concentrated loads, both static and by impact;

(ii) uniform-load testing to demonstrate the ability of the product to sustain wind or snow load;

(iii) testing of fastener-holding ability to ensure that the panel has the ability to hold covering materials in place and to develop lateral loads in mechanically fastened connections to lumber or other framing; and

(iv) testing to demonstrate that wall sheathing panels can supply resistance for wall bracing.

Tests of physical properties include measuring the expansion of the panels when exposed to elevated moisture conditions. Two methods for measuring linear expansion have been developed. One is the oven-dry to vacuum-pressure soak technique, which is adequate for quality control purposes, but does not reflect field conditions. Accordingly, a performance test was developed which measures linear expansion when wetting on one side for a period of 14 days. The test approximates severe exposure conditions as might occur during construction and should serve as a relative measure of linear expansion conditions that might be expected in service.

Finally, the bond durability of the panel must be demonstrated for site-built construction since panels will be called upon to resist wetting and drying and still be able to perform following exposure to these conditions. Results of extensive research have indicated that large-scale specimens exposed to hot water soaking and oven drying and then subjected to the same structural performance criteria is adequate evidence of the ability of the panel to remain intact during exposure to weathering. These tests are equivalent to several years of permanent exposure to the weather. Retention of strength following moisture cycling is also used as a measure of bond performance.

Certification of performance is a straightforward process under a performance-based system. First a sample of the candidate product is tested according to the individual performance criteria discussed above. After demonstrating adequate structural performance, physical properties, and bond durability, a span rating can then be assigned. Concurrent with performance-oriented tests, a product evaluation is also performed in which properties unique to the product and suitable for quality assurance are measured. Such properties include bending strength and stiffness, thickness, density, and others which may be useful in monitoring quality under a third-party basis. A mill specification is drawn up following this intensive product evaluation. This individualized mill specification is unique to the mill and product qualified under the standard.

2.2 Physical Properties

Physical property data have been collected for commercial products and this will be continuing as the industry matures.

(*a*) *Effects of moisture.* Many of the physical properties of structural panels are affected by the amount of moisture present in the wood. The EMC of structural panels is highly dependent upon RH, but is essentially independent of temperature between 0 °C and 85 °C. Examples of EMC values for structural panels at 25 °C include 4% at 40% RH, 7% at 70% RH, and 23% at 100% RH.

The expansion in length or width of structural panels from dry (less than 1% moisture content) to saturation is less than 0.5%. Linear expansion when exposed to a change in RH from 50% to 90% is typically less than 0.3%. The dimensional stability of panels exposed to liquid water also varies. Tests were conducted with panels exposed to wetting on one side as would be typical on a rain-delayed construction site. Such exposure to continuous wetting on one side of the panel for 14 days resulted in less than 0.35% expansion across or along the major axis of the panel.

(*b*) *Permeability.* The permeability of structural panels is different from solid wood in several ways. The overlapping flakes from which panels are made

create many small gaps, which provide pathways for fluids to pass when entering through the panel edge. Typical permeability for untreated or uncoated ṁ in (9.5 mm) structural panels is about $0.23\,\mathrm{g\,m^{-2}\,h^{-1}\,mm\,Hg^{-1}}$.

2.3 Mechanical Properties

APA–The Engineered Wood Association has collected extensive data on all types of structural-use panels. The data collection effort has been over time and across a number of mechanical properties. The results were first published in a technical note (APA 1998), and subsequently as a supplement to the consolidated industry design document (APA 1999b). The work details design principles for using structural-use panels in a variety of ways.

Wood: Thermal Properties

Thermal mechanisms play important roles in living trees, during the conversion of wood into useful products, and in affecting the performance of such products in service. This article summarizes how the main thermal properties of wood, including its coefficients of thermal conductivity and expansion, and heat capacity, influence the way wood and wood-based composite materials may be processed and used. Thermal effects on wood formation are also summarized.

Wood consists of elaborate spatial arrangements of diverse types of cell which are themselves sophisticated rigid-walled polymeric structures with a central axial void (lumen). The cellular structure of wood renders it highly anisotropic in terms of many of its properties (see *Wood: Ultrastructure*; *Wood: Macroscopic Anatomy**): heat flow and thermal expansion differ relative to orientation within the stem. The thickness of cell walls relative to lumen size directly influences the density of wood and hence the availability of pathways for conductive heat transfer (see *Wood: Density[#]*). Moisture may reside in wood both in the hydrogen-bonded state in cell walls and as liquid water or water vapor in the lumens (see *Wood: Moisture Content, Hydroscopicity, and Sorption**). The form and concentration of water in wood influences all of its thermal properties.

Wood is chemically degraded by prolonged exposure to temperatures in excess of about 375 K, and charring and combustion occur at higher temperatures. The present discussion is, however, limited to the behavior of wood at temperatures below 375 K (see *Wood Products: Thermal Degradation and Fire[#]*). It should, however, be appreciated that the combustion of wood is dependent upon some of its intrinsic thermal properties, including conductivity and heat capacity.

1. Thermal Effects in Living Trees

Heat affects the very nature and speed of wood formation in living trees. The biochemical processes

upon which the formation of xylem (wood sub-stance) at the cambial zone (lying immediately be-neath the bark) depend are highly influenced by temperature. Substantial fluctuations of temperature occur within stems both seasonally and in daily cy-cles. Daily fluctuations of all-important vertical temperature gradients are often dominated by the magnitude of liquid movement. Sap is drawn up from roots, via lumens of sapwood (outer annulus of the stem cross-section), to minute openings (stomata) on the underside of leaves (the process of transpira-tion). Significant quantities of heat are carried with the moving sap. Such movement is usually rapid dur-ing daylight hours and all but stops at night. Heat exchange at the external bark–atmosphere interface is often secondary to the effects of fluid movements within.

2. Thermal Effects in Wood Processing

The stiffness of wood and the deformation that it sustains under prolonged loading (see *Wood: Creep and Creep Rupture**) is co-dependent on its temper-ature and moisture content (wood may be termed thermo-hygro-viscoelastic). Thermally induced sof-tening may be used to advantage during industrial procedures such as cutting and fiber separation, and in the heated consolidation of wood-based composite materials. Manipulation of temperature and moisture conditions during such processes can often be critical to their effectiveness and economic viability. In ad-dition to temporarily softening the wood during the consolidation of composite materials in hot presses, the application of heat is also critical since adhesives used to bind the wood components together are pre-dominantly of the thermosetting type: the rate at which they polymerize and form bonds increases al-most exponentially with temperature (see *Wood: Ad-hesives*[#]; *Wood: Structural Panel Processes**).

Judicious application of heat is also employed to hasten the drying of lumber and the subdivided wood components used to make composite products. Dry-ing is a necessary stage in the production of almost all wood-based products, and effecting the necessary in-ternal heat transfer (usually while also controlling moisture movement) while minimizing damage to the structure is an important challenge.

The application of heat to wood being processed often leads to the generation of vapor pressure gra-dients among its pore spaces as hydrogen-bonded water in the cell walls migrates into the lumen and changes phase. Convection and diffusion of the water vapor so produced can be a very important mecha-nism of internal energy transfer, often exceeding that contributed by thermal conduction. Such can, for example, be the case in the kiln drying of wood and in the hot pressing of wood-based composite materials. Temperature and moisture gradient fluctuations

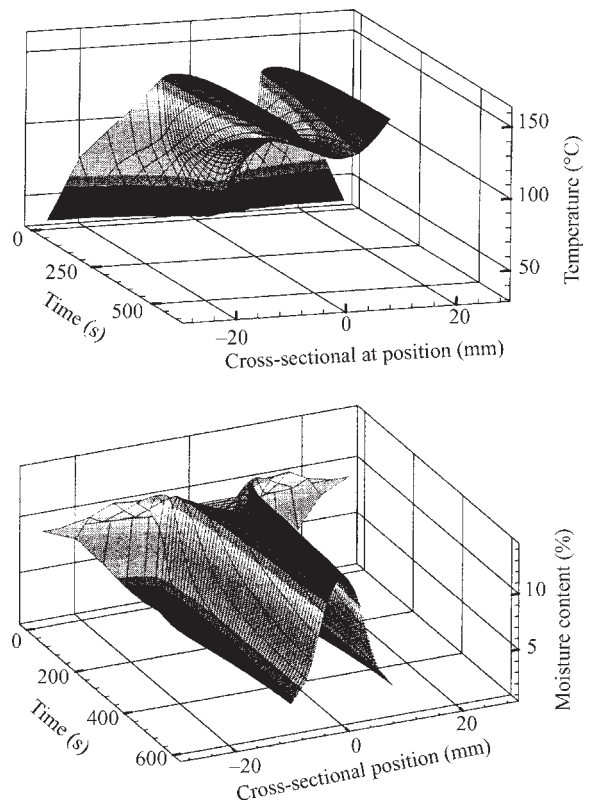

Figure 1
Temperature and moisture distributions through the thickness of a medium density fiberboard panel during consolidation in a simulated industrial hot press.

through the thickness of a medium density fiber-board panel (see *Wood: Structural Panels**) during computer-simulated consolidation in a hot press are shown in Fig. 1. Rapid internal temperature increases are due to the combined effects of thermal conduc-tion and the evaporation, migration, and subsequent re-condensation of water vapor. Permeability and tortuosity (respectively affecting convection and dif-fusion of vapor in the porous composite structure), and hygroscopicity (affecting vapor generation per unit energy input) are therefore important material properties in such situations (see *Wood: Diffusion and Permeability*[#]).

Vapor generation and convection makes meas-urement of the thermal properties of wood (such as thermal conductivity and heat capacity) problem-atic. Conventional steady-state methods in which temperature gradients are applied for prolonged periods are not appropriate. Rapid unsteady-state methods are usually necessary to avoid the onset of significant moisture migration within test specimens.

3. Thermal Effects in Service

Heat movement in the walls, floors, and ceilings of buildings may be minimized by taking advantage of the thermal insulating properties of wood and appropriately designed wood-based composite materials. The high volume fraction of air spaces in dried wood of low density can offer an effective barrier to heat transfer. Indeed, most thermal properties depend upon wood density since this affects the proportion of the structure that is void (occupied by air or liquid water) versus that of solid cell wall substance (see *Wood: Density*[#]). The density of dry wood cell wall material remains remarkably uniform among fiber types and wood species (approximately $1500 \, kg \, m^{-3}$). The quantity of water adsorbed within the hygroscopic cell wall material does, however, affect thermal conductivity and consequent heat transfer rates in specific applications. Furthermore, wood structure is highly anisotropic since the wood fibers are predominantly aligned nearly vertically in the standing stem, though typically 5% are oriented radially. Such anisotropy leads to important differences in the material properties, which affect how heat and fluids move through wood and wood-based materials.

Wood undergoes only modest dimensional changes with temperature, although temperature changes of wood products in service often lead to concomitant changes of moisture content. Moisture content fluctuations below fiber saturation point (where the concentration of water molecules adsorbed within the wood cell walls varies) can cause substantial and often problematic anisotropic shrinkage and swelling or the development of internal stresses (see *Wood: Dimensional Change from Moisture*[#]).

Figure 2
Effect of density on thermal conductivity of wood and two wood-based composite products at 12% moisture content and temperature of 300 K (reproduced by permission of Springer, Berlin, from *Principles of Wood Science and Technology*, Vol. 1, *Solid Wood*, 1968).

4. A Summary of Thermal Property Values

Summarized in Table 1 are selected thermal property values of wood. Values do, however, vary widely; those readers requiring greater accuracy should refer to the literature. Properties for wood-based composites depend upon the organization of the wood constituents, adhesive, and method of consolidation, and are beyond the scope of this article. Note: moisture content values (mc) are expressed on an oven dry wood basis.

Table 1
Selected thermal property values of wood.

Thermal conductivity, κ	typical value 0.1–$0.13 \, W \, m^{-1} \, K^{-1}$ (for transverse flow in a softwood of density $450 \, kg \, m^{-3}$ and mc of 12%)
density effect	see Fig. 2
moisture content effect	near-linear positive correlation (up to 25% mc)
flow direction effect	transverse to longitudinal ratio typically 1:1.8
Heat capacity, c	typical value $1.6 \, kJ \, kg^{-1} \, K^{-1}$ (for wood at mc of 12% and temperature of 17 °C)
density effect	minimal
temperature effect	moderate positive correlation
moisture content effect	additive for water and wood (plus a small positive adjustment factor)
Coefficient of thermal expansion	typical value $30 \times 10^{-6} \, K^{-1}$ (for wood of density $450 \, kg \, m^{-3}$, mc of 12%, radial direction)
density effect	minimal in longitudinal direction, near linear positive correlation in transverse
directional effect	longitudinal-to-radial ratio typically 1:7, radial-to-tangential ratio typically 1:1.4
temperature effect	small; up to 50 °C

Figure 2 shows the effect of density on k for wood and two types of composite.

Wood: Ultrastructure

Other articles describe wood composition and cellular structure on a macroscopic scale, but in many instances the successful processing of wood requires a more in-depth understanding of these characteristics. A brief overview of wood chemical composition is given to provide a better understanding of cellular ultrastructure.

1. Chemical Composition of Wood

Wood is composed of three primary constituents: cellulose, a linear, crystalline carbohydrate polymer with a high degree of polymerization ($\sim 10\,000$–$14\,000$); hemicelluloses, a term used to collectively refer to the numerous pentosan and hexosan carbohydrate polymers having a much lower MW and a greater solvent reactivity than cellulose; and lignin, a highly cross-linked polyphenolic material.

Two so-called secondary constituents are also present in, but not an integral part of, the cell wall structure: ash (salts of minerals such as calcium, potassium, and magnesium) and extractives (any compound that is removable with a neutral solvent). Ash content is usually $< 0.5\%$ for all North American species, but may be as much as 5% or more for tropical species. Silica is sometimes present in appreciable quantities. Extractives frequently add color, odor, or other characteristics such as decay resistance to wood e.g., chemicals such as oleoresins (pine "pitch") and tannins. Different species contain different types of extractives, and wood from different parts of a tree will likely contain varying amounts of extractives e.g., heartwood usually has a greater extractive content than sapwood.

Table 1 lists the amounts of cellulose, hemicelluloses, and lignin in wood compiled from the literature on North American gymnosperms (conifers, "softwoods") and angiosperms (broad-leaved trees, "hardwoods") (Browning 1963, Timell 1967, Koch 1972, 1985, Page *et al.* 1975, Panshin and de Zeeuw 1980, Weil *et al.* 1998). Q3–Q1 represents the inner quartile spread. Tropical angiosperms may have significantly more lignin than temperate-zone angiosperms (Timell 1967). A study of 20 tropical woods (mostly from Nigeria) found that lignin content ranged from 22% for iroko (*Chlorophora excelsa*) to 50% for mpingo (*Dalbergia melanoxylon*) (Sosanwo *et al.* 1995). Cellulose contents were $\sim 35\%$.

There are statistically significant differences between the hemicelluloses and lignin determinations for temperate-zone angiosperms and gymnosperms, the latter having less hemicelluloses and more lignin. Variability could be from differences in analytical procedures, but it is known that trees having different genetic heritage contain differing proportions of the primary constituents, and there is also variation within trees. In gymnosperms, for example, the juvenile wood surrounding the pith of the tree has more lignin and less cellulose than wood just beneath the bark formed from a more mature cambium. There is a similar trend with tree height; topwood (with a higher juvenile wood percentage) generally has less cellulose and more lignin than bottomwood. Hemicelluloses seem to be more concentrated in the juvenile regions as well, and usually decrease by a few percent in mature wood regions (Panshin and de Zeeuw 1980).

Table 1
Primary constituents of wood (%) (moisture-, extractive- and ash-free basis).

	Cellulose	Hemicelluloses	Lignin
Gymnosperms			
Medians of 28 analyzes (Q3–Q1)	43.0 (7.7)	25.0 (11.7)	28.6 (2.9)
Minima (maxima)	38.1 (57.4)	13.3 (34.1)	23.5 (33.9)
Angiosperms			
Medians of 62 analyses (Q3–Q1)	45.8 (4.7)	31.1 (6.5)	26.4 (3.6)
Minima (maxima)	38.5 (55.2)	18.7 (39.7)	17.3 (34.7)

2. Cell Wall Structure

There are four essential relationships in the structure of wood cell walls: (i) aggregation of cellulose, lignin, and hemicelluloses molecules to form larger structures; (ii) arrangement of these structures to form a multilayered cell wall; (iii) variation of concentrations of cellulose, hemicelluloses, and lignin within the cell wall and the intercellular domain; and (iv) specialization of cell walls, such as interconnecting pits. Reaction wood has an abnormal cell wall structure that is described later.

2.1 Aggregation of the Primary Constituents into Larger Structures

As stated previously, cellulose is the principal constituent in cell walls. Recent work suggests that cellulose molecules are formed at macromolecular terminal complexes (TCs) in the cell plasma membrane. There is a multistage self-assembly sequence. Parallel glucan chains form planar sheets that quickly hydrogen bond to other sheets to produce mini-crystals, and associate with others to form highly-ordered cellulose microfibrils. Microfibrils are approximately square, and the atomic force microscope (AFM) has shown them to have repeat patterns along their length corresponding to the lengths of a glucose molecule and a cellobiose unit (two glucose molecules) (0.52 and 1.04 nm, respectively) (Hanley *et al*. 1992, Baker *et al*. 1998).

Measurements of bacterial cellulose and beaten kraft-pulped spruce fibers have shown that the lateral microfibril dimensions can be as small as 1.0–1.5 nm (Haigler and Weimer 1991, Okuda *et al*. 1994, Hanley 1995, Tsekos *et al*. 1996). Microfibrils have not been observed to be this small in undelignified structures. Other workers have demonstrated that the space between cellulose microfibrils is ∼3–4 nm (Terashima *et al*. 1993) and that hemicelluloses at least partially cover the cellulose in native wood (Tenkanen *et al*. 1999). Hanley (1995) found that the widths of microfibrils from microtomed sections of undelignified black spruce were ∼7.5 nm in diameter, probably an indication of the combined cellulose-hemicelluloses dimension. Lignin is deposited after the cell wall formation is initiated and does not affect cellulose dimensions or structure.

The wood cell wall structure is frequently thought of as a two-phase system in which cellulose is a discrete component and the lignin and hemicelluloses are blended together to form an encrusting matrix around the cellulose. Figure 1 illustrates this two-phase model, which has recently been questioned by some researchers. Studies using the cellulose-producing bacteria *Acetobacter xylinum* as a model system have shown that cellulose and hemicelluloses coaggregate to form complex celluloses. It is possible that hemicelluloses are blended with the cellulose in most higher plant cell walls (particularly in wood), and that microfibrils that are generally observed in isolated celluloses are consequences of the extraction of the hemicelluloses. Work by Salmén and Olsson

Figure 1
Two phase model for organization of the cell wall components (after Salmén and Olsson 1998).

(1998) used dynamic mechanical analysis to study spruce specimens at varying relative humidities, which indicated that hemicelluloses may be associated with both lignin and cellulose. According to their findings, xylan is associated with lignin and glucomannan with cellulose in spruce (*Picea abies*).

Molecular mechanics and dynamics studies indicate that the hemicelluloses are hydrogen bonded and oriented parallel to cellulose, and that lignin may have a helical structure (Faulon *et al.* 1994). However, the interactions are complex and many inferences remain to be verified.

X-ray diffraction studies have demonstrated departures from an infinitely extended linear lattice in native cellulose microfibrils; consequently it has often been stated that microfibrils contain both crystalline regions and less well ordered (amorphous) regions. Raman spectroscopy and solid-state ^{13}C-NMR studies have shown that this model is inadequate to describe cellulose structure. Through use of the alga *Valonia,* and other native celluloses as experimental substrates it has been shown that two different forms of cellulose (I_α and I_β) are present in the same microfibril. There is speculation that the I_α and I_β forms of cellulose may correspond to triclinic and monoclinic unit cells. In wood, the concomitant presence of these two forms probably affects x-ray crystallinity measurements to a lesser degree than cellulose chain ends or the intimate associations with hemicelluloses. There is much yet to learn about nanoscale level of organization of constituents in wood.

2.2 Multilayer Structure of Cell Walls

Wood cells are hollow layered structures with a primary cell wall on the outside and a secondary cell wall and a lumen contained within. Each layer contains oriented cellulose microfibrils together with hemicelluloses and lignin, and the microfibril orientation affects the ultimate strength of the tissue. The primary cell wall (P) is very thin and contains randomly oriented microfibrils surrounded by a lignin-rich material containing lesser amounts of cellulose, hemicelluloses, pectins, and structural glycoproteins. The secondary cell has layers visually distinguishable by differences in microfibrillar orientation; progressing from the primary cell wall inward towards the lumen, the layers are sequentially designated as S_1, S_2, and S_3. Figure 2 is a generalized diagram of a woody cell wall based on latewood tracheids of longleaf pine (*Pinus palustris*) (Dunning 1968).

The S_1 layer is slightly thicker than the primary cell wall, and the microfibrils are arranged in several thin lamellae with the outermost lamellae oriented at angles approaching 90° to the fiber axis. Two inner lamellae of the S_1 layer are arranged in alternating right- and left-hand helices at angles of $\sim 65°$ from the fiber axis, with several overlapping lamellae at

Figure 2
Cell wall structure of a longleaf pine (*P. palustris*) latewood tracheid (after Dunning 1968).

progressively steeper orientations that create a gradual transition to the S_2 layer. The S_2 is the thickest layer, typically comprising around 75% of the cell wall, with the microfibrils arranged in a right-hand helix of 5–25° to the fiber axis. The S_3 layer is slightly thinner than the S_1, and similarly has several crisscrossed lamellae. The microfibril angle within the S_3 layer varies from ~ 60–85°, with the outermost S_3 lamellae having similar angles as the S_2, acting as transitional elements between the S_2 and S_3. Finally, most gymnosperms (and some angiosperms) contain a thin "warty layer" on the innermost lamella of the S_3, the surface of the cell lumens. The warty layer is $\leqslant 0.1\mu m$ thick and characterized by wart-like protuberances, which may be remnants of protoplasmic contents, and have no effect on fiber strength, although they may affect permeability.

Surrounding the primary cell wall is a thin lignin-rich layer termed the middle lamella (or inner cellular layer). In early microscopic studies these layers could not be clearly distinguished and the term compound middle lamella arose to refer to the combination of the (true) middle lamella and the primary cell wall. Table 2 lists the approximate thickness of the various cell wall layers of gymnosperm tracheids. Interested readers are referred to Dunning (1968) for more detailed information and micrographs of cell wall structures.

2.3 Distribution of Chemical Constituents

The distribution of the primary chemical constituents within wood cell walls has a significant effect on wood processing operations, and investigations have been ongoing since the seminal work by Bailey (1936). Studies have relied upon a number of destructive and nondestructive techniques e.g., microdissection, acid digestion, polarizing light microscopy, UV-microspectroscopy, enzyme-gold complex studies, Raman spectroscopy, bromine-tagged lignin measurements using x-ray spectroscopy, etc. All of these techniques have some limitations, and some contradictory results have been published that are difficult to resolve. General agreement exists on the qualitative distribution of cellulose, hemicelluloses, and lignin in the middle lamella and the secondary cell wall, but there is considerable disagreement on quantitative values. Table 3 and Fig. 3 show one possible distribution of cellulose, hemicelluloses, and lignin within the various cell wall layers of gymnosperms based on reports from Meier (1961), Fergus *et al.* (1969), Wood and Goring (1971), Saka *et al.* (1978), Hardell and Westermark (1981), Donaldson (1987), and Westermark *et al.* (1988).

When the nominal cell wall layer thicknesses listed in Table 2 are used to calculate the overall chemical composition, the results compare favorably to those presented in Table 1 (i.e., about 42% cellulose compared to 43% in Table 1, 32% hemicelluloses vs. 25%, and 25% lignin vs. 29%). In spite of the greater concentration of lignin in the compound middle lamella, it must be apparent that most of the lignin is actually present within the secondary cell wall due to its greater thickness.

Table 2
Cell wall layer thicknesses of gymnosperm tracheids (µm)

Middle lamella	$\geqslant 0.1$
Primary cell wall	0.03
S_1	0.2
S_2	$\geqslant 5$
S_3	0.07–0.08
Warty layer	$\leqslant 0.1$

2.4 Cell Walls and Distinguishing Features

Up to this point the woody cell wall has been described in terms of chemical composition and structural organization of the principal constituents in the cell wall. However, wood cells are not balloon-like bodies with smooth walls and closed ends, but have many features that characterize the cell walls. Foremost are the paired openings in adjacent cell walls that permit the passage of fluids. In both gymnosperms and angiosperms some cell walls are penetrated by openings called pits. Angiosperms also have openings (perforation plates) at the junctures between ends of individual vessel elements. Other features are less uniformly present and are of diagnostic significance to identify wood species.

(*a*) *Gymnosperm pits*. In gymnosperms pits are found in three locations: intersections of longitudinal parenchyma and ray parenchyma cells, radial walls of adjacent longitudinal tracheids, and intersections of longitudinal tracheids with ray parenchyma or ray tracheids. Simple pits between adjacent parenchyma cells are thin, membrane-like structures comprising

the middle lamella and the primary cell walls. A bordered pit pair has overarching structures on the lumen side of each cell wall surrounding apertures between two adjacent longitudinal tracheids (Fig. 4). Each bordered pit pair encloses a web-like microfibril structure called a *margo* that supports (except in western redcedar (*Thuja plicata*)) a central and much less permeable *torus*, the assembly acting as a valve to open or close the openings between tracheids (Fig. 5). When the torus is moved enough to block the pit aperture, as by surface tension during wood drying, the pit is said to be aspirated (Fig. 6). Longitudinal tracheids and ray tracheids are also interconnected via bordered pits, but the pits are much smaller than those between longitudinal tracheids.

Pits occurring at the crossfields between ray parenchyma and longitudinal tracheids are termed half-bordered pits because they have the characteristics of bordered pits on the longitudinal tracheid and simple pits on the ray parenchyma cell. These pits can be classified into five categories by differences in the shapes of apertures and overhanging borders:
fenestriform (also called windowlike), pinoid, piceoid, taxodioid, and cupressoid. Figure 7 illustrates a fenestriform crossfield pit in eastern white pine (*P. strobus*). The ray is heterocellular, and the cell types are thereby distinguishable. For more information and examples of crossfield pits the reader is referred to Panshin and de Zeeuw (1980).

(*b*) *Angiosperm pits.* Since numerous cell types may be present in angiosperms, pitting can be complex, including simple, half-bordered, and full-bordered types. Except for pitting between adjacent vessel elements, the pit appearance on the various types of cells has little diagnostic value. Intervessel pitting (largely on radial walls) is designated as opposite or alternate. Opposite pitting is arranged in more-or-less regular horizontal rows like a checkerboard while alternate pitting is either unordered or arranged somewhat diagonally. A third type of pitting, perforation plates, is found at adjoining ends of vessel elements, having simple openings or more complex structures. In commercial temperate-zone species only two types of perforation plates are found: simple and scalariform. Simple perforation plates are uncomplicated openings surrounded by a thin rim on the ends of the vessel elements, however, scalariform are characterized by numbers of bar-like portions of the cell wall that extend across the vessel openings (Fig. 8). The type of opening and the number of bars are most readily seen on the radial surface and have diagnostic significance.
Figure 6
Cross-section of a bordered pit pair. Arrow indicates the aspirated torus blocking one of the pit apertures (after Hanley 1995).

Figure 8
Birch (*Betula* species) vessel element with scalariform perforation plates.

(*c*) *Cell wall sculpturing*. Wood cell walls may be ornately structured, termed sculpturing. The most frequently observed marking is helical (also called spiral) thickening, which is a coil-like pattern of microfibrillar ridges on the lumen surface. These are a species-specific trait and can be found in gymnosperm tracheids, and in angiosperm vessel elements and vascular tracheids (and occasionally fibers). The feature is distinctive and easily observed using light microscopy. A good example of a North American coniferous species containing this structure is Douglas fir (*Pseudotsuga menziesii*) (Fig. 9).

(*d*) *Inclusions*. Two types of inclusions are commonly found in lumens of wood cells: mineral crystals and tyloses. Crystals are found in a limited number of species (e.g., iroko (*C. excelsa*), teak (*Tectona grandis*), red mulberry (*Morus rubra*)) and may even be visible to the naked eye (Fig. 10). Tyloses are balloon-like membrane structures that grow into vessel elements from adjacent parenchyma cells (Fig. 11). Tyloses are more common in some species than others; in species where they are usually absent, they may be found in heartwood. Tyloses can block the longitudinal passage of air or other fluids, and may affect the selection of wood for certain uses. Tight cooperage, for example, makes use of white oak (*Quercus species*) with its plentiful tyloses.

Figure 7
This radial view of a piece of eastern white pine contains both ray parenchyma (*RP*) and ray tracheid (*RT*). FP = fenestriform-type of crossfield pits, and BP = the small bordered pits between the ray tracheids and longitudinal tracheids.

3. Reaction Wood

Reaction wood is the generic term used to refer to wood that has atypical anatomical and chemical characteristics, usually from its origin in leaning stems or branches. In gymnosperms this wood is called compression wood and in angiosperms, tension wood. Each form of reaction wood is distinctly different from normal cell tissues.
Figure 9
Transmitted light and scanning electron micrographs of Douglas-fir (*P. menzisii*) tracheids showing spiral thickenings.

3.1 Compression Wood

Compression wood is found on the underside of leaning stems and branches of conifers. Its cells are characterized by unusually high lignin and lower cellulose content. The cell walls contain spiral gaps (called "spiral checks") along the steeper S_2 microfibril angle that is a characteristic of these tissues (up to $\sim 45°$ instead of the normal 5–25° from the tracheid axis) (Fig. 12). The cell walls of longitudinal

tracheids are unusually rounded compared to normal tracheids, and there are intercellular spaces at some cell corners. The cell walls are frequently slightly thicker than normal wood and the S_3 layer is typically lacking.

3.2 Tension Wood

Tension wood is found on the upper side of leaning stems and branches in angiosperms. It contains more cellulose and less lignin, and the fiber structure is markedly different from that of normal wood. Tension wood fibers are characterized by a layer of microfibrils that is almost pure cellulose, the gelatinous or G-layer, and the fibers are known as gelatinous fibers. (Gelatinous fibers may also be found intermixed with normal fibers in oaks even when no reaction wood is present.) The G-layer occurs on the lumen side of the fibers and is easily detached from the rest of the cell wall (Fig. 13), causing a distinctive fuzzy appearance on the surface of machined wood.

Gelatinous fibers can be found in several types of cell wall configurations. The G-layer may occur in addition to the more normal S_1–S_2–S_3 configuration, replace the S_3 layer, or occur in place of both S_2 and S_3. The cellulose microfibrils in the G-layer are oriented at very small angles to the longitudinal fiber axis.

4. Concluding Remarks

The ultrastructure of wood is a very useful diagnostic tool for species identification and also explains some

Figure 13
Tension wood showing the G-layer detached from the rest of the cell wall (courtesy of the Institute of Paper Science and Technology).

of the gross properties of wood. However, despite the use of many analytical techniques, details of the molecular ultrastructure of wood remain to be resolved.

Wood–Plastic Composites

Wood has commonly been used as inexpensive filler by the plastics industry. During the late 1980s, researchers and industries began investigating high levels of filler content (40–70%) and coupling agents to encourage interaction between the wood and thermoplastic components. An improved sophistication in processing and formulations led to the development of wood-plastic composites (WPCs) that exhibit synergistic material properties.

WPCs consist primarily of wood and thermoplastic polymers combined using technologies similar to other filled thermoplastics. While often seeking improved strength, stiffness, creep, and thermal stability, the commercial success of these materials has been primarily driven by improved moisture performance, recycled and waste material utilization, and efficiency in product and process design.

1. Products and Applications

WPCs have been used in many of the molded applications common to commodity thermoplastics. However, the improved mechanical, thermal, and processing characteristics of the materials have facilitated extensive use in highly contoured parts for the automotive and building products markets (Laver 1996, Puppin 1999). Interior automotive components experience significant thermal changes that provide performance challenges to traditional thermoplastics.

The increased thermal stability imparted by the addition of 40–50% wood improves the product performance. The thermoplastic component imparts improved levels of moisture performance and thermal formability to the wood. The low impact strength of WPCs does limit their use to nonstructural components like door, roof, and trunk liners.

The most rapidly growing application for WPCs is in extruded sections for residential building markets. Poly(vinyl chloride)–wood compounds are becoming common for replacement window lineals (Fig. 1). A solid thermoplastic cap can bond with the WPC to control color stability while the WPC core facilitates an easily processed, high modulus section. Low- and high-density poly(ethylene) polymers are compounded with up to 70% mass fraction wood to produce deck boards and railing. The increased thermal stability of the WPC facilitates the production of detailed sections that can be engineered for load-bearing applications (Fig. 2).

Figure 1

Figure 2
Hollow wood–HDPE deck board (courtesy of Strandex Corp.).

2. Raw Materials

WPC formulations are comprised primarily of a thermoplastic and lignocellulosic component. However, a number of additional components are commonly used to improve both the processing and properties of the resulting materials.

Wood is the most common source of the lignocellulosic component of WPCs. A variety of species is used and where species differences may exist, they have not been explicitly studied. Many agricultural fibers have also been successfully used in WPCs. Agricultural fibers often display certain advantages with respect to aspect ratio and specific mechanical properties (Sanadi *et al.* 1997, Tjong *et al.* 1999). For both wood and agricultural fibers, the material is used in fiber, flour, or particle form (Wolcott and Englund 1999). Particles and flour are formed using hammermills and grinders common to wood-based particleboard. Fibers can be produced with thermomechanical and chemical pulping methods that are used for pulp and fiberboard manufacture.

The primary criteria in selecting thermoplastics for WPCs are those with a processing temperature less than ca. 250 °C. Above this threshold, unmodified lignocellulosic materials undergo rapid thermal degradation. This thermal criterion has limited WPCs to polyolefins. Commonly used thermoplastics include poly(propylene) (PP), high and low density poly(ethylene) (HDPE, LDPE), poly(vinyl chloride) (PVC), and poly(styrene) (PS). In addition, impact modified versions of PP and PS have been explored. Both recycled and virgin sources of these commodity thermoplastics are commonly employed in powder or pellet forms.

Several minor components are added to WPCs to assist in performance of the material during processing or end use. Most commercial formulations for extrusion include lubricants that can be in the form of waxes or other solid components (Laver 1996). These lubricants primarily facilitate flow in the extruder barrels but may impede moisture movement in the product. Compounds composed of PVC typically utilize various stabilizers and plasticizers that are common to most PVC compounds (Zehner 2000). These components mainly act to alter the PVC component but the polar plasticizer components could conceivably alter the wood polymers.

3. Wood and Thermoplastic Compatibility and Dispersion

The most varied of components added to WPC formulations are materials aimed at improving the compatibility of the wood and thermoplastic. These components include surfactants, copolymers, and reactive compounds (Lu *et al.* 2000). The energetic differences that exist between the wood and

thermoplastic impede both adhesion and dispersion of the two phases. The chemical treatments may be applied prior to composite processing. Preliminary applications typically include coating or copolymerization in solvents. However, commercial operations most commonly use methods of direct mixing in dry blending, melt compounding, or extrusion steps. In many of these compounds both the chemical structure and the modification procedure have great influence on the effectiveness of a coupling agent.

The most popular coupling agents include maleic anhydride (MA), maleic anhydride modified poly(propylene) (MAPP), isocyanates, and silanes. MA, MAPP, and PMPPIC (poly(methylene) poly(phenyl) isocyanate) are very effective for improving the mechanical properties of composites presumably by improving the wood-thermoplastic interface. Silanes exhibit some coupling effects but seem more dependent on the types of plastic. Some physical methods like corona and plasma discharges can have a positive influence on mechanical properties of WPCs (Young *et al*. 1995). Most coupling agents are proposed to facilitate chemical linkages and/or hydrogen bonds between the wood and thermoplastic. However, the wood-thermoplastic adhesion is believed to be dominated by physical adsorption and acid/base interaction if any.

Although the interaction between unmodified wood and thermoplastics is limited at best, commercial materials are often produced with no chemical treatment. Physical means of improving component dispersion are most commonly employed. Both high energy mixing methods and decreased particle sizing have been shown to increase dispersion of wood within thermoplastics (Wolcott and Englund 1999). Compression-molded composites without prior compounding tends to produce structures with stacked wood elements leading to poor moisture performance (Fig. 3). In addition, penetration of the thermoplastic into the void structure of the wood has been observed (Fig. 4). Small particle sizes increase dispersion and mechanical properties when coupling agents are not employed. This fact bolsters the use of wood flour in commercial applications that do not employ chemical treatments.

4. Physical and Mechanical Properties

The combination of wood and thermoplastics results in materials with unique physical properties. In general, the wood component tends to increase the stiffness, thermal stability, UV resistance, and workability of the composite. Thermoplastics improve moisture resistance, resistance to decay, and impart thermoforming characteristics. Mechanical properties are often the most studied of the physical properties, although other characteristics like thermal and moisture stability seem to drive commercialization. In

all cases, the material performance is significantly influenced by the processing methods used.

Mechanical properties of WPCs are influenced by composition in different ways. Elastic modulus increases with increasing wood fractions. Although the trend is consistent across the type of thermoplastic and wood particle (Table 1), the magnitude of the increase appears to be influenced by several factors. Composite strength is highly dependent on several factors, including the wood form, plastic type, processing method, and wood–thermoplastic interaction. In unmodified composite systems, small particle sizes are more effective at increasing the elastic modulus, favoring the use of wood flour (Törmälä *et al.* 1985). However, it appears more difficult to improve strength properties with wood flour. Decreased strength properties are generally cited with increasing wood content with a few exceptions. Woodhams *et al.* (1984, 1993) found that the tensile strength of wood fiber/PP WPCs produced with a dispersing agent or high shear mixer increase with increasing wood content (Fig. 5). Impact strength decreases with fiber loading in all cases, although elastomeric coupling agents lessen the effect (Oksman and Clemons 1998).

As with many reinforced composites, impact energy decreases with increased fiber content for wood flour and fibers (Oksman and Clemons 1998). Methods used to address this deficiency include toughened thermoplastic or matrix/fiber interphase region, optimized particle geometry, and foaming of the composite (Matuana *et al.* 1998). Introduction of a controlled cellular structure in both modified and unmodified WPCs can significantly increase the impact energy of a composite. However, the strength and stiffness typically decreases in proportion to the density. Polar elastomeric copolymers can increase impact energy while maintaining other properties, especially in maleated versions.

Moisture absorption and swelling performance of WPCs improve with increasing thermoplastic fraction. The wood moisture content during processing is
Figure 5
Tensile strength of wood-PP composites. Increased wood content can improve composite strength properties with mechanically or chemically facilitated dispersion (after Wolcott and Englund 1999).

generally below 1% and therefore will absorb moisture when exposed. Whereas equilibrium moisture contents well below 3% are noted with exposure to water vapor, liquid water soaks can result in moisture uptake greater than 10–20% depending on formulation. Researchers have reported that water absorption and swelling decreased disproportionately to the amount of plastic added (Wolcott and Englund 1999). These findings may indicate that material structure changes with thermoplastic content have a strong influence on material properties.

5. Melt Blending and Compounding of Components

Dispersion of wood throughout the thermoplastic melt is a major processing step that influences the quality of the finished product. Melt blending wood and

thermoplastics is facilitated through input of high shear forces. Wood flour is generally easy to disperse in a matrix but fibers and larger particles require longer times and higher mixing intensity. Twin-screw extruders provide simultaneous mixing with extrusion or injection molding. They are often used in conjunction with dry blending. Intensive-shear mixers can achieve preparation of wood fiber and thermoplastics before injection molding (Park and Balatinecz 1997).

The blending conditions play an important role in the final parameters used in processing and properties of the resulting product. Processing temperature, filler type and percentage, mixing time, and rotation speed are important parameters that govern the blending procedure. Blend properties such as viscosity, melt elasticity, and fiber length are all influenced by the mixing procedures used. Higher temperature decreases polymer viscosity and can facilitate mixing. However, thermal decomposition of lignocellulosics can become significant in the processing range of polypropylene (180–200 °C). Effectiveness can often be maximized at intermediate temperatures.

Filler dispersion in the thermoplastic matrix can depend on the duration and speed of mixing. However, the optimal time and rotation rate of mixing are controlled by the polymer type, filler properties, and mixing equipment. Both long compounding times and high rotation rates will independently increase the dispersion of fillers throughout the matrix. However, these same conditions can degrade or pulverize fibers. Takase and Shiraishi (1989) noted that tensile strength and stiffness of the composite reaches a maximum value after a finite time interval. However, composite ductility continued to increase with increased mixing time and rotation rates. The extent of fiber damage during mixing depends on fiber and polymer type, processing or mixing method, and fiber–fiber interaction.

6. Conclusions

WPCs are emerging hybrid materials that combine lignocellulosics and synthetic thermoplastics. As with synthetic polymer materials, this thermoplastic version of wood composites adds several processing advantages. Materials can be thermoformed using compression molding of sheet products, extrusion, or injection molding. The thermoforming capabilities also facilitate recycling capabilities for the product. Most WPC products are being used in exterior applications where water resistance is paramount. However, control of product shape through processing techniques may be of equal value in the end.

Xerogels

A xerogel is a dry gel ("xero" being a Greek word root meaning "dry") prepared by evaporating the pore liquid under ambient conditions. The structure of the solid network is drastically altered during the drying process, because large stresses are exerted by capillary pressure (during evaporation) or crystal growth (during freezing). Those stresses and their effects are the subjects of Sect. 1. The structure and properties of the dried gel are discussed in Sect. 2 and applications are briefly reviewed in Sect. 3. A much more detailed discussion is given by Brinker and Scherer (1990). For information on related materials see *Organic Aerogels** and *Inorganic and Inorganic–Organic Aerogels**

1. Preparation of xerogels

1.1 Shrinkage During Evaporation

The specific energy of the solid/vapor interface, γ_{SV}, is greater than that of the solid/liquid interface, γ_{SL}, or the liquid/vapor interface, γ_{LV}. Therefore, rather than allowing the solid network to be exposed to the atmosphere during evaporation, it is energetically

favorable to increase the area of the liquid/vapor interface by creating concave menisci, as indicated in Fig. 1. The curvature of the liquid/vapor surface creates negative capillary pressure (suction), P_c, in the liquid given by

$$P_c = \frac{2\gamma_{LV}}{r_m} \qquad (1)$$

where r_m is the radius of the meniscus; for a concave meniscus, r_m is defined as negative. It is the suction in the liquid that causes the solid network to contract during drying. Initially, the soft gel contracts under small pressures; i.e., r_m is very large and the menisci are relatively flat (Fig. 1(a)). As the gel shrinks, it becomes increasingly rigid, so the menisci deepen and P_c increases. As the bulk modulus of the network, K, increases, the radii of the menisci finally become equal to the radii of the pores, and the liquid recedes into the interior of the network (Fig. 1(c)). At that point, the gel stops shrinking, and one can say that a xerogel has been created.

Even the lowest density inorganic gels have average pore sizes smaller than 100 nm (Ruben *et al.* 1995), and xerogels typically have pore radii from 1 nm to 10 nm, so the capillary pressures generated during drying are large. If $\gamma_{LV} = 0.02 \, \mathrm{J \, m^{-2}}$ (typical of organic
Figure 1
Concave menisci form at surface of drying body. (a) Initially the curvature is small, because the compliant network contracts under small capillary pressure; (b) as the network stiffens, the curvature of the meniscus increases, until (c) it is small enough to penetrate the pore; shrinkage stops when stage (c) is reached.

\# Cross references marked by a hash can be found by consulting the Encyclopedia of Materials: Science and Technology.

solvents) and $r_m = 10\,\mathrm{nm}$, then Eqn. (1) yields $P_c = 4\,\mathrm{MPa}$; for water, $\gamma_{LV} = 0.072\,\mathrm{J\,m^{-2}}$, so the same size pore would generate 7.2 MPa of pressure. These large pressures cause 8- to 10-fold volumetric shrinkage during drying. The elastic modulus of the gel network has been found to increase with the volume fraction of solids, ρ, approximately according to

$$K = K_0 \left(\frac{\rho}{\rho_0} \right)^m \qquad (2)$$

where ρ_0 and K_0 are the initial values of ρ and K (before drying starts) and m is roughly equal to 3.5. If the gel shrinks in volume by a factor of 10, then $\rho/\rho_0 = 10$ and Eqn. (2) indicates that the modulus increases by a factor of almost 10 000. The gel is transformed from an initial consistency similar to that of a gelatin dessert or tofu into a solid almost as hard as window glass.

In most cases, drying shrinkage is irreversible, because strained bonds in the network react with the pore liquid, and the broken bonds result in permanent deformation; moreover new bonds are formed in the network as it shrinks, and these bonds prevent the compressed network from springing back. Treatment of silica gels with chlorosilanes covers the solid surface with alkyl groups that are chemically inert, allowing the drying shrinkage to be completely recovered (Prakash *et al.* 1995). The spring back is so complete that such materials retain the density of the original gel network, and so are called "ambient pressure aerogels."

1.2 Damage During Evaporation

If the capillary pressure is uniform throughout the gel, then the network is put under a hydrostatic load and it contracts isotropically without any tendency to warp or crack. Damage results only when *gradients* in pressure are created, because nonuniform suction will cause different regions of the gel to contract at different rates.

When liquid evaporates from the surface of a gel, the movement of liquid toward the surface obeys Darcy's law:

$$J = -\frac{D}{\eta} \nabla P \qquad (3)$$

where J is the flux of liquid (i.e., the volume passing through a unit area per unit time, giving units of velocity), η is the viscosity of the liquid, and D is the permeability of the network (units of area). The permeability is proportional to the volume fraction of liquid and the square of the average pore size, r_p:

$$D \propto (1 - \rho) r_p^2 \qquad (4)$$

Until air invades the gel (Fig. 1(c)), the flux to the surface must be equal to the rate of evaporation,

$$V_E = J_{\mathrm{surface}} = -\frac{D}{\eta} \nabla P \big|_{\mathrm{surface}} \qquad (5)$$

where V_E is the volume of liquid evaporating per unit area of gel per unit time. Thus, the pressure gradient within the gel near the surface is

$$\nabla P \big|_{\mathrm{surface}} = -\frac{V_E \eta}{D} \qquad (6)$$

This equation explains why damage can be avoided by slow drying: if V_E is small, then large pressure gradients are not created. High drying temperatures are favorable, because they reduce η. Equations (4) and (6) indicate why it is so much more difficult to dry gels than conventional ceramics without cracking: the small pores in gels make the permeability very low (in spite of the small volume fraction of solids), so a modest rate of evaporation creates a substantial pressure gradient in a gel. Details on the phenomenology of drying and the analysis of drying stresses are discussed in Brinker and Scherer (1990, chaps. 7 and 8).

1.3 Films

Drying of films begins before gelation, so it is difficult to measure, much less to predict, the modulus and pore size that control drying shrinkage. There is no opportunity to age the gel before drying, so the structure of the network must be controlled by manipulation of the clusters in the sol. For example, the pH and aging time of the sol can be used to make clusters that are more or less robust, and thereby influence the final porosity of the film (Brinker and Scherer 1990, chap. 13). As for a bulk gel, the amount of shrinkage is determined by the capillary pressure and the modulus of the network, but the stresses that cause cracking are not caused by a pressure gradient. For a film, the stress results from the fact that adhesion prevents shrinkage in the plane of the substrate. The resulting stresses are enormous and are independent of the drying rate; nevertheless, cracking only occurs when the thickness of the film exceeds a certain critical value, which is of the order of 1 μm for an inorganic film. The reason for this behavior is that a growing crack releases strain energy stored in a certain volume surrounding the crack, but expends energy in creating the new surface of the crack. In a thin film, the volume relaxed is small compared to the new area created, so it is energetically unfavorable for a crack to extend; i.e., if the film is thin enough it *cannot* crack, regardless of the magnitude of the stress (Hu and Evans 1989). It is possible to build up thick films by applying multiple layers, but it is generally

necessary to fire each layer to increase its strength before the next one is deposited.

2. Structure of Xerogels

Inorganic gels have pore diameters in the mesopore (2–50 nm) and/or micropore ($\leqslant 2$ nm) range, and surface areas ranging from about 100 to $1000 \, m^2 \, g^{-1}$. This means that about half of the atoms in the gel are on the surface, so that substantial changes in the composition of the gel can be produced via surface reactions (such as nitridation by ammonia or dehydration by chlorine vapor). The main structural difference between aerogels and xerogels is their pore size and density; if an aerogel is soaked in liquid and dried, it contracts enormously, but its surface area changes by no more than 10%.

For silica xerogels, the lowest density reported is about $0.2 \, g \, cm^{-3}$ (~ 90 vol.% porosity) whereas acid-catalyzed gels dried slowly reach $\sim 50\%$ porosity. Substitution of methyl triethoxysilane (MTEOS) for tetraethoxysilane (TEOS) reduces the connectivity of the silica network, and the increased compliance leads to an abrupt drop in porosity when the MTEOS/TEOS ratio exceeds about 60% (Fahrenholtz and Smith 1992); the resulting materials contain nothing but a small volume of micropores. Such collapse of the pore structure can be obtained in pure silica gels during film formation if the clusters are prepared at low pH so that they are highly compliant.

Control of pore size and shape can be achieved by use of surfactant templates (Beck *et al.* 1992). Hierarchical structures can be made by inducing phase separation in the sol before gelation (Nakanishi 1997): a micrometer-scale pore network is created by spinodal decomposition within a matrix that is micro- or mesoporous.

3. Applications

Dense xerogel films are used as coatings to protect against corrosion and abrasion, whereas porous films are used as membranes (in some cases permitting size-selective separation). Sensors can be prepared by incorporating dyes, enzymes (Avnir *et al.* 1994), or other sensitive species within a xerogel applied as a coating on an optical fiber or other substrate. Xerogel films have long been used for passive optical coatings, such as reflective or antireflective films, but there is also tremendous interest in their use for active optical elements (Klein 1994). This application depends on the ability of gels to encapsulate sensitive organic molecules and to preserve their activity.

Xerogel powders have been used for decades for catalyst substrates, owing to their high surface areas. Sol–gel processing has also been used to prepare nuclear fuel pellets and abrasive powders. Sols can be drawn into fibers to prepare xerogel fibers. Monolithic gels are of interest for lens and fiber-optic preforms. These and other applications are reviewed in Brinker and Scherer (1990, chap. 14) and Klein (1988).

Zeolites

The word "zeolite" comes from two Greek words meaning "boiling stones." The name was given in 1756 by a Swedish mineralogist, Axel von Cronstedt, to a mineral which released water visibly when heated (the property of intumescence). The mineral later acquired the name stilbite.

Since that date many similar minerals have been discovered and the word zeolite now describes a family of minerals. They are commonly formed as a result of volcanic activity, either by the action of meteoric water in the environs of a volcano, or by the alteration of wind-blown volcanic dusts deposited in saline lakes. The latter mode of formation has created massive deposits on the earth's surface. Some of these deposits are mined commercially as building stone, and for other uses such as soil remediation agents, waste-water treatment, and animal feed supplements.

Historically zeolites were defined as aluminosilicates possessing three-dimensional frameworks of linked silicon–aluminum–oxygen tetrahedra. This restrictive definition has been widened to include *all* crystalline materials characterized by frameworks of linked tetrahedra, each consisting of four oxygen atoms surrounding a cation which can be Al, Si, P, Be, Zn, Mg, Co, B, etc. The frameworks contain channels and cavities in which are found water molecules and cations. The water can be lost reversibly and the cations can usually undergo facile ion exchange. The channels are in the microporous region and are large enough to accommodate guest molecules, which can be organic molecules.

A further extension to the original definition has been to accept some frameworks which are incomplete in so far as some of the apical oxygen atoms to the tetrahedra are occupied by OH or F groups.

Commonly conference reports and scientific journals will consider frameworks containing octahedra

(e.g., titanosilicates) and mesoporous substances (e.g., MCM-41; a Mobil company code) alongside the more traditional zeolites because they have related properties. This article will not include these materials.

1. Classification

1.1 Zeolites Which Are Natural Minerals

The International Mineralogical Association has a Commission on New Minerals and Mineral Names which has suggested an approach to natural zeolite classification. The zeolites can be grouped into *series* within which various cation compositional ranges can occur. These are listed in Table 1 with the appropriate cations. They are all aluminosilicates with complete frameworks. In addition, zeolite *species* can be recognized. A full list of these can be found in Coombs *et al.* (1998).

1.2 Synthetic Zeolites

The foregoing classification does not include many zeolite phases which have been synthesized in the laboratory. In some cases the phases are identical in structure to a natural analogue but many have no (currently) known natural counterpart. This may change and there is an increasing number of zeolites first recognized as a synthetic species which have subsequently been found in nature. A full list of synthetic zeolites will not be included for reasons of space. Table 2 gives some illustrations of zeolites which can be made with differing atoms in their tetrahedral positions, including some initially identified from laboratory synthesis but which have later been found as natural minerals.

A definitive list of natural and synthetic zeolite structures, with their idealized compositions and full crystallographic data, has been compiled by Meier

Table 1
Zeolite series, their three-letter codes, and compositional variants (species).

Series	Code	Cation forms (species)	Series	Code	Cation forms (species)
Brewsterite	BRE	Sr,Ba[a]	gmelinite	GME	Na,Ca,K
Chabazite	CHA	Ca,Na,K	heulandite	HEU	Ca,Na,K,Sr
Clinoptilolite	HEU	K,Na,Ca	levyne	LEV	Ca,Na
Dachiardite	DAC	Ca,Na	paulingite	PAU	K,Ca
Erionite	ERI	Na,K,Ca	phillipsite	PHI	Na,Ca,K
Faujasite	FAU	Na,Ca,Mg	stilbite	STI	Ca,Na
Ferrierite	FER	Mg,K,Na			

[a] As an example of the link between zeolite series and zeolite species, the names of the species of zeolites in the brewsterite series will be brewsterite–Sr and brewsterite–Ba.

* Cross references marked by an asterisk are included in this volume.
Cross references marked by a hash can be found by consulting the Encyclopedia of Materials: Science and Technology.

Framework	Code	Material[a]
Chabazite	CHA	AlPO$_4$-34, CoAPO-44, CoAPO-47, GaPO$_4$, MeAPO-47, MeAPSO-47, SAPO-34, SAPO-47
Faujasite	FAU	SAPO-37, beryllophosphate X, zincophosphate X,
Pahasapite	RHO[b]	berylloarsenate RHO, beryllophosphate RHO, gallosilicate ECR-10

[a] The symbols refer to synthetic phases: A = Al, P = phosphate, S = Si, Me = Mn, Mg. Other numbers and codes are synthesis batch numbers or company codes. [b] RHO is the code for a synthetic zeolite structurally characterized before pahasapite was found in nature.

Figure 2
A "ball and stick" representation of the structure of a sodalite unit (β cage) in which the tetrahedra can be indentified (left) with a framework diagram for comparison.

are shown in Fig. 1. It is common to simplify the tetrahedral linkages to lines which represent the oxygen atoms, in much the same way as lines are used to represent the tetrahedral carbon bonds in organic molecules. This is illustrated in Fig. 2. This method of representation highlights the ways in which the tetrahedra make rings of oxygen atoms, and the resulting restrictions to the channels and cavities making up the interior void of the structure. These restrictions are of molecular dimensions. They are responsible for the ability of zeolites to act as molecular sieves and perform selective sorption of molecules on the basis of their size to achieve useful separations. Similarly cation-sieving can occur in certain structures.

Figure 1
The secondary building units recognized in zeolite frameworks: (a) single four-oxygen ring (S4R), (b) single six ring (S6R), (c) single eight ring (S8R), (d) double four ring (D4R), (e) double six ring (D6R), (f) complex 4–1, (g) complex 5–1, and (h) complex 4–4–1.

et al. (1996). Each framework structure has been allocated a three-letter code by the Structure Commission of the International Zeolite Association. The Structure Commission maintains a website with structural information.

2. Structural Architecture

The molecular structures of zeolites are characterized by the unique ways in which their component tetrahedra are linked to each other to create open microporous frameworks. The void volume of some zeolites can be as high as 50% of the total crystal structure. They contain repeating elements of structure which are known as secondary building units (sbu). These

3. Synthesis

Earlier methods used to synthesize zeolites tended to mimic their formation in nature by making use of hydrothermal conditions to crystallize out zeolite phases from aqueous gels composed of aluminum and silica sources under highly alkaline conditions. Alteration of Si/Al compositions, amount of water, and differing cation(s) coupled with temperature, autogenous pressure, and time variations resulted in a wide range of products.

Later many zeolites have been synthesized by similar routes but with the inclusion of an organic molecule in the gel as a template, or "void-filler." This

approach has generated a number of zeolites with low aluminum contents in their tetrahedral sites (high-silica zeolites).

4. Industrially Significant Zeolites

4.1 Synthetic Zeolite A (LTA)

The structure of zeolite A, which has no natural counterpart, is shown in Fig. 3. It is created by the joining together of subunits which are the main structural unit of sodalite—a felspathoid. These units are joined by all their rings of four oxygen atoms into a cubic array like that adopted by the sodium chloride structure. Fig. 3 shows that the consequence of this is a series of cavities—those from the sodalite cage (Fig. 2) itself and those in the central cavities they surround. Entry to the sodalite cage (β-cage) is via a six-oxygen window of 0.23 nm approximate diameter. That to the main cavity (α-cage) is through an eight-oxygen window with a diameter of 0.41 nm. The void volume is 48%. As synthesized, the cavities are occupied by sodium ions and water molecules.

This is the commercial product Molecular Sieve 4A, well-known as an effective laboratory desiccant. Zeolite crystals (about 5 μm) are bound together with a clay (e.g., 10–20% of attapulgite or kaolinite) to form beads or extrudates. They are pre-activated to remove the inherent water prior to use.

The cation present can be changed by cation exchange which moderates the effective eight-oxygen window size. Introduction of the larger potassium cation reduces the working diameter to about 0.3 nm in Molecular Sieve 3A. Replacement of about 40% of the sodium ions by calcium results in a widening to about 0.5 nm, and hence Molecular Sieve 5A. This increase in effective window size arises from the positioning of the calcium cations away from one which constricts the 8-oxygen ring.

(*a*) *Desiccant uses*. Zeolite A is widely used as a desiccant in sealed units for refrigerant gases, in heavy duty oil-filled transformers, double glazing units, vehicle air-brakes, and air conditioning systems.

On a larger scale, zeolite beads are used to dry industrial feedstock gases, such as hydrogen and oxygen. The processes are dynamic with continuous regeneration via temperature- or pressure-swing. Both 3A and 4A are used to dry liquid propane gas (LPG), halocarbons, and natural gas. 3A is preferred for the drying of "cracked" gas (refinery olefin streams), ethylene, propylene, and methanol. 4A dries other alcohols and benzene. It also is preferred for natural gas drying when "peak-shaving" is required. This is the adjustment of the gas calorific value by removing water and carbon dioxide.

The basis of the desiccant action described above relies on the scavenging of the water molecule on the basis of its size and polar nature in the presence of other larger/less polar molecules—a molecular sieving.

(*b*) *Gas purification*. The best known of all gas purifications employing a zeolite substrate is in natural gas treatment where, in addition to the peak-shaving mentioned above, 4A "sweetens" the gas by removing hydrogen sulfide. There are many other examples of similar removals of sulfur and nitrogen compounds from gas streams.

(*c*) *Bulk separations*. The window size of 5A is convenient to execute the important separation of *n*-paraffins from *i*-paraffins. Many commercial processes have been developed to carry this out as part of feedstock preparation for the detergent and chemical industries.

Another large-scale sieving separation comes in the use of zeolite A to enrich the gases of the air (oxygen, nitrogen, and inert gases). This can be carried out cryogenically but pressure-swing processes are gaining in use. Oxygen supplies for patients with breathing difficulties and for field hospitals (as in the Gulf War) can be achieved by pressure-swing operations. Other systems provide oxygen for welding and water-oxygenation, and nitrogen for large-scale chemical plant use. Zeolite A has long been an important gas–solid chromatographic support for the analysis of permanent gases.

(*d*) *Liquid phase separations*. Zeolite 5A can be used in small-scale plants for the Union Oil Products' (UOP) Molex process, which is designed for the separation of *n*-paraffins from *i*-paraffins, naphthalenes, and other aromatics.

(*e*) *Cation sieving*. The use which accounts for the highest industrial production of zeolite 4A is as a powder for inclusion in industrial and domestic detergent packs. It acts as a water softener (builder) selectively to remove calcium (and to a lesser extent magnesium). This accounts for nearly 1 million tons per annum. A synthetic gismondine—zeolite MAP—is a modern competitor to A for this purpose.

Figure 3
The structure of zeolite A (LTA) as a stereopair.

Zeolite A also has been used for clean-up after the Three Mile Island accident to remove radioactive caesium selectively from contaminated waters in the reactor.

4.2 Synthetic Zeolites X and Y (FAU)

Zeolites X and Y form a series of structures which are isostructural with the rare natural mineral faujasite. X and Y differ only in silicon/aluminum ratio (and hence cation content) with X having Si/Al $\sim$ 1.0–1.4 and Y Si/Al $\sim$ 1.5–3.0.

Their structure resembles that of zeolite A but with the β-cages joined via half of their six-rings to create an diamond-like array (Fig. 4). Access to the main cavity is controlled by a 12-oxygen ring with a crystallographic diameter of 0.74 nm. The void volume is 53%.

(*a*) *Industrial use*. The zeolite X is commercially available as Molecular Sieve 13X (sodium form) and 10X (calcium form). Molecular sieve 13X contributes to gas purification, being able to scavenge larger molecules containing sulfur and nitrogen. It has also been used for air-enrichment and in sealed window units.

Ion-exchanged forms (K, Ba, Sr) of both X and Y can separate liquid mixtures and have been developed by UOP to separate *p*-xylene from its isomers (Parex process), ethylbenzene from its isomers (Ebex), and in the Sarex process to separate fructose from other sugars.

The major use of zeolite Y is as a catalyst of great significance to the oil industry. This is covered elsewhere in this encyclopedia.

5. Other Zeolites of Commercial Significance

5.1 Clinoptilolite (HEU) and Mordenite (MOR)

Both these zeolites have silica-rich frameworks based on five-oxygen rings linked together: 5–1 for mordenite and 4–4–1 for clinoptilolite (Fig. 1). The structures have lower void volumes than those of zeolites A, X, and Y. HEU has channels bounded by two eight-ring windows (0.26×0.47 nm, 0.33×0.46 nm)

Figure 4
The structure of zeolites X and Y (FAU) as a stereopair.

and one by a 10-ring (0.30×0.76 nm). MOR has eight-and 12-ring windows of 0.26×0.57 nm and 0.65×0.70 nm dimensions, respectively.

HEU has not yet been commercially synthesized. It is a very abundant mineral and is mined commercially in many countries. MOR has been used both as a natural mineral and as a synthetic phase.

Their relatively high silicon content enables them to withstand exposure to acid gases and they have been used for acid-gas drying and removal of sulfur and nitrogen oxides. HEU has the useful property of being able to separate nitrogen from natural gas. HEU also has a selectivity for caesium (and strontium). This ion-sieving has been used to clean up after the Chernobyl accident and in the Site Ion-Exchange Plant at British Nuclear Fuel's Sellafield site. It also has selectivity for the ammonium cation which promotes its use in waste-water treatment, soil amendment, and as an animal feed additive.

5.2 Chabazite (CHA)

Although a laboratory synthesis is available for this zeolite, such use that has been made of its properties has been from natural sources. It has found use as a cheap drying agent and as a selective caesuim cation exchanger in the nuclear industry. It has been used in this way in an admixture with zeolite A in the Three Mile Island clean-up and for low-activity waste streams at the Oak Ridge National Laboratory, Tennessee.

5.3 ZSM-5

Zeolite Socony Mobil-5 is a high-silica synthetic zeolite catalyst. It is mentioned here because it is a shape-selective catalyst that acts as a molecular sieve to tailor both reactants and products. This will be described in more detail elsewhere in this encylopedia. The high silica content confers a hydrophobic nature to enable its use in separating organic from aqueous phases, such as in fermentation processes.

6. Other Comments

The nuclear industry has also made use of gas sorption by various zeolites to scavenge and contain tritium, tritiated water, and radioactive krypton from nuclear plant-off gases. Silver-loaded zeolites have been used to scavenge radio-iodine species. Some of these uses have included the deliberate engineering of the pore sizes by deposition of other phases at the pore openings.

7. Conclusion

Most of the studies on the many novel synthetic zeolites have contained an over-emphasis on their potential use as catalysts. The future should see some

of them finding wider use as selective sorbents (and cation exchangers) as they offer the prospect of tailoring their molecular sieve properties to meet specific industrial and environmental needs.

LIST OF CONTRIBUTORS

Contributors are listed in alphabetical order together with their addresses. Titles of articles that they have authored follow in alphabetical order. Where articles are coauthored, this has been indicated by an asterisk preceding the title.

Adcock, T.
Washington State University
Pullman, Washington
USA
Wood: Nonstructural Panels

Ahmad, Z.
Quaidi-i-Azam University
Islamabad
USA
Ceramic-modified High-temperature Polymers

Alderliesten, R. C.
Delft University of Technology
The Netherlands
Fiber Metal Laminates, Fatigue of

Allison, J. E.
Ford Motor Company
Dearborn, Michigan
USA
Fatigue of Particle Reinforced Materials

Ashby, M. F.
University of Cambridge
Cambridge
UK
Composite Materials, Microstructural Design of
Elastic Structures in Design
Materials Selection and Mechanical Design
Plastic Deformation of Cellular Materials

Avnir, D.
Hebrew University of Jerusalem
Israel
Reactive Ceramic Nanocomposites with Organic and Bio-organic Phases

Bailie, J. E.
Cardiff University
UK
Supported Catalysts

Baker, R. T. K.
Northeastern University
Boston, Massachusetts
USA
Carbon Nanofibers

Bažant, Z. P.
Northwestern University
Evanston, Illinois
USA
Creep of Concrete

Becher, P. F.
Oak Ridge National Laboratory
Tennessee
USA
Ceramics: Whisker Toughening

Béguelin, Ph.
EPFL
Lausanne,
Switzerland
Polymer Matrix Composites with Roughly Equiaxed Reinforcements: Microstructure and Mechanical Behavior

Bergmans, L.
Catholic University of Leuven
Belgium
Composite Dental Materials: Wear

Beukers, A.
Delft University
The Netherlands
Polymer Matrix Composites: Applications

Biswas, A.
State University of New York at Buffalo
New York
USA
Ceramic Nanocomposites with Organic Phases, Optics of

Blum, J.
Hebrew University of Jerusalem
Israel
Reactive Ceramic Nanocomposites with Organic and Bio-organic Phases

Boehner, A. W.
Trus Joist – A Weyerhaeuser Business
Boise, Idaho
USA
Wood: Structural Panel Processes

947
